hole (Twedt and Henne-Kerr 2001). The average diameter of nest-box entrance used by Manitoba bluebirds was 3.93 cm compared with 4.16 cm for unused boxes (Munro and Rounds 1985). When given a choice and there are no competing species, bluebirds prefer nest boxes with a slot entrance rather than a circular entrance (Davis et al. 1986; McComb et al. 1987). In Kentucky, bluebirds preferred boxes with a 3.8-cm wide opening at the top of the front of the box. Next favoured were regular boxes with 3.8-cm diameter holes. Boxes with a slot in the top were seldom used and produced no young. The circular entrance excluded starlings but the slot entrance did not. Bluebirds used boxes with entrances as narrow as 2.9 cm (McComb et al. 1987). In North Carolina, 90.3% of bluebirds nested in woodcrete boxes when given a choice between a clean wooden and woodcrete box (Stanback and Rockwell 2003). Although most nest boxes constructed for the Eastern Bluebird are wooden, it has nested in cardboard half-gallon cartons (Twedt and Henne-Kerr 2001; Woodward and Woodward 1979a), boxes made of tar paper (Low 1933), woodcrete boxes (a mix of sawdust and concrete; Stanback and Rockwell 2003), and polyvinyl chloride tubes (Tyson et al. 2011).

In Kentucky, Davis et al. (1994) put up pairs of boxes with 1 being clean and the other a nest that had fledged young. Thirty-eight new nests were established in boxes with old nests compared with only 3 in clean boxes. In North Carolina, 71% of bluebirds chose an unused box over a box that contained a successful nest for their second brood, but 75% renested in a cleaned used box versus an unused box. Used nests may carry a high burden of parasites within the breeding season, but these parasites disappear over winter. Bluebirds appeared to avoid parasites rather than choose known successful nests (Stanback and Devan 2001). Also in North Carolina, 73% of bluebirds chose a used woodcrete box to a wooden clean box for their second brood, but when given a choice between a clean and used woodcrete box, 71% chose the clean box. Nest-site fidelity was dependent on the quality of the alternate nest site (Stanback and Rockwell 2003). In South Carolina, there was no significant difference between numbers of birds that used a box for a second brood whether the old nest was cleaned out (62%) or left in the nest box (57%). Overall, 68% of males and 60% of females remained to nest at their original box. Leaving old nests in boxes had little effect on nest-site suitability or quality (Gowaty and Plissner 1997).

The Eastern Bluebird is territorial; males and females fight among themselves over other mates and nest sites. In addition to other bluebirds, it attacks Great Crested Flycatchers, Blue Jays, Tree Swallows, American Robins, Northern Mockingbirds, European Starlings, Brown-headed Cowbirds, and House Sparrows. Many of these are potential nest-site competitors, predators, or parasites. Territory size decreases as the nesting season advances and adults are indifferent to trespassers after the young of the last brood fledge. When a territory becomes vacant, the pair in the next territory may extend their hunting range and move into the acquired land for the next breeding cycle while still retaining their original territory. In Illinois, a single territory was 1.4 ha; 3 Arkansas territories measured 0.8-1.2 ha. In Kansas, outlying areas constituting a large part of each territory were seldom used. Activity was concentrated in a smaller central core. Over 3 years, the territory size and more intensively used core area were 2.2 and 0.8 ha, 3.5 and 0.6 ha, and 2.8 and 0.6 ha. In Michigan, home range or territory sizes were 1.1-8.4 ha. Average territory size was 2.1 ha in New York and South Carolina. Territories in burned or harvested areas are smaller than those in old fields, pastures, and orchards. Territory size can be substantially reduced by increasing the number of available nest

cavities. In South Carolina, males had breeding season home ranges averaging 19.2 ha compared with 13.7 ha for females. Four males had home ranges averaging 30.8 ha immediately after breeding (Fitch 1958; Gowaty and Plissner 2020; Graber et al. 1971; Thomas 1946a). When the bluebird nested predominantly in natural cavities, woodpecker holes, and fence-post cavities, nests were seldom closer than 100 m to each other and, in some cases, rarely closer than 400 m. In the 1940s, 2 Arkansas nests were only 8 m apart, but the territories spread away from the dividing line, each encompassing 0.8 ha, and there was no territorial overlap (Brodrick 1938; Graber et al. 1971; Musselman 1935; Thomas 1946a; Zeleny 1976). Now that artificially high nesting densities occur due to provision of nest boxes, it has been suggested that the bluebird may nest semicolonially. Nests have been reported as close together as 30 m in Ontario (Risley 1981). Gowaty and Plissner (2020) considered it a semicolonial nester, tending to settle where other bluebirds had already settled. In their South Carolina study area, the closest nests were 9 m apart. When an excess of nest boxes was present, bluebirds preferred neighbours to be closer (36 m) rather than more distant; some birds still nested solitarily.

Natal philopatry rates are lower in northern migratory populations than in southern resident populations. In resident populations, families often spend the winter together and arrive at the natal area as a unit. Near Chesley, 1 of 309 nestlings (0.3%) returned to nest (Krug 1941). In a Michigan area where some birds were resident and others were migratory, 34 of 592 fledglings (5.7%) returned to the natal area. Taking mortality into account, about 21% of surviving yearlings returned (Pinkowski 1979). In Massachusetts, 3 of 38 nestlings (7.9%) returned to breed in the natal area (Low 1933). In Minnesota, 11% of young returned (Gowaty and Plissner 2020). In Arkansas, 4 nestlings wintered in the natal area and remained to breed (Thomas 1946a). In Tennessee, 6.5% of females that were banded as nestlings returned. One female nested for the first time 8 km from her natal nest (Laskey 1940, 1943). In South Carolina, where the Eastern Bluebird is a resident, the overall return rate of young was 13.3% (11.9% of females and 14.6% of males). In total, 0.58% of nestlings nested in their natal box, 1.7% in or next to their natal territory, and 3.7% within their natal subpopulation. Four females and 2 males emigrated from their natal area to nest in another area 6 km away. The mean distance dispersed by males between natal and breeding territories (1.08 km) was significantly less than for females (1.39 km). Median dispersal distances were 0.57 km for males and 0.90 km for females. Maximum local dispersal distances were 8.69 km for females and 8.17 km for males. Males moved an average of 2.3 territories compared with 2.9 for females, and this difference was significant. One male banded as a nestling was recovered the following breeding season almost 800 km from his natal territory. Yearling females have been reported breeding for the first time more than 500 km from their natal sites (Gowaty and Plissner 2020; Plissner and Gowaty 1996). In Alabama, recoveries of birds banded as nestlings indicated that resident birds either remained in the area or radiated out into surrounding areas no more than 1.9 km from the natal nest box (Holliman 1997).

There are 2 temporal types of adult site fidelity: fidelity between years and within breeding seasons. Return rates of adults to nesting areas in successive years vary depending upon whether birds are resident or migratory, and breeding success the previous year may affect return rates. Near Chesley, of 69 adults, 3 females (4.3%) returned to the same nest box the following year. A female that nested in a fence post nested in a box 2 km away 2 years later (Krug 1941). In Wisconsin where

all birds were migratory, 16.0% of 2,527 adults returned the first year after banding, 3.7% returned for a second year, 1.4% for a third year, 0.4% for a fourth year, and 0% for a fifth year or more. Return rates were similar for males (15.5%) and females (16.4%). Return rates varied annually and ranged from 2.6% to 37.5%. After the coldest winter, only 4.6% of birds returned to breed and all were males. The return rate after the severe winter of 1976 (15.6%) was similar to that of the second warmest winter of 1982 (15.8%). The largest decline in return rates was associated with a slightly warmer than normal winter. Return rates were affected by winter mortality in severe winters. Winters following summer droughts may result in poor over-winter survival because of decreased numbers of insects. During breeding seasons with high populations, returning birds may be forced out of the study area due to higher competition, thus decreasing the apparent return rate (Bauldrey et al. 1996). In Michigan, all birds that returned to nest a second consecutive year had nested successfully the previous year (Pinkowski 1977a). Return rates were also related to nest success in a resident population in South Carolina. If nests were successful, 56% of individuals stayed to nest the following year compared with 15.4% of unsuccessful breeders. Overall, 39% of females and 44% of males returned to breed the following year (Gowaty and Plissner 1997, 2020). In Michigan, 62.9% of 89 returning adults were birds that remained in the area for the entire previous breeding season, rather than those that were there for only the spring, midseason, or late breeding season. Of returning birds, 77.1% of adult males and 54.5% of adult females spent the entire breeding season on site (Pinkowski 1979). In Minnesota, 26% of adults returned to breed at their previous year's nest site (Gowaty and Plissner 2020). In a resident population in Arkansas, 60% of males and 61.5% of females remained or returned to nest in the same territory. One female returned for the third year; another returned for the third and fourth years (Thomas 1946a). In Tennessee, return rates were 40-53.8% for females, with 61.5-85.7% using the same nest box in subsequent years. Some females used the same nest box in 3 consecutive years and one used the same box in 4 years, as did 1 male (Laskey 1939, 1940). Both sexes occasionally move further than 100 km from their previous year's nest site (Gowaty and Plissner 2020). In Maryland, the average return rate for 84 birds over 3 years was 61.2%. Of these, 77.1% returned to the same nest box (88.2% of males and 66.7% of females). Return rates to a specific box were highly correlated with pair reunion (Coss et al. 2019).

The Eastern Bluebird raises more than 1 brood per season in much of its range. There are reports of it using the same nest site all season and also of it switching sites within a season. Some nest boxes may have 3-4 nests per season in them, but not necessarily by the same birds (Graber et al. 1971; Laskey 1939, 1940; Low 1933; Thomas 1946a). In Michigan, site fidelity within breeding seasons was highly dependent on nesting success. Following an unsuccessful spring nest, at least 1 member of every pair left the study area, and both adults left on 16 occasions. Of failed spring nesters, 65.6% of females left compared with 39.3% of males. No females remained after failure if the male left. A few males moved 3-5 km after nest failure. One female nested 19 km from a failed nest and the remainder were not found, suggesting that failed breeding females may move considerable distances between subsequent within-season nests. When a pair remained together and renested in the study area, 81.0% of replacement nests were in a different location and the same nest site was used 19% of the time. There was much movement of birds in and out of the study area within breeding seasons. About 33% of bluebirds remained the entire breeding season and were responsible for a high percentage of nests and an even greater number of successful nests than

those that nested only in spring, mid-season, or at the end of the season. Adult males were more frequent in the spring-only group than the season-end group (6:1); the reverse was true for yearling males (1:4). Significantly more birds that arrived after the start of a season were new to the area (88.2%) than was the case for birds at the start of the season (74.8%; Pinkowski 1977a, 1979). Gowaty and Plissner (2020) reported that 69% of females failing in their first nesting attempt moved for their second attempt compared with 39% of successful females. At Chesley, many females raised both broods in the same box but different boxes were usually used (Krug 1941).

Limiting Factors

Eggs have been reported in Ontario nests from mid-April to early September, but mostly from 21 May to 21 June (Peck and James 1987). In Algonquin Park, nestlings are present from mid-May to late June, and fledglings have been observed from mid-July until mid-August (Tozer 2012).

The time required to build a nest ranges from 1 to 14 days, with most nests built in 3 or 4 days. For subsequent broods, the nest is often built in a day. First nests of the season take the longest to build and construction is halted during cold or wet weather. Egg laying may commence almost immediately after the nest is complete, or there may be a delay as long as 3 weeks. One egg is typically laid a day, but a day is skipped in 5-10% of clutches. This usually occurs in early spring when short-term shortages of insects may occur. Incubation usually begins with the laying of the last egg, but occasionally with the penultimate egg. The incubation period at 41 Ontario nests was 10-15 days, mostly 13 or 14 days. The short incubation period of 10 days plus 2 reports of hatching taking place over 24 hours suggest that incubation occasionally began before the clutch was complete. Other Ontario nests took 17, 19, and 21 days to hatch, suggesting a delay in the onset of incubation after laying the last egg. In Michigan, some females laid 1 egg and then waited 2-10 days before resuming a normal laying sequence. In Arkansas, incubation started with the fourth or fifth egg in some 6-egg clutches. Of 1,121 nests reported to the Cornell nest records scheme, the incubation period ranged from 11 to 19 days with more than 80% taking 12-15 days to hatch. Incubation periods are longer in spring and at high altitudes, reflecting the effects of cooler air temperatures. The incubation period decreased with increasing clutch size. Early in the season, most eggs hatch in a 1-day period, but hatching of the entire brood may take 2-3 days late in the season. The age at fledging ranges from 14 to 22 days, mostly 16-19 days. In Michigan, fledging took significantly longer (mean 19.39 days) in spring than summer nests (mean 18.63 days). The time for a full nesting cycle from initiation of nest building to fledging ranges from 35-47 days, but 37-40 days is typical. Nest initiation in spring is usually fairly synchronous but timing may vary annually depending on weather conditions. Yearling birds may not establish territories and initiate nesting until about a month after adult birds. In Ontario, the interval between fledging of the first brood and initiation of the next clutch was 6-23 days, but was mostly around 2 weeks. Elsewhere, the interval was 2-41 days. In Michigan, the average interval between completion of 1 nesting and initiation of another was 19.5 days for successful nests and 13.0 days for unsuccessful nests (Bent 1949; Brodrick 1938; Butcher 1988; Gowaty and Plissner 2020; Graber et al. 1971; Hartshorne 1962; Herbert 1988; Laskey 1939, 1940, 1943; Low 1933; Peck and James 1987; Pinkowski 1975b, 1977a, 1979; Risley 1981; Thomas 1946a; White and Woolfenden 1973; Zeleny 1976).

In Ontario, the Eastern Bluebird frequently raises 2 broods and there are 4 confirmed records of 3 broods (Peck and James 1987). Throughout its range, it raises 2 broods in most locations. In the central portion of its range, 3 broods are commonly reared and there are rare cases of females successfully raising 4 or 5 broods per year. In Arkansas, 3 pairs successfully raised 4 broods in a season. These pairs laid their first and last eggs on 18 March and 18 September. One male successfully raised 4 broods in a season, but with 2 different females. In Michigan, all birds raised 2 broods per season at 1 study area. All birds were single-brooded at another area a short distance away. These differences may have been due to low availability of nest sites at 1 area. Adults raise more young per season than yearlings because they attempt more broods (Bent 1949; Brodrick 1938; Gowaty and Bridges 1991; Gowaty and Plissner 2020; Graber et al. 1971; Harrod et al. 2021; Laskey 1943; Pinkowski 1976a, 1977a, 1979; Plissner and Gowaty 1988, 1996; Stanback and Dervan 2001; Thomas 1946a; Tucker 1990; White and Woolfenden 1973). The bluebird is a persistent renester if it is unsuccessful at nesting. In Ontario, clutches of 2-8 eggs have been reported, with most containing 4 or 5 eggs. Second and third clutches were smaller; in 44 of these, 25 contained 4 or fewer eggs. All August and September clutches contained 3 or 4 eggs (Peck and James 1987). Risley (1981) reported the average clutch size of 344 southern Ontario nests to be 4.45, with 5-egg clutches most frequent. The average clutch size for Ontario and Quebec combined was 4.18 eggs (Peakall 1970). Outside Ontario, clutches of 2-9 eggs have been reported with most containing 4 or 5 eggs with a normal range of 3-6 eggs. One 9-egg clutch was known to have been laid by 2 females. Seven eggs may be the largest clutch size laid by a single female. Clutch size declines with the season. In Illinois, first nests averaged 4.9-5.1 eggs compared with 4.2-4.4 for second nests. In Tennessee, average clutch size was 5.00 eggs for first nests, 4.65 for second nests, and 3.69 for third nests. In Michigan, average clutch size was 4.7 in early spring, 4.53 in late spring, 4.17 in early summer, and 3.25 in late summer. In Michigan, there was no significant difference in clutch size of yearling and adult females. Similar results were obtained in Arkansas in 1 year, but in another year yearlings laid larger clutches than older females (Bent 1949; Gowaty and Plissner 2020; Graber et al. 1971; Hartshorne 1962; Herbert 1988; Laskey 1939, 1940; Musselman 1935; Peakall 1970; Pinkowski 1977a, 1979; Robinson et al. 2010; Thomas 1946a; White and Woolfenden 1973; Zeleny 1976).

Both sexes are capable of breeding when they are 1 year old, and breeding occurs every year thereafter. In Michigan, some yearling males do not nest due to factors such as nest-site and territory availability, but it is likely that all would nest under ideal conditions. Three returning males did not breed as yearlings but 91.2% of returning yearlings bred (Gowaty and Plissner 2020; Laskey 1943; Pinkowski 1977a, 1979).

Most birds are apparently monogamous, although there are rare cases of polygyny and polyandry. In South Carolina, more than 95.5% of nesting attempts were monogamous; 5 of 177 (3%) were polygynous. In Wisconsin, a male simultaneously overlapped his second and third broods with 2 females using nest boxes more than 200 m apart (Khan 2021). Mate fidelity in Michigan was related to nest success; 139 of 140 adults (99.3%) that nested successfully in spring either remained paired, stayed in the same territory, or remained in the company of the juveniles. Adults nesting successfully in spring usually remained paired and attempted summer nests in the same general area. Renesting together occurred by 34.4-60.7% of unsuccessful pairs and by 70.0-84.3% of

successful pairs. If a pair was successful in spring and failed at the summer nest, the pair bond was preserved and the pair renested in a different location (Pinkowski 1977a). In Maryland, divorce rates in a subsequent year were significantly higher after nest failure. Of failed nests, 56% resulted in divorce compared with 23.7% of successful nests. Of pair bonds, 84.7% lasted the entire season, but on 7 occasions pairs divorced after their first nest attempt. Six of 59 pairs (10.2%) remained together for at least 2 years before divorce or disappearance (Coss et al. 2019). Both sexes are capable of raising a brood on their own if their mate is lost. Males may abandon the nest and either leave the territory for a while and return with a new mate, or remain in the territory until a new female arrives. When a replacement mate arrives, it may adopt the existing brood but typically expends less energy in raising the young than the original mate. Replacement females may occasionally kill the nestlings and replace them with their own eggs. In some cases, replacement mates may not help and the original eggs or nestlings may be abandoned. There are some cases when both members of a pair died during a nesting and the brood was raised by a new male and female. This usually happens when the replacement pair is a neighbouring pair that lost its own brood at about the same time the other adults disappeared (Gowaty 1983a, 1983b; Krug 1941; Ligon et al. 2009; MacDougall-Shackleton et al. 1996; Meek and Robertson 1991; Pinkowski 1978a; Plissner and Gowaty 1988; Thomas 1946a; Wetzel and Chandler 2008).

Extra-pair paternity and intraspecific parasitism occur. Near Kingston, 24% of broods contained extra-pair young and approximately 8% of young were extra-pair. Forty-eight of 90 bluebird offspring (53.3%) had DNA banding that was not seen in either parent. Fourteen percent of broods where the male was present contained extra-pair young; overall 7% of nestlings were extra-pair. Females whose mates were removed were 3 times as likely to have extra-pair young. Nest sites were limited in this population and non-territorial floater males often appeared on territories where males were removed. They were usually accepted by artificially widowed females. Near Kingston, 7 nestlings (8.4%) were fathered by extra-pair males and 24% of nests contained at least 1 extra-pair nestling. Two cases of intraspecific brood parasitism accounted for 2.4% of nestlings and 9.5% of nests. In Arkansas, almost 5% of nestlings were not related to their caretakers. In South Carolina, at least 5% of males and 15% of females took care of young that were not their own, and 9% of broods showed evidence of multiple parentage. Also in South Carolina, nestlings unrelated to parents were significantly more common in areas of high-density nesting where neighbours were close together. Extra-pair fertilizations were most likely to be by neighbouring males rather than non-territorial floaters. An estimated 1% of nestlings in this population resulted from nest parasitism and 19.8% from extra-pair copulations (Gowaty 1983a, 1985; Gowaty and Bridges 1991; Gowaty and Karlin 1984; Gowaty and Plissner 2020; Karlin et al. 1990; MacDougall-Shackleton et al. 1996; Meek et al. 1994; Plissner and Gowaty 1996; Tucker 1990). Extra-pair paternity accounted for approximately 20% of nestlings at 1 study area where an exceptionally high density of nest boxes was provided (Gowaty and Plissner 2020).

Rarely there may be helpers at nests. Nesting females usually chase away helpers, but occasionally they are tolerated. Helpers are usually fledglings from a previous nest during the same breeding season. Fledglings may begin this behaviour when they are as young as 37 days. In 1 case, a helper was a yearling male that left his natal territory, raised a brood, and then returned to assist

his parents in raising nestlings. Helping typically consists of removing fecal sacs and feeding nestlings, but these activities may not actually be very helpful (Gowaty and Plissner 2020; Hartshorne 1962; Laskey 1939; Pinkowski 1975b, 1975c, 1976b).

The Eastern Bluebird forages mostly on the ground, but searches for prey from elevated perches. Food is obtained from habitats such as lawns, pastures, and old fields dominated by grasses and forbs with scattered trees. Sparse ground cover is essential for effective foraging, as are suitable perches for searching for prey. Habitat that is otherwise suitable is not used if there are no suitable perches available. Common foraging perches include tree limbs and branches (especially those that are dead or defoliated), fence posts, boulders, and coarse weed stalks such as mullein and evening-primrose. If low perches are not available, it may perch horizontally part way up tree trunks to view the ground. In Ohio, foraging perches were 0.6-8.2 m high and offered unobstructed views of the ground. There was no significant difference in average height of perches selected by males (2.3 m) and females (1.8 m). The most common foraging technique is dropping from a perch to capture prey. In Michigan, this method was used in 78.8% of 2,638 foraging efforts and 87.4% of 508 attempts in Ohio. Flycatching is the next most abundant foraging technique, representing 10.7% of Michigan and 8.8% of Ohio foraging attempts. Flycatching may occasionally become the only foraging technique when aerial insects are highly visible, after a rain, or when swarming ants are abundant. Gleaning and hover-gleaning from foliage was used in 6.8% of foraging attempts in Michigan and in 3.7% in Ohio. These techniques are often used in areas of tall vegetation and become more common as the season advances and vegetation grows. In Michigan, 2.6% of foraging bouts were by hopping and 1.1% were by dropping from a perch to glean. It uses 3 foraging techniques when obtaining fruit: hovering in the air, perching on a limb and plucking berries, and perching on a fruit head, such as sumac, and plucking fruit directly beneath its feet. Flycatching is more common during favourable weather (14.7%) than inclement weather (1.2%), but the reverse is true for gleaning (20.2% during inclement weather and 7.9% during favourable weather). Ten spring foraging ranges in Michigan were 4.5-38.9 ha, but the size of the area containing the perches was fairly constant at 3.9-8.4 ha, suggesting that perch distribution may affect territory size. For 1 Ohio pair, food captured for young was obtained an average of 141 m from the nest. In Michigan, males obtained food for nestlings closer to the nest (average of 113.6 m) than females (152.4 m), but in some areas they foraged at the same distances (Goldman 1975; Gowaty and Plissner 2020; Graber et al. 1971; Pinkowski 1977b, 1978b; Risley 1981). The bluebird tends to select prey items that are larger than those generally available. In Ohio, 38% of potential prey was 3.3 mm in length; prey this size represented 19% of food. Rates for different size categories were: 6.5 mm, 47% availability compared with 27% of food; 13 mm, 19% availability compared with 31% of food; 26 mm, 1% availability compared with 10% of food; 39 mm, less than 1% availability compared with 10% of food; and 52 mm, 1% availability compared with 5% of food. Young received most of the large prey items. Adults ate 40% of the smaller items and fed 79% of the larger items to the young (Goldman 1975). In Michigan, adults appeared to feed nestlings larger prey items than fledglings (Pinkowski 1978b).

In Tennessee, food items fed to nestlings consisted of 22.4% grasshoppers, 14.7% crickets, 16.3% spiders, 25% caterpillars, 2.4% moths, and 19.2% items too infrequent to be listed individually (including 1 skink) or too small to identify (Gowaty and Plissner 2020). Braman and Pogue (2005)

reported that adults brought a small snake to a nest but it was not eaten. Six pairs in Oklahoma fed skinks to nestlings. Of animal food brought to nestlings in Michigan, 32.4% consisted of caterpillars (adult butterflies and moths comprised 3.6%), 25.6% were orthopterans (12.8% grasshoppers, 9.3% crickets, 3.1% katydids, and 0.4% mantis nymphs), 11.3% spiders including egg sacs (predominantly ground-dwelling species), 11.0% beetles, 5.2% earthworms, 3.9% hymenopterans, 2.3% millipedes, 1.5% leafhoppers, 1.2% snails and snail shells, 0.8% isopods, 0.5% flies, 0.3% scorpionflies, 0.1% dragonflies, 0.1% cicadas, 0.1% bugs, and 0.04% lacewings. Unusual prey included 2 centipedes and 1 fairy shrimp. Spiders and caterpillars were the primary food of recent hatchlings. More grasshoppers, crickets, beetles, and earthworms were provided as the young matured. Seventy-five percent of items fed to 1-day-old nestlings were spiders; larger spiders were fed as the young aged. Three-day olds were fed grasshopper nymphs, but the coarser male grasshoppers were not fed to young until day 7 and the larger females were first fed on day 9. Spiders were provided to nestlings more in May and June (13.1% and 14.3%) than in July and August (7.9% and 4.4%). Ground-dwelling spiders were common in the diet but not as common as spiders dwelling on herbaceous plants. Adult moths were more common in the nestling diet in summer (5.6%) than spring (2.9%). Earthworms comprised 10.8% of the nestling diet in May, 3.3% in June, and were absent in the diet after the first of July. Beetles comprised 17.9% of the diet in May, 8.3% in June, and 0.8% in August. Caterpillars were more common in the diet in May (35.4%) and June (41.8%) than in July (20.8%) and August (28.9%); cutworms were 46.6% of all caterpillars consumed. Bluebirds tended to select ground-dwelling species in spring and those on plants in summer. Fruit was fed to nestlings at only 4 of 45 nests (8.9%) and included mulberries, raspberries, red-osier dogwood, chokecherry, and honeysuckle. Fruit was not fed until late June when it became abundant. At 2 of 4 nests, fruit comprised 37.0% and 33.0% of the nestling diet over 3- and 5-day periods, but was fed to nestlings only once at the other 2 nests. In New York, most of very young nestlings' diet consisted of caterpillars as well as other small, soft invertebrates such as spiders. Later, at least 50% of the food fed to nestlings was orthopterans (grasshoppers, crickets, and katydids). These items were supplemented with berries, moths, beetles, centipedes, millipedes, and preying mantises. One young was fed a spring peeper (Hartshorne 1962). Foods fed to fledglings differed from those fed to nestlings. Caterpillars were more common in the diet of fledglings (44.0% of all food) reflecting peak consumption in June when most young were out of the nest. Earthworms (11.4%) and beetles (7.7%) were more common in fledglings' than nestlings' diet, but the reverse was true for grasshoppers (8.8%), spiders (4.4%), crickets (3.3%), and bugs (3.3%). Fruit (mulberries and cherries) comprised 11.0% of the fledgling diet, but was consumed only in July and August (Pinkowski 1978b).

Beal (1915a) analyzed the contents of 855 bluebird stomachs taken throughout its range in all months of the year. The food consisted of 68% animal matter and 32% vegetable matter. The animal matter consisted of 22.0% orthopterans (mostly in August and September), 20.1% beetles (ground and June beetles and weevils), 18.5% caterpillars, 3.5% ants, 1.6% wasps and bees, 2.8% bugs (predominantly stink bugs), 0.3% flies, 0.3% miscellaneous insects, 4.4% spiders, 1.2% millipedes, and 0.6% miscellaneous animals (isopods, snails, earthworms, lizards, and treefrogs). The vegetation eaten was predominantly fruit. Almost all domestic fruit (raspberries and cherries) was eaten in June and July. Honeysuckles and mulberries became important in the diet in late summer and throughout winter. In spring, cutworms and beetles were important with grasshoppers and crickets

important later in summer. It may glean stoneflies from tree trunks in spring. It may rely on fruit such as staghorn sumac and multiflora rose early in spring before insects become readily available. It has eaten shrews, snakes, salamanders, and western chorus frogs (Gowaty and Plissner 2020; Graber et al. 1971; Pinkowski 1977b; Tekiela 2004; Zeleny 1976). Bluebirds with access to mealworms began laying eggs earlier and had a 5% higher nestling survival rate than birds without supplemental food (Bailey and Bonter 2022).

The Eastern Bluebird is rarely parasitized by the Brown-headed Cowbird. In Ontario, 4 of 5,102 nests were parasitized, less than 0.1% (Peck and James 1998a). Throughout its range, usually less than 1% of nests are parasitized. The rate of parasitism has probably declined recently due to most bluebirds nesting in boxes with entrance holes that are too small to admit cowbirds. Nests in boxes that have lost their tops are vulnerable to parasitism. In Virginia, 6 of 27 nests (16.2%) were parasitized. The nest boxes provided were open cardboard half-gallon cartons that allowed cowbirds access. Cowbirds did not remove any bluebird eggs from these nests. In Illinois, parasitism rates were low, except in 1945 when 7 of 268 nests (2.6%) were parasitized. Parasitized nests were in nest boxes without tops. Parasitized nests were also found in undamaged nest boxes. In natural nests in Kansas, 1 of 4 nests was parasitized. Parasitism rates in Iowa are less than 1%. In South Carolina, 75% of parasitized nests were covered with new nesting material and renesting occurred. When cowbirds fledge, adults feed both cowbird and bluebird fledglings. Often both species are successfully reared from a nest. It is likely that the effects of cowbird parasitism are minor (Gowaty and Plissner 2020; Graber et al. 1971; Lowther 1985, 1991, 1997; Musselman 1935; Rivers et al. 2010; Woodward and Woodward 1979a). Peer et al. (2006) experimentally parasitized bluebird nests with bluebird and cowbird eggs. All parasitic bluebird eggs were accepted, but 65% of cowbird eggs were ejected from the nest box. Butler et al. (2020) demonstrated that bluebirds quickly ejected eggs with a speckled pattern but not those with a solid colour. It is likely that bluebirds eject most cowbird eggs.

Extreme weather during the breeding season is the greatest limiting factor for the Eastern Bluebird. Late winter or early spring snow or sleet storms can result in local, massive mortality. Cold weather after eggs are laid can cause freezing of eggs and desertion. Near Chesley during a cool spell, several birds abandoned their nests. Near the end of May, there were several cool, wet days and this resulted in entire broods dying. Death of young was probably due to the inability of adults to find sufficient food rather than exposure (Krug 1941). The cold spring of 1971 resulted in a 54% decline in the number of nesting attempts on a bluebird trail near Oshawa (Risley 1981, 1994). The ice storm of early April 2003 killed many bluebirds in the Hamilton area (Read 2006) and probably throughout Ontario. In Illinois, 3 severe April freezes over a 7-year period froze many eggs and killed many adult birds. It was estimated that half the bluebird population in west-central Illinois died in spring 1940 due to cold and snow (Graber et al. 1971; Musselman 1939, 1941). Cool or wet spring weather may delay initiation of nesting. This may result in first nests or renesting attempts coinciding with the nesting period of the Northern House Wren, which normally initiates nesting after the first nests of bluebirds are well underway. The delay results in increased competition for nest sites, increased incidence of piercing of bluebird eggs by wrens, and reduced reproductive success (Graber et al. 1971; Musselman 1935, 1939). Hot dry weather late in the summer may reduce nesting

success of second nests. Prolonged periods of temperatures in excess of 30°C may literally cook eggs in nests and result in a high rate of desertion. High temperatures may result in nestlings leaving the nest prematurely; young may also die from heat in the nest (Graber et al. 1971; Musselman 1935; Thomas 1946a; White and Woolfenden 1973).

Nest-site competition is another significant limiting factor for the Eastern Bluebird. Most competition occurs south of the Canadian Shield and near homes and residential areas in the Shield. The 4 main competing species are the Tree Swallow, Northern House Wren, European Starling, and House Sparrow. The Tree Swallow is the most significant nest-site competitor for the Eastern Bluebird. On Ontario bluebird trails, 70-80% of nest boxes are occupied by swallows (Risely 1994). As early as 1938, Tree Swallows were occupying nest boxes designed for bluebirds near Chesley (Krug 1941). Graber et al. (1971) stated that nest boxes situated near water would likely be taken over by Tree Swallows, but swallows now occupy nest boxes in a wide variety of habitats. In Massachusetts, the Tree Swallow was always victorious over the bluebird in disputes over nest boxes (Low 1933). Hersey (1933) reported extreme harassment of nesting bluebirds by Tree Swallows that led to abandonment of nests containing eggs and even nestlings. The swallows prevented bluebirds from feeding young to the point where the bluebirds gave up.

The bluebird may occasionally be successful in outcompeting the Northern House Wren for nest cavities and even evicting them from their nests (Bent 1949; Gowaty and Plissner 2020), but the wren usually prevails. In 1 area in Illinois, the bluebird population decreased as the wren population increased (Graber et al. 1971). Wrens may drive away adult bluebirds, puncture eggs, and fill nest boxes with active and dummy nests. In normal breeding seasons, bluebirds initiate nests prior to the arrival of wrens and nests normally contain nestlings when the wrens arrive. These nests are usually safe from wren competition, but presence of wrens may reduce success of second nests or renests, and bluebirds may be forced to nest in suboptimal areas. In Michigan, 23.3% of nest failures in natural cavities were due to Northern House Wrens. Competition with the Northern House Wren is mostly restricted to areas within 30 m of wooded or shrubby areas. This prevents the Eastern Bluebird from accessing large areas of potentially suitable habitat (Horn et al. 1996; Lumsden 1989; Pinkowski 1977a; Risley 1981; Zeleny 1976).

Declines in bluebird populations in the 1930s in the Oshawa area were attributed to the ingress of the European Starling. By the 1950s, the starling's range included most of rural southern Ontario, and a widespread decline in the bluebird during the same period was partially due to the increase in starlings. Starlings do not evict bluebirds from boxes, but they appropriate most available cavities that are large enough. As starlings increased, they started taking over cavities in wooden fence posts and in orchards that were previously used by bluebirds. The bluebird may initiate nesting earlier than the starling and may be successful in raising the first brood in a natural cavity without interference from starlings. Usage of natural cavities by bluebirds for subsequent broods declines due to competition with starlings. Bluebirds nesting where there are no available nest-boxes may be forced to nest in suboptimal cavities or may not find a nesting cavity (Baillie 1967; Bent 1949; Davis et al. 1986; Krug 1941; Pierson and Scanlon 1986; Pinkowski 1977a; Read 1998, 2006; Risley 1981, 1994; Stewart 1976; Zeleny 1976). Starlings can be effectively eliminated from bluebird boxes

through appropriate design. Cavity entrances smaller than 3.8 cm preclude entrance by starlings (Graber et al. 1971; Lumsden 1986; Risley 1994; Zeleny 1976).

The bluebird cannot compete with the House Sparrow, which evicts bluebirds from nest boxes and may kill nestlings and even adult bluebirds. A noticeable decline in the bluebird was evident in Ontario as early as the 1880s and 1890s due to House Sparrows displacing bluebirds from rural residential areas. Near Vineland, it was noted in the 1930s that interference from the House Sparrow seriously affected bluebird nesting. Nest sites within 400 m of buildings are likely to be used by House Sparrows and be unavailable to bluebirds (Bent 1949; Gowaty 1984; Graber et al. 1971; Herbert 1988; Laskey 1940; Lumsden 1989; McIlwraith 1894; Read 1998; Risley 1981, 1994; Sheppard et al. 1936; Summerour 1988; Zeleny 1976).

Habitat loss and degradation is another significant limiting factor. Much habitat has been lost due to interspecific competition: areas near water and most roadside habitats to the Tree Swallow; areas within 30 m of shrubbery to the House Wren; natural cavities in rural woodlots, hedgerows, and roadsides to the European Starling; and areas within 400 m of residences and barns to the House Sparrow. Habitat losses have occurred due to urbanization and agricultural practices. Fewer fence posts are wooden now, with many having been replaced with metal posts. The amount of total area farmed has declined, and the quality of farmland as habitat has declined. Removal of dead trees, hedgerows, and edge habitats as well as putting fallow fields back into production results in fewer natural cavities and poorer feeding areas. Grazed pasture has the potential to remain good habitat indefinitely provided that grazing is not too intense, but the amount of pasture has declined significantly. Heavier pruning and replacement of old trees in orchards has reduced the number of available nest sites. Natural succession results in habitat becoming unsuitable when vegetation covers patches of bare ground and shrubs become taller than about 1 m (Baillie 1967; Conner and Adkisson 1974; Pierson and Scanlon 1986; Read 1998; Risley 1981, 1994). Forest management practices in the Canadian Shield may be creating habitat for the bluebird.

Pesticides applied to orchards, roadsides, and fields may be a cause of mortality. The bluebird may prey preferentially on pesticide-weakened insects, thereby increasing contaminant burdens in nestlings (Gowaty and Plissner 2020; Risley 1981; Zeleny 1976). DDT and other persistent pesticides were used extensively on fire ants in the southern United States and this may have caused declines (Risley 1994). Read (2006) noted that bluebird numbers began to decline just after 1945 when intensive spraying of DDT began. At that time, apple orchards were sprayed routinely every day with DDT, lead arsenate, or sulphur. Bishop et al. (2000) studied bluebird reproductive success in pesticide-sprayed apple orchards in southern Ontario. Organophosphorus and carbamate insecticides have been sprayed in orchards for decades. There was a significant increase in the number of unhatched eggs as organochlorine levels in eggs increased. Although declines in survival were statistically significant, they were not high, with a maximum decline in survival of 4%. Both carbamate and organochlorines were potentially highly toxic to birds, particularly DDE which may affect egg survival. Oil and sulphur appear to be potentially toxic when birds are exposed. The fungicides used in apple orchards appeared to have low toxicity to birds, but they are applied repeatedly at high rates and often in combination with other chemicals and contribute to the overall toxicity. In Virginia, Bouland et al. (2012) studied clutches of the bluebird nesting in floodplains of

rivers contaminated with mercury and compared them with clutches in uncontaminated floodplains. Blood mercury concentrations of females were 7 times higher in contaminated than uncontaminated sites. Bluebirds in reference areas raised male-biased broods. Those in contaminated areas produced approximately equal numbers of male and female nestlings. Females in poor condition tend to produce female nestlings, which are less fit than male nestlings. In Indiana and most likely elsewhere, PCBs continue to be released into the environment despite their having been banned in the United States in 1977. It is an endocrine-disrupting chemical that results in heart deformities in the bluebird (Gowaty and Plissner 2020). Near lead mines in Missouri, the probability of a female fledging a young decreased from 94% to 84% in areas with elevated soil lead concentrations. Most nest failures were due to predation suggesting that lead may affect birds' behaviour and activity at the nest or affect nest-site quality (Thompson et al. 2024).

In burns in Montana, there were fewer bluebirds and nests per unit area where salvage logging occurred, but the differences between control and logged areas were not significant (Kronland and Restani 2011). In New York, Keller et al. (2003) surveyed bird populations in clear-cuts for several years after harvesting. The bluebird was observed only in 2-year-old cuts.

Bluebird nests are often infested with parasitic blow flies, and this problem may be exacerbated in nest boxes. Wittmann and Beason (1992) found no significant differences in nestling development, weight, fledging, or survival in parasitized or unparasitized nests and concluded that blow fly removal in boxes may not be necessary. Hannam (2006) reported similar results, but found that nestlings in unparasitized nests had a 12.5% higher level of blood hemocrit and a 35% higher concentration of hemoglobin. Nestlings in parasitized nests compensated by taking longer to fledge (19 days) than those in unparasitized nests (17.6 days). The time required for infested fledglings to recover from anemia and the long-term effects of parasitism were unknown. Roby et al. (1992) found that some nestlings died in heavily parasitized nests and that 10-day-old nestlings lost about 28% of their total blood volume daily. Nonetheless, the effects of blow fly parasitism were small and nestlings may recover from anemia prior to or shortly after fledging. Zeleny (1976) concluded that nestlings are generally able to withstand blow fly infestations, but that infestations in excess of 150 larvae per nest may result in death. Risley (1994) reported significant losses of nestlings in Ontario due to blow fly parasitism. In 1980, 23% of broods on a bluebird trail died as a result of blowfly larvae.

Bluebirds are often attracted to smokestacks and chimneys because they may be potential nest sites or roosts. These birds are often asphyxiated by smoke or cannot get out (Gowaty and Plissner 2020).

Anthropogenic noises may affect reproductive success of the bluebird. Low-pitched loud human-generated noises are associated with smaller clutches and fewer fledglings (Gowaty and Plissner 2020; Williams et al. 2021). In Florida, Sieving et al. (2024) studied the effects of chronic highway noise and experimental intermittent playback of construction noise on the bluebird. Nests in quiet areas had higher nest success than any exposed to noise. Nests exposed to chronic road noise and nests in quiet areas that were subjected to 3-4 days of construction noise had the lowest hatching success.

Price (2004) predicted that the breeding range of the Eastern Bluebird could increase in southern Ontario if the average summer temperature increased by 2°C.

Status

The Eastern Bluebird population has fluctuated considerably both in Ontario and throughout its range. It was probably rare to uncommon in Ontario prior to European settlement. Prior to settlement, it was probably restricted to forest fire burns, clearings created by First Nations, prairies, and forest edges. Forest clearing and establishment of stump fences and wooden fence posts created ideal habitat and nest sites. Highest abundance of the bluebird may have occurred in the latter half of the 19th century (Read 1998, 2006). McIlwraith (1894) stated that the bluebird was formerly one of the most abundant breeding birds in the province, but that it was decreasing due to presence of the House Sparrow. Although seldom seen near towns or villages at that time, it was still common in rural areas. Fleming (1907) considered the bluebird abundant in the Toronto area. In the 1930s, it was common to abundant south of the Canadian Shield from Middlesex County east to Ottawa. It was uncommon and occasional in the Shield and central Ontario (Risley 1981). Breeding at that time was documented north to at least the transcontinental railway west to southern Kenora District. There were scattered summer records north to Moose Factory, but it was comparatively rare everywhere north of Lake Nipissing (Baillie and Harrington 1937). Declines in the 1920s in the Oshawa area were attributed to competition with the starling. Gradual declines became apparent in the 1940s and 1950s, and a significant decline of 60-90% occurred in Ontario after the severe winter of 1957-58. This was the first time that populations did not rebound in a few years after a severe winter, probably because starlings had populated rural areas by then. In the Hamilton area, the bluebird remained common as a breeding species throughout the 1940s and early 1950s, but declined dramatically by the end of the 1950s. From 1951-85, there were records of only 1-3 pairs per year, with no records 1951-58, 1960, 1967, and 1968. Populations throughout Ontario remained low in the 1960s and 1970s, although successes were starting to be realized on bluebird trails. The severe winters of 1977-78 and 1978-79 devastated populations and they reached an all-time low in 1978. In 1980, there were only 236 known pairs of bluebirds in the province, although it was thought that the population was more in the order of 1,000 pairs. It was most abundant then along the southern edge of the Shield and on Manitoulin Island. Populations were considered stable or possibly increasing at that time, and the Eastern Bluebird was designated special concern in Canada (Read 1998, 2006; Risley 1981, 1994). During the first atlas, it was more numerous and widespread than previously thought. It was estimated that there were about 2,000 pairs in the province. Numbers appeared to have been increasing since about 1980, largely due to the efforts of bluebird trail operators. In 1998, its status was reassessed as not at risk (Read 1998; Risley 1994). James (1991) considered the bluebird a locally common summer resident in the agricultural south, rare to locally common in the north to Lac Seul and Cochrane, and formerly present and still possible north to Favourable Lake and Moosonee.

The second atlas showed a significant increase in the probability of observation of the Eastern Bluebird for the province as a whole and in all regions that it occurred in, compared with the first atlas. Highest densities occurred south of the Canadian Shield, where it was typically associated with well-managed bluebird trails, and in western Rainy River District where there are extensive pastures

that provide suitable breeding habitat. Distribution was patchy in the Shield indicating a scarcity of suitable habitat, although birds nesting in clear-cuts and burns may have been missed due to lack of coverage (Read in Cadman et al. 2007).

Breeding Bird Survey data for 1970-2021 indicate that the bluebird increased at annual rates of 1.29% in Canada and 0.956% in Ontario. The trends 2011-21 were annual decreases of 2.23% in Canada and 2.53% in Ontario. The long-term results for Ontario were highly reliable; the other results were of medium reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Young birds that fledge prematurely cannot fly, but are capable of climbing trees to reach cover and shelter. Fledglings remain in or near cover for 7-10 days after leaving the nest and may remain in family groups for 3 weeks. Young are typically fed by the adults until they are 35-40 days old, rarely to age 47 days. Females raising a second brood stop feeding the first fledglings when they are 7-10 days old. Young begin feeding themselves at 22-28 days of age. Those from first nests often leave the natal territory upon independence. Those from later broods often remain on the territory and may stay with their parents all winter. Consequently, natal philopatry may be lower for birds of first broods (Gowaty and Plissner 2020).

Family groups may remain near the nesting area in late summer and early autumn. In Michigan, a group of 12 birds that included a pair, some of their young, some fledglings from the yearlings' nest, and young from a nest that juveniles had helped at, all expelled other bluebirds from the area they occupied (Pinkowski 1976b). Once birds become independent, juveniles form flocks comprised of many families. Flocks range widely, but usually remain in the vicinity of the natal area, although there are reports of juveniles recovered in their natal year 20-300 km from the natal site. Single and multifamily flocks of juveniles may make flights of several kilometres at a time (Gowaty and Plissner 2020).

MIGRATION

Within a given area, some bluebirds migrate whereas others remain all winter. More birds migrate from harsher climates and all birds nesting in central and northern Ontario migrate. Some northern migrants pass over resident populations in the south to winter even further south. Ontario birds have been recovered in winter or late spring in Kentucky, North Carolina, Georgia, and Florida. Individuals may migrate some years and stay over winter in others. In Michigan, birds remained over winter only if they had nested successfully. Food availability influences migration and this may be affected by weather. In the Hamilton area, cool summers result in poor crops of buckthorn and sumac. More bluebirds migrate south then and do so earlier than after summers with ample supplies of fruit. The bluebird is a diurnal migrant with no evidence of nocturnal migration. Movement is in small, loose flocks that travel mostly in the morning (Brewer et al. 2018; Gowaty and Plissner 2020; Pinkowski 1976b, 1977a; Read 2006).

In spring, males usually arrive a few days earlier than females although pairs sometimes arrive together (Banfield and Robert in Gauthier and Aubry 1996; Bent 1949; Gowaty and Plissner 2020). In southern Ontario, bluebirds begin arriving in mid-March and the peak of migration is in mid-April. In the southern Shield, average arrival is mid-April with the earliest arrivals in mid- to late March. In

the southern Shield, family groups begin wandering in August and small flocks may be seen throughout September and into October. In the south, migration begins in mid-September and peaks mid- to late October (Curry 2006; LaForest 1993; Lancaster et al. 2004; Mills 1981; Risley 1981; Tozer 2012; Weir 2008).

During migration, habitat used by the Eastern Bluebird is similar to that of the breeding season, except for greater use of open-canopy forests. Birds may prefer to move along corridor edges. Roosts continue to be an important habitat component. In Arkansas, migrating birds frequently roosted in trees at the base of a hill. In early spring in Michigan, an adult male and his offspring male roosted together in the same nest box they used as a roost the previous winter. This appears to be the first record of fidelity to a roosting site (Gowaty and Plissner 2020; Pinkowski 1976b; Thomas 1946a).

During spring migration, the bluebird feeds predominantly on residual fruit until insects become available. During autumn migration, fruit dominates the diet. In Ontario, it is likely that buckthorns and sumacs are important in the diet (Read 2006; Risley 1981).

The Eastern Bluebird was formerly an abundant migrant in Ontario and is more common in autumn than spring. Fleming (1907) considered it an abundant migrant in the Toronto area. There are records of many thousands passing over Toronto from west to east each day for a week during spring migration in the early 1900s (Risley 1994). It is now an uncommon migrant (James 1991), although it may occasionally be locally common.

WINTER

The winter distribution of the Eastern Bluebird is strongly correlated with temperature. In the north, its distribution infrequently extends into regions with an average January temperature lower than –7°C. It is highly concentrated in winter in areas that are warm and moist. It is most common where the frost-free period averages about 180 days and there is more than 61 cm of precipitation annually (Root 1988).

In Elgin County, most wintering flocks of bluebirds are found in sheltered places in gullies, predominantly near Lake Erie, particularly where there is lots of sumac, one of the staple foods (Lancaster et al. 2004). In Illinois, it winters along major rivers and in forests and forest edges, shrubby areas, ungrazed grasslands, pastures, and alfalfa fields. In Kansas, preferred winter habitat included open groves of black walnut and honey locust, particularly those on hilltops with shallow soils and short grasses. In Missouri, it was present in moderate density in savannahs, with highest density in woodlands and lowest density in forest. In Arkansas, Kentucky, and Mississippi, there was no difference in its density in fields with or without grassy buffers. Other habitats that may be used in winter include orchards and parklands (Evans et al. 2015; Fitch 1958; Graber and Graber 1963; Graber et al. 1971; Gowaty and Plissner 2020; Kendrick and Thompson 2013).

Roosts are even more important in winter to protect bluebirds from the elements. In Arkansas, 1 roosted in a rotting stump; nest boxes were used for roosting only on the coldest nights. In Tennessee, nest boxes were used only once the temperature dropped below –10°C. Nest boxes containing used nests provide additional protection from cold. Bluebirds have also roosted in old robins' nests (Bent 1949; Gowaty and Plissner 2020; Pinkowski 1977a; Pitts 1979; Thomas 1946a).

Winter flocks of 2-30 bluebirds may defend feeding areas, although defence is less intense than during the breeding season. Family groups and pairs may defend areas around nesting cavities where most birds are year-round residents. Winter home ranges are larger than the defended areas. In South Carolina, where it is resident, home ranges averaged 105.9 ha for males and 120.8 ha for females. Two females had an average home range size of 224 ha from February until April (Gowaty and Plissner 2020).

The winter diet of the bluebird is dominated by fruit, although Pinkowski (1976c) observed several small flocks preying on winter stoneflies emerging from fast-flowing streams. Over 60 species of fruit have been documented in its winter diet, but sumac is one of the staples throughout its range. In Tennessee, analyses of fecal and regurgitated matter indicated that individual birds typically foraged on a single species during each feeding. The diet consisted of 54% sumac, 37% Japanese honeysuckle, 5% holly, and less than 1% each for greenbrier, wild rose, bittersweet, pokeweed, hackberry, and wild grape. In Illinois, mistletoe was most prominent in the winter diet, but grapes, sumacs, hawthorns, and holly were important and Virginia creeper was occasionally consumed. Winter fruits eaten in Georgia included those of black gum, blueberry, black cherry, currants, flowering dogwood, Japanese honeysuckle, pokeweed, red cedar, smooth sumac, and several species that do not occur in Ontario (Bent 1949; Gowaty and Plissner 2020; Graber et al. 1971; Petrides 1942; Pitts 1979).

The Eastern Bluebird is a rare visitor to winter feeders in Ontario, but may visit almost 25% of feeders further south. It is less frequent at urban feeders than elsewhere. Even where it visits feeders, it usually is not present week to week. Flock sizes decline from January on, but the number of feeders visited increases at the same time, probably reflecting the beginning of spring migration. Dried fruit is the most favoured food at feeders followed by water. It infrequently eats mixed seeds, striped sunflowers, suet, and bird puddings. It may also eat peanut hearts, peanut butter mixes, and peanuts in the shell (Dunn and Tessaglia-Hymes 1999).

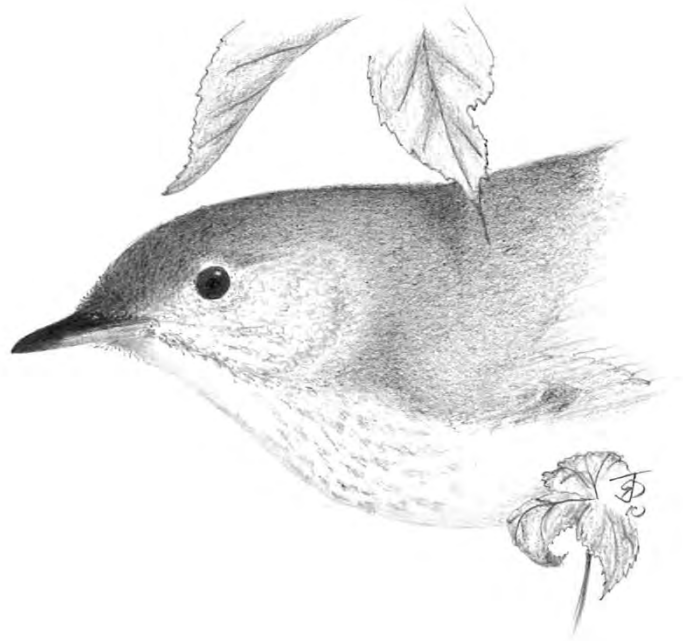
Severe winter weather may now be the greatest limiting factor to the Eastern Bluebird. Severe weather may result in massive mortality and this can affect continental populations if cold, wet weather is widespread in the southern United States. The first reported significant decline was after the winter of 1894-95 when populations declined throughout its range, but full recovery occurred in a few years. In Ontario, populations were significantly depressed after the severe winters of 1894-95, 1911-12, 1957-58, 1976-77, and 1977-78, with a lesser decline after the winter of 1939-40. After the winter of 1957-58, only 3 bluebirds were found in the Kingston region in the summer of 1958. Prior to 1957, populations recovered within 3 or 4 years of a severe winter, but there was limited recovery after bad winters in the 1950s and 1970s. The Michigan breeding population declined by 50% after the winter of 1976-77 and similar declines occurred across North America. Local winter storms may result in declines if food supplies are covered in ice or snow or the weather is extremely cold. There appeared to be massive mortality in Illinois following an intensive winter storm (Bent 1949; Graber and Graber 1963, 1979; Pinkowski 1979; Risley 1981, 1994; Weir 2008; Zeleny 1976).

The Eastern Bluebird is rare and locally uncommon in winter north to Kingston (James 1991). In Elgin County, it was rare in winter in the 1950s. Highest numbers in Canada were reported on Elgin County Christmas Bird Counts (CBC) in 1999, 2000, and 2001 (Lancaster et al. 2004). In the Hamilton

area, the first winter bluebird was not seen until 1954, but small numbers began overwintering regularly in the mid-1980s. Bluebirds were documented on every Hamilton CBC since the mid-1980s except 1993 and 1996 (Curry 2006). The increase in wintering bluebirds may be related to weather conditions and food supplies. From 1947 to 2005, rainfall increased from 340 to 400 mm during the May to September growing season which was beneficial to growth of fruit-bearing trees and shrubs, and therefore bluebirds. Numbers overwintering in the Hamilton area are related to weather conditions with more occurring in warmer winters and winters following hot summers that produce ample supplies of soft mast (Read 2006).

Veery

Catharus fuscescens

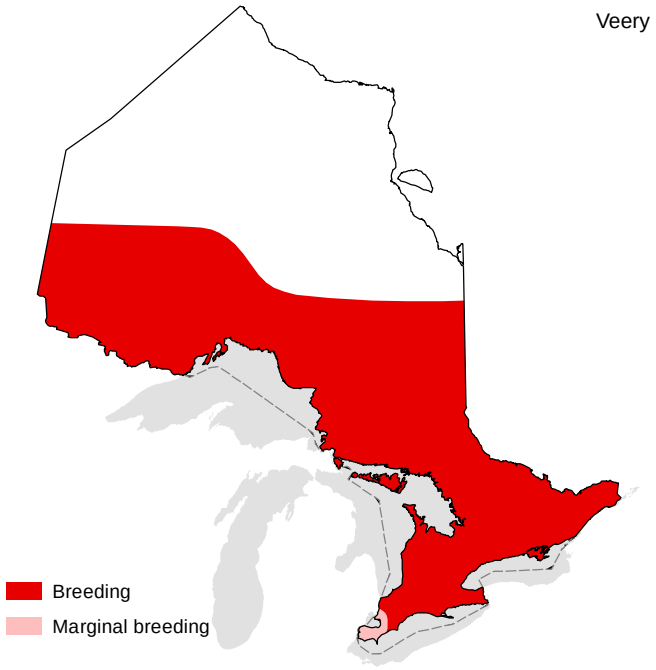


BREEDING SEASON

Habitat Requirements

The Veery usually breeds in woodlands in Ontario, but 4 nests were reported in overgrown fields and one of these was near a woodland edge. Mixed (50.3% of nests) and deciduous (41.5%) woodlands were selected for breeding much more than coniferous (8.1%) forests. Most wooded areas that supported the Veery were open second growth with a heavy understorey or dense ground cover. Several nests were at woodland edges near roads, shorelines, clearings, or fields. Wet habitats were used for nesting much more often than dry sites (Peck and James 1987).

In the Boreal Forest Region of Ontario, abundance of the Veery was significantly correlated with edge. This was a measure of forest-cover configuration and age-class interspersion rather than interfaces between forested and open habitats. It was associated with immature to younger deciduous stands with fairly open conditions (Rempel 2007). In Quetico Park, it was most abundant in early succession forests 1-23 years after a forest fire. It occurred in low numbers in mature stands, but was absent in intermediate-aged and old-growth forests (Apfelbaum and Haney 1985). Welsh (1993) concluded that it was a mid-succession species in northwestern Ontario, reaching highest



density in forests 12-21 years old. Near White River, it was more common in clear-cuts 23-25 years old than clear-cuts 3-20 years old and mature forest, but not significantly (Venier and Pearce 2005).

In jack pine stands near Gogama, the Veery always occurred in forests where there were few or no conifers. It first appeared when forests reached about 10 years of age and persisted in low numbers in more mature forest as long as the undergrowth remained lush. Deciduous trees in stands could be widely spaced provided that taller shrubs were numerous (James and Peck 1995a). In Algonquin Park, Martin (1960) considered the Veery characteristic of deciduous forests, especially those dominated by aspen and white birch. Density declined with intrusion of balsam fir and spruce into aspen-birch stands. It was absent in balsam fir–black spruce, immature white pine, and hemlock stands. In Muskoka District and Haliburton County, it was associated with intermediate canopy volume and slightly less than mean tree density. Singing perches were in deciduous woodlands with a well-developed understorey. Nest sites were associated with intermediate canopy volume and tree density and very high shrub coverage. It would be expected to benefit from tree removal in mature forests if the understorey was not disturbed, resulting in greater shrub density and development of the understorey (Clark et al. 1983). In Parry Sound District, it nested in a moist, open deciduous forest dominated by sugar maple, black ash, and basswood. The forest had a dense understorey of sugar maple and red elderberry. The forest floor was dominated by tree seedlings, spotted jewelweed, raspberries, and spinulose woodfern (Reynolds and Mills 1981).

In Durham Region, the Veery occurred over a wide successional range, but reached its greatest abundance in mid-succession forests. It was most abundant in a young forest with open canopy, poor drainage with standing water, and rank growth of raspberries and tree seedlings. It was also common in a black spruce bog rimmed by deciduous swamp; another open woodland with much of the forest floor under water and a rank growth of ferns and raspberries; mature maple-oak forest adjacent to a floodplain with standing water and dense growth of sensitive and royal ferns; and in a mature sugar maple–beech woodlot with a few springs and gullies and a sparse understorey (Speirs and Orenstein 1975). In the Lake Simcoe watershed, territories had higher mean abundance of black cherry trees, a greater number of logs, and a lower number of trees with a diameter at breast height (DBH) of 23-38 cm than unoccupied areas. It occupied areas characterized by second growth having low, open forest canopies with standing water, little leaf litter, and few mature trees. Second-growth habitat was either regenerating forests, degraded, or floodplain forests. The Veery was found in areas

with high ground coverage by ferns and mosses with large numbers of vines and logs. It was most likely to occupy deciduous forests rather than mixed or coniferous forests and occurred most often in forests with an overstorey of ash and red maple and an abundance of understorey balsam fir. Food sources such as riverbank grape, bunchberry, and black cherry may be important habitat components (Hawey et al. 2020). In the Kingston area, it bred in small numbers in open space within urban areas, and on Amherst and Wolfe islands (Weir 2008).

In the Carolinian Forest Region in Elgin County, the Veery's preferred breeding habitat was larger deciduous or mixed woodlands with patches of cool, damp, dense undergrowth (Lancaster et al. 2004). McIlwraith (1894) stated that some nested in the Hamilton area among the undergrowth in moist, uncleared forests. In the South Walsingham Forest in Norfolk County, its abundance was significantly correlated with shrub density and shrub layers 0-0.3 m, 0.3-1 m, and 1-3 m in height. Its presence was negatively associated with the basal area (BA) of trees smaller than 38 cm DBH and total BA, but there was no relationship with the BA of trees larger than 38 cm DBH. Shrub development was particularly important to the Veery (McCracken et al. 1998).

In addition to forests, the Veery occasionally nests in shrub thicket swamps, in old fields grown up with shrubs and saplings, and in regenerating clear-cuts. These habitats are used only occasionally in Ontario, but are more readily and widely used in the western portion of its range. In Wisconsin, it nested in willow and alder shrub thickets (Hoffman 1989b). In mountainous areas of Wyoming, it was most abundant in lower communities of cottonwood and willows, but was also common in mid-elevation willow shrublands (Finch 1991a). In British Columbia, it nests in aspen and birch forests, in steep hillside gullies filled with shrubs, margins of clearings or abandoned farmland, shrubs along borders of beaver ponds, and other moist woodlands with dense shrubbery (Campbell et al. 1997). In Maine, it was most abundant in alder thicket swamps. Most singing males were in either pure alder or deciduous and mixed forest with red maple and alder (Morse 1971a). In North Dakota, it nested in all forest habitats, but highest densities occurred in willow shrubs (Faanes and Andrew 1983). In New Jersey, it was absent in 10- and 20-year-old successional fields, but present in a 40-year-old field. This field had wooded borders. The Veery increased as shrubs choked out open spaces or as herbaceous cover got shaded out by trees (Suthers 1988).

The Veery nests in a wide range of deciduous and mixed forest types throughout its range, and much less frequently in coniferous forests. It is most likely to occur in swamps and lowland forests, but occasionally nests in forest stands on dry soils. If dry upland forests have damp depressions or seeps, it is often associated with these, or colonizes these areas first in spring. Forest types it has nested in include hemlock bottomland forest, northern hardwoods, lowland hardwoods, aspen-birch, occasionally in pine forests and upland spruce-fir forests, lowland black spruce, lowland tamarack, maple-beech–yellow birch forests, sandy hillsides interspersed with wetlands, mature bottomland forest, white oak, red oak, red maple swamps, black spruce–white cedar swamps, young white pine–alder, dry oak-pine woods, apple orchards (at least formerly), aspen forests, beech-maple-oak forests, and pine-oak barrens with pockets of forest (Back 1979; Beals 1960; Campbell et al. 1977; Capen 1979; Crawford and Titterington 1979; Dawson 1979; Erskine 1977; Gates and Giffen 1991; Golet et al. 2001; Graber et al. 1971; Hoffman 1989a; Holmes and Robinson 1988; Leighton et al. 2002; Martin 1960; Morse 1971a; Mossman et al. 1991; Noon et al. 1979; Samson 1979; Temple et

al. 1979; Tyler in Bent 1949). In the Boreal Forest Region, Erskine (1977) considered the Veery one of the typical species in poplar or birch stands, but also characteristic in swamps and floodplain forests. It is strongly associated with deciduous trees and shrubs, but also nests in mixed and coniferous woods and uses areas dominated by coniferous shrubs. In many areas, mixed and coniferous stands dominate lowland areas and provide suitable habitat. Areas supporting hemlock and balsam fir may be attractive to it. In some areas, its abundance has been correlated with the density of coniferous shrubs. In forests heavily browsed by deer in Michigan, its abundance was somewhat greater in areas with abundant deciduous understorey than in understorey dominated by balsam fir. Nonetheless, presence of balsam fir and some deciduous shrubs shorter than 1 m (presumably protected by snow depth) allowed it to persist in heavily browsed forests. It commonly nested in firs 2-3 m tall indicating that an abundance of taller firs may be important in some stands, although density of balsam fir was not a reliable predictor of its abundance (Dilger 1956; Gates and Giffen 1991; Kearns et al. 2006; Tyler in Bent 1949).

The Veery was restricted to landscapes with 65-75% forest cover in North Dakota and 99-100% forest cover in New York. In North Dakota, the maximum tree coverage present was 75% (Cunningham and Johnson 2019).

Although the Veery nests in a wide variety of forest types and forest ages, it has some specific habitat requirements. The most important appears to be a well-developed understorey of shrubs or lush fern or herbaceous plant coverage. Moisture regime is also important, with wet or damp sites preferred over dry forests. Finally, deciduous shrub and tree cover is important; it generally declines in abundance with increasing conifer coverage, although it may be associated with understorey balsam fir.

The Veery prefers a dense understorey, but may find very high densities of saplings unattractive. In New York, it declined with forest maturation and the associated loss of vertical and horizontal structural diversity. In West Virginia, it occurred in selective cuts but not in mature forest (Litwin and Smith 1992). In Maryland, it was significantly associated with both herbaceous and overall ground cover and with short and tall coniferous shrub coverage (Gates and Giffen 1991). In New Jersey, it occurred in second-growth and climax logged forests but not in wet disturbed forests. Climax forests tended to attract more Wood Thrushes than Veeries as the understorey became increasingly open (Suthers 1988). In eastern northern hardwood communities, it occurred in 18% of mature, undisturbed forests compared with 77% of disturbed and successional habitats. It exhibited a negative trend with forest succession (Noon et al. 1979). Temple et al. (1979) considered it associated with increasing abundance of yellow birch and sugar maple and also with late and mature seral stages of forest. Niemi and Pfannmuller (1979) reported that it was associated with increasing numbers of shrubs but decreasing numbers of saplings. In the mid-Atlantic states, it was positively correlated with foliage density at 0.3-1.0 m and the number of dead standing trees larger than 3 cm DBH. It was negatively associated with the number of trees and mean canopy height (Robbins et al. 1989). In Wisconsin upland forests, it inhabits cool, damp pockets and stream bottoms where there is often a dense understorey; it also nests in the dense understorey of cutovers. In New York, moist disturbed bottomland deciduous and coniferous forests with a lush understorey of ferns and other plants provided optimal conditions. Undisturbed forests probably did not support a dense enough

understorey for the Veery (Dilger 1956). In Connecticut, the amount of herbaceous cover was important. Important plants in territories were either early succession species or those associated with moist soils, and included grey alder, gray birch, black cherry, apple, white elm, and nannyberry (Bertin 1977). On islands in Wisconsin, it occurred in greatest numbers in aspen and red oak forests, especially where the understorey was densest (Beals 1960). In Vermont, it was significantly associated with shrub density, percent coniferous shrubs, and percent ground cover (Noon 1981). In his habitat suitability index (HSI) model, Sousa (1982) considered the structure of the shrub layer to be the key vegetation habitat component for the Veery. It occurred in open and undisturbed areas of deciduous, mixed, and coniferous forests where the density of deciduous shrubs was significantly higher than in the surrounding forest. More than 70% deciduous shrub coverage provided ideal habitat. Areas with less than 20% shrub coverage were probably unsuitable. Shrubs 1.5-3.0 m tall were considered optimal, shrubs less than 0.5 m tall were considered unsuitable, and shrubs or regenerating trees 5 m in height were considered to be half as valuable as shrubs 1.5-3.0 m tall. For ground cover, optimal conditions were more than 90% coverage with herbaceous plants taller than 30 cm. Less than 30% herbaceous cover was considered unsuitable. Herbaceous cover added to the overall quality of habitat, but was only half as important as shrub coverage. In New Hampshire, the shrub and sapling layers became denser over time and all thrush species declined (Holmes and Robinson 1988). Heckscher et al. (2020) stated that shrub cover is the main vegetative consideration in habitat selection by the Veery. In Quebec, Falardeau (in Gauthier and Aubry 1996) considered it characteristic of deciduous woodlands with a fairly open canopy and a dense understorey; it also occurred in mixed-wood forests. In Wisconsin mesic forests, young dense forests of aspens formed after clear-cutting or fire were favourable (Hoffman 1989a). In Delaware, nest sites differed significantly from random sites and were characterized by dense foliage below 1.5 m with sparse vegetation within the 2.5-3.0 layer (Heckscher et al. 2020). In a Connecticut woodlot over a 59-year period, there was a progressive shift to larger trees, a sparser shrub layer, and a less diverse tree canopy. The Veery decreased, probably due to the decrease in shrub cover (Buchanan et al. 2016). Almost all studies concur that dense shrub coverage is the most important habitat variable for the Veery and that lush herbaceous growth may be important but not essential. An exception is in mountainous areas of Wyoming. Bare ground comprised as much as 50% of the surface area in any territory compared with 14.3% at random sites and shrub coverage (34.4%) was always less than at random sites (Finch 1989b).

Although the Veery occasionally nests in dry forests, it reaches its greatest abundance in damp and wet habitats. In many areas, it shows a decided preference for riparian floodplain forests and may be confined to these areas. In eastern Quebec balsam fir–white cedar forests, it was present only in riparian stands and was absent in nonriparian stands of similar composition. When forests covering a wide range of moisture regimes are inhabited, territories along watercourses and in wet areas are occupied first, indicating selection for these areas. In Connecticut, small seeps and springs led birds to establish territories in areas that would probably be unoccupied otherwise. Although presence of water appeared to be important in this study, many territories were far from water in 1 study area and another area supported larger numbers in moist areas away from water. Moisture regime and microclimate variables appeared to be more highly correlated with Veery abundance than vegetation structure (Bertin 1977; Campbell et al. 1997; Dilger 1956; Gates and Giffen 1991;

Heckscher et al. 2020; Holmes and Robinson 1988; LaRue et al. 1995; Leighton et al. 2002; Morse 1971a; Robbins et al. 1989; Sousa 1982).

Other microhabitat preferences have been identified for the Veery. Robbins et al. (1989) found that its presence was associated with the total BA of forest stands. Noon (1981) determined that it was positively associated with BA of coniferous trees, BA of deciduous trees, percent canopy cover, canopy height, density of trees less than 15 cm and more than 22.9 cm DBH, density of trees larger than 38 cm DBH, density of deciduous trees, number of trees per ha, tree size-class diversity, average diameter of trees within a 0.04-ha circle, ratio of total tree BA to average shrub BA, and diameter of the largest tree within a 0.04-ha circle. In New Hampshire and Maine, its presence was significantly correlated with percent ground cover, coniferous trees larger than 10 cm DBH, the number of woody stems per ha, and total foliage volume of coniferous trees 2-10 cm DBH. It was negatively correlated with coniferous trees 2-10 cm DBH, the foliage volume of deciduous trees larger than 10 cm DBH, and the foliage volume of both coniferous and deciduous trees less than 2 cm DBH (DeGraaf et al. 1998). In Delaware, nest sites were characterized by dense foliage below 1.5 m with a sparse overstorey at 2.5-3 m (Heckscher et al. 2020).

The Veery is an area-sensitive species and the minimum size of forest it requires increases as the amount of forest cover in the landscape decreases. In southern Ontario, its probability of detection was positively correlated with the amount of forest 100 m or more from edge, woodlot size, and amount of forest within 2 km, but was negatively associated with the amount of regional forest cover. Woodlot size was the only significant relationship, although the relationship with the amount of forest 100 m from edge was significant at the 10% level (Austen et al. 2001). Also in southern Ontario, the amount of core forest area was the most important predictor of abundance at the scale of 500 m, but was less important at broader scales (Smith et al. 2011). In red maple swamps in Rhode Island, it nested in swamps smaller than 1 ha, but all the swamps were surrounded by upland deciduous forest. Even when the combined area of swamp and upland forest was considered, there was no relationship between its presence and forest size, probably because approximately 60% of the landscape was forested. Its presence was significantly correlated with the amount of deciduous forest within 1 km. Regional forest abundance may be more important in determining its presence and abundance than forest size (Golet et al. 2001). In the mid-Atlantic states, its probability of observation was highest in forests 250 ha in area and was reduced to 50% in 20-ha woodlands. The 3 smallest isolated woodlands that it was detected in were 9.3, 11.3, and 24.1 ha (Robbins et al. 1989). In aspen stands in North Dakota, it was most likely to occur in groves with a greater proportion of trees larger than 23 cm DBH. Probability of detection was 20% in 1-ha stands, 55% in 10-ha stands, and 90% or more in woodlands 100 ha and larger (Grant and Berkey 1999). In northern Illinois where forest cover is only 4-7%, the Veery bred in forest patches ranging from 27 ha to more than 1,000 ha. Only 2 of the 22 forest patches where it nested were smaller than 100 ha; over half were larger than 200 ha (mean 309 ha). Occupied sites had an average of more than 250 ha of additional noncontiguous forest habitat within 2.5 km of the breeding area (Herkert 1995). In southern Wisconsin, the minimum size of forest that had a 50% chance of supporting a breeding population was 24 ha (Mossman and Hoffman 1989). The Veery is area sensitive in Ontario south of the Shield, where it is generally thought to require about 20 ha of forest. It may require much larger forests than

this in extreme southwestern Ontario where there is little forest cover, but may not be area sensitive at all in more heavily forested areas such as the Bruce Peninsula and along the Niagara Escarpment.

Some authors considered the Veery a forest-interior species (Faanes 1987; Freemark and Collins 1992; Golet et al. 2001). In Maryland, Gates and Giffen (1991) considered it an edge species. In eastern northern hardwood communities, Noon et al. (1979) considered the Veery an edge species. In Ontario, it does not appear to be a forest-interior species. It nests throughout forests from the interior to the very edge, and occasionally in unforested shrubby areas. It may tend to nest more in the interior in woodlands that are near the minimum size that it occupies or in landscapes with a low percentage of forest cover, but readily nests near or at forest edge in larger woodlands or when the landscape is heavily forested.

Veery territories frequently overlap with those of other thrush species, including the Wood Thrush, Hermit Thrush, Swainson's Thrush, and American Robin. Agonistic behaviour between these species is rare. Several studies examined microhabitat preferences of the thrushes to determine how they separate themselves without competing for resources.

The greatest overlap in habitat preferences is between the Veery and Wood Thrush and the 2 species commonly have overlapping territories. In mature woodlands in Connecticut, 90% of Wood Thrush territories were overlapped to some extent by Veery territories, and 42% of Veery territories were overlapped by Wood Thrush territories. In this population, moisture was the most important variable for both species. Average microhabitat components in Veery populations were 51.6% shrub coverage, significantly higher than for the Wood Thrush; 15.0 m tree height, significantly lower than for the Wood Thrush; 28.2% early successional stage coverage, significantly higher than for the Wood Thrush; 17.9% late successional stage coverage, significantly higher than for the Wood Thrush; significantly higher moisture regime than for the Wood Thrush; and 6.5% exposed soil, significantly higher than for the Wood Thrush. In Veery territories, there were significantly more striped maple, gray birch, witch-hazel, and Canada mayflower than in Wood Thrush territories, and significantly less red oak, black oak, perfoliate bellwort, and maple-leaved viburnum. The amount of flowering dogwood was almost significantly less in Veery territories. The Veery appeared earlier in succession than the Wood Thrush. When territories in mature woodlands were compared to eliminate the effects of successional stage, no structural or physical parameters differed significantly between Veery and Wood Thrush territories, although shrub coverage was slightly greater in Veery territories (40.2% compared with 33.0%). The amount of shrub coverage was the most important factor separating the 2 species, reflecting the absence of the Wood Thrush in thickets and early successional woodlands. Other significant factors were the presence of striped maple and flowering dogwood (Bertin 1977). Morse (1971a) studied an area in Maine that was originally occupied only by the Veery and Hermit Thrush, but later inhabited by the Wood Thrush. The Veery used moister habitats than the Wood Thrush and was characteristic of damp deciduous forests. The Veery was the only thrush that occupied the wettest habitat, which was alder thicket. As the Wood Thrush became more common, it colonized areas that were more mesic than those used by either the Veery or Hermit Thrush. In 1 case, a Wood Thrush used essentially the same territory that was used by a Veery the previous year; the Veery did not occupy this area when the Wood Thrush was present. The Wood Thrush is larger and may be socially dominant to the Veery. In Vermont, Noon (1981) studied

habitat characteristics of 5 thrush species on a mountain gradient. The Veery overlapped territories with all other thrush species, but there was only about 300 m of elevational overlap in Veery and Wood Thrush territories. The Veery was separated from the Wood Thrush by preferring higher canopy cover, shrub density, and ground cover, and lower density of deciduous trees. The primary difference was shrub density, which consistently separated habitat preferences of the Veery and Wood Thrush. In West Virginia, Dellinger et al. (2007) examined habitat variables around nests of 4 thrush species and found that habitat partitioning occurred at all 3 scales examined: the nest substrate, nest site, and territory scales. Wood Thrush and Veery nest sites had many overlapping variables and were most often misclassified as each other. Both species occurred in forested areas where the ground cover was predominantly leaf litter and woody debris. Veery nests tended to be 1.6 m or lower from the ground; Wood Thrush nests were 1.6 m or higher. Veery nest sites had less woody-debris ground cover, more saplings, and less canopy cover above the nest than Wood Thrush nest sites. The Veery nested at intermediate elevations; the Wood Thrush nested at the lowest elevation. Veery territories were mostly on slopes facing southwest; Wood Thrush territories had a more northeasterly aspect. Both the Veery and Wood Thrush frequently nested in beech, with the Veery usually nesting lower in epicormic branches and the Wood Thrush higher in a main crotch. The Veery was the only species to nest in shrubs such as raspberries, greenbrier, and roses. In New Jersey, climax forests attracted more Wood Thrushes than Veeries as the understorey became increasingly open (Suthers 1988). The primary variables separating the Veery and Wood Thrush appear to be that the Veery prefers areas with denser shrub growth and moister conditions.

The Veery and Hermit Thrush often coexist and may have overlapping territories. In New York, the Veery was positively associated with the Hermit Thrush in the Shield, but not significantly. South of the Shield, Veery presence was significantly negatively correlated with presence of the Hermit Thrush (Dilger 1956). Tyler (in Bent 1949) reported coexisting Veery and Hermit Thrush in Ontario, where the 2 species selected different habitat. The site contained dry, lichen-covered, rocky ridges separated by moist valleys dominated by bracken and other ferns. The Veery was restricted to valleys and the Hermit Thrush occurred only on ridges. On an elevational gradient in Vermont, the Hermit Thrush and Veery did not occur together, but Noon (1981) concluded that Veery habitat might be constrained by the presence of both the Hermit Thrush and Swainson's Thrush. In Maine, the Veery and Hermit Thrush did not occupy any habitat in nearly equal numbers. The only habitats where both occurred regularly were mixed coniferous-deciduous forests and deciduous forests with red maple and alder. Within these habitats, the Veery occurred in the wettest areas, the Hermit Thrush in the driest areas, and the Wood Thrush in areas of intermediate moisture. The Veery selected much wetter areas than the Hermit Thrush. In West Virginia, the Veery placed its nest 2.8 m or further on average from an edge, a greater distance than for the Hermit Thrush. Veery territories were mostly on southwest-facing slopes; those of the Hermit Thrush tended to have a more northeasterly aspect. The Veery was evenly located among slope locations but the Hermit Thrush tended to nest on upper and lower slopes (Dellinger et al. 2007). In Wisconsin, both species occupied disturbed second-growth coniferous forests where over half of each territory was covered with a canopy with a maximum height of approximately 20 m. A well-developed understorey of bracken ferns, shrubs, and tree seedlings grew to a height of 3 m on more than 80% of thrush territories. Both species frequently had adjoining or overlapping territories. Vegetation type and height were important in

partitioning patterns habitat of the 2 species. The Hermit Thrush spent more time in conifers; the Veery concentrated its activities in deciduous species. The Hermit Thrush fed more in conifers and the Veery fed more in shrubs. Both species made little use of aspen relative to its abundance (Paszkowski 1984). Laughlin et al. (2013) studied habitat partitioning by the Veery and Hermit Thrush in Virginia, North Carolina, and Tennessee where the Hermit Thrush has recently colonized. The Veery was a habitat specialist whereas the Hermit Thrush was more of a generalist. Veery territories had a high percentage of cover between 0.5 and 3 m. They had a lower percentage of canopy closure, less leaf litter, and fewer and smaller coniferous trees than Hermit Thrush territories. The microhabitats of the 2 thrushes were significantly different despite the fact that they often nested close together. In Quebec, the Veery nested in damper areas than the Hermit Thrush (Mousley 1916a). The primary habitat features separating the Veery and Hermit Thrush are moisture regime and tree type. The Veery prefers wetter areas dominated by deciduous species; the Hermit Thrush prefers drier areas, often with conifers.

No detailed comparative studies have been undertaken on the habitat preferences of the Veery and Swainson's Thrush. In New York, presence of the Veery was positively associated with presence of Swainson's Thrush in the Shield but the relationship was negative south of the Shield. These relationships were not significant (Dilger 1956). Coexistence of these 2 species in Ontario is predominantly in the southern Shield.

Dellinger et al. (2007) compared nest sites of the Veery and American Robin in West Virginia. Veery nests averaged 2.8 m or further from an edge; robin nests were closer than 2.8 m from edge. Although both species nested in shrubs, the Veery was the only thrush species to nest in very low and weak-stemmed shrubs such as raspberries, greenbrier, and roses.

Males roost in dense vegetation away from the nest at night (Heckscher et al. 2020).

Ontario nests were both on (38.3%) and above (61.7%) the ground. Nests were elevated in or situated at the bases of shrubs, saplings, and trees (61.6% of nests); on, in, or at the bases of stumps (15.3%); among herbaceous plants or clumps of grass (9.5%); on, under, or beside fallen trees, logs, and branches (8.7%); on or under brush or debris (3.3%); and on mossy hummocks (1.7%). For nests in trees and shrubs, deciduous species were preferred (18 species, 58.4% of nests). The other nests were in 6 species of conifers. Nest-tree species in order of preference were balsam fir, maple, alder, spruce, and birch. A small proportion of nests (11) were in crotches of trees and shrubs. Heights of nests above ground ranged from 0.08 to 5.2 m, with most 0.2-0.6 m up (Peck and James 1998). A nest in Parry Sound District was 5.1 m from the ground and positioned against the trunk of a sugar maple. The tree had a dead crown and there was only sparse foliage above the nest (Reynolds and Mills 1981). Tyler (in Bent 1949) reported an Ontario nest that was 0.8 m from the ground in the forks of a fallen limb.

Throughout the Veery's range, it may nest either on the ground or a short distance above it in trees or shrubs, or on stumps. Nests have been found as high as 7.6 m from the ground, but nests higher than 2 m are uncommon; most are lower than 1 m. Most nests are in deciduous trees but balsam fir may be an important nest-tree species. Nests have been reported in the fork of a black cherry tree and in shrubs including raspberries, Japanese honeysuckle, Japanese barberry, mountain

laurel, grape, alder, mountain maple, juniper, greenbrier, and rose. In the mid-Atlantic states, 83% of nests were in multiflora rose, 25% in fallen branches, 8% in Christmas ferns, 5% in spicebush, and 3% in other species; 84% of nests were supported by nonnative species. Of 84 New York nests, 25% were in barberry, 22% in fallen oak limbs, 17% in honeysuckle, 13% in multiflora rose, 5% in open grass tussocks, 3% in witch-hazel, and 15% in others. Based upon availability, most native species were avoided and barberry and rose were preferred. Unusual nests have been reported in tree hollows, in a tin can, and 3 m up on the horizontal limb of an apple tree. There is no evidence that nests are reused, but the same shrubs may be used for nesting in subsequent years (Campbell et al. 1997; Day 1953; Halle 1949; Heckscher et al. 2020; Kearns et al. 2006; LeBlanc 1999; Meyer et al. 2015; Mousley 1916a; Tyler in Bent 1949).

The Veery defends a territory. It can distinguish between the vocalizations of neighbours and strangers and reacts aggressively when strangers intrude (Heckscher et al. 2020). Near Quebec City, territories were evenly distributed with no evidence of clumping or coloniality (Bourque and Desrochers 2006). The size of 61 territories in Algonquin Park averaged 0.27 ha (range 0.04-1.09 ha). Territories extended from the ground upward to the lower tree branches, with an average depth of 7.0 m (Martin 1960). Territory sizes north of Montreal were approximately 0.5 ha in a sugar maple stand and a hemlock stand (Falardeau in Gauthier and Aubry 1996).

No information is available on initial dispersal from the natal site or dispersal from the breeding area (Heckscher et al. 2020), and very little is known about natal philopatry and adult site fidelity. In New Hampshire, Day (1953) banded 105 fledglings and 1 adult over a 15-year period and had no returns. In New Jersey, Suthers (1988) banded 142 and had 14 returns (9.9%) including 1 yearling. In Delaware, 1 of 23 nestlings (4.3%) returned; the return rate of adults over a 12-year period was 62% (Heckscher et al. 2011, 2020).

Limiting Factors

Eggs have been found in Ontario nests from the first week of May until the last week of July, mostly in the first 3 weeks of June (Peck and James 1987, 1998a). Pair formation occurs as soon as the female arrives; the female begins building the nest shortly thereafter. Nest building takes 6-10 days depending on weather conditions. Egg laying begins within 4 days of nest completion. A single egg is laid per day and incubation begins with the laying of the last or penultimate egg. At 1 Delaware nest, incubation began with laying of the second of 4 eggs. The incubation period at 10 Ontario nests was 10-14 days, mostly 11-12 days. Elsewhere, the incubation period has been reported as 10-13 days. Young remain in the nest for 10-15 days. Total time from initiation of nest building to independence of young is about 48 days: 6 days for nest building, 4 days for laying, 12 days for incubation, 12 days for the nestling period, and 2 weeks for feeding fledglings (Allen 1939; Campbell et al. 1997; Day 1953; Dilger 1956; Halley and Heckscher 2013; Heckscher et al. 2020; Peck and James 1998a; Tyler in Bent 1949).

It is uncertain if the Veery raises 1 or 2 broods. Allen (1939) stated that 2 broods were raised but provided no substantiating evidence. Heckscher et al. (2020) stated that there were suggestions of double broods, but no confirming data. In Ontario, Peck and James (1987) noted the possibility of double broods but none were positively confirmed. Campbell et al. (1997) concluded that it frequently attempted 2 broods in British Columbia. In 18 years in Delaware, only 3 females were

known to attempt a second brood but all failed. These attempts may have followed the mortality of fledglings. LeBlanc (1999) provided circumstantial evidence of renesting in New York. Ontario egg dates suggest that at least renesting occurs in the province and it is possible that some birds raise 2 broods. Clutches of 1-5 eggs have been reported in Ontario, with most containing 4 eggs (Peck and James 1987). Small clutches may be due in part to cowbird parasitism. Overall, clutches of 1-6 eggs have been reported. The Veery typically lays 4 eggs, sometimes 3, and occasionally 5 (Campbell et al. 1997; Heckscher et al. 2017, 2020; Tyler in Bent 1949).

The Veery first breeds when it is 1 year old and annually thereafter (Heckscher et al. 2020). It was long considered to be strictly monogamous. Multiple modes of parental care were identified in 1 population: multiple male feeders at nests, males attending multiple nests each with a different female, and 2 males that co-attended the same 2 broods. Of 6 genotyped broods, 2 contained a young sired by an unknown male. All females were the genetic mother of their entire broods. In this population, all 37 genotyped adults were related to at least 1 other bird at the cousin level or greater, and 81% were related to at least 1 other bird at the half-sibling level or greater. It appeared that the kin structure was maintained by natal philopatry in both sexes and that the Veery avoids nesting with close genetic kin. At all nests where adult feeders were genotyped, males were unrelated to the female. There was close kinship between 2 male co-feeders at the nests of 2 females and among 3 of 4 females that were mated to the same polygynous male. At 60% of nests of monogamous pairs, the male was detected as a feeder at a second, third, or fourth nest in the same season, each with a different female. One socially monogamous pair remained together in the second year (Halley et al. 2016).

Foraging occurs on the forest floor and at low heights in vegetation. The Veery may forage on the ground by flipping over leaf debris and gleaning in the shrub layer. In Connecticut, 76% of prey items were obtained by ground foraging, 22% by foraging on vegetation, and 2% by flycatching. In New Hampshire, 74.0% of prey attacks were at heights of 0-0.2 m, 24.4% were in the shrub layer 0.3-2 m from the ground, 0.8% were in the sapling layer 2.1-8 m from the ground, 0.2% were in the subcanopy 8.1-14 m from the ground, and none were in the canopy layer. Fifty-six percent of all prey attacks were in the ground/litter layer, 3.3% in herbs and ferns, 35.8% in foliage, 4.1% on bark, and 0.8% in the air. Prey-attacking manoeuvres were 7.4% probing, 40.6% gleaning, 0.7% jumping and hovering, 33.3% hovering, 15.1% diving and gleaning, and 2.9% hawking. It occasionally perched on rocks or logs, especially near streams, and searched the banks and foliage. When prey was spotted, it dove to the ground and snatched the prey (dive-gleaning). While foraging in Wisconsin, it spent 32% of its time in hardwood deciduous trees, 26% in shrubs, 19% in conifers, and 23% in aspens. Fifty-three percent of foraging time was spent at heights of 3 m or less; it foraged equal amounts of time at other heights (6 m, 9 m, 12 m). During migration, foot quivering to flush prey may be a significant foraging technique that may represent as many as 48% of observations. Although almost all foraging occurs in forested habitat (or thicket swamps if these are used for nesting), it may sometimes visit fields in early morning to feed (Dilger 1956; Heckscher et al. 2020; Holmes and Robinson 1988; Holmes and Sturges 1975; Malmborg and Willson 1988; Paszkowski 1984; Sousa 1982; Tyler in Bent 1949).

Several authors studied the foraging techniques of the Veery, other thrushes, and other low-foraging birds to define habitat partitioning among these species. In New York, all thrush species fed on the ground but the Veery and Swainson's Thrush differed in that they fed more often in the foliage and frequently flycatched. The Veery was primarily an arboreal species that foraged in the interior of forests. The differences in feeding niches involved both the height at which foraging occurred and location with respect to forest edge or interior (Dilger 1956). In Wisconsin, the Veery and Hermit Thrush differed significantly in the amount of time spent in 5 height strata: the ground, 0-3 m, 3-6 m, 6-9 m, and above 9 m. The Hermit Thrush spent 3 times as long on the ground as the Veery and concentrated its activities at heights of 3 m or less. The Veery spent its time equally among the 5 strata. The Hermit Thrush did approximately 25% of its foraging on the ground; ground foraging was less than 10% of the Veery's foraging activity. Overall, the Hermit Thrush was more terrestrial and active most commonly in the lowest forest growth. The Veery was more arboreal, ranging throughout the canopy. Shrubs were the most important foraging site for the Veery in the understorey, with 52% of feeding occurring in the 3-m stratum. Saplings and low tree growth were more important at this height for the Hermit Thrush (79% of feedings; Paszkowski 1984). In New Hampshire, Holmes and Robinson (1988) studied the foraging habitat and diet of 7 ground-foraging bird species: Winter Wren, Veery, Swainson's Thrush, Hermit Thrush, Wood Thrush, Ovenbird, and Dark-eyed Junco. Pairwise comparisons of foraging heights indicated that the Veery was significantly different from the other species. It directed 65% or more of its foraging attacks in the leaf litter, similar to the Wood Thrush, Ovenbird, and Dark-eyed Junco, whereas the remaining species foraged on the ground less than 50% of the time. All species differed significantly in their use of prey-attack manoeuvres. The Veery and Swainson's Thrush were the only species that used the dive-glean technique. The *Catharus* thrushes, especially the Veery and Swainson's Thrush, differed from other species in their search behaviour by flying more often. The Veery was a variable-distance searcher rather than a near-surface or manipulative searcher, along with the Hermit Thrush and Swainson's Thrush. These species searched substrates both near and far from a perch and often took flight to capture more distant prey. Each thrush species had a particular way of foraging that differed from the others. The Veery foraged more on the ground and took a larger proportion of flies, especially crane flies which are often on the litter surface. The Hermit Thrush and Swainson's Thrush foraged from the ground to the canopy, but the Swainson's Thrush was more arboreal. The results from Wisconsin and New Hampshire are somewhat conflicting. In Wisconsin, the Veery was more arboreal than the Hermit Thrush but the reverse was true in New Hampshire. Ground foraging was uncommon in Wisconsin; the high density of shrubs and saplings in the understorey may have inhibited ground foraging (Paszkowski 1984). The species of thrushes present may influence where each individual species forages. There were no Swainson's Thrushes in the Wisconsin study area and it was more arboreal than the Veery in New Hampshire. Presence of the Swainson's Thrush may limit the Veery's use of higher strata. The thrushes partition habitat based on their foraging techniques, but how they do this may vary geographically and be dependent upon which species are present.

Adults initially feed the young hairless caterpillars about 1 cm long, grubs, and small insects. From the fifth day until young leave the nest, they were fed dragonflies, larger insects than during the first 4 days, grubs, caterpillars, and occasionally black swallowtail butterflies (Day 1953). In

Delaware, young were frequently fed crane flies, adult moths, and earthworms (Heckscher et al. 2020).

Early in the breeding season, adult Veeries feed predominantly on insects and other invertebrates but eat increasing amounts of fruit as it becomes available late in the breeding season through to autumn migration. The diet may consist of two-thirds fruit by late summer (Sousa 1982; Tyler in Bent 1949). Beal (1915b) analyzed the contents of 176 stomachs throughout the Veery's breeding range from April through October. The diet consisted of 57.3% animal matter and 42.7% vegetation. Beetles comprised 14.7% of the diet, with no families especially prevalent. Ants comprised 10.4% of the food items and were eaten regularly; other hymenopterans were eaten regularly but accounted for only 3.3% of the diet. Caterpillars were eaten every month and totalled 11.9% of the diet. Grasshoppers were eaten every month except April, with greatest consumption occurring in October (24%), but the annual average was only 4.9%. Bugs (1.3%) and flies (0.9%) were not particularly important in the diet. Isopods, snails, and miscellaneous insects comprised 3.7% of the diet. Spiders (6.3%) were eaten regularly except that none were consumed in October. The vegetation component of the diet was comprised chiefly of fruit, with a few seeds and incidental material. Fruit comprised 35.3% of the diet, of which 12.1% was cultivated and 23.2% was wild. Cultivated fruit included strawberries and raspberries, and it is probable that these were actually taken from wild plants. Besides fruit, the Veery eats a few sumac, grass, and weed seeds. Holmes and Robinson (1988) examined the contents of 18 stomachs from New Hampshire from mid-June to mid-July. They contained 41.5% adult beetles (in order of abundance: soldier, click, scarab, ground, long-horned, and rove beetles, and weevils), 18.8% flies (crane fly adults, larvae of various species, and other adults), 12.9% caterpillars (mostly cutworms and geometer moths), 12.9% hymenopterans (mostly ants), 5.0% spiders, 4.0% bugs, 4.0% molluscs, and 0.9% other. Beetles were the most frequent food item in samples of all 7 ground-foraging species and the same major beetle families (which occur on the forest floor or vegetation) were consumed by all of them. The diet of the Veery differed significantly from the other 6 species except for the Ovenbird. Both fed frequently on spiders and bugs, mostly leafhoppers. The Hermit Thrush ate more beetles, the Swainson's Thrush consumed more ants than other species, the Hermit Thrush and Ovenbird ate large numbers of moth caterpillars, and the Veery, Wood Thrush, and Ovenbird fed more often on flies, particularly crane flies. In New Jersey, 45% of the Veery's diet consisted of fruit. Animal food consisted of 17% beetles, 12% hymenopterans, 10% lepidopterans, 5% grasshoppers and crickets, and 5% spiders. Of 28 stomachs sampled in Louisiana, 12 contained invertebrates only (snails, caterpillars, and centipedes), 11 contained both fruit and invertebrates (snails, caterpillars, and isopods), and 5 contained only fruit (Heckscher et al. 2020). Another study found that the overall diet consisted of 60% invertebrates and 40% fruit. Of the animal foods, the staples were beetles, ants and other hymenopterans, caterpillars (including those of the gypsy moth), grasshoppers, and spiders. Wild fruits consumed included juneberries, strawberries, blackberries, cherries, sumacs, dogwoods, blueberries, wild grape, elderberries, mulberries, spicebush, and honeysuckles. Red elderberry may be favoured because it is found under the canopy in gaps in forests and is one of the earliest woody plants to fruit. It is available during the nesting season and is occasionally fed to fledglings. Where it is available, spicebush fruit may be preferred. In Illinois, 94% of fruit consumed was spicebush and the remainder was wild grape. Foraging occurred more often than expected in forest gaps than

interior. The Veery occasionally eats small vertebrates such as tiny frogs and salamanders (Allen 1939; Dilger 1956; Heckscher et al. 2020; Malmborg and Willson 1988; Stutchbury et al. 2005a; Tyler in Bent 1949). Near Manitouwadge, abundance of the Veery increased significantly overall and in stands 1-21 years old with increasing numbers of spruce budworms (Venier et al. 2009). In Maine, spruce budworm larvae and pupae constituted 46% of the volume of food consumed by 2 birds (Mitchell 1952).

The Veery is a common host of the Brown-headed Cowbird. The rate of parasitism varies geographically and is probably higher where forest habitat is fragmented and less extensive. In Ontario, 82 of 429 nests (18.9%) were parasitized and 17 of 128 southern Quebec nests (13.3%) were parasitized. In south and central Ontario, distance from forest edge did not affect parasitism rates. In New York, 7 of 30 nests (23.3%) were parasitized; 0 of 11 nests were parasitized in Minnesota. In Maryland, 28.2% of 39 nests were parasitized; 0 of 42 nests were parasitized in Delaware. In 2 study areas in British Columbia, parasitism rates were 24.0% and 38.7%. In Alberta and Manitoba parasitism rates may be as high as 87%. The Veery appears to have no defences against the cowbird and readily accepts eggs. Both Veery and Brown-headed Cowbird young may be fledged from nests. In a sample of 11, the Veery fledged more of its own young in unparasitized nests (2.5 young per nest) than in parasitized nests (2.0; Burke and Nol 2000; Campbell et al. 1997; Falardeau in Gauthier and Aubry 1996; Hahn and Hatfield 1995; Hanski et al. 1996; Heckscher et al. 2020; Peck and James 1998a; Tyler in Bent 1949).

South of the Canadian Shield, forest loss and fragmentation may have adverse effects on the Veery. In different-sized forest patches in southern and central Ontario, reproductive success was similar in large forest fragments (average size 849 ha, range 81-2,353 ha, average of 121 ha of forest 100 m or more from edge) and contiguous forest. Success rates in small forest fragments (average size 93 ha, range 11.8-365 ha, average of 7.8 ha of forest 100 m or more from edge) were close to maintenance levels, but were population sinks. Predation rates were highest in small woodlots (64.3%), but only 23.1% in large woodlands and 33.0% in contiguous forest. Parasitism rates by the cowbird were not influenced by forest size and were 0%, 15.4%, and 9% in small, large, and contiguous forests, respectively. There were no significant differences in reproductive success rates between fragmented landscapes and continuous forest (Burke and Nol 2000). In Ontario south of the Shield, the effects of fragmentation on the Veery were scale dependent. The amount of core forest area had a strong positive effect at small scales of 500 m, but a strong negative effect at larger scales. The amount of habitat was more important than fragmentation. The effects of fragmentation were weak at large scales (Smith et al. 2011). Negative effects of fragmentation are more important when the amount of available habitat is low. Nol et al. (2005) found that the probability of the Veery occurring in small forest fragments was associated with distance to the closest large woodland that acted as a source for it. There was a 12-15% reduction in its probability of occurrence with every 1 km increase in distance from a large fragment. The number of large forests within a region did not affect occupancy rates of small woodlots. Occupied small fragments were generally less than 14 km from large fragments and much closer than this on average.

Forest practices may be beneficial or detrimental to the Veery, depending on the technique used and the intensity of the operation. Selective thinning tends to be beneficial because this opens

up the canopy and allows the shrub layer to develop. In Algonquin Park, it was unaffected by typical and intensive group-selection tree harvesting. There were no differences in its abundance in uncut stands and in recent and old single-tree selection cuts (Jobes et al. 2004; Tozer et al. 2010). In the Sault Ste. Marie area, it increased in all forests where selection thinning occurred, but not until 6-7 years after harvest. It was associated with hardwood regeneration (mostly sugar maple) rather than small shrubs (Holmes and Pitt 2007). In the Carolinian Forest Region of Ontario, it exhibited a preference for recent cuts over old cuts, and heavy cuts (diameter limit) were most preferred (Holmes et al. 2004). In the Boreal Forest Region of Ontario, there was no difference in its abundance in early successional or mid-successional clear-cuts compared with similarly aged burns, and it was equally abundant in early succession, mid-succession, and mature forests (Zimmerling et al. 2017). In some areas, the Veery may have experienced a northward range expansion due to deciduous growth once large tracts of coniferous forest were logged (Falardeau in Gauthier and Aubry 1996; Webb et al. 1977). In Pennsylvania, 2 types of improvement cuts were made in forests. In the first, all dead, dying, diseased, suppressed, and low-quality trees were removed. The second treatment was the same except that snags were retained. The Veery was much more abundant in stands where snags were retained. These plots had significantly more low-growing vegetation and shrubs than sites where snags were removed (Stribling et al. 1990). In Quebec, the Veery did not appear to be particularly affected by clear-cutting of areas 1-8 ha in size, but after larger areas were clear-cut it was absent for about 6 years (Falardeau in Gauthier and Aubry 1996). In New York, Webb et al. (1977) did not observe the Veery in unharvested forest stands, but it was present in selectively harvested stands and increased in abundance with the intensity of harvest. Logging changed unacceptable mature stands into acceptable second-growth stands. In New York, it colonized clear-cuts soon after cutting, particularly in those exhibiting rapid regeneration and early canopy closure. It was the dominant species by the eighth year after harvest (Keller et al. 2003). In Minnesota, Manolis et al. (2002) examined edge effects near regenerating clear-cuts for several species, including the Veery. For all species, distance to the nearest clear-cut edge was the best predictor of nest failure. There was strong evidence of a negative edge effect on ground nests extending 100 m or more from clear-cut edges in a forest-dominated landscape. Also in Minnesota, it was more abundant in riparian buffers that were clear-cut than those that were uncut (Hanowski et al. 2005). In Nova Scotia, it was absent in clear-cuts until about 5 years after cutting, with highest densities occurring in stands 8-30 years old (Morgan and Freedman 1986). In Vermont, it tended to avoid small (0.7-1.6 ha) cut patches in hardwood forest (Lent and Capen 1995).

High densities of white-tailed deer can be detrimental to the Veery. Extreme browsing reduces the density of shrubs or saplings in the understorey and makes habitat less favourable (Kearns et al. 2006).

In New York, Veery nests were built in areas with significantly higher eastern chipmunk density than random sites. Its preference for situating its nests in dense shrub patches may make it more vulnerable to predation by chipmunks (Emmering et al. 2018).

In North Carolina, Veery abundance was significantly negatively correlated with temperature, suggesting that it may be vulnerable to climate change in that area. It was negatively correlated with the number of houses and buildings within 200 m of the centre of the breeding patch, but not

significantly. Its abundance was significantly negatively correlated with temperature and number of buildings combined (Lumpkin and Pearson 2013).

In Pennsylvania over a 15-year period, hemlock basal area declined from 56% of the total to 46% as a result of mortality from the hemlock woolly adelgid. There was an increase in deciduous undergrowth as a result of openings in the canopy. The Veery responded positively to the decline in hemlock, probably because of the increase in deciduous shrubs and saplings (Toenies et al. 2018).

In New York, there was no difference in daily nest survival rates in nonnative and native species. Veeries facultatively used nonnative shrubs as nest sites (Meyer et al. 2015). Similar results were documented in Pennsylvania. Almost 60% of 289 nests were in nonnative shrubs, particularly Japanese barberry and multiflora rose. Nest survival, clutch size, and number of young fledged did not differ between nests in native and nonnative shrubs (Goguen and Murray 2025).

Status

The Veery has always been common in Ontario and was probably more common south of the Shield prior to European settlement. McIlwraith (1894) considered it the most common thrush in Ontario next to the robin. Baillie and Harrington (1937) reported that it bred from the southern boundary of the province north to at least southern Sudbury District and Ottawa, and also in southern Thunder Bay and Kenora districts. They considered it common, especially in the southern portion of its range. Mills (1981) reported that it was one of the most common birds of mixed and deciduous forests in Muskoka and Parry Sound districts. It was third in abundance in the South Walsingham Forest where it represented 7.45% of all records (McCracken et al. 1998). It was very common in the Kingston area in the 19th century and there was little change in its status except for some habitat loss due to expanding urban areas (Weir 2008). In Elgin County, where forest habitat is more fragmented, the Veery was common in 1891, but not as common as the Wood Thrush. It was still fairly common in 1954, but by 2000 it was uncommon, breeding in small numbers (Lancaster et al. 2004). During the first atlas, the Veery occurred in high densities and was common both in the north and south. It bred further north than previously recorded, to Timmins, Kirkland Lake, Matchewan, Virginiatown, Schreiber, and northeast of Lake Nipigon. These records probably represented a recent range extension. It was virtually absent from the agricultural areas of Essex County, the fruit lands of Niagara below the Escarpment, and the urban area of Toronto (Sadler in Cadman et al. 1987). James (1991) considered the Veery common in the south, becoming uncommon in the north to Sioux Lookout and Cochrane.

The second atlas indicated that there had been no change in the breeding distribution of the Veery since the first atlas. It disappeared from some more intensively farmed areas in the southwest, notably in western Chatham-Kent and Lambton counties. There was no overall difference in its probability of observation between the 2 atlases. Significant declines south of the Canadian Shield were offset by a significant increase in the Boreal Forest Region. It was most abundant in the Shield in the Great Lakes–St. Lawrence Forest Region, particularly from the Sudbury area south to the edge of the Shield. Within this area, the Veery was found in 95% of squares during both atlases. Its abundance was considerably lower in the Algonquin Highlands, possibly due to the controlled selective cutting in Algonquin Park which may create less suitable habitat for the Veery than is found in adjacent areas (Friesen in Cadman et al. 2007).

Breeding Bird Survey data indicate that the Veery decreased at annual rates of 0.577% in Canada and 0.987% in Ontario 1970-2021. The trends 2011-21 were annual decreases of 0.266% in Canada and 1.04% in Ontario. All results were highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Young are led to dense habitat as soon as they leave the nest. The brood is split for the first 2 weeks after fledging, with the female caring for the larger number in odd-numbered broods. In an 18-year study, there was only 1 observed case of both adults caring for an individual fledgling. Fledglings begin to hunt insects and find fruit on their own after about 2 weeks and parental care ceases 14-17 days after fledging (Heckscher et al. 2020).

During the postbreeding period in West Virginia clear-cuts, presence of adults was positively associated with arthropod biomass and the total amount of fruit available. Abundance of juveniles was positively associated with the amount of ripe fruit and negatively associated with the vertical complexity of the vegetation (McDermott and Wood 2010). In Michigan, 83% of juveniles were captured in riparian areas that were dominated by shrubs (alders and honeysuckles) and trembling aspen compared with 17% in upland trembling and large-toothed aspen stands. Capture rates of adults and juveniles combined were 1.8 per 100 net-hours in upland habitat and 4.9 in riparian habitat (Akresh et al. 2009). In Minnesota, Streby et al. (2011b) captured 23 Veeries in regenerating clear-cuts during the breeding season and 216 adults and 95 fledglings during the postbreeding season. In Virginia and West Virginia, Marshall et al. (2003) captured 13 adults, 4 juveniles, and no family groups in the centre of clear-cuts. In Pennsylvania, Stoleson (2013) captured 8 adults and 7 juveniles in clear-cuts and 3 adults and 3 juveniles in adjacent mature forest with a dense understorey during the postfledging period.

Hobson and Kardynal (2015) demonstrated that Veeries breeding in the Okanagan Valley of British Columbia undertook long (mean 263 km) postbreeding flights from their territories prior to autumn migration. Timing of the movement overlapped with the moulting period suggesting that this may be a moult migration. Suitable breeding habitat is limited in that region and birds may have to move to find suitable moulting habitat.

MIGRATION

The Veery is a nocturnal, long-distance migrant with the entire population migrating between the North American breeding grounds and the South American wintering grounds. Birds undertook nocturnal migratory flights about 1 night in 6, typically after the temperature rose to 22°C and when it was calm or there were only light surface winds. Thirty of 40 birds migrated solely; of the remaining 10 observations, 8 birds flocked with other Veeries (Cochran et al. 1967; Heckscher et al. 2020).

Males usually arrive on the breeding grounds 5 days before females (Dilger 1956; Heckscher et al. 2020). In southern Ontario, the Veery arrives in very late April or early May, with the peak in mid-May. Arrival in the southern Shield is usually in mid-May. Adults and juveniles migrate at the same time in autumn. In the southern Shield, it begins to move south in August. Most leave the province by early September with stragglers until late September or early October. Birds may rarely persist into November or even December (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Mills 1981; Sandilands and Dance 1984; Tozer 2012; Weir 2008).

Spring migration is rapid with birds frequently arriving directly at breeding territories, so migration habitat does not differ from breeding habitat. In autumn, the Veery occurs primarily along forest edges and in the understorey of second-growth deciduous and mixed forests, much the same habitat that is used during the breeding season. During the day during migration, activity may be limited to 0.04-0.2 ha territories (Campbell et al. 1997; Heckscher et al. 2020).

During spring migration in Pennsylvania, there were no significant differences in numbers of the Veery in forest and shrub habitats. It was only 1 of 3 species out of 30 species that showed no habitat preference (Smith and Hatch 2008).

The Veery is vulnerable to being killed by collisions with TV towers, office buildings, and airport ceilometre beams (Graber et al. 1971; Heckscher et al. 2020). Weir (2008) reported that 55 had been killed at the Lennox generating station in the Kingston area.

In Pennsylvania, an outbreak of the viburnum leaf beetle resulted in almost complete mortality of the southern arrowwood, previously the third most abundant shrub species. Prior to the infestation, spring migrant Veeries gained significant mass after sunrise, but no weight gains occurred after the infestation (Smith and Hatch 2017).

The Veery is a common migrant in Ontario (James 1991), although it may be uncommon to rare in certain areas such as Elgin County (Lancaster et al. 2004).

Banding trends at Long Point Bird Observatory showed a significant decline of 3.3% annually 1961-88. Trends within this longer period were –6.3% 1961-70, + 1.4% 1970-79, and –4.2% 1979-88 (Hussell et al. 1992).

Gray-cheeked Thrush

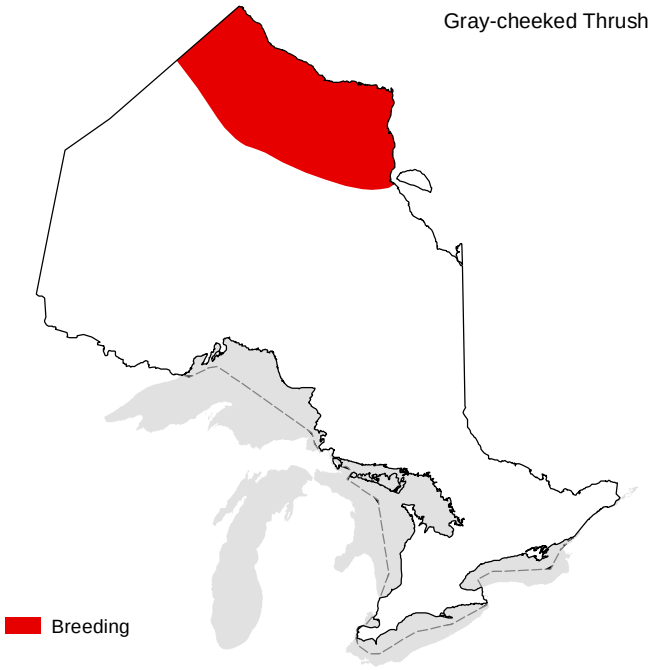
Catharus minimus

BREEDING SEASON

Habitat Requirements

In Ontario, the Gray-cheeked Thrush nests in the northern portion of the Hudson Bay Lowland and the Tundra Region. It occurs in riparian willow-poplar-alder thickets, along edges of extensive burns with dense spruce-willow-birch-alder regeneration, and in open, stunted spruce woodlands with an understorey of willow and birch occasionally interspersed with wet willow and alder thickets. It may also nest occur along rivers and streams bordered by open spruce woodlands and mature aspen stands (Friesen in Cadman et al. 2007). Austen et al. (1994) stated that the Gray-cheeked Thrush nested in dense spruce woods near the treeline.

During the breeding season in Quebec, the Gray-cheeked Thrush occurs in coniferous woods and denser stands near the tree limit. The dominant species in these stands are black and white spruce and, to a lesser extent, tamarack. It prefers a fairly thick, mossy ground cover and rather moist subsoil. In the Quebec boreal forest, it occurs along rivers and streams, lakes, and ponds in clumps of alders or willows. It may also inhabit muskeg, spruce and fir stands, and areas of regeneration after fire (Ouellet in Gauthier and Aubry 1996). In Labrador and northern Quebec, it may occur in tall shrubby enclaves in taiga or above the treeline. At Hamilton Inlet, Labrador, it nested in undergrowth surrounding houses (Bent 1949; Whitaker et al. 2020). In Newfoundland, it has an



affinity for coniferous scrub, but also nests in mature balsam fir forests and clear-cuts (Thompson et al. 1999; Whitaker et al. 2015). British Columbia nesting habitat includes stands of white spruce with a dense undergrowth of blueberries and willow. It also nests in thickets of stunted subalpine fir and spruce interspersed with willows and the neighbouring subalpine parkland coniferous forest, where there is thick growth of blueberries, willows, and other shrubs. It has only been reported nesting in British Columbia between altitudes 840 and 870 m and has the narrowest range of habitat requirements of all thrushes (Campbell et al. 1997). The Gray-cheeked Thrush occurs in open, wet shrubby habitats throughout the Yukon. It is characteristically at or near the treeline in mountainous areas, usually along creeks, gullies, or wet draws with abundant shrubs, and along creeks and rivers that support abundant tall shrubs. It typically occurs in habitats with tall shrubs such as willows or dwarf birch, with or without scattered coniferous trees. It may occur among willows on lakeshores, in burned areas, and in taiga areas such as open black spruce forest with tall shrubs (Sinclair et al. 2003). In the Boreal Forest Region, Erskine (1977) considered it characteristic of both the tundra and alpine ecotones with boreal forest, typically in open black spruce forests. In the Hudson Bay Lowland area of Manitoba, McLaren and McLaren (1981) found the Gray-cheeked Thrush in coniferous forest with a shrub understorey, in coniferous shrubs and heath, and in deciduous and mixed shrubs. It was absent in deciduous forest, coniferous forest without a shrub layer, mixed forest, and tundra. In Alaska, it breeds in tundra where trees are absent, but only where there are clumps of willows or alders. It favours a closed canopy of medium-height shrubs combined with dense woody undergrowth in a layer of dwarf shrubs shorter than 0.4 m tall. Habitats in Alaska include riparian alder and willow thickets, shrubbery in open woodlands, open spruce forests near the treeline, bogs, edges of coastal tundra, alder patches in tundra and coastal hillsides, shrubbery on glacial moraines, and understorey of floodplain cottonwoods. Forest canopy is tolerated if a shrub layer is present. In central Alaska, it occurred in habitats with a high percentage of low shrub cover but not where the vegetation was less than 1.1 m tall. Mean shrub height was 4.2 m for 42 plots where it was present. Shrub species present in inhabited plots included northern red currant, prickly rose, red raspberry, dwarf birch, and black spruce seedlings. The Gray-cheeked Thrush prefers habitat structure with an open canopy, tall shrubs, and very dense cover (Whitaker et al. 2020).

Whitaker et al. (2015) examined environmental factors that affected the distribution of the Gray-cheeked Thrush in Newfoundland. The most important factor was elevation, with its probability of observation increasing with elevation. It was absent below 375 m elevation. There was also strong

support for an influence of shrubs taller than 6.5 m on its occurrence. At the landscape scale (1,250 m), there was a curvilinear relationship between shrub and thrush abundance. Its occurrence was highest where tall scrub comprised 20-25% of the landscape cover. At the neighbourhood scale (115 m), there was a strong linear increase in its occurrence with increasing cover of tall shrubs. Presence of shrubs shorter than 6.5 m had only moderate effects on its abundance. Its occurrence was stable or slightly increasing with old-growth forest at the landscape scale, increasing up to 35% landscape cover then declining. Presence of old-growth forest or 20-80-year-old second-growth forest at the neighbourhood scale had no influence on abundance. At the neighbourhood scale, it was most likely to be observed where there was 60-70% coverage by clear-cuts, but it was negatively correlated with the amount of clear-cuts within 1,250 m. It was most abundant in areas having 50% cover of partially harvested forest (strip and row) at the neighbourhood scale. In Newfoundland at the 5.5-ha scale, it was associated with 10-30-year-old clear-cuts, conifer forests, and tall scrub. At the 490.8-ha scale, it avoided tall scrub, regenerating stands, and second-growth forest (McDermott et al. 2023). In boreal forest plots in New York, Vermont, Maine, Nova Scotia, and Newfoundland, the Gray-cheeked Thrush was associated mostly with high latitude and high elevation sites with colder temperatures. Sites it inhabited had high coverage by moss and lichen ground cover, low numbers of dead snags, low canopy cover, and low numbers of deciduous trees. Because it is associated with colder temperatures, it could be adversely affected by warming due to climate change (Ralston et al. 2019).

Two nests were reported in Ontario. The first was among stunted willows 20 cm from the ground at the base of a willow. The second nest was in a dense spruce-alder-willow bog with sphagnum moss and a few areas of open water. It was 1.5 m from the ground in a 3.0-m tall spruce (Baillie 1961; Peck and James 1987; Schueler et al. 1974).

Nests are typically close to the ground or on it. All 6 reported British Columbia nests were within a metre of the ground and one was underneath a root. Two of 3 Yukon nests were on the ground; one was 1.2 m above water in a willow overhanging a lake. In Alaska, most nests were in crotches of willow or alder shrubs but some were on horizontal or slanting trunks of fallen trees, atop broken-off stubs or rotting stumps, or on the ground; 2 nests were on a ledge of a building. Nests may be as high as 6 m from the ground in spruce in open woodlands, but mean nest height was 0.8 m with only 2 nests higher than 2.5 m from the ground (Bent 1949; Campbell et al. 1997; Sinclair et al. 2003; Whitaker et al. 2020).

No information is available on territoriality, natal philopatry, or adult nest-site tenacity (Whitaker et al. 2020). Territories appear to be fairly spread out and distant from each other (Ouellet in Gauthier and Aubry 1996). Campbell et al. (1997) reported that territorial songs were given from the highest available perches, but most activity was within dense thickets.

Limiting Factors

Eggs are most likely to be present in Ontario nests throughout June into very early July (Peck and James 1987). A nest at Fort Severn contained 3 eggs on 2 July 1940 (Baillie 1961). The time required to build the nest is unknown. One egg is laid per day. The incubation period is uncertain, but is probably 11-12 days. The nestling period is also unknown, but is probably about 11-13 days. In

Alaska, 4 of 6 nests still contained young at age 11 days; young left the other 2 nests by day 11. Three Alaskan young were still together 320 m from the nest 8 days after fledging.

A single brood is raised annually, although renesting may occur if a clutch is lost. Clutches laid after mid-June in Alaska were probably replacement clutches (Whitaker et al. 2020). Of the 2 Ontario nests, one contained 3 eggs and the other contained 3 young (Baillie 1961; Peck and James 1987; Schueler et al. 1974). The most frequent clutch size is 4 eggs with a range of 3-5 eggs. In Alaska, the mean and modal size of 82 clutches was 4 eggs. Most 5-egg clutches occurred early in the season; most 3-egg clutches were late in the season (Bent 1949; Whitaker et al. 2020).

The Gray-cheeked Thrush is apparently monogamous. The age at first breeding is probably 1 year and breeding occurs annually thereafter (Whitaker et al. 2020).

While foraging, the Gray-cheeked Thrush usually hops over the ground, picking prey from the leaf litter. It may visit fruiting shrubs or pick prey off vegetation a short distance above ground. Foot-quivering was an important foraging method (43% of observations) during autumn migration. This involves rapid movement of the legs and feet against the substrate without any forward locomotion. After foot-quivering, it scans the substrate for prey and pecking was observed 67% of times. During autumn migration in Illinois, it fed 89% of the time on fruit in treefall gaps in forests, significantly more than expected (Malmborg and Willson 1988; Whitaker et al. 2020).

The diet is dominated by invertebrates, especially insects, during spring migration and early in the breeding season. As the breeding season progresses, fruit becomes more important in the diet and, by autumn migration, the Gray-cheeked Thrush feeds chiefly on fruit. In Illinois, the diet of 10 spring migrants consisted of 93% insects; ants constituted almost half the food. Eighteen percent of the diet consisted of beetles, especially ground beetles, the lowest percentage of beetles eaten by thrush species in that state. Other food items included 15% caterpillars, 9% crane flies and their larvae, 5% grasshoppers, 5% molluscs, and 2% millipedes. The amount of molluscs eaten was high compared with other thrushes. During spring migration in Wisconsin, it consumed mostly fly larvae (Bent 1949; Graber et al. 1971). A sample of 111 stomachs of birds collected mostly during migration contained 75% animal matter and 25% vegetable matter. The sample was a mix of Gray-cheeked and Bicknell's thrushes stomachs. Animal food in order of importance included 33% beetles (weevils and ground, scarab, and click beetles), 16% ants, 9% caterpillars, 6% bees and wasps, 6% spiders, 2% grasshoppers, and 3% other groups. The remaining food was predominantly fruit (Beal 1915b). One bird collected in Alaska during the breeding season had eaten 3 blow flies, 2 dung flies, 4 ground beetles, 1 rove beetle, and 1 weevil (Whitaker et al. 2020). During the breeding season, the Gray-cheeked Thrush may also feed on crayfish, isopods, and earthworms (Bent 1949). During autumn migration, it often feeds on owlet moth caterpillars, but much of the diet is fruit; in Illinois, 92% of foraging bouts were on fruit. Fruit commonly consumed includes wild grape, Virginia creeper, greenbrier, Canada moonseed, spicebush, raspberries, black cherry, flowering dogwood, elderberry, spikenard, nightshade, barberry, poison ivy, and pokeweed (Bent 1949; Graber et al. 1971; Malmborg and Willson 1988).

There appear to be no breeding season limiting factors for the Gray-cheeked Thrush in Ontario. The ranges of this thrush and the Brown-headed Cowbird do not overlap, so brood parasitism has

not been reported. The Gray-cheeked Thrush is more likely to be affected by habitat alteration during the nonbreeding season than on the breeding grounds (Whitaker et al. 2020).

The Newfoundland population of the Gray-cheeked Thrush has declined precipitously due to introduction of red squirrels to the island. High nest-predation rates appear to have restricted it to high-elevation sites where the red squirrel is scarce or absent (Whitaker 2017). In the remainder of Canada, the ranges of the Gray-cheeked Thrush and red squirrel overlap extensively. It is uncertain if depredation of nests by squirrels is an issue in areas other than Newfoundland.

In northeastern Quebec and Labrador, the Gray-cheeked Thrush was associated with cool, drier stands. Its potential response to climate change in that region is uncertain (DesGranges and LeBlanc 2012).

Status

The breeding status of the Gray-cheeked Thrush in Ontario is not fully understood, but it is uncommon at best. McIlwraith (1894) thought that it occurred only as a migrant in Ontario. The first confirmation of breeding was a collection of a female and 2 young just out of the nest on 13 July 1900 in the Hudson Bay Lowland (Manning 1952). Clifford Hope found the first nest at Fort Severn on 2 July 1940 and collected a juvenile male on 15 July from a brood of fledged young. He was there 15 June to 23 July of that year and his highest daily count was 15 on 20 June (Baillie 1961). Schueler et al. (1974) found a female with a brood patch at Hawley Lake and the second nest for the province at Aquatuk Lake on 6 July 1964. It was uncommon in suitable habitat at Winisk and common at Hawley Lake. None were seen on a field expedition to the Sutton Ridges in 1980 or at Kerine Lake, 80 km southeast of Winisk in 1981. Peck and James (1987) concluded that it probably bred mainly in the northwest within a short distance of the Hudson Bay coast, regularly at least as far east as Fort Severn, and with perhaps fewer and more isolated populations east to Winisk and the Sutton Ridges. No abundance estimates were available from the first atlas. The full extent of its range was uncertain, but it was concluded that it could occur in much of the Hudson Bay Lowland. It appeared to be only sparsely distributed in the northernmost areas of the province (Sadler in Cadman et al. 1987). James (1991) considered the Gray-cheeked Thrush locally rare and a likely irregular summer resident near Hudson Bay and possibly throughout the northern Hudson Bay Lowland. Wilson and McRae (1993) observed single birds at Shagamu on 5, 6, and 8 June and concluded that Gray-cheeked Thrushes were breeding there.

The second atlas provided little additional information on the distribution and abundance of the Gray-cheeked Thrush; it was documented in only 8 squares. Distribution data from the 2 atlases suggest that it breeds throughout the Hudson Bay Lowland south to about 53°N in the vicinity of the Attawapiskat River. It may have been overlooked due to the species' weak song that is delivered only at dawn and dusk, but it is unlikely that it could have been consistently missed if it were present (Friesen in Cadman et al. 2007).

Breeding Bird Survey (BBS) data for Canada indicate that the Gray-cheeked Thrush declined at an annual rate of 0.991% from 1970 to 2021 but increased at an annual rate of 1.36% 2011-21. The long-term results were of medium reliability; the short-term results were of low reliability. There are no BBS data for Ontario (A.C. Smith et al. 2023).

MIGRATION

The Gray-cheeked Thrush is a nocturnal long-distance migrant, typically travelling 200-700 km (mean 300 km) in a night. One bird banded at Mitchell's Bay, Ontario was recovered 3 years 7 months later in Texas (Brewer et al. 2018; Whitaker et al. 2020; Winker et al. 1992). During migration, it often accompanies flocks of Swainson's Thrushes (Bent 1949; Whitaker et al. 2020). In Illinois, 8 Gray-cheeked Thrushes confined their daytime activity during spring migration to an area of 0.04-0.2 ha and migrated solely at night (Cochran et al. 1967).

The Gray-cheeked Thrush is the latest thrush to arrive in spring, arriving around mid-May. Spring migration may extend as late as mid-June. Wilson and McRae (1993) observed autumn migrants at Ekwan on 5 September and at Longridge on 8 September. In Algonquin Park, it occurs from late August to mid-October. In the south, it usually occurs from about mid-September to the first or second week of October. There are a few December records for the province but it is likely that these records are of ill or incapacitated birds (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; McRae 1984; Tozer 2012; Weir 2008).

Most records of the Gray-cheeked Thrush during migration in the Kingston area were from wooded areas with an open understorey and low ground vegetation (Weir 2008). In Quebec, it may be observed in any treed or shrubby area, including city parks and suburban gardens. Whitaker et al. (2020) stated that migrants preferred well-wooded sites with a thick understorey or shrub layer, were scarcer in more open woodlands, and infrequent in areas with sparse or no canopy. During migration in British Columbia, it usually occupies subalpine habitats, but also occurs at forest edges and in river bottomland forests and willow edges in muskeg (Campbell et al. 1997). In the Yukon, it is most often seen at forest edges or openings during migration, but has been seen along narrow roads through dense forests. Occasionally, it visits residential yards with tall shrubs and open forest habitat. It is possible that Yukon migrants may be more common in dense forest, but they are seen less frequently in these habitats (Sinclair et al. 2003).

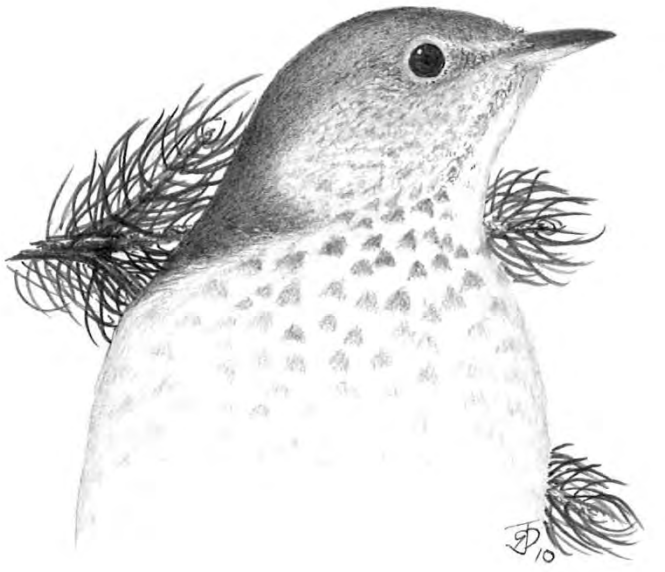
In Algonquin Park, the Gray-cheeked Thrush has eaten wild raisin during autumn migration (Tozer 2012).

The Gray-cheeked Thrush is vulnerable to striking tall structures during migration. In Illinois, it represented about 11% of birds killed at television towers. Some kills occurred at television towers in North Carolina during autumn migration (Graber et al. 1971; Lee 1995; Whitaker et al. 2020).

The Gray-cheeked Thrush is an uncommon migrant in Ontario, but 2,000 occurred on 21 September 1985 at Presqu'ile during a grounding event. It is more common in autumn than spring, due in part to the more prolonged season, but probably mostly because birds that breed west of Ontario migrate through the province in autumn but not in spring (Curry 2006; LaForest 1993; Weir 2008).

Swainson's Thrush

Catharus ustulatus



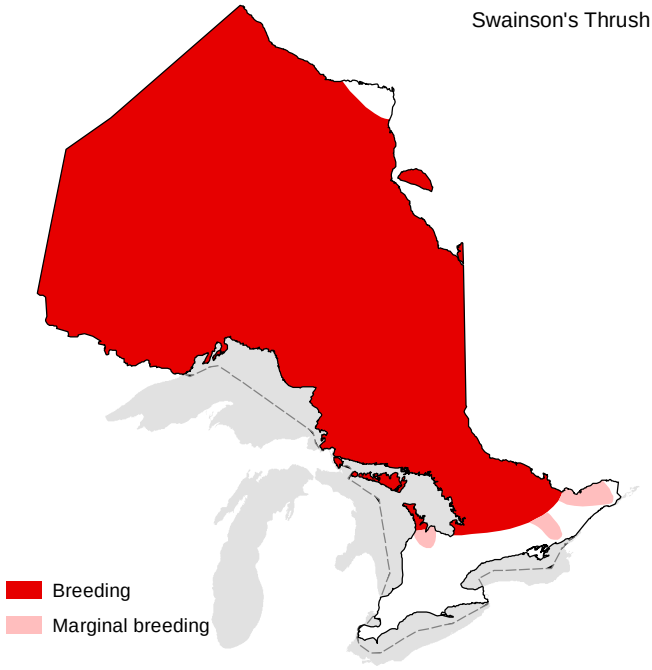
BREEDING SEASON

Habitat Requirements

In Ontario, the Swainson's Thrush has nested in both dry and wet forested areas (85.7% of nests), on rocky outcrops with sparse deciduous growth (5.9%); in sphagnum bogs (4.2%); on blueberry barrens (1.7%); on limestone savannahs (0.8%); in rocky, open burns (0.8%); and in a grassy area of alder growth near a woodland. Forested areas containing nests were coniferous (35.3% of nests), mixed (24.5%), deciduous (22.5%), and unspecified (17.6%). Most forests supporting nests had open canopies; otherwise, nests were often in clearings or near forest edges, shorelines, or roads (Peck and James 1987).

In the Boreal Forest Region of Ontario, the amount of edge at the landscape level (5,000 ha) was a significant predictor of the Swainson's Thrush's abundance. It showed no strong pattern for habitat selection based on other parameters (Rempel 2007). Near Pickle Lake, it was one of the most frequently encountered species, occurring in all forest types including black spruce, black spruce bog, and trembling aspen–white birch mixed forest (James 1980). Near White River, it was significantly more abundant in clear-cuts 23-25 years old than in clear-cuts 3-20 years old or in mature forests (Venier and Pearce 2005). Near Hearst, it was absent in clear-cuts younger than 6

years old. In lowland conifers, it was present in clear-cuts 11-19 years old, but absent in older or younger cuts and in uncut coniferous stands. In mixed-wood stands, it was present in uncut stands and clear-cuts 6-24 years old, reaching highest densities in cuts 17-24 years old (Welsh and Fillman 1980). In the Boreal Forest Region, it was essentially absent from tamarack-cedar, black ash, and balsam poplar stands, but occurred in other forest types. It reached its greatest abundance in balsam fir–white spruce, trembling aspen–white birch, red pine–white pine, and black spruce stands (Welsh 1993).



In Quetico Park in the Great Lakes–St. Lawrence Forest Region in the Canadian Shield, the Swainson's Thrush was most abundant in mature stands followed by early successional stands (1-23 years old). It was not recorded in intermediate-aged (67-73 years) or old-growth stands (175-370 years; Apfelbaum and Haney 1985). Near Gogama, it was most abundant in mixed forests where jack pine predominated, but rare in pure pine stands. It occurred in both these habitats where there were significant amounts of tall shrubbery. It occupied young, dense stands with both coniferous and deciduous growth that was approximately equal in height. It began to inhabit stands once they reached 10 years of age, and was most abundant in 20-year-old stands. Large areas of tall deciduous shrubs were scarce in older pine forests, so it seldom occurred in these areas (James and Peck 1995a). In jack pine woodlands near Parry Sound, it occurred in open stands with less than 25-50% crown closure. All stands were mixed with other species such as trembling aspen, white birch, white pine, silver maple, tamarack, red and white oak, and white spruce (James 1979a). In Muskoka District and Haliburton County, it was associated with high canopy volume and intermediate tree density indicative of undisturbed forest. It was also associated with a high composition of conifers with little understorey (Clark et al. 1983). In Algonquin Park, the Swainson's Thrush was most abundant in black spruce stands followed by hemlock, black spruce–white cedar, and balsam fir–spruce-hardwood stands. It occurred in white birch–aspen-fir-spruce stands where it remained in the shrubs and lower branches of conifers. In black spruce–white cedar stands, it occurred from the ground to a height of 5.5 m, just above the bottom of the canopy (Martin 1960). In Algonquin Park, it typically nests in fringes of coniferous forests around lakes (Tozer et al. 1996). In Muskoka and Parry Sound districts, it preferred mixed forests, often nesting at water's edge (Mills 1981).

The western subspecies of the Swainson's Thrush is a riparian woodland specialist during the breeding season. Eastern and northern populations occupy mixed hardwoods and boreal spruce-fir

forests, respectively (Ruegg 2007). In Colorado montane habitat, it nested in riparian willows and avoided aspen stands (Glass and Floyd 2015). California populations are unique in that they breed primarily in deciduous riparian forests rather than coniferous woodlands (White et al. 2005). Eastern and northern populations nest in habitats similar to those it uses in Ontario. It is most typical of coniferous forests, particularly those dominated by spruce and fir, and is one of the most common and characteristic species of these habitats. The presence of at least some spruce or fir appears essential in most areas. It appears to prefer spruce-dominated forests to those dominated by balsam fir; it may be locally common in hemlock and jack pine stands. It may be a common or even dominant species in poplar and birch stands. It nests in both upland stands and swamps. Although coniferous and mixed stands are more frequently inhabited, it also uses deciduous stands, predominantly those dominated by aspens and birch, but also northern hardwoods dominated by sugar maple and beech, often mixed with hemlock. It may be quite common in regenerating clear-cuts and burns, especially 10-20 years after disturbance. It was common in New Brunswick clear-cuts regenerating with white birch and pin cherry and those that had been replanted with black and white spruce and jack pine. In Quebec, it nests in thickets along forest edges, in clear-cuts with saplings shorter than 2 m and 2-5 m tall, and in young and mature forests. It was not observed in recent burns where saplings were less than 2 m tall. Its abundance was similar in all age classes of habitat. In Wisconsin, it nested in pine, aspen, white birch–red oak, white birch–yellow birch–white cedar, hemlock–yellow birch, and sugar maple–yellow birch stands. In the Yukon, the Swainson's Thrush nests in forests dominated by spruce, trembling aspen, balsam poplar, spruce-cottonwood, and thick growths of spruce, as well as willow and alder thickets. In British Columbia, 39% of nests were in mixed forest, 17% in deciduous stands, 17% in coniferous stands, 12% in rural and suburban areas, and 9% in shrublands. In the Boreal Forest Region, it was in a guild of birds associated with coniferous species, although it did not show a strong preference for any forest type. Occupied sites tended to be dry and nutrient poor. In New York, it nests in large plantations dominated by Norway spruce and white spruce (Back 1979; Beals 1960; Bent 1949; Campbell et al. 1997; Crawford and Titterington 1979; Dawson 1979; Dilger 1956; Eaton 1998; Erskine 1977; Evans Mack and Yong 2020; Falardeau in Gauthier and Aubry 1996; Imbeau et al. 1999; Kirk et al. 1996; Nixon et al. 2001; Noon et al. 1979; Sinclair et al. 2003; Temple et al. 1979; Thompson et al. 1999). In boreal forests in New York, Vermont, Maine, Nova Scotia, and Newfoundland, it had broad habitat preferences and an ability to use multiple boreal forest habitat types. It was associated with high numbers of dead snags, high canopy cover, and high numbers of deciduous trees (Ralston et al. 2019).

Many studies identified microhabitat preferences of the Swainson's Thrush with canopy closure, understorey cover, tree density, and presence of conifers being the most important habitat attributes. In Alaskan taiga, it occurred in forest habitat and not shrub thickets. There were more territories where tree height, canopy cover, and canopy thickness were greater, where the distance between trees was less, and the shrub layer was open. In Oregon, it was positively associated with density of trees 10 cm diameter at breast height (DBH) or larger, reaching peak abundance where this measure was highest. In mixed coniferous forests in Idaho, nests were nearer water in areas with denser shrubs and saplings, where there were more trees 8-23 cm DBH, more trees with a DBH greater than 38 cm, and greater canopy coverage (85%) than random sites. Similar characteristics were noted in Utah: 86% canopy cover and a high density of fir trees in all size classes. In New

Hampshire and Maine, its abundance was positively correlated with the number of deciduous trees 2-10 cm DBH. It was negatively correlated with the total foliage volume of both deciduous and coniferous trees 2-10 cm DBH. It occurs in open jack pine forests in the Boreal Forest Region, but the Hermit Thrush is more common than the Swainson's Thrush in this forest type. Over 30 years in New Hampshire, the Swainson's Thrush disappeared as a breeding species. During this time, the forest changed from having a dense, fairly closed canopy with an open subcanopy and a dense low shrub layer to a more open and patchy canopy with a denser and taller shrub and subcanopy layer, and a more sparse low shrub layer. In subalpine communities in New Hampshire, territories were on mid-slopes, contained wet depressions, had a canopy height of 9.0 m, canopy closure of 64%, 61% conifer foliage volume, 28% conifer volume 0-2 m from the ground, 45% deciduous foliage volume, and average DBH of 12 cm for live trees. The western subspecies may prefer more open canopies (DeGraaf et al. 1998; Evans Mack and Yong 2020; Erskine 1977; Holmes and Sherry 2001; Sabo 1980; White et al. 2005). In Minnesota, it was negatively associated with the amount of black spruce and tamarack within 200 m and 1 km, and the amount of sedge meadow within 500 m. It was associated with white cedar but avoided black spruce and tamarack (Zlonis et al. 2017).

Presence of low shrubs is essential, with the Swainson's Thrush preferring moderate to high density of shrubs. Coniferous shrubs are preferred but in some areas deciduous shrubs are important. In New York, it selected areas with moderate to dense shrub densities, and all territories contained some coniferous shrubs. In California and British Columbia, its abundance was positively correlated with shrub density, particularly species bearing fruit during the breeding season. In Idaho, occupied sites had a higher density of shrubs, saplings, sapling firs, higher sapling species diversity, and greater cover within 1-2 m of the ground than unoccupied sites (Campbell et al. 1997; Evans Mack and Yong 2020; Falardeau in Gauthier and Aubry 1996; Noon 1981; White et al. 2005).

In many areas, the Swainson's Thrush is associated with water or damp areas. Bent (1949) stated that it showed a preference for the lower and damper portions of forests, particularly near woodland streams, but that it often nested in dry woodlands. In Michigan, it preferred damp areas along streams among balsam fir and spruce, especially the lower 0.9-1.5 m where tree branches had died off. In British Columbia, almost 40% of nests were in riparian areas regardless of forest type (Campbell et al. 1997). In British Columbia rainforest, it was more common near rivers than distant from them, but Shirley (2005) did not consider it a riparian specialist and termed it a forest generalist. In subalpine communities in New Hampshire, most territories contained at least a damp depression (Sabo 1980). Nests in Muskoka and Parry Sound were often adjacent to water (Mills 1981).

The Swainson's Thrush is often considered a species that requires mature or old-growth forests, but some studies found equal or higher densities in early successional forests, particularly closed-canopy plantations (Evans Mack and Yong 2020). In white pine stands in the southern Canadian Shield in Ontario, it was more common in old-growth than mature stands, but not significantly. Its abundance was significantly negatively correlated with presence of supercanopy white pines (Kirk et al. 2012). In Saskatchewan, it occurred more frequently in forests older than 50 years. Probability of detection was 20-49% in 50-60-year-old forests, 50-79% in 80-110-year-old forests, and 100% in forests older than 140 years. The percentage of coniferous trees increased with increasing forest age and the amount of shrub and moss cover was highest in the oldest forests. The amount of litter was

significantly higher in the youngest forests (Cumming and Diamond 2002). In Alberta, it was significantly more abundant in old-growth than in mature and young aspen-dominated stands and selected areas with conifers within these stands (Schieck et al. 1995). In Wisconsin, it tended to increase as vegetation matured and reached climax conditions (Beals 1960). In the western Boreal Forest Region, Kirk et al. (1996) considered it an old-forest species. It occurred in 33% of very young stands (0-9 years), 83% of young stands (15-20 years), 100% of mature stands (40 years), and 67% of old stands (80 years). Also in the Boreal Forest Region, Erskine (1977) reported that it was characteristic of mature coniferous stands and scarce or lacking in young coniferous stands. In Pennsylvania, the Swainson's Thrush occurred in 63.6% of old-growth forests, 0.9% of woodlands statewide, and in 1.9% of woodlands on the Appalachian Plateau. Haney (1999) considered it to have old-growth affinity but thought that it should be considered an old-growth associate rather than an old-growth obligate. In the Yukon, it is most common in mature mixed forests but reaches its highest density in old-growth white spruce stands (Sinclair et al. 2003). Bent (1949) concluded that it was less common in mature, dense forests than in the bordering growth of small trees where young balsam firs were growing. It was originally found throughout the West Virginia spruce belt. When most of the mature timber was removed, it adapted well to the brushy second growth, particularly if there was some spruce regeneration. It is possible that the structure of the shrub layer within forests is more important than the age of the forest, although forest age can have a large influence on the density of the shrub layer.

The Swainson's Thrush has been termed both a forest-interior and edge species. Freemark and Collins (1992) considered it a forest-interior species, as did Dilger (1956) in New York and Morse (1972) in Maine. Stanwood (1913) stated that Maine birds were just as common in narrow strips of forests abutted by hayfields as in larger woodlots that provided forest interior habitat. In California, its density at forest edge was twice that at 400 m from edge (Brand and George 2001). In Newfoundland balsam fir stands, it was significantly more abundant in forest interior than in riparian and nonriparian forested edges. Although it occurred in intact forests 20-50 m from edge in riparian habitat, it was absent in similarly sized buffer strips adjacent to clear-cuts (Whitaker and Montevecchi 1997, 1999). In balsam fir–white cedar stands in eastern Quebec, there was no significant difference in its density in riparian and nonriparian stands (LaRue et al 1995). In coniferous forests in British Columbia, it was significantly more abundant in riparian habitat during the breeding season and autumn migration, but not during spring migration. It was observed mostly in the willow and alder understorey in riparian areas and may have been responding to the deciduous shrub layer rather than the proximity of water or edge (Wiebe and Martin 1998). In British Columbia, it frequently builds its nest at the edge of forests (Campbell et al. 1997), and the same is true in Ontario (Peck and James 1987). In Ontario, the Swainson's Thrush does not appear to be a forest-interior species. Where it nests within forests may be influenced by which other thrush species are present and by shrub density.

There is evidence to both suggest that the Swainson's Thrush is and is not area sensitive. In riparian cedar-hemlock forests in northern Idaho, it was considered area sensitive, but it was not along the Pacific coast. It was not detected in aspen woodlands smaller than 10 ha in an agricultural matrix. In Saskatchewan, it was more common in contiguous forests, with 46 records in contiguous

forest and only 2 in forest fragments. In Quebec, there were no significant differences in its distribution relative to the amount of forest cover, edge, or interior habitat within 100-ha landscapes. Its abundance in the northern Rocky Mountains was not associated with the patch size of forests within landscapes, but stands in more fragmented landscapes had fewer nests and lower success rates than stands in more contiguous landscapes. In Maine, the Swainson's Thrush occurred on islands as small as 0.49 ha, and it was regular on islands 1.5 ha and larger (Drolet et al. 1999; Evans Mack and Yong 2020; Hobson and Bayne 2000; Morse 1972).

Where the Swainson's Thrush overlaps with other closely related thrushes, they may inhabit mutually exclusive ranges partitioned by elevation, foraging tactics, and differential use of habitat structure. Of thrushes in the same genus, it is most adapted to an above-ground foraging niche, possibly due to competitive pressures (Evans Mack and Yong 2020). In Ontario, thrush species typically occur together where there are no significant elevational gradients, so other types of habitat partitioning are required. The greatest overlap in habitat with the Swainson's Thrush occurs with the Hermit Thrush, but overlaps also occur with the Veery and Gray-cheeked Thrush.

In New York, there was a high association between the breeding habitat of Swainson's and Hermit thrushes. Habitat partitioning was achieved by the Swainson's Thrush feeding more often in above-ground foliage than the other thrushes (Dilger 1956). Also in New York, Noon (1981) found extensive overlap of territories of Swainson's and Hermit thrushes. The Swainson's Thrush selected habitats with moderate to high shrub densities and this separated it from all other thrushes except the Veery. Swainson's Thrush territories were discriminated from other thrush territories by a higher percentage of coniferous shrubs, with all territories containing some coniferous shrubs. It keyed in on coniferous patches created by disturbance in the largely deciduous forest. In Maine spruce forests on large islands and on the mainland, the Swainson's Thrush occurred in areas of denser growth than the Hermit Thrush. On small islands where the Hermit Thrush was absent, the Swainson's Thrush consistently used mixed forests of mountain and striped maple, yellow birch, white spruce, and balsam fir, but these habitats were not used when the Hermit Thrush was present. This strongly suggests that the Swainson's Thrush is excluded from these habitats by the Hermit Thrush (Morse 1972). Both Dilger (1956) and Morse (1972) considered the Swainson's Thrush to occur predominantly in forest interior. Morse (1972) concluded that the Hermit Thrush was chiefly an edge species, thereby resulting in some habitat partitioning. In the Boreal Forest Region, Erskine (1977) concluded that the Hermit Thrush typically replaces the Swainson's Thrush in more open forests such as bogs and disturbed or young successional forests. On Haida Gwaii in British Columbia, ecological segregation between the Swainson's Thrush and other thrush species was achieved by different timing of breeding. The Hermit Thrush arrives there about 6 weeks earlier than the Swainson's Thrush and its young have begun to fledge when the Swainson's Thrush begins to arrive. The differences in nesting phenology result in a reduction of competition for resources (Sealy 1974). The difference in timing of nesting of these 2 species is not as pronounced in Ontario, with the Hermit Thrush initiating egg-laying only 10-14 days before the Swainson's Thrush and the peak periods of nesting of the 2 thrushes overlap considerably (Peck and James 1987).

Erskine (1977) concluded that the Swainson's Thrush may experience competition with the Veery in the Boreal Forest Region because the Swainson's Thrush occurs regularly in deciduous

forests only northwest of the Veery's range. In New York, Swainson's Thrush territories differed from those of the Veery by containing coniferous shrubs (Noon 1981). In New York, there was a positive association between breeding habitat of the Swainson's Thrush and Veery, but it was weak (Dilger 1956). Where it shares habitat with the Veery in British Columbia, the Swainson's Thrush forages higher above the ground and prefers areas with less undergrowth Veery (Campbell et al. 1997).

In Ontario, breeding territories of the Swainson's and Gray-cheeked thrushes may potentially overlap in the Hudson Bay Lowland. Where these species coexisted in Alaskan taiga, the Swainson's Thrush used the ground layer more than the Gray-cheeked Thrush (Evans Mack and Yong 2020).

It appears as though the presence of the Hermit Thrush and Veery may inhibit use of certain types of mixed and deciduous forests by the Swainson's Thrush. When thrush species coexist, habitat partitioning may be achieved through density of the woody understorey, by the amount of coniferous cover in the understorey, and by the height at which different thrush species forage. The Swainson's Thrush may select different foraging strata, depending upon which other thrush species are present.

Ontario nests were mostly in trees and shrubs that were alive, although a few were dead or partially dead. Coniferous trees were chosen more often (70.2% of nests) than deciduous trees and shrubs, and most nest trees were small (DBH 2.5-15 cm). Trees selected most often were spruce (53 nests), balsam fir (21), alder (11), willow (8), and birch (8). Eight nests were in tops of tree stubs, 6 were in fallen trees, and 1 was in an open cavity in the side of a standing tree. Nests were in tree crotches or less often on lateral branches, and were more apt to be near the trunk (29 nests) than away from it (6 nests). Distance from the trunk of 4 nests was 1-1.8 m. One nest was wedged between the trunks of a small balsam fir and a large yellow birch. Nests were placed from the top to the lower part of a tree or shrub without any apparent preference. An unusual nest was on the top of a hummock outside the centre of an alder clump, and was about 0.3 m above the surrounding ground level. Nests were 0.3-9 m above ground, with most 0.9-2.4 m up (Peck and James 1987). A nest in Algonquin Park was on top of a small bracket fungus growing on a sugar maple (Tozer et al. 1996).

Most nests reported outside Ontario were in trees and shrubs. They were most frequently in the understorey, particularly in thickets of deciduous shrubs or conifer saplings and less often below 3 m from the ground on top of a horizontal branch away from the bole of a large diameter tree. In New York, almost all nests were on the lowest living branch of a hemlock in an area of thick hemlock needles several metres from the trunk. This was an adaptation to heavy deer browsing that essentially eliminated hemlock from the understorey; nest placement far from the trunk presumably reduced predation by red squirrels. Tree and shrub species that nests have been reported in include 17% willow, 15% fir, 14% spruce, and 11% blackberry. Other species include alder, aspen, birch, maple, oak, hemlock, gooseberry, rose, sumac, cedar, pine, and lilac. A few British Columbia nests were among tree roots, 1 was on a post, and 6% were in snags. Nests have been reported on driftwood, a rock, and the ground. Heights of 981 British Columbia nests were 0-24 m with 60% between 1.0 and 2.4 m. Higher placement typically occurs in coniferous forests. More than 90% of nests in California and the Pacific Northwest were less than 3 m from the ground, 53% of inland northwestern nests were 3 m or less from the ground, and 70% of northeastern North American

nests were at heights of 1-2.5 m. Mean nest height in Alaskan taiga was 1.8 m. Nests in over-browsed hemlock forest in New York averaged 5.8 m from the ground with a range of 2.3-9.8 m (Bent 1949; Campbell et al. 1997; Eaton 1998; Evans Mack and Yong 2020; Sinclair et al. 2003; Stanwood 1913).

The Swainson's Thrush is territorial but boundaries are loosely defined and may not be entirely exclusive. The breeding home range is approximately the same as the territory. In California, adults tolerated each other in close proximity; active nests may be within 4-5 m of each other. In Algonquin Park, average territory size was 0.96 ha (range 0.04-1.09 ha). Territories ranged from the ground to a height of 5.5 m, slightly above the bottom of the canopy. Where it occurred in high densities in Idaho, territories averaged less than 1 ha. Within a breeding season, 75% of observations of birds were within 125 m of the capture site (maximum distance 350 m) and 80% of adults were captured within 100 m of the nest. In subalpine communities in New Hampshire, average territory size was 2.1 ha (Evans Mack and Yong 2020; Martin 1960; Sabo 1980; White et al. 2005).

In California, 37 of 200 hatch-year birds (18.5%) banded over 11 years returned to nest in at least 1 subsequent year. This is a different subspecies and habitat for it is limited, thus increasing the probability of young returning to the same area (Gardali et al. 2003).

Adults of both sexes often return to previous breeding sites. In Idaho, 42% of males and 31% of females returned. The distance between the original and subsequent capture sites was less than 150 m and less than 1 territory width. More than 50% of birds were present at least 2 years after the original capture and 6 were present at least 3 years. Two females returned to the same plot 5 consecutive years (Evans Mack and Yong 2020).

Limiting Factors

Eggs have been found in Ontario nests from the end of May until the end of July, with most present in the last half of June and first week of July (Peck and James 1987). In Algonquin Park, nest construction occurs from late May to mid-July, eggs are present from late May to late July, nestlings occur from mid-June to early August, and dependent fledglings occur from late June to mid-August (Tozer 2012)

A new nest is built every season and for renesting attempts. The time that it takes to build a nest does not appear to have been quantified. Egg laying commenced within 5 days of nest completion at Idaho nests. One egg is laid per day. Incubation begins by noon of the day that the last egg is laid, but timing of initiation of incubation may be variable because eggs often hatch at irregular intervals. The incubation period of 4 Ontario clutches was 12-13 days. Overall, the incubation period is 10-14 days. Young leave the nest when they are 10-14 days old, but usually at age 12-14 days if they are undisturbed (Campbell et al. 1997; Evans Mack and Yong 2020; Stanwood 1913; White et al. 2005).

Egg dates suggest that only a single brood is raised in Ontario. Throughout its range, it appears as though the Swainson's Thrush is single-brooded, but double broods have been confirmed in British Columbia. There is no evidence of second broods in Quebec; second broods were suspected but unconfirmed in Maine. Renesting may occur if a clutch is lost early in the season. Clutches of 2-4 eggs have been reported in Ontario, with most containing 3 or 4 eggs. Overall, clutches of 1-5 eggs have been reported. Five-egg clutches are rare, with 3 and 4 eggs most frequent and almost equal in occurrence. Mean clutch sizes were 3.53 eggs in the northeast, 3.48 in the inland of the

northwest, and 3.69 in the Pacific Northwest (Bent 1949; Campbell et al. 1997; Evans Mack and Yong 2020; Falardeau in Gauthier and Aubry 1996; Peck and James 1987; Stanwood 1913).

The Swainson's Thrush probably first breeds when it is 1 year old and annually thereafter. The mating system is presumed to be monogamous (Evans Mack and Yong 2020).

Closely related thrushes partition habitat using different foraging techniques. Dilger (1956) found that the Swainson's Thrush fed more often in foliage than other thrushes and engaged in frequent flycatching. Only the Veery and Swainson's Thrush flycatch and the Swainson's Thrush does so much more frequently. The Swainson's Thrush may forage in treetops during migration and during the breeding season. It is the most highly adapted of the thrushes for arboreal foraging based on its leg morphology, wider and shorter bill, and long wings. Foraging heights of the Swainson's Thrush averaged 1.4 m in subalpine habitats and 2.7 m in hardwoods suggesting an opportunistic shift to a lower and denser understorey in subalpine habitats. Foraging heights vary depending upon what other thrush species are present because vertical habitat partitioning of species occurs (Evans Mack and Yong 2020). In subalpine habitats in New Hampshire, foraging techniques consisted of 0.4% aerial flycatching, 21.6% leaf gleaning, 6.7% leaf hawking, 6.7% leaf hovering, 1.4% twig pecking, 7.1% twig gleaning, 4.6% twig hawking and hovering, 0.7% branch pecking, 1.1% branch gleaning, 18.8% litter pecking, 27.9% litter gleaning, and 3.9% fallen log manoeuvres. Foraging locations were 17.6% distant from the trunk, 20.0% near the trunk, 12.4% in coniferous tree foliage, 25.2% in deciduous tree foliage, 14.9% in herbaceous foliage, 48.6% on the forest floor, 22.3% in the understorey (0.1-2 m), 19.9% in the midcanopy (5-8 m), and 0% in the upper canopy (above 8 m; Sabo 1980). Adults may feed nestlings after dusk and into the night, particularly at high latitudes where provisioning occurred all night. Night provisioning did not occur until day length exceeded 19.3 hours, suggesting that some ambient light is required for foraging. Adults that fed young at night were compensating for a lower delivery rate during the day. Nests provisioned during the night were not more successful or productive (Ball et al. 2011).

Nestlings in Maine were fed cherry sphinx caterpillars, rosy maple moth caterpillars and adults, numerous unidentified caterpillars, earthworms, spruce budworm moths, glowworm beetles, crane flies, flying ants, grasshoppers, cutworms, geometer moths and caterpillars, ground beetles, ants, spiders, bees, and wild fruit. Young snapped at insects, including mosquitoes, when they flew near the nest (Stanwood 1913). The diet of 25 nestlings of the western subspecies consisted of 92.6% animal matter and 7.4% vegetable matter. Caterpillars were found in all but 7 stomachs and comprised almost 27% of the diet. Other food items included 22% beetles (7.7% ground beetles), 13.8% bugs, 12% hymenopterans (mostly ants), 12% spiders (predominantly harvestmen), and 6% miscellaneous insects. The vegetation consumed was chiefly blackberries and raspberries (Beal 1915b).

During spring migration and early in the breeding season, the Swainson's Thrush is largely insectivorous, but fruit becomes increasingly important in the diet as the breeding season progresses. By autumn migration wild fruits are more prevalent in the diet than invertebrates. During spring migration in Illinois, 6 Swainson's Thrushes ate 98% insects, the highest percentage of any thrush species. Dominant prey included 31% hymenopterans (mostly ants), 30% beetles, and 22% caterpillars (Graber et al. 1971). Beal (1915b) analyzed 560 stomachs collected in all seasons. The diet

consisted of 63.5% animal matter and 36.5% vegetation. Animal food included 21.5% hymenopterans (15.2% ants and 6.3% bees and wasps), 16.3% beetles (mostly ground beetles and weevils), 11.1% bugs (stink and shield bugs, treehoppers, leafhoppers, and cicadas), 10.3% caterpillars, 6.2% flies (mostly crane flies and march flies including larvae and adults), 3.8% scale insects, 2.4% orthopterans (primarily crickets eaten mostly in August and September), 2.2% spiders plus a few millipedes, 0.5% miscellaneous insects, and 0.3% snails, isopods, and earthworms. Domestic fruit constituted 12.6% of the diet, including cherries, blackberries, and raspberries. Only the western subspecies ate domesticated fruit; the eastern subspecies ate wild fruit. Fruits eaten included those of red and white cedar, false solomon's-seal, greenbrier, hackberry, pale smartweed, pokeweed, mountain-ash, juneberry, blackberries and raspberries, roses, black cherry, chokecherry, domestic cherry, domestic plum, sumacs, holly, grape, spikenard, flowering dogwood, gray dogwood, red-osier dogwood, huckleberry, nightshade, honeysuckles, snowberry, maple-leaved viburnum, and common and red elderberry. Deckel et al. (2025) analyzed the diet of breeding males in the White Mountains of New Hampshire. The diet consisted of 33.4% flies, 23.2% spiders, 15.2% beetles, 12.5% hymenopterans, 7.4% true bugs, 5.8% lepidopterans, and 2.5% millipedes. At higher elevations, they ate more isopods and ghost spiders, suggesting that they may be eating lower-quality food than birds at low elevations. In Illinois, autumn migrants ate 60% fruit, especially grapes plus cherries, elderberries, and blackberries. It frequently ate elderberries but preferred pokeweed if it was available. It also ate Virginia creeper fruit (Graber et al. 1971). Tietz and Johnson (2007) analysed fecal matter of autumn migrants in California. Food items in order of frequency were 87% arthropods, 70% huckleberries, 43% wax myrtle bracteoles, 7% blackberries, and 4% heaths. Over 2 years in Maine, spruce budworm larvae and pupae constituted 30.3% and 42.0% of the invertebrates it consumed (Mitchell 1952). In New Hampshire and Maine, it showed no significant response to spruce budworms, with an average of 0.9 present per stomach (Crawford and Jennings 1989). Venier et al. (2009) found no significant relationship between thrush and budworm abundance near Manitouwadge. In New Brunswick, Morris et al. (1958) observed a direct but weak relationship between the abundance of the Swainson's Thrush and budworm numbers. In California, it foraged on saddled prominent caterpillars and spruce budworm moths and was more abundant when these species were present. Use of mixed hardwoods later in the season occurred in areas of irruptive caterpillar abundance. The amount of fruit present was important in determining abundance of juveniles later in the breeding season. Fruit that was consumed included red elderberry, dogwood, honeysuckle, and blackberries. Fruit eaten was 4.2-17.6 mm in diameter and 0.1-2.4 g (White et al. 2005). In British Columbia rainforests, it frequently feeds on fruits of raspberries and devil's club (Shirley 2005).

The Swainson's Thrush is rarely parasitized by the Brown-headed Cowbird. In Ontario, 1 of 174 nests (0.6%) was parasitized (Peck and James 1998). Bent (1949) was aware of only 5 cases of parasitism. None of 526 nests reported to the Western Foundation of Vertebrate Zoology from 1867 to 1970 and 1 of 110 Idaho nests (0.9%) were parasitized. The highest rates of parasitism were 8%, reported from British Columbia and 2 areas in California (Campbell et al. 1997; Evans Mack and Yong 2020).

The Swainson's Thrush experiences a very high rate of nest predation and subsequent low reproductive success, and this may be its greatest limiting factor. In Idaho, 63% of failed nests were depredated as were 62% of nests reported to the Cornell Nest Records Scheme. The red squirrel appears to be the most significant predator (Evans Mack and Yong 2020). Creation of forest edge and the Swainson's Thrush's propensity to nest near forest edge may contribute to high predation rates. In Alaska, there was a slightly lower rate of daily survival in narrow (less than 250 m) than wide (more than 350 m) forested corridors (97.8% versus 98.6%), although results were not significant. Predation was the primary cause of nest failure, mainly due to red squirrels (D.M. Sperry et al. 2008). In California, Brand and George (2001) concluded that the Swainson's Thrush may be caught in an ecological trap because it may suffer higher levels of predation near the edges that it prefers for nesting. In urbanizing areas near Seattle, it was most abundant in forested portions of cities and in specific forest patches where American Crows, squirrels, and chipmunks were uncommon, indicating that it tended to avoid areas with high densities of predators (Marzluff et al. 2007).

Because the Swainson's Thrush typically nests in the shrub layer, habitat changes to this layer such as clearing of shrubs around cottages may have detrimental effects (Clark et al. 1983). In a forest over-browsed by deer in New York, it was forced to nest in the lower limbs of large hemlocks, thus making nests more susceptible to predation by red squirrels (Eaton 1998). Over a 30-year period in a New Hampshire forest, it declined as the original dense, low shrub layer grew into a dense, tall subcanopy layer with sparse coverage by low shrubs (Holmes and Sherry 2001).

The effects of forestry on the Swainson's Thrush vary depending upon the prescription used. Studies related to forestry impacts have focused on its abundance but effects on survival and nest success have not been studied (Evans Mack and Yong 2020). Selective thinning may have little impact (Webb et al. 1977) and may be beneficial by opening the canopy, thereby promoting shrub growth. Clear-cutting results in an initial loss of habitat, but areas may support substantial numbers of Swainson's Thrushes 10-20 years after treatment. It may then decline during the pole- and timber-size stages of forest maturation, and once again become common in mature stands. In the Boreal Forest Region of Ontario, its abundance did not change when 30% or 50% of trees were removed, but decreased when 70% of trees were removed. It experienced a 25% decrease in abundance when 65% of trees were removed, a 50% decrease when 70% of trees were removed, and a 75% decrease when 75% of trees were removed (Vanderwel et al. 2007, 2009). Single-tree selection in Algonquin Park had no effect on its abundance (Jobes et al. 2004). In the Ontario Canadian Shield, there was no difference in its abundance in early and mid-successional clear-cuts compared with similarly aged stands after fire. It was significantly less abundant in early and mid-successional stands than in mature stands (Zimmerling et al. 2017). In British Columbia where forests were thinned or thinned and treated with herbicides, the Swainson's Thrush consistently selected patches for breeding that had either escaped or recovered from silvicultural treatments (Easton and Martin 2002). In Alberta, it declined significantly when 50-100% of trees in mixed forests were removed (Harrison et al. 2005). On treatment plots in New Brunswick northern hardwoods, an average of 41.9% of the basal area was removed and the canopy closure was reduced by about 20%. In the first 3 years postharvest, density of the Swainson's Thrush tended to be higher in controls. The opposite was true 5 years postharvest (Háche et al. 2013). In Maine clear-cuts, it was absent in the earliest seral stages: dense

slash and abundant open ground, and dense raspberries and regenerating hardwoods less than 2 m tall. It first reappeared when hardwood regeneration was more than 2 m tall and there was a well-developed, slow-growing coniferous stratum. Highest abundance occurred when hardwood regeneration was taller than 4.5 m with trees with DBH of 10-15 cm. It also occurred at lower density in the final seral stage which was a dense softwood overstorey with an open forest floor (Titterington et al. 1979). In Alberta, residual tree blocks were left in uniform patterns in all clear-cuts and non-merchantable timber was retained. It declined significantly in the cut areas. Tittler et al. (2001) estimated that more than 40% of trees and more than 46% of tree basal area would have to be retained in cut areas to maintain it. Logging of boreal mixed-wood forests may be contributing to its decline; maintenance of old-growth reserves may be critical to its conservation. In Saskatchewan boreal forests, it was significantly more abundant in tracts older than rotation age. Cumming and Diamond (2002) concluded that it was likely to suffer reduction in population density if stands older than rotation age were lost entirely from the landscape. In a netting survey in Newfoundland, 48% of Swainson's Thrushes were captured in areas that had been clear-cut; there was no difference in survival rates in cut and uncut areas. Whitaker et al. (2008) suggested that it may be resilient to a moderate level of clear-cutting.

In Alberta, the Swainson's Thrush was significantly more abundant at pipelines than in adjacent forest interior, significantly less abundant at well pads than in adjacent forest interior, and there was no difference in its abundance at seismic lines and in adjacent forest interior (Bayne et al. 2016). There was no difference in its abundance near noisy compressor stations and quiet well pads. It did not appear to be affected by chronic noise (Bayne et al. 2008).

In Quebec, DesGranges and Morneau (2010) concluded that the Swainson's Thrush was associated with boreal forest and cooler and wetter summers. They considered it sensitive to climate change.

Status

The Swainson's Thrush has always been a common breeder in Ontario. Baillie and Harrington (1937) stated that it occurred commonly from southern Georgian Bay and Hastings County to the southern edge of James Bay. It bred at that time west to southern Kenora District and to Lake of the Woods and on Manitoulin Island. It was the most common thrush along the northeastern shore of Lake Superior (Baillie and Hope 1943). In white pine forests in the Shield portion of the Great Lakes–St. Lawrence Forest Region, it was the fourth most abundant species and represented 5.4% of all birds documented (Kirk et al. 2012). The first atlas documented breeding throughout the Hudson Bay Lowland to the north coast, except in the northeastern corner of the province. It was widespread on Manitoulin Island and the Bruce Peninsula, with only scattered records elsewhere south of the Canadian Shield (Sadler in Cadman et al. 1987). James (1991) considered it a common summer resident throughout the province south to the Bruce Peninsula and central Peterborough County and occasional and rare to Wellington and southern Frontenac counties.

The second atlas revealed that there were no changes in the distribution of the Swainson's Thrush between atlases. Overall, there was a nonsignificant increase in its probability of observation, with a significant increase in the Boreal Forest Region. Greatest abundance occurred in the Boreal Forest Region and southern portion of the Hudson Bay Lowland (Friesen in Cadman et al. 2007).

Breeding Bird Survey data indicate that the Swainson's Thrush increased at an annual rate of 0.0964% in Canada and decreased at an annual rate of 0.31% in Ontario 1970-2021. The trends 2011-21 were an annual increase of 0.78% in Canada and an annual decrease of 1.67% in Ontario. The trends for Ontario were highly reliable; the Canadian trends were of medium reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

White et al. (2005) and White and Faaborg (2008) studied habitat use by fledglings in California. Their results may not be representative of populations in other areas because this is an endemic subspecies that nests in different habitats than eastern birds. Seventy percent of juveniles stayed an average of 54 days postfledging in their natal watershed until transmitter batteries failed. The other 30% remained an average of 41 days before dispersing. During the first 2 weeks postfledging, 27% of adults led their broods to upland mixed hardwoods or coastal shrubs at least once. Broods were found in upland vegetation communities 38% of the time. Independent juveniles used upland areas an average of 56% of the time and 74% of individuals used uplands at least once. Juveniles were attracted to sites with abundant fruit. They used sites with less tree cover than random sites whereas a high percentage of canopy cover was important in adult nest-site selection. The habitat used by fledglings was not used by adults for nesting. Immediately after fledging, juveniles used thicket areas near the nest. Adults of 21 broods remained on the territory during the postfledging period and adults of 9 broods moved. There was no difference in mobility between late and early nesters. Mobility was low for both groups for the first few days postfledging, with mobility increasing for drifting broods 3-7 days after fledging and again 8-12 days postfledging. Drifting adults led young hundreds of metres from the nest, but the maximum distance moved in a day was only 40 m. Brood-rearing areas used by drifting adults were fruiting-shrub thickets with abundant fruit, or, in 1 case, where there were abundant moths. After independence, all juveniles established at least 1 dispersal area and some established 3 or 4. The home range for most juveniles consisted of disjunct dispersal areas. The median home range of juveniles was 2.0 ha (range 0.2-9.0, mean 2.58 ha) and the median core area was 0.41 ha (range 0.05-1.6 ha, mean 0.49 ha). Time spent in different dispersal areas was 3-39 days, with most time spent in the first dispersal area. Mean length of time spent in the first dispersal area was 22.7 days compared with 9.6 days in the second area. Juveniles did not move far within dispersal areas, often remaining in the same shrub thicket, but they made long-distance movements between dispersal areas. The mean initial dispersal distance was 242 m (range 28-1,040) and the mean subsequent dispersal distance was 598 m (range 154-2,624 m). Adults were faithful to brood-rearing areas, leading young to the same areas in subsequent years. Brood-rearing areas may have an important role in territory or nest-site selection. Juveniles became independent at 15 days postfledging in stationary broods and at 20 days in drifting broods.

In Quebec, Major and Desrochers (2012) captured Swainson's Thrushes in clear-cuts during the postfledging period. It was more abundant in control plots than in those where fruit had been removed, and this difference approached significance. Fruit availability may be an important factor in attracting it to clear-cuts. In Pennsylvania, Stoleson (2013) captured 11 adults and 1 juvenile in clear-cuts and 11 adults and 2 juveniles in mature forest habitat with dense understorey. The capture rate was slightly higher in forests than clear-cuts, indicating that it may be a habitat generalist during

the postfledging period. In Minnesota, Streby et al. (2011b) captured only a single Swainson's Thrush in regenerating clear-cuts during the breeding season, but caught 31 adults and 1 fledgling during the postbreeding period.

Whittaker and Marzluff (2009) studied movement patterns of fledgling, juvenile, and postbreeding adult Swainson's Thrushes in Washington. Of 4 species studied, areas used by Swainson's Thrushes had the lowest proportions of heavy to medium urban (10%) and light urban cover (19%) and the lowest road density. There was no significant difference in its usage of forested and urban habitats.

MIGRATION

The Swainson's Thrush is predominantly a nocturnal migrant, but some early morning daylight flights may occur. Fat birds may continue migrating in the morning. Lean birds tend to remain in 1 location for the day. In Illinois, no daytime movements were observed during spring migration and all remained within an area of 0.04-0.2 ha. Two birds banded during autumn migration in Ontario were later recovered in Nebraska and Alaska. A bird banded at Long Point in autumn 2001 and another banded the following autumn were recovered in Peru, a flight distance of 6,100 km. A bird banded in spring at Long Point was recaptured the following morning at Prince Edward Point, a distance of 300 km (Brewer et al. 2018; Cochran et al. 1967; Evans Mack and Yong 2020; Graber et al. 1971; Mackenzie and McCracken 2002; Weir 2008).

Mills et al. (2011) radio-tagged 28 Swainson's Thrushes at Long Point during autumn migration. The mean duration of stopover was 3.4 days (range 0.3-11.4 days). The mean duration of time from capture to landscape-scale movement was 3.0 days and the mean duration from time of capture to final detection was 6.4 days. Nocturnal local movement occurred late in stopover, 0-5 nights prior to final departure. Multiple nocturnal movements occurred locally prior to final departure. On most successive days, birds were found within a few hundred metres of their previous location, but some undertook movements exceeding 1 km. Most local nocturnal flights were from the tip of Long Point where the habitat is less suitable for migrants than at the 2 other banding stations.

In spring, males migrate before females but there are insufficient data to determine autumn migration schedules. In Illinois, males arrived an average of 4.5 days earlier than females. In southern Ontario, birds arrive in late April and migration continues until late May, with the peak in mid-May. In central and northern Ontario, it arrives in mid-May with migration continuing until early June. At Long Point, the midpoint of spring migration is 21 May (Black and Roy 2010; Bowlin 2007; Curry 2006; Evans Mack and Yong 2020; Kendeigh 1947; Lancaster et al. 2004; Mills 1981, 2005b; Tozer 2012; Weir 2008).

The Swainson's Thrush may start to leave northern breeding grounds in early to mid-July, but some remain near the nesting areas until August or September. Some leave the breeding areas prior to starting to moult or when they are in the early stages of moult. Others move at least 250 km from the breeding area before undertaking the moult. Few birds are likely to move during the middle of the moult. Near Montreal, birds that moulted there remained an average of 47 days compared with 7 days for those that had moulted on the breeding grounds. Birds have been captured at banding stations at Long Point, Prince Edward Point, and New York from late July to mid-September (Cherry

1985; Evans Mack and Yong 2020; Morales et al. 2022). At Long Point in 1990, there was no difference in the timing of autumn migration of adults and juveniles, but the median passage period of adults was significantly earlier than that of juveniles in 1991. There were no differences in timing of the 2 age classes at 2 other eastern banding stations during this period (Woodrey and Chandler 1997). In the southern Shield, birds are moving southward by August and are seen into the second week of September, with late records to mid-October. Birds may arrive in southern Ontario in July, but mid- to late August is more typical. The peak of autumn migration is in September and October, with late birds occurring until mid-October (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Mills 1981, 2005b; Mills et al. 2011; Tozer 2012; Weir 2008). McNicholl (1985, 1991) examined winter records of the Swainson's Thrush in Ontario, most of which were actually late autumn records from December. December records may be of birds that were injured or sick during autumn migration or those responding to unseasonably warm weather. A bird observed in High Park, Toronto on 3 March 1984 may represent a true winter record.

Mills (2005b) examined the timing of spring and autumn migration at Long Point in relation to global warming 1975-2000. In spring, there was a trend toward earlier migration based on the first arrival date, but this trend was not significant. Results were similar when quartile means were examined. The Swainson's Thrush also exhibited a nonsignificant trend toward later autumn departure.

During migration, the Swainson's Thrush uses a wider variety of habitats than during the breeding season. These may include several forest types and shrubby areas. Within forested areas, presence of some shrub cover appears important, but it will use woodlands without a shrub layer. Presence of fruit may be important in determining usage of an area. In addition to wooded areas in forested or agricultural landscapes, it may inhabit urban areas such as parks, university campuses, and gardens. Other habitats it may use include brushy fields, shrubby fencerows, orchards, cattail marshes, and shrubbery near farm houses and cottages. Riparian shrubby and wooded areas as well as moist woods with shrub cover may be favoured. In Ohio urban landscapes, spring migrants occurred significantly more often in upland forests than riparian forests. In British Columbia, it is common along shorelines with dense thickets of fruit-bearing shrubs, around lakes and beaver ponds, at edges of forest openings, in fields, at sewage lagoons, at muskeg edges, in coniferous forests and subalpine fir, in deciduous woodlands with scattered conifers, and in swales and gullies in grassland slopes that support thickets of hawthorn, chokecherry, and juneberry. In Minnesota, spring migrants were found approximately equally in floodplains, swamps, willows, and uplands. In autumn, it demonstrated a switch from upland habitat toward wetter sites such as floodplains and willows (Bent 1949; Campbell et al. 1997; Craves 2009; Evans Mack and Yong 2020; Graber et al. 1971; Leighton et al. 2002; McIlwraith 1894; Rodewald and Matthews 2005; Winker et al. 1992).

Juvenile autumn migrants in California showed no consistent selection of forest types within the study area or within their home ranges. They selected microhabitats with abundant huckleberries, but the widespread and variable distribution of this species may have precluded selection for or against any particular forest type. On average, Swainson's Thrushes showed no selection or avoidance of coniferous forest. Some individuals strongly selected conifers and others strongly avoided them. A mixture of habitats may be important to fulfill the stopover requirements

of different birds (Tietz and Johnson 2007). It was more abundant on a treed island in the Gulf of Maine during spring migration than on an adjacent island dominated by shrubs (Suomala et al. 2010).

In Michigan, Oguchi et al. (2018) examined use of nonnative and native shrublands by the Swainson's Thrush during autumn migration. Nonnative shrublands were dominated by autumn olive, 3 nonnative honeysuckles, and multiflora rose. Gray dogwood, winterberry holly, and spicebush dominated native shrublands. Over 2 years, it was significantly more likely to be captured in native shrubs, with 21% and 29% more captures than in nonnative shrubs. Recaptured birds were more likely to be recaptured in native than nonnative shrublands. Differences were nonsignificant in 1 year and significant in the other. No thrushes moved back and forth between shrubland habitats. The number of days spent in different habitats included 2.4 days in nonnative shrublands, 2.9 days in native shrublands, 0 day in open habitat, 1.0 day in marshland, and 0.9 day in woodland. Selection of native shrubland over other habitats was highly significant; use of nonnative shrublands was 44% less than expected. Ninety-nine percent of fecal matter contained fruit. Significantly more spicebush was consumed in native than nonnative shrublands and significantly more common buckthorn and autumn olive was consumed in nonnative than native shrublands. Native shrublands were more important for the Swainson's Thrush during autumn migration than nonnative shrublands because it preferentially selected spicebush fruits.

Migration stopover sites for Swainson's Thrush need not be large provided the habitat is suitable. In California, birds used a highly fragmented narrow strip of vegetation along a creek. Stopover sites in Minnesota were only 1-3 ha. Both sites were used extensively by migrants; many individuals stayed considerable periods and almost all gained weight (Othahal 1991; Winker et al. 1992). Migrating Swainson's Thrushes may require a minimum forest patch size in urban areas during spring in Columbus, Ohio. All thrushes relocated to larger sites (11.9-38.4 ha) remained within the release site until departure; 28% of those released in small patches (0.7 ha and 4.5 ha) moved away from the release site. Those that left the patch where they were released moved 100-1,000 m to small hedgerows where they remained for 1-2 days (Matthews and Rodewald 2010).

In California during autumn migration, the average home range size was 1.9 ha. The home range size of lean birds (2.5 ha) was twice that of fat birds (1.2 ha). The smaller home range of fat birds suggests that they did not have to search for food as much as lean birds (Tietz and Johnson 2007). In Michigan, the 50% kernel foraging range averaged 5.4 ha (range 1.1-11.2 ha); the 99% kernel range was 34.1 ha (range 6.4-71.0 ha; Oguchi et al. 2018).

The Swainson's Thrush may exhibit site fidelity to migration stopover sites. Two banded in Nashville, Tennessee on 15 May 1932 were recaptured on 18 September 1932; 1 returned 30 May 1933 and was captured again on 24 September 1933 (Bent 1949).

Craves (2009) concluded that there may be limitations to the quality of urban migration stopover areas. These include frequent human disturbance, competition for fruit by urban-adapted species, domination by nonnative fruiting plants, and depletion of high-quality fruits early in the autumn migration season leaving thrushes to rely heavily on low-lipid nonnative fruits. Fruits of nonnative shrub species such as autumn olive, common buckthorn, and honeysuckles have higher

sugar and water content but lower energy content compared with native species such as spicebush, gray dogwood, and Virginia creeper (Oguchi et al. 2017).

Oguchi et al. (2018) reported that the Swainson's Thrush consumed fruits of common buckthorn, guelder-rose, nightshade, autumn olive, multiflora rose, nonnative honeysuckles, spicebush, winterberry holly, common elderberry, nannyberry, and Virginia creeper as well as a few arthropods during autumn migration. It highly selected for spicebush berries.

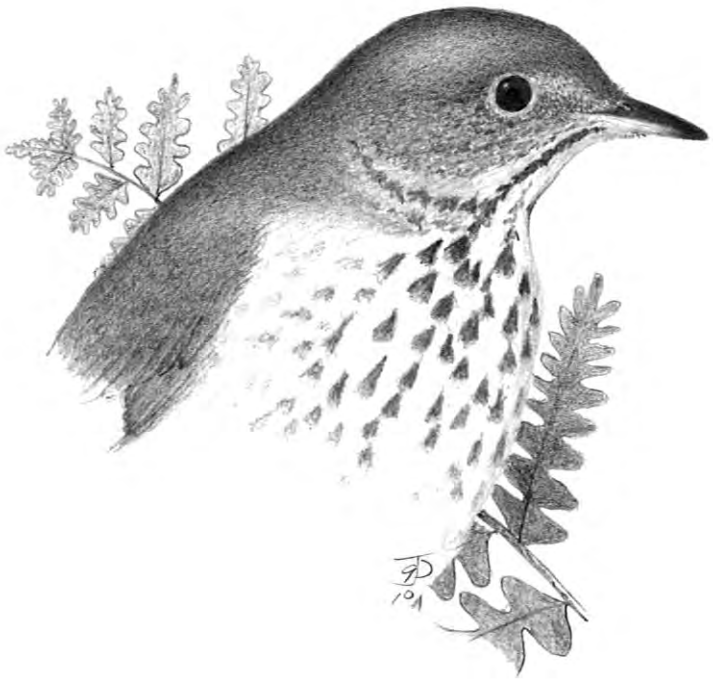
Collisions with television towers, lighthouses, tall chimneys, and tall buildings are the most significant limiting factor during migration. More Swainson's Thrushes are killed than any other species some nights at towers. It was the number 1 species killed at the Long Point lighthouses 1961-2001. It represented 9% of 17,500 casualties. Fifty-seven were killed at the Lennox generating station chimneys (Anonymous 2002; Bent 1949; Evans Mack and Yong 2020; Graber et al. 1971; Leighton et al. 2002; Weir 2008). Throughout the United States, it was particularly vulnerable to striking residences 1-3 stories tall, where it was 34.7 times more likely to suffer a collision than birds on average. It was not among the top 20 species most vulnerable to striking low-rises and high-rises (Loss et al. 2014).

The Swainson's Thrush is a common to locally abundant migrant in much of the province (James 1991), although it is uncommon in Elgin County (Lancaster et al. 2004).

Data from Long Point Bird Observatory indicated a significant decrease of 2.9% per year 1961-88. This included a decrease of 7.8% per year 1961-70, an increase of 1.2% 1970-79, and a decrease of 3.3% 1979-88 (Hussell et al. 1992). More recent data suggest that numbers at Long Point have been stable the past 40 years (Anonymous 2002).

Hermit Thrush

Catharus guttatus

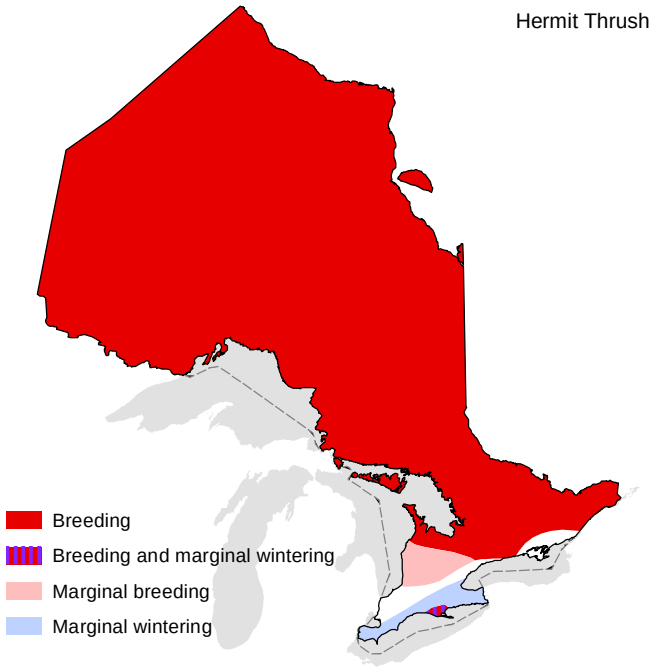


BREEDING SEASON

Habitat Requirements

In Ontario, Hermit Thrush nests have been found in dry and wet forests (85.7%) of nests); on rocky outcrops, usually with sparse deciduous growth (5.9%); in sphagnum bogs (4.2%); on blueberry barrens (1.7%); on a limestone savannah (0.8%); in a rocky, open burn (0.8%); and in a grassy area of alder growth near a forest (0.8%). Of nests where forest type was specified, 42.9% were in coniferous forests, 29.8% were in mixed forests, and 27.4% were in deciduous forests. Canopies of forests selected for nesting were more open than closed. In closed forests, nests were often in clearings or near forest edges, shorelines, and roads (Peck and James 1987).

In the Boreal Forest Region of Ontario, the Hermit Thrush was significantly associated with hardwood forest cover type, but not forest age at the 50-ha scale. At the 5,000-ha scale, it was significantly associated with edge, a measure of forest cover configuration and age-class interspersion. It was associated with open, mixed-wood forest with high edge density (Rempel 2007). From Pickle Lake to Little Sachigo Lake, it occurred in low densities in coniferous forest with understorey, in mixed forest, and in deciduous, coniferous, and mixed shrubs. It was absent in deciduous forest, coniferous forest without understorey, heath, and tundra (McLaren and McLaren 1981). Near Hearst, it bred in 17-24-year-old clear-cuts in coniferous lowland forests and in a 19-year-



old lower-slope mixed forest. It was absent in uncut or clear-cut upland mixed stands or in uncut or young (3-13 years) clear-cuts in lowland coniferous stands (Welsh and Fillmore 1980). In the Clay Belt, it was most abundant in nutrient-poor, wet forest stands (Welsh and Lougheed 1996).

In Quetico Park in the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region, the Hermit Thrush occurred in early successional and intermediate-aged stands, but not in mature or old-growth stands (Apfelbaum and Haney 1985). In jack pine forests near Gogama, it was one of the most ubiquitous and characteristic species of pine forests and, to a lesser extent, mixed woods. It tended to move into an area once vegetative cover of any type reached a height of 3 m. It preferred more open areas, either between dense patches of trees or shrubs or preferably where dense tree cover rose above low shrubs, leaving open space between low shrubs and lower tree branches. Maximum densities occurred when pines were about 20 years old. Lower numbers in more mature forests were probably because deciduous shrubs were usually numerous, but numbers remained high in maturing pine forests where tall shrubs were less abundant (James and Peck 1995a). In Muskoka District, it nested in a mature hemlock forest (Armstrong and Euler 1983). It was found in open forests in Muskoka and Parry Sound districts and preferred areas where there were natural bedrock openings (Mills 1981). In Algonquin Park, it was characteristic of pioneer deciduous forest and one of the most conspicuous species in white birch–poplar stands (Martin 1960). In Parry Sound District, it occurred in pure and mixed stands of jack pine with less than 25-50% canopy closure (James 1979a). In the Kingston area, it occurred mostly in the Canadian Shield where it was partial to red pine plantations (Weir 2008).

In the Kingston area south of the Shield, high-quality white cedar forests for the Hermit Thrush were associated with the presence of a contiguous and varied forested landscape, pockets of distinct vegetation within the forest community type, vegetative layering, and microhabitat features such as snags, woody debris, and standing water (McLeish and Robertson 1997).

Throughout its range, the Hermit Thrush nests in a variety of forest types and much less frequently in open areas such as bogs, old fields at edges of forests, along edges of forest roads, in open thickets, barrens and rock outcrops, lake shorelines, cemeteries, golf courses, and on hydro rights-of-way through forested habitat. In Quebec black spruce forests, it nested in recent burns and clear-cuts where saplings were less than 2 m and 2-5 m tall, in young forests with saplings 5-11 m tall, and mature forests 120 and 200 years old. It was most abundant in recent burns where shrubs were less than 2 m tall and least abundant in clear-cuts where saplings were 2-5 m tall. Abundance

in young and mature forests was not significantly different from recent burns or clear-cuts (Imbeau et al. 1999). In New York, it occurred most often along interior forest edges such as margins of old burns, fire lanes, power-line cuts, and edges of lakes and burns rather than exterior forest edges. It was tolerant of dry habitats but occurred frequently in damp areas. It occurred more frequently in coniferous and mixed woods than deciduous forests, and was most abundant in coniferous forests in both disturbed and undisturbed areas (Dilger 1956). In mountainous areas of New York, it selected mid-successional forests with high canopy cover of dense stands of intermediate-diameter (15.3-38.0 cm diameter at breast height [DBH]) trees (Noon 1981). In Quebec, it occurred where there was a mean of 56.4% forest cover within a radius of 500 m (Bourque and Desrochers 2006). Dellinger et al. (2020) reported that 93% of nests east of the Rocky Mountains were in forests; 5% were in wet areas, and 2% were in open areas. More nests were in undisturbed (64%) than disturbed (29%) forest. Nest records from disturbed forests included 19% in mixed second growth, 17% near forest roads, 16% in recent clear-cuts, 13% in coniferous second growth, and 35% collectively in old fields, forest edges, hydro rights-of-way, deciduous and open second growth, selectively logged or regenerating forests, blowdowns, and burned areas. In wet habitats, 22 nests were in spruce bogs and 10 were in cedar swamps, mixed swamps, or marshes. Nests in open areas were in open barren lands, upper beaches, golf courses, and cemeteries. The Hermit Thrush also nests in open woodlands with bunchberry or fern thickets, and on borders of pastures skirted by shrubbery and trees. In the Boreal Forest Region, it is regular in black spruce communities along the subarctic border where open stands occur. It is found in most jack pine stands. Jack pine stands are much more open than spruce, balsam fir, or hemlock stands, often with only 20-30% canopy cover. In Vermont, territories encompassed both hardwood forests and clear-cuts (Lent and Capen 1995). In Saskatchewan, it was more common than expected in aspen forests (Hobson and Bayne 2000). In Wisconsin, it was rare in pine and oak barrens but fairly common in areas that were nearly forest (Mossman et al. 1991). Also in Wisconsin, it occasionally occurred in coniferous plantations. It was common in northern mesic forests in sapling-stage deciduous stands and occurred in pole-sized or mixed stands (Hoffman 1989a; Bielefeldt and Rosenfield 1994). In the Boreal Forest Region, it was in a guild of species associated with conifers and occurred in drier, nutrient-poor stands. It had a slight tendency to occur in younger than older stands, but not significantly (Kirk et al. 1996). On islands in Wisconsin, maximum density occurred in a red pine stand but it occurred in small numbers in white birch–red oak, aspens, white birch–yellow birch–white cedar, and sugar maple–yellow birch stands (Beals 1960). High densities of the Hermit Thrush occurred in Wisconsin woodlands where clubmosses were abundant (Loss 2012). In the northeast, it had a major association with mature coniferous upland stands, a moderate association with mature coniferous lowland forests, and a minor association with alder thickets, mature deciduous upland forests, disturbed shrubby areas, young plantations, aspen regeneration, and recent clear-cuts. It was associated with a high density of low shrubs, trees, and saplings (Niemi and Pfannmuller 1979). In the northeast, it occurs in northern hardwoods, lowland hardwoods, aspen-birch stands, upland spruce-fir stands, lowland conifers, and mixed forests. In northern hardwoods, it was found in 13% of mature, undisturbed habitats and 23% of disturbed and successional habitats. In aspen-birch, it occurred predominantly in the seedling-sapling and pole-mature stands. It was absent in 1- and 2-year-old burns and clear-cuts, and in sapling-pole-stage stands. In pine and mixed pine-hardwoods stands, it occurred in all ages of

forests and first appeared in burns 1 year after fire. In lowland conifers, it was present in shrubby areas with scattered conifers, all-aged black spruce stands, and tamarack and white cedar stands. In mixed forests, its abundance was associated with increasing abundance of pines (Back 1979; Capen 1979; Crawford and Titterington 1979; Dawson 1979; Noon et al. 1979; Samson 1979; Temple et al. 1979). In Quebec, it occurs in a variety of forest types but prefers edges of lakes, clearings, burns, and mid-successional areas. It also nests in black spruce plantations (Falardeau in Gauthier and Aubry 1996). In British Columbia, preferred nesting habitat is mixed coniferous forests with a dense shrub understorey. At low elevations, the Hermit Thrush is most abundant where berry-bearing shrubs are abundant. In low areas, it nests in coniferous forests, trembling aspen forests, pine-aspen stands, spruce-tamarack stands, and black spruce muskeg. Away from the coast, it nests in subalpine spruce, alpine fir, and krummholz forests. It inhabits the upper edges of forests where openings and shrub patches, including blueberries, provide late summer and autumn food. It favours moist areas (Campbell et al. 1997). In the Yukon, it occurs in subalpine areas and in trembling aspen forests and burned areas at lower elevations. It uses 2 distinct habitats for nesting: open, mixed forests near the treeline in mountainous areas, especially along creeks, wet draws, and gullies with tall deciduous shrubs; and, at lower elevations, in trembling aspen forests, including burns. In central Yukon, it occurs in deciduous and mixed growth where it favours second growth, especially trembling aspen in burned areas (Sinclair et al. 2003). On Long Island, it frequented the hottest and driest barrens where the ground was carpeted with bearberry and pine-barren sandwort. In northern Michigan, nests were in dry upland covered with second growth after fire a few years previously (Gross in Bent 1949).

In New Jersey, the Hermit Thrush was a primary facultative hemlock species. It occurred within hemlock woods and on dry deciduous ridge tops with dense ground cover. It tolerated a wide range of moisture gradients and occurred in dense young mixed growth along interior edges and within heavy cuts. The relative importance of habitats for it was 40% for hemlock growth, 60% for hardwoods with some pine, and 0% for coniferous plantations. Canopy reduction may temporarily increase understorey habitat for it (Benzinger 1994). In Connecticut, it was strongly associated with intact hemlock stands and exhibited 34% declines in forests with high hemlock mortality (Dellinger et al. 2020). In New Jersey and Pennsylvania, it was adversely affected by hemlock decline due to the hemlock woolly adelgid and decreased in abundance (Toenies et al. 2018).

A forest burn in California was intense and left no cover except for scattered snags and occasional live trees. The Hermit Thrush was absent in the burned area but bred in the adjacent intact forest. It was the only ground-foraging species that was absent in the burn. It was characteristic of only the most shaded and concealed areas of the forest floor (Bock and Lynch 1970).

In balsam fir stands in Newfoundland, Whitaker and Montevecchi (1997) considered the Hermit Thrush a forest-interior species, although there were no significant differences in its abundance in riparian habitat, forest interior, and nonriparian forest edges. In eastern Quebec, it was significantly more abundant in nonriparian than riparian balsam fir–white cedar stands (LaRue et al. 1995).

Some studies indicated that the Hermit Thrush is associated predominantly with older-growth forest; others suggested that it is more common in young forests. In Pennsylvania, it occurred in 100% of old-growth forests, in 27.8% of forests state-wide, and in 49.2% of forests on the

Appalachian Plateau. Haney (1999) considered it to have a positive old-growth affinity but concluded that it was probably an old-growth associate rather than an obligate. In West Virginia, it was most likely to be present in forests older than 120 years and least likely to occur in 0-19-year-old stands (Dimmig et al. 2020). In Newfoundland balsam fir stands, it occurred in forests that were slightly older than average and relatively nutrient-poor. It may be associated with older-growth forests that have larger snags, large conifers, forest gaps, and shrub growth within the gaps (Thompson et al. 1999). In Nova Scotia, it inhabited older stands (Morgan and Freedman 1986). In Alberta trembling aspen forests, it was significantly more abundant in young than mature or old-growth stands. It occurs in poplar–white birch stands but is associated with scattered coniferous trees or clumps of trees, especially white spruce and balsam fir, within these stands. It tends to be associated with rather open canopies and small trees (Schieck et al. 1995). The Hermit Thrush was more common in young or slightly younger than average stands in the Boreal Forest Region. It actively selects young and open jack pine forests in the Boreal Forest Region thereby reducing habitat overlap with the Swainson's Thrush (Erskine 1977; Kirk et al. 1996). In southern Ontario, the Hermit Thrush nests in more mature stands in the Carolinian Forest Region and on the Bruce Peninsula, but also occurs in younger coniferous plantations on the Oak Ridges Moraine.

It is uncertain whether the Hermit Thrush is an area-sensitive species. In Saskatchewan, it was randomly distributed within a fragmented landscape and there was no significant relationship between its abundance, forest size, or amount of forest in the region (Hobson and Bayne 2000). In the Saskatoon area, it was restricted to aspen stands 24 ha and larger (Leighton et al. 2002). In Michigan, its abundance was correlated with forest size (Crozier and Niemi 2003). In Ontario, it appears to be restricted to very large forest tracts in the Carolinian Forest Region. In the remainder of the area south of the Shield, it is becoming increasingly common on the Oak Ridges Moraine where the relatively high proportion of forest cover may be more important than forest size.

Several studies studied habitat partitioning of the Hermit Thrush with the Veery, Wood Thrush, Swainson's Thrush, and American Robin.

In New York, the Hermit Thrush had only a moderate breeding-habitat association with the Veery (Dilger 1956). Along an elevational gradient in New York, it bred at low elevations along with the Veery, but it had the greatest elevational range of the thrushes studied. All thrush species showed significant habitat segregation along at least 1 axis and the Hermit Thrush had an exclusive area of niche space where there was no competition with other thrushes (Noon 1981). In Maine, it mostly occurred in dry to mesic coniferous and deciduous forests, particularly those dominated by pines and oaks. The Hermit Thrush and Veery did not overlap much except in mixed woods with red maple and/or alder. In these areas, the Hermit Thrush occurred in the driest areas and the Veery occurred in the wettest. Although there were few differences in areas used by the Hermit Thrush and Veery, the 2 species seemed to use different parts of these habitats. Some of the driest habitats used by the Hermit Thrush were not occupied by the Veery or Wood Thrush, and the Hermit Thrush enjoyed exclusive use of these areas without competition (Morse 1971a). In Wisconsin, the Hermit Thrush and Veery occurred in forests containing both deciduous and coniferous trees with sapling aspens being most abundant. Over half of both species' territories were covered by an overstorey with a maximum height of about 20 m and there was a well-developed understorey of bracken

ferns, shrubs, and tree saplings to a height of 3 m over more than 80% of territories. There were no significant differences between the 2 species' territories in the distribution of tree species, tree size, or overstorey or understorey structure, and no macrohabitat difference in use of coniferous and deciduous stands. Habitat partitioning between the Hermit Thrush and Veery was achieved by the amount of time spent in different height strata. The Hermit Thrush spent 8% of its time on the ground, 23% under 3 m, 45% at 3-6 m, 18% at 6-9 m, and 5% above 5 m; the Veery spent approximately equal time in each height stratum. The amount of time the Hermit Thrush spent on the ground was approximately 3 times that of the Veery. The Hermit Thrush concentrated its singing in the 6-m stratum; the Veery sang most frequently at heights above 9 m. The Hermit Thrush spent more time in conifers; the Veery concentrated its activities in hardwoods. Both species made little use of aspens in relation to their abundance (Paszkowski 1984). In Virginia, North Carolina, and Tennessee, the Hermit Thrush was a habitat generalist; the Veery was more of a specialist. Hermit Thrushes preferred forests with high percentage canopy closure, a high percentage of leaf litter, and low percentage coverage by woody stems shorter than 3 m. Veeries preferred high percent coverage between 0.5 and 3 m and less canopy closure. Hermit Thrushes preferred more and larger conifers than the Veery. The microhabitats of the 2 thrushes were significantly different despite the fact that they often nested close together (Laughlin et al. 2013). In West Virginia, Hermit Thrush nests were separated from those of the Veery by distance to edge, with the Hermit Thrush nesting closer to roads and skid trails than the Veery. Hermit Thrush nests were at the highest elevations; Veery nests were at intermediate elevations. The Hermit Thrush was completely isolated from other thrushes at the higher extreme of its range. The Hermit Thrush tended to nest on upper and lower slopes; the Veery was evenly distributed but absent from the highest elevations (Dellinger et al. 2020).

Habitat partitioning occurs between the Hermit Thrush and Wood Thrush. There is no evidence of interspecific territoriality between these 2 species but the Wood Thrush appears to be behaviourally dominant to the Hermit Thrush. Initial encounters between these 2 species may be sufficient for the Wood Thrush to establish a territory even though a Hermit Thrush may have previously established a territory (Morse 1971a; Noon 1981). In a New York area with elevational gradients, the Hermit Thrush bred at low elevations with the Wood Thrush but the species were separated along an index of tree spacing. The Hermit Thrush also occupied higher elevations than the Wood Thrush (Noon 1981). In Maine, both the Hermit Thrush and Wood Thrush occupied coniferous and deciduous woodlands, but the Hermit Thrush selected areas that were drier than those inhabited by the Wood Thrush (Morse 1971a). In West Virginia, Hermit Thrush nests were significantly closer to roads and skid trails than those of the Wood Thrush. Hermit Thrush nests were at the highest elevations; the Wood Thrush nested at the lowest elevations (Dellinger et al. 2007).

On Haida Gwaii, British Columbia and Forrester Island, Alaska, ecological segregation of the Hermit and Swainson's thrushes is temporal. The Hermit Thrush returns about 6 weeks before the Swainson's Thrush and their young have begun to fledge by the time the Swainson's Thrush arrives (Sealy 1974). In other areas of British Columbia, these 2 thrushes are separated by habitat and altitudinally. The Hermit Thrush is mostly a species of spruce woods at elevations of about 1,900 m; the Swainson's Thrush is more numerous 300 m lower in willow and poplar thickets (Campbell et al.

1997). In New York, there was a high breeding-habitat association between Hermit and Swainson's thrushes. Dilger (1956) considered the Hermit Thrush a bird of interior edges that foraged mostly on the ground and the Swainson's Thrush a bird of interior that foraged largely in trees. Also in New York, there was extensive overlap of the Hermit and Swainson's thrushes at lower elevations, but the Hermit Thrush ranged higher (Noon 1981). In Maine, Hermit and Swainson's thrushes both nested in spruce forests along the coast. On large islands and the mainland, the Swainson's Thrush preferred denser growth and was more arboreal than the Hermit Thrush. The Hermit Thrush did not nest on islands 4 ha or smaller, but the Swainson's Thrush did. The Hermit Thrush appeared to be socially dominant to the Swainson's Thrush and may have prevented it from breeding in some habitats (Morse 1972). Dellinger et al. (2020) stated that the Hermit Thrush was displaced by the Swainson's Thrush in the Appalachians in West Virginia.

In West Virginia, both the Hermit Thrush and American Robin nested significantly closer to roads and skid trails than other thrushes. Hermit Thrush and robin nest sites differed by their being more medium-sized trees present at Hermit Thrush nests than those of the American Robin. The Hermit Thrush tended to nest on upper and lower slopes; the robin nested on midslopes (Dellinger et al. 2007).

Most Ontario nests were on the ground (87.5%); 7.7% were elevated in deciduous and coniferous shrubs, saplings, and trees; 1.9% were on fallen logs and trees. Single nests were found in a cavity in a 12.7-cm DBH sugar maple, on a tree stub, and on roots. Elevated nests were 0.08-1.8 m from the ground but most were 0.3-0.9 m up. Two nests were in the sides of road cuts 0.8 and 1.3 m from the toe of the bank, one was in a crack in a vertical rock face 1.2 m from the bottom, and one was on the edge of a boulder at 1.8 m. Another nest was in an abandoned mine shaft. Nests on the ground were often in depressions and were among or at the bases of shrubs and vines (44.0% of nests); at the bases of trees and stumps (20.2%); among clumps of ferns, grasses, and other plants (20.2%); sunk in moss and mossy hummocks (13.1%); under tree branches (11.9%); beside a rock (1.2%); under a log (1.2%); and on an upturned root (1.2%; Peck and James 1987). A nest in Hastings County was 4.3 m up in a hemlock and 4.3 m from the trunk on a limb (Peck and James 1998a). In Muskoka and Parry Sound districts, 14 of 15 nests (93.3%) were on the ground; the other was 1.3 m up on a rock face (Mills 1981). In Muskoka District, 1 nest was on an open ledge of a 2.25-m tall rock face in a rectangular-shaped cavity 1.5 m up the cliff. Two old nests were found in the same cliff. The presence of 3 nests within 1 m suggested that rock faces may be fairly typical nesting habitat, or that the same thrush may have returned to the same site for 3-4 breeding seasons (Armstrong and Euler 1983). A nest near Huntsville was on top of an Eastern Phoebe nest that had been active the previous year. The nest was on a nesting tray 2.1 m from the ground under the eaves of a cottage adjacent to a house. The dwellings were in a 0.4-ha opening surrounded by mixed forest (Tozer 1997a). A nest in Peterborough County was in a potted plant on the deck of a cottage. The plant was on a picnic table directly outside a door providing access to the deck, which was 3.6 m above ground. The nest was in a 25-cm plastic flowerpot among planted ornamental flowers and grasses (Lemieux and Sutherland 2007).

Throughout its range, the Hermit Thrush nests predominantly on the ground or in shrubs, saplings, or trees at low heights from the ground. A minority of West Virginian Hermit Thrushes

nested atop boulders or in small trees (Dellinger et al. 2007). In Arizona, all nests were in trees: 93% in trees 1-3 m tall, 5% in maples, and 2% in firs taller than 3 m. Nest orientation was mostly south-southwest. Birds selected trees for nesting that had high cover density. Nests were positioned to take advantage of the afternoon sun. High-quality nest sites may not be as abundant as typically assumed because suitable nest trees must be dense but provide a small opening for a nest with a southwest exposure (Martin and Roper (988). In Quebec, nests were invariably on the ground and usually at the base of a small balsam fir or hemlock whose lowest branches touched the ground and provided cover for the nest. The only exception was one built 1.2 m from the ground at the trunk of a small balsam fir (Mousley 1916a). In British Columbia, 64% of nests were in trees, including snags, or among tree roots. Coniferous trees (42% of nests) were preferred to deciduous (8%). Nests in trees were among branches (71%), either saddled on the branch or in a fork or crotch (45%), against the tree trunk (20%), or near the top of a tree (6%). Six percent of nests were in shrubs. Fifty-seven percent of nests were on or close to the ground at the bases of trees, on banks, in tree or rock crevices, or under fallen logs. Nest height ranged from 0 to 6 m, with 57% between 0.3 and 1.5 m (Campbell et al. 1997). Nests east of the Rocky Mountains were typically on the ground in a natural depression and under a small conifer that provided protection. Eighty-nine percent of nests were covered: 295 under a live tree, shrub, or sapling; and 200 under live nonwoody vegetation such as ferns, grasses, forbs, mosses, and sedges. Of the remaining nests, 8% were in open areas with no vegetative cover (on dead logs or stumps, road-cut banks, in dead leaves, on bare ground) and 2% were in slash, on roadsides and mounds, or at forest edge. The mean height of 621 nests was 0.07 m (range 0-0.3 m; Dellinger et al. 2020). Unusual nest sites include 1.2 m up on bean poles, in old robin and phoebe nests, on a barren ledge of rock in an abandoned quarry, on shelves under the eaves of buildings, in a tin gutter under the eaves of a 2-storey house, on a rafter under the roof of a building, in deciduous tree cavities, in golf-course rough, in a previously used Northern Waterthrush nest, in an abandoned mine shaft, and in short grass under a cemetery grave marker (Dellinger et al. 2020; Gross in Bent 1949; Lemieux and Sutherland 2007).

In Algonquin Park, the average size of 23 territories was 0.78 ha (range 0.06-3.38 ha). In white birch–poplar stands, the Hermit Thrush was active from the ground to 11.6 m, and this was the average depth of territories overall. It was not seen above 12.2 m in white birch–poplar–balsam fir–spruce stands, which represented the top of the coniferous forest canopy. In hemlock stands, it ranged up to 11.6 m which was 2.4 m above the bottom of the canopy but well below the top of the canopy (24.4 m; Martin 1960). The average size of territories in Quebec was 1.0 ha, but was 0.6 ha in a hemlock forest near Mirabel (Falardeau in Gauthier and Aubry 1996). Morse (1977) reported a mean territory size of 2.00 ha in white spruce stands in Maine. In Quebec, the Hermit Thrush clustered territories at all spatial scales (Bourque and Desrochers 2006). In Wisconsin, Loss (2012) found nests as close together as 12 m but in a second year nests were more evenly spaced with a minimum of 46 m between nests.

No information is available on natal philopatry but it is probably low. Almost nothing is known of adult site fidelity during the breeding season. Dellinger et al. (2020) reported that 8 of 18 males (44%) returned to the same territory the following year in Algonquin Park. Schlossberg (2009) summarized return rates of 127 adults from 2 studies and estimated a site-fidelity rate of 35%.

Limiting Factors

Eggs have been found in Ontario nests from mid-May until the third week of August, with most present in June and the first week of July (Peck and James 1987). In Algonquin Park, nests are under construction from mid-May to early July, eggs are present from mid-May to late July, nestlings are present from late May to early August, and dependent fledglings have been observed from late June to mid-August (Tozer 2012).

It takes 7-10 days to build the nest, and eggs are laid at the rate of 1 a day. Incubation begins continuously with laying of the last egg, or a day later. The incubation period of 7 Ontario nests was 11-13 days. Overall, the incubation period has been reported as 10-13 days. Eggs hatch synchronously or a day apart. Young fledge at age 10-15 days, but typically on day 12 (Campbell et al. 1997; Dellinger et al. 2020; Dilger 1956; Gross in Bent 1949; Morton and Pereyra 2010; Peck and James 1998a).

Most Hermit Thrushes raise a single brood but some have been documented raising second broods, and second broods have been suspected in many areas. There are a few cases of nests being reused, including in Ontario, and this is suggestive of second broods. A probable second nesting was reported in Ontario and egg dates strongly suggest 2 broods, but second broods have not been confirmed in the province. In Quebec, egg dates indicate high probability of second broods, but none have been confirmed. In California, 3 of 66 pairs (4.5%) were confirmed attempting second broods after successfully rearing the first. Double broods usually occurred in years when the snow melted early. It has been suggested that it may raise 3 broods in the southern portion of its range, but this has not been confirmed. Renesting is common if the first clutch is lost. In Arizona, all birds that renested moved to another patch of firs for the replacement nest. In Ontario, clutches of 2-5 eggs were reported, with most containing 4 eggs. Elsewhere, clutches of 3-6 eggs have been documented with 4 eggs typical. The average clutch size east of the Rocky Mountains is 3.36 eggs (Armstrong and Euler 1983; Campbell et al. 1997; Dellinger et al. 2020; Falardeau in Gauthier and Aubry 1996; Gross in Bent 1949; Martin and Roper 1988; Peck and James 1998a; Smyth 1947).

The age at first breeding is assumed to be 1 year but this requires confirmation. The Hermit Thrush probably breeds annually thereafter. The mating system is monogamous (Dellinger et al. 2020).

Different foraging techniques and substrates further partition habitat among coexisting thrush species. All thrush species that Dilger (1956) studied in New York occasionally foraged on the ground, but the Hermit Thrush and Wood Thrush did so most frequently. They were primarily ground feeders at forest edges; the Veery and Swainson's thrushes were predominantly arboreal foragers in forest interior. The Hermit Thrush did some flycatching as well as foraging in trees and shrubs for small fruits, especially in autumn and winter. In Wisconsin, the Hermit Thrush and Veery differed significantly in the heights at which they foraged. Foraging methods of both species were dominated by capturing prey on foliage, often while in flight similar to flycatchers. The Hermit Thrush spent only 8% of its time on the ground, but 24% of prey was captured on the ground. Ground foraging accounted for less than 10% of Veery prey captures. Both thrushes fed mostly below 6 m, but the Veery concentrated its activities in the lowest stratum (0-3 m). Shrubs were the most important site for Veery (52% of feeding bouts occurred in the 3-m stratum); saplings and low

tree growth were most important for the Hermit Thrush (79%). The Hermit Thrush fed more in conifers and the Veery fed more in shrubs (Paszkowski 1984). Foot-quivering is another foraging technique of the Hermit Thrush whereby the feet are moved rapidly in the leaf litter to flush potential prey. On the ground, hopping and gleaning is its most frequent foraging technique (Brackbill 1960b; Davis 1996; Thurber 1999).

Nestlings are initially fed small caterpillars, but by age 3 days the diet is supplemented with winged insects, spiders, and ants. By days 7 and 8, large moths, grasshoppers, and beetles were fed to the young. In Pennsylvania, nestlings were fed blueberries and cherries. Young at 1 New York nest were fed geometer moth caterpillars and blueberries. In New York, 1 pair brought Allegheny Mountain dusky and red-backed salamanders to nestlings on about a quarter of trips (Dilger 1956; Gross in Bent 1949; Smyth 1947).

Beal (1915b) analyzed 551 stomachs collected in all months of the year. The diet consisted of 64.5% animal matter and 35.5% vegetation. The animal foods were predominantly insects with some spiders; the vegetable matter was mostly wild fruit. Animal food included 15.1% beetles (ground and scarab beetles and weevils), 12.5% ants (consumed mostly May through September with lesser numbers in July), 5.4% other hymenopterans (bees and wasps), 9.5% caterpillars (eaten every month with peak numbers in June), 3.6% bugs (mostly stink bugs), 3.0% flies (mostly crane and march fly eggs and larvae), 6.3% grasshoppers and crickets, 0.3% miscellaneous insects, 7.5% spiders and centipedes, and 1.3% miscellaneous animals such as isopods, snails, and earthworms. The Hermit Thrush seldom eats domestic fruit, but occasionally consumes strawberries, grapes, currants, apples, and raspberries. Wild fruit constituted 26.2% of the vegetable food; 8.1% was seeds, ground-up vegetation, and seeds of poison ivy and poison sumac. Fruits eaten included those of sumacs, blackberries and raspberries, dogwoods, huckleberries, blueberries, greenbriers, pokeweed, and winterberry holly. It subsists almost entirely on invertebrates in spring and early in the breeding season, with fruit becoming increasingly important in the diet as the breeding season continues until fruit dominates by autumn. Dellinger et al. (2020) stated that it eats insects, other small invertebrates, amphibians, reptiles, fruit, snails, earthworms, centipedes, millipedes, and termites. Fruit consumed includes elderberries, pokeweed, sassafras, dogwoods, hollies, greenbriers, juneberries, sumacs, poison ivy, raspberries and blackberries, alders, spicebush, mulberries, Virginia creeper, privet, and juniper. Leckie (2006) observed a Hermit Thrush eating a DeKay's brownsnake and Dellinger et al. (2020) reported an adult bringing a red-bellied snake to nestlings. It has eaten salamanders in New York, Maine, Michigan, and Rhode Island. Due to their abundance in woodlots, salamanders are potentially a significant component of the diet. When given a choice between holly berries, earthworms, and salamanders, 1 bird selected salamanders (Gross in Bent 1949; Thurber 1999). In late summer and autumn in Illinois, its degree of frugivory differed significantly over 3 years, with 28-100% of birds exhibiting frugivory yearly with an average of 44%. The Hermit Thrush was the least frugivorous of the species studied. It foraged significantly more in forest interior than in gaps created by treefalls. It foraged significantly more for fruits in gaps and for insects in the interior. Areas with clumps of fruit were preferred to those with isolated plants. The type of fruit consumed annually differed significantly. In the first year, 100% of the fruit eaten was Canada moonseed; in the second year, it was 53% grapes, 35% greenbriers, and 12% moonseed; in the third year, it was 39%

grapes, 48% Virginia creeper, 4% greenbriers, and 8% spicebush. The annual differences in diet were not correlated with levels of fruit abundance. All bird species tended to concentrate on 1 or 2 particular fruits each year, but the favoured fruit was seldom the same year to year. The Hermit Thrush was one of the most important species in consuming and dispersing Canada moonseed (Malmborg and Willson 1988). In Maine, it ate few spruce budworms at low budworm densities, but increased its consumption of them as the budworm density increased to a level where the budworm content per stomach reached about 14 larvae or pupae (Crawford and Jennings 1989). Near Manitouwadge, Venier et al. (2009) found no relationship between abundance of the Hermit Thrush and the spruce budworm. Over 2 years in Maine, spruce budworm larvae and pupae constituted 13% and 12% of its invertebrate diet (Mitchell 1952).

The Hermit Thrush is a relatively infrequent host of the Brown-headed Cowbird, although it has been suggested that it is a regular, if not preferred, host choice of the cowbird. The Hermit Thrush tends to nest in habitats that are inhospitable for the cowbird. In Ontario, 11 of 154 nests (7.1%) were parasitized. In New York, 46.2% of 13 nests found at 1 site were parasitized. Hahn and Hatfield (1995) concluded that parasitism rates in 1 region could not be used to predict parasitism rates in other regions. Most Hermit Thrush nests were 1 m or less from the ground, and low-nesting forest birds experienced the highest parasitism rates. Parasitism rates vary in different regions: 2.3% in Minnesota, 5% in Quebec, 21.7% in northern Michigan, and 6% in British Columbia. The average parasitism rate east of the Rocky Mountains is 4.7% compared with 1.5% west of the Rockies. The Hermit Thrush accepts cowbird eggs, and both species may fledge successfully from a parasitized nest. East of the Rockies, parasitized nests had an average of 2.7 Hermit Thrush eggs (range 2-4); unparasitized nests contained an average of 3.4 thrush eggs (range 1-5; Campbell et al. 1997; Dellinger et al. 2020; Gross in Bent 1949; Manolis et al. 2002; Peck and James 1987).

South of the Canadian Shield, habitat loss and fragmentation do not appear to be an issue for the Hermit Thrush. Maturation of coniferous plantations in this area has increased the amount of available habitat.

The effects of forestry practices on the Hermit Thrush vary depending on the type of management undertaken. In the Boreal Forest Region, with particular reference to Ontario, its abundance did not change significantly when 30% or 50% of trees were removed, but decreased when 70% of trees were removed. It experienced a 25% decrease when 35% of trees were removed, a 50% decrease when 50% of trees were removed, and a 75% decrease when 70% of trees were removed (Vanderwel et al. 2007, 2009). In Algonquin Park, there was no significant change in its abundance as a result of single-tree selection harvesting (Jobes et al. 2004). In the Ontario Canadian Shield, there was no difference in its abundance in early successional and mid-successional clear-cuts compared with similarly aged stands after fire. It was equally abundant in mid-successional and mature stands but significantly more abundant in early successional than mature stands (Zimmerling et al. 2017). In New York, there was no trend in its abundance in unlogged forests and those where 25%, 50%, 75%, or 100% of the merchantable timber was removed. It was not affected by logging (Webb et al. 1977). In New Brunswick and Nova Scotia, it was absent in recent clear-cuts, burns, and shelterwood cuts where the basal area was reduced by 55%, and was uncommon in strip-cut areas relative to uncut areas. It returned in low densities after 8 years and became most

abundant after 40 years (Falardeau et al. 1999; Freedman and Johnson 1999; Freedman et al. 1981; Morgan and Freedman 1986). In Newfoundland balsam fir stands, its density was significantly higher in uncut stands than in 40- and 60-year-old second growth (Thompson et al. 1999). In Newfoundland, its overall occurrence tended to be higher in natural than harvested landscapes, especially at higher percentages of forest cover. It was negatively associated with the amount of woodland in harvested landscapes and positively associated with amount of woodland in natural landscapes. In harvested landscapes, the proportion of sites occupied was 30% at 15% forest cover, peaking at 60% for 45% cover, and declining to 20% at 95% cover. In natural landscapes, there was a regular increase with increasing forest cover from 0% occupation at 10% forest cover to 50% at 95% cover. Taylor and Krawchuk (2005) concluded that the Hermit Thrush could fulfill its resource needs in harvested landscapes. Whitaker et al. (2008) studied its annual survival in relation to forest fragmentation by clear-cuts and natural openings in Newfoundland. They concluded that it may be resilient to moderate amounts of clear-cutting. In Newfoundland balsam fir stands, Whitaker and Montevecchi (1999) examined the effectiveness of 20-50-m wide riparian strips between clear-cuts and watercourses and water bodies. There were no significant differences in its abundance within 30 m of water in undisturbed areas, within buffer strips including adjacent clear-cut areas, in undisturbed buffer strips only, and in buffer strips when observations in clear-cuts were excluded. Buffer strips may provide suitable habitat for the Hermit Thrush. In Quebec, it nested in aggregations. Forest fragmentation could be detrimental if the forest became too small to support more than 1 territory (Bourque and Desrochers 2006). In Minnesota, nesting success increased significantly with distance from forest edge (Manolis et al. 2002). In Michigan, it avoided recent clear-cuts in jack pine, but was common in stands cut 5-23 years previously. In Maine, forests were used for nesting 16 years after clear-cutting, and possibly sooner (Dellinger et al. 2020). In Alaska, distance from edge (the coastline) was the most important factor in determining Hermit Thrush nest survival. In narrow corridors (less than 250 m) successful nests averaged 90 m from edge compared with 37 m for depredated nests. In corridors wider than 350 m, successful nests averaged 202 m from edge compared with 107 m for depredated nests (D.M. Sperry et al. 2008). In New Hampshire, it was less abundant near edges of clear-cuts, but its distribution did not differ from that of randomly placed territories. King et al. (1997) concluded that its lower abundance in edge habitats was not necessarily evidence of edge avoidance, but may be due to the absence of suitable habitat beyond clear-cut edges.

Fire may result in short-term avoidance of burned areas, but long-term effects depend upon the severity of the burn and on changes to vegetation. The Hermit Thrush will nest in burned areas and early postfire successional areas. In California, it was absent 8 years after fire. In Labrador, its density peaked 14 years after fire. Presence of residual snags in burned forests may be important in determining if it will still use the area. Snags provide cover, food, and singing perches. In a burned forest in Newfoundland, numbers of breeding pairs were 5.5 where snags were retained and 0 where snags were removed (Dellinger et al. 2020). In Oregon, it declined after fire regardless of the severity of the burn. Populations were still depressed 9 years after the fire (Stephens et al. 2015).

Akresh et al. (2024) determined that the Hermit Thrush had a significant increase in nest success as distance from forest edge increased. Core areas greater than 250 m from edge tended to have higher nest success.

Loss and Blair (2011) studied the effects of introduced earthworms on Hermit Thrushes breeding in northern hardwoods in Wisconsin. Nonnative earthworms consume leaf litter and organic layers below the leaf litter, mix soil horizons, reduce the abundance of mycorrhizal fungi and arthropods, and alter nutrient dynamics. Significantly lower densities of Hermit Thrushes occurred at areas with earthworm invasion (Loss 2012). Nonnative earthworms may be a contributing factor to its decline in some areas.

Gutzwiller and Anderson (1999) researched the effects of human disturbance in a remote area. Intrusions consisted of a person walking around for an hour in a 1-ha plot. The mean abundance of the Hermit Thrush was 57% lower in intruder than control plots. Intrusions resulted in displacements and prevented normal access to habitats and their associated resources. Sensitivity to intrusion can depend significantly on whether previous interactions with humans were positive, neutral, or negative. It is likely that birds nesting in remote areas where humans are seldom encountered will be greater affected by disturbance than those nesting where interactions with humans are frequent.

In Alberta, there were no differences in Hermit Thrush abundance adjacent to noisy compressor stations and quiet well pads. It did not appear to be affected by chronic noise (Bayne et al. 2008). It was significantly less abundant at well pads than in adjacent forest interior. There was no difference in its abundance at seismic lines and pipelines than in forest interior adjacent to these features (Bayne et al. 2016).

Extreme cold and/or heavy snowstorms early in the spring may cover up food and result in significant mortality (Gross in Bent 1949).

Status

Baillie and Harrington (1937) considered the Hermit Thrush a fairly common summer resident of the central and less settled portions of the province, from Halton and Leeds north and west to Lake of the Woods and Thunder Bay and Algoma districts. They thought that it probably bred north to James Bay. The first atlas indicated that the Hermit Thrush was a common and widespread breeder in Ontario. The breeding range was continuous throughout the Canadian Shield and Hudson Bay Lowland, and it was well distributed on Manitoulin Island and the Bruce Peninsula. There were numerous breeding records south of the Canadian Shield in eastern Ontario and east and west of Lake Simcoe and it also bred in the Long Point area. There was a retraction in range south of the Shield from what Baillie and Harrington (1937) reported, with no records from Halton (Knapton in Cadman et al. 1987).

The second atlas indicated that the Hermit Thrush range had not changed significantly except south of the Shield. It was found in virtually every square on Manitoulin Island and the Bruce Peninsula. There were many additional records south of the Shield, particularly on the Oak Ridges Moraine, the Niagara Escarpment, and in eastern Ontario. Maturation of pine plantations on the Oak Ridges Moraine coupled with a general increase in forest cover are probably key in its increased distribution south of the Shield. It remains rare in the portions of southwestern Ontario that support

extensive agriculture from Grey County south to Lake Erie. Its probability of observation increased significantly province-wide and in all regions except the Carolinian Forest Region, where the increase was nonsignificant. It was most abundant in the Boreal Forest Region and Hudson Bay Lowland. High densities also occurred between Lake of the Woods and Thunder Bay. The Shield south of the North Bay area supported moderate densities; its density in the Great Lakes–St. Lawrence Forest Region south of the Shield was low (Friesen in Cadman et al. 2007).

Breeding Bird Survey data indicate that the Hermit Thrush decreased at annual rates of 0.987% in Canada and 0.242% in Ontario 1970-2021. The 2011-21 trends were annual decreases of 3.05% in Canada and 5.01% in Ontario. All estimates were of medium reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

In Michigan, Akresh et al. (2009) netted birds in riparian habitat (a mix of alder, honeysuckle, and trembling aspen) and in upland trembling aspen stands during the postbreeding period. Seventy-nine percent of Hermit Thrush juveniles were caught in riparian habitat and most adults occurred in the shrubbier habitat. In Minnesota, Streby et al. (2011b) captured only 4 Hermit Thrushes in regenerating clear-cuts during the breeding season, but caught 18 adults and 32 fledglings during the postbreeding period, suggesting that dense woody vegetation is important during that period. During the postfledging period in Pennsylvania, Stoleson (2013) caught 9 adults and 23 fledglings in clear-cuts and 3 adults and 27 fledglings in mature forests. Capture rates in clear-cuts and forests were identical. Some birds that were recaptured had switched habitats.

MIGRATION

The Hermit Thrush migrates mostly at night, stopping to rest during the day, but moves more during the day than other thrushes in the same genus and the Wood Thrush. Nocturnal spring migration occurs when the maximum daily air temperature is 21°C or higher. It is rarely seen in conspecific flocks during migration, but individuals may occur in flocks of chickadees, kinglets, and titmice. In spring, males arrive about 2 weeks before females. In autumn, females migrate slightly sooner than males. Autumn migration is often precipitated by cold fronts, high pressure, clear skies, and strong northerly winds. In Louisiana, adults arrive in autumn before juveniles (D.R. Brown et al. 2002; Campbell et al. 1997; Dellinger et al. 2020; Graber et al. 1971; Gross in Bent 1949; Stouffer and Dwyer 2003).

The Hermit Thrush arrives in southern Ontario in mid-April and spring migration continues until early or mid-May. The midpoint of migration at Long Point is 27 April (Mills 2005b). In the Hudson Bay Lowland, a bird seen on 27 July was presumed to be an autumn migrant, and other migrants were seen 3-12 September. In the southern Shield, autumn migration occurs mainly in September and early to mid-October. In the south, autumn migrants may appear as early as mid-August but the average arrival is early to mid-September, with the peak in October. Stragglers persist into November and December and some overwinter (Black and Roy 2010; Curry 2006; LaForest 1993; Mills 1981; Tozer 2012; Weir 2008; Wilson and McRae 1993). At Long Point, the midpoint of autumn migration was 13 October 1975-2000 (Mills 2005b) and was 12 October in 2008 (Mills et al. 2011).

Mills (2005b) examined migration timing of the Hermit Thrush at Long Point in relation to global warming for 1975-2000. The date of first spring arrival tended to be earlier in later periods, but not

significantly. When spring migration data were analyzed by quartile, there was a nonsignificant tendency to migrate later with time. In autumn, it departed significantly later over time. Smith and Paton (2011) analyzed 48 years of data from a Rhode Island banding station and found that the Hermit Thrush departed significantly later in autumn in recent years. They attributed the delay in migration to climate change.

At Long Point Bird Observatory (LPBO), spring stopover times of Hermit Thrushes were 2.42-4.30 days. Stopover duration may be related to habitat features including food and shelter (Dellinger et al. 2020). During autumn migration at Long Point, the duration of stay averaged 8.9 days (range 0.8-20.5 days). Some birds made nocturnal local landscape-scale flights. The mean duration of time from capture until a landscape-scale flight was 3.6 days compared with the mean duration of 9.9 days from capture to final detection. Landscape-scale movements exceeded 1 km. Most flights were from the tip of Long Point which offers lower-quality habitat than the other 2 LPBO banding stations (Mills et al. 2011). In Michigan, the average duration of autumn stopover was 5.4 days. Birds that were lean when they arrived stayed significantly longer (average 6.4 days) than those that were fatter (4.8 days; Craves 2009). One bird stayed in the same location for 2 weeks in northeastern Illinois in October (Graber et al. 1971).

The Hermit Thrush may occupy a variety of habitats during migration including city parks, urban churchyards and gardens, university campuses, and several natural habitats. These may include old shrubby fields and forests of all types, but especially those with moderately dense understorey and an abundance of fruit. It may prefer edges and openings in woodlands. It is often associated with moist areas such as lakeshores, floodplains, and margins of ponds and marshes (Campbell et al. 1997; Craves 2009; Dellinger et al. 2020; Gross in Bent 1949; Leighton et al. 2002; Sinclair et al. 2003; Weir 2008). In Pennsylvania, it was detected significantly more on transects through forests than in shrub habitat during spring migration. There was no significant difference in capture rates of nets placed in forest or shrub habitat although more birds were captured in shrubby areas (Smith and Hatch 2008).

Few Hermit Thrushes inhabit cities. Urban areas may pose constraints such as human disturbance which may interfere with foraging time. In addition, urban-adapted bird species compete for fruit. Nonnative fruits predominate and high-quality fruits are usually depleted earlier in the season leaving Hermit Thrushes to rely heavily on low-lipid nonnative fruits (Craves 2009).

During migration, the Hermit Thrush may establish small foraging areas that are approximately 100 m in radius, an area of about 3 ha (Dellinger et al. 2020).

S.B. Smith et al. (2007) studied the diet of autumn migrants in Rhode Island. Daily dry food intake was 8.67 g for autumn olive, 8.06 g for pokeweed, 7.65 g for roses, 7.39 g for chokecherry, 7.20 g for bittersweet, 6.80 g for winterberry holly, 6.04 g for Virginia creeper, 4.97 g for southern arrowwood, and 4.71 g for bayberry. Fruit selection may have been due in part to availability. In Illinois, 21 stomachs collected during spring migration contained 84% insects. Of these, 20-30% were beetles, with timing of spring arrival coinciding with the emergence of many beetles. Lepidopterans (18-19%) and ants (13-15%) constituted much of the rest of the diet. It ate more millipedes (12%) than most other bird species. The spring diet also included 7-8% grasshoppers, 7-8% bugs, and 4%

spiders. In autumn, it fed on grapes and was particularly fond of pokeweed berries (Graber et al. 1971). In subalpine areas of British Columbia, blueberries were an important source of food for autumn migrants (Evans Ogden et al. 2013).

During migration, the Hermit Thrush may strike tall structures such as buildings, television and communications towers, and lighthouses. A 3-year study in Toronto found 139 at the bases of tall buildings. Fifty-five died; 84 were alive but possibly injured. In Arkansas, 127 were killed in 1 night at a transmission tower. Few casualties occurred at Illinois television towers with the Hermit Thrush representing 0.02% of victims (Graber et al. 1971; Gross in Bent 1949; Dellinger et al. 2020).

Snowstorms accompanied by cold weather may result in mass mortality during migration, especially if food supplies are covered up. After a heavy snow and cold temperatures on 10 October 1906, there was a massive kill of birds on the Ontario shoreline of Lake Huron. Although the bulk of Hermit Thrushes had already passed through by 6 October, they were still well represented among the dead. In Illinois, there was a large kill of Hermit Thrushes by a storm at the southern end of Lake Michigan on 16 April 1960 (Dellinger et al. 2020; Graber et al. 1971; Gross in Bent 1949).

The Hermit Thrush is a common migrant in Ontario (James 1991), although it is an uncommon spring and autumn migrant in Elgin County (Lancaster et al. 2004). Spring numbers are generally lower than those in autumn.

LPBO data suggest that numbers of the Hermit Thrush are stable or increasing during migration. Hussell et al. (1992) reported a net change of 0.0% 1961-88. Changes within different time intervals were: 1961-70, –4%; 1970-79, +0.5%; 1978-88, +3.2%. From 1961 to 1994, there was a significant increase of 1.26% per year with increases in both spring and autumn (Dellinger et al. 2020). From 1967 to 2007, it increased at a rate of 1.0% per year (Anonymous 2009b).

WINTER

The Hermit Thrush prefers to winter south of where snow stays on the ground for a prolonged period and usually winters south of latitude 40°N. Christmas Bird Count (CBC) data indicated that it is mostly absent from regions with January temperatures below –4°C, but there are 3 populations, including southern Ontario, that winter in areas colder than this. It requires open water in winter and is common only in forests that rarely get below –1°C in January. Females migrate further south than males, but there appears to be no difference in winter distribution between age classes. The mean December to February latitude of males is about 1.2° north of that of females; the mean winter latitude of the sexes differs by 130 km. In Louisiana, 75% of winter birds were females. It is most likely that birds overwintering in Ontario are males (Gross in Bent 1949; Root 1988; Stouffer and Dwyer 2003).

In the Hamilton area, wintering birds are often found in ravines with open water and abundant fruit (Curry 2006). During winter, the Hermit Thrush tends to inhabit dense, moist forests and concentrate in forest openings and at forest edges, possibly because fruit may be more abundant in these areas. In the southeast, it is most common in woodlands with a moderate density of understorey, especially where broad-leaved evergreens are present. In the Midwest, it winters among dense berry-bearing vegetation, particularly in ravines and other sheltered locations. In Louisiana, it was most abundant in pole-stage pine stands and least abundant in hardwoods, which

had an open understorey and low fruit availability. There was no difference in the habitats selected by males and females, or adults and juveniles. During winter, it may also occur in well-vegetated residential areas surrounded by a wooded landscape (D.R. Brown et al. 2002; Dellinger et al. 2020; Dunn and Tessaglia-Hymes 1999; Root 1988; Stouffer and Dwyer 2003). In South Carolina, winter distribution of the Hermit Thrush was largely explained by the dry mass of ripe fruit, habitat types, and interactions between habitat and year. Abundance was positively associated with the mass of dry pulp. Twice as many were detected in bottomland hardwood stands than in regeneration, pine plantations, and upland hardwoods. Although habitats differed in the number of Hermit Thrushes they supported, each habitat exhibited an increase in thrushes with increasing dry pulp mass. Much of the variation in abundance among habitats was independent of fruit biomass indicating that other factors are important. Some habitats that were not sampled, such as 10-40-year-old pine plantations, may be important wintering sites in South Carolina (Kwit et al. 2004).

Some Hermit Thrushes defend a territory in winter; others are non-territorial floaters. In Louisiana, 86% of birds were territorial and 14% were floaters. There is little territory overlap, averaging 15.9% (range 0-79%). In Louisiana, the territory size of 34 birds was 0.55 ha (range 0.22-0.97 ha). Territory size did not vary by sex or age class, but did by habitat. Average territory sizes were 0.69 ha in hardwoods, 6.78 ha in sapling-stage pines, 0.48 ha in mature pine, and 0.45 ha in pole-stage pines. Pole-stage pines appeared to be superior habitat due to the smaller territories and the fact that they were settled first. In South Carolina, territory size was unrelated to the availability of either fruit or arthropods. Home ranges of floater birds averaged 5.83 ha (range 2.53-11.3 ha). Floaters included both sexes and age classes. The average distance between consecutive locations was 55.30 m for territorial birds and 121.28 m for floaters. Floaters often had very small core home ranges from which they wandered widely. Many birds were site faithful from November until March. Vacated territories were quickly occupied by either expanding or shifting of neighbouring territories, or by floaters (Brown and Long 2007; D.R. Brown et al. 2000, 2002; Diggs et al. 2011).

The Hermit Thrush has a tendency to return to the same wintering area in successive years. In South Carolina, 10 of 81 birds (12.3%) returned the following winter. In California, 18% of 306 returned to the same site the next winter and in Mexico several were captured in the same mist net over a 3-year period. In Louisiana, 18% of individuals returned to winter in the same plot. Of 25 returns, only 2 were captured more than 30 m from where they were originally caught. No marked bird was captured or observed at more than 1 plot or more than 1 point count location. Returning birds used the same territory that they defended the previous winter (Brown et al. 2000; Dellinger et al. 2020; Gross in Bent 1949).

The Hermit Thrush is largely frugivorous in winter, even in the south where arthropods are still available. The diet consists mostly of fruit until just prior to spring migration when it eats invertebrates almost exclusively. Wild fruits, berries, and seeds consumed in winter include those of dogwoods, pokeweed, juneberries, hollies, blueberries, mistletoe, grapes, elderberries, viburnums, spicebush, mulberries, greenbriers, Virginia creeper, sumacs, poison ivy, and privet (Gross in Bent 1949; Kwit et al. 2004; Long and Stouffer 2003). Over 2 winters near Branchton, one fed regularly on the fruit of staghorn sumac (personal observation). In South Carolina, larger birds (mostly males) occupied territories with more arthropods and had a diet with a higher proportion of arthropods

than smaller birds, often females. Arthropods were a critical component of the winter diet. Smaller-bodied females may be excluded from optimal territories and be forced to spend more time foraging to meet their energy requirements (Diggs et al. 2011).

The Hermit Thrush is a rare visitor to winter bird feeders. Even in the core of its winter range usually only one comes to an individual feeder on a casual basis. One that spent the winter of 1941-42 at London fed on currants supplemented by suet crumbs from under the feeder. A bird at a Toronto feeder in February 2002 fed on bits of suet dropped by woodpeckers. It also seemed to feed on bits of sunflower seeds after finches and cardinals had opened the shells. It took bits of suet and shelled sunflowers from the feeder. Feeders are most likely to be visited in midwinter or during spring migration; most visits are for water rather than food. Infrequent items consumed at feeders include mixed seeds, niger, bird puddings, peanut butter mixes, dried fruit, suet bits, and bread crumbs (Dunn and Tessaglia-Hymes 1999; Gross in Bent 1949; Iron and Pittaway 2002).

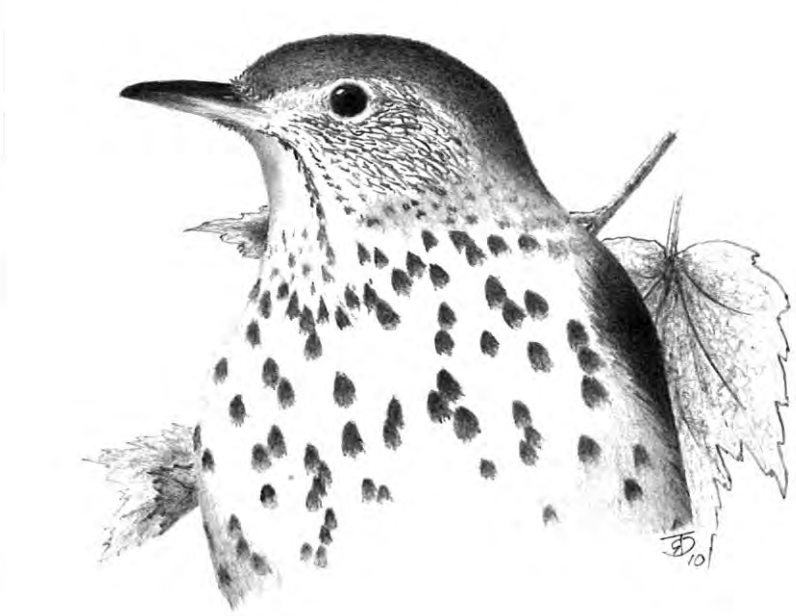
Severe winter weather is probably the most significant limiting factor to the Hermit Thrush. Populations may experience significant declines after a severe winter. Large numbers perished in South Carolina during cold temperatures in February 1899 and hundreds died in January and February 1895 due to cold weather even though food was abundant. Population declines in the Maritimes in the late 1950s were attributed to severe winter weather in the southeastern states. Low populations in Illinois in 1958, 1959, and 1960 were thought to be a result of severe winter weather. During a severe winter storm in Illinois, its density declined from 7.9 birds per km^2 to 0. It was concluded that the storm resulted in 100% mortality (Dellinger et al. 2020; Graber and Graber 1979; Graber et al. 1971; Gross in Bent 1949; Stouffer and Dwyer 2003).

The Hermit Thrush is local and rare in winter in Ontario and the northern portion of its winter range (Dellinger et al. 2020; James 1991). Beginning in the 1970s, it began to overwinter with increasing frequency in the Hamilton area and at least 1 or 2 are found each winter now (Curry 2006). It was reported in Elgin County on 7 of the last 10 CBCs (Lancaster et al. 2004). Dellinger et al. (2020) reported that it wintered regularly on islands in western Lake Erie. Of 7 CBCs when data were collected on Pelee Island, it was observed 5 years. Numbers present ranged from 1-21 and averaged 5.9 birds over all 7 years and 8.2 birds if only the years when it was detected are considered (Allen Woodliffe, unpublished data).

Based on Project FeederWatch data, the Hermit Thrush increased in abundance in the 30 years prior to 1996 despite cold winters (Dunn and Tessaglia-Hymes 1999).

Wood Thrush

Hylocichla mustelina

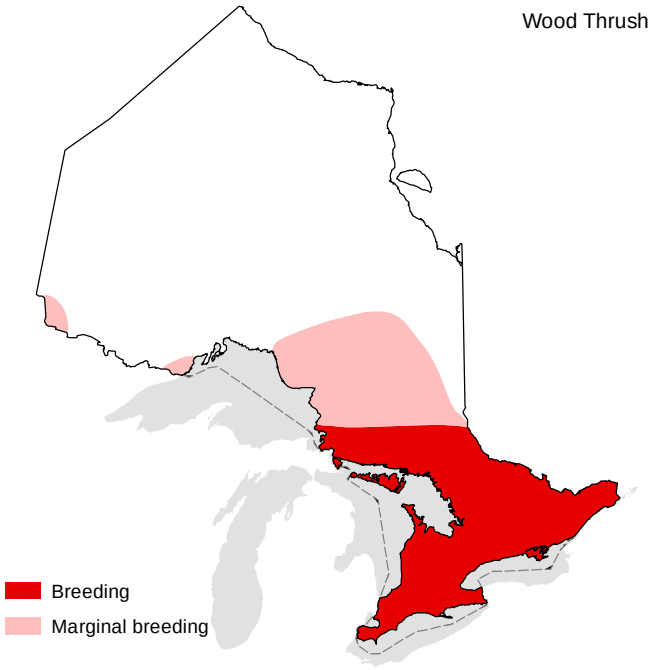


BREEDING SEASON

Habitat Requirements

In Ontario, the Wood Thrush breeds predominantly in forested areas. Deciduous (58.6% of nests) and mixed (37.9%) woodlands were preferred for nesting over coniferous woods and plantations (3.4%). Nesting occurred in wet and dry forests; second-growth woodlands were selected over mature woods. Four nests were in overgrown fields, 2 in fencerows, and 2 in alder swamps (Peck and James 1987).

McIlwraith (1894) stated that the Wood Thrush preferred moist beech woods for nesting. It nests in small woodlots surrounded by agriculture, in some urban woodlots, and in contiguous forest such as along the Niagara Escarpment and the southern Canadian Shield (Friesen et al. 1995). Woodlots where it nested in the Peterborough and Ottawa areas were dominated by sugar maple, with white ash and basswood frequent in the canopy. Peterborough sites contained some hophornbeam, white cedar, and beech in the canopy (Phillips et al. 2005). In the Region of Waterloo and along the Niagara Escarpment, it nested in upland deciduous forests dominated by sugar maple, beech, and white ash, with lesser amounts of hemlock and white cedar. These were early to mid-successional forests with occasional pockets of older growth. They had openings created by selective logging with an understorey of sugar maple and white ash saplings, alternate-leaved dogwood, and red



elderberry (Friesen and Campbell 2002; Friesen et al. 1999a, 1999b). Near Metcalfe, occupied woodlots were mostly dominated by sugar maple, white ash, basswood, and hophornbeam (Villard et al. 1995). In Algonquin Park, it was most likely to occur in half-open second growth and heavily culled areas (MacLulich 1938). Also in Algonquin Park, it was detected only in pure hardwood stands or in hardwoods mixed with balsam fir and spruce. It was absent from stands dominated by poplar and white birch, balsam fir and spruce, immature white pine, and hemlock (Martin 1960). In Durham Region it occurred, in order of decreasing abundance, in mature sugar maple–red oak forest; a woodlot with an open canopy and a rank growth of ferns and raspberries; mature white cedar–elm swamp; a farm woodlot dominated by beech; mature beech-maple with a sparse understorey; mature pine plantation with a small sugar maple–red oak forest; and sugar maple forest sloping down into white cedar–balsam fir–spruce swamp (Speirs and Orenstein 1975).

F.G. Weaver (1939) and Weaver (in Bent 1949) summarized Wood Thrush habitat as cool, damp woodlands, often near streams. Moisture is considered essential to provide mud for nest building; it tends to avoid sandy areas. Presence of understorey shrubs and saplings are important habitat components. Nests have been reported in bogs and rarely in dense thickets. Some Wood Thrushes nest in cities near human habitation. Nests were often only 1 or 2 m from a house, but in all cases houses were near gorges, streams, woods, or damp places. In Maryland, it was common for nests to be 244-610 m, or even 975 m, from water in suburban areas (Brackbill 1943). M.L. Evans et al. (2020) characterized its habitat as interior and edges of deciduous and mixed forests, especially well-developed mesic ones. The key elements in sites frequently used were trees taller than 16 m, a high variety of deciduous tree species, moderate subcanopy and shrub density, shade, a fairly open forest floor, and decaying leaf litter.

The average characteristics of 165 territories were: ground cover, 44.9% (range 32.3-71.6%); shrub stems per 0.002 ha, 6.6 (range 3.8-25.1); trees 7.5-15 cm diameter at breast height (DBH) per 0.04 ha, 11.2 (range 7.4-13.8); trees 15-22.5 cm DBH per 0.04 ha, 5.9 (range 3.5-7.0); trees 22.5-37.5 cm DBH per 0.04 ha, 5.6 (range 4.1-6.7); trees larger than 37.5 cm DBH per 0.04 ha, 2.8 (range 0.6-3.8); species of trees per 0.04 ha, 5.6 (range 3.4-6.8); canopy height, 21.3 m (range 16.6-25.7 m); and canopy cover, 87.2% (range 81.2-98.1%). There were regional differences in all vegetation parameters except the number of small trees. Canopy height and shrubbiness varied most among regions, but there was considerable variation in number of tree species present. It occupied many

types of deciduous forest, but all had a well-shaded understorey that contained at least a few small trees with low, exposed branches and a fairly open forest floor with moist, decaying leafy litter. These were probably the primary determinants of its distribution and abundance. Highest densities occurred in upland mesic forests with a well-developed but sparse understorey and greater canopy height and fewer small trees. Bottomland swamps supported fewer pairs than upland mesic stands. There is a narrow range in the number of medium-sized trees in forests that support the Wood Thrush. Its range coincides with areas that receive more than 15 cm of rain during June when the birds are nesting; this may be important in providing mud for nests (James et al. 1984).

Due to regional differences in habitat preferences, there are numerous and occasionally conflicting descriptions of the Wood Thrush's habitat. In Illinois, lowland forest appeared to be preferred, although it nested in upland forests, residential areas, and shrubby areas (Graber et al. 1971). In New Jersey, it was significantly more abundant in hardwood swamps than in upland oak-pine forests (Rich et al. 1994). In New York, it required an abundance of sapling growth and was most abundant in edge situations associated with undisturbed hardwood forests. It tended to avoid drier habitats (Dilger 1956). Beal (1915b) stated that it preferred open groves and bushy pastures and could be found along little-travelled roads and near low, shrubby swamps. In Connecticut, territories tended to be clustered along streams and wetter areas at 1 area but not at another site with no water. Presence of water appeared to be important in areas that had water because the earliest established territories tended to be along small streams. Small seeps and springs sometimes led birds to establish territories in habitats that would otherwise be unoccupied. Mean vegetation parameters of territories were 43.9% shrub coverage, 16.3 m tree height, 16.2% of territory in early succession, 9.6% in late succession, moderate moisture regime (average 2.8 on a scale of 1 [dry] to 7 [wet]), and 2.4% exposed earth. Moisture, tree diameter, herbaceous cover, and shrub cover were significant determinants of its abundance (Bertin 1977). In New Hampshire and Maine, it was positively correlated with the number of trees 2-10 cm DBH, total foliage density of both deciduous and coniferous trees larger than 10 cm DBH, and total foliage volume of deciduous trees smaller than 2 cm DBH. It was negatively correlated with canopy closure, percent ground cover, number of coniferous trees larger than 10 cm DBH, and total foliage volume of deciduous trees 2-10 cm DBH (DeGraaf et al. 1998). In South Dakota, it was absent from isolated woodlots near farmsteads, but nested in floodplains dominated by Manitoba maple, elm, silver maple, green ash, cottonwood, and hackberry (Gentry et al. 2006). Within the city limits of Newark, Delaware, it nested in upland areas of tulip tree, sweet gum, oaks, and hickories, and lowland areas of red maple, sweet gum, and pin oak (Longcore and Jones 1969). In Baltimore, Maryland, it was a common breeder in wooded residential areas. Nesting occurred on lots of occupied houses, on vacant lots between houses, in trees growing at the curb, and at the edges of a park near houses (Brackbill 1958). In Michigan, it occurred in wide bands of riparian wetland forest but was most abundant in the outer edge of upland forest (Inman et al. 2002). In New Jersey, it preferred second growth but occurred in wet, disturbed forest and climax logged forest. It was the most abundant species in a climax forest of beech, red maple, and several oak species with an understorey of red maple, spicebush, and black raspberry. It first appeared in successional fields 40 years after they had been abandoned. It increased as shrubs choked out open spaces or trees shaded out herbaceous areas. It also increased in climax woods as the understorey became more open (Suthers 1988). In Wisconsin, it preferred

closed or semi-open canopy with patches of dense saplings in upland forests. It preferred moderate understorey growth and moister conditions than occur in dry-mesic oak forests. Small openings filled with saplings create favourable habitat if enough canopy remains intact (Mossman and Hoffman 1989). In the mid-Atlantic states, its abundance was positively correlated with mean canopy height, forest area, and number of trees per 0.04 ha. It was negatively correlated with the percentage of forest cover within 2 km, number of trees larger than 3 cm DBH per ha, the percentage of canopy cover by conifers, and the number of trees larger than 38 cm DBH (Robbins et al. 1989). In Wisconsin, it inhabited primarily younger and intermediate-age stands dominated by climax species (maple, oak, beech). It occupied a wide range of habitats but was uncommon in most pioneer stages (birch, poplar). It was more common in mesic than xeric forests but was uncommon in damper forests. It exhibited a wide tolerance to moisture regime (Bond 1957). In Wisconsin, it was scarce in coniferous plantations (Bielefeldt and Rosenfield 1994). Also in Wisconsin, it was uncommon in mesic forests and first appeared once trees became pole-sized (12.5-22.9 cm DBH). At this stage, the canopy is nearly closed but the self-thinning process has begun, allowing a shrub layer to develop (Hoffman 1989a). In Maryland, it was positively correlated with canopy height and total basal area of trees but negatively associated with woodlot isolation (Lynch 1987). In Indiana regenerating 7-9-year-old clear-cuts, its abundance was positively correlated with fruit availability and negatively with vegetation density (Ruhl et al. 2020).

In a New Hampshire northern hardwoods forest over a 30-year period, the Wood Thrush was common the first 15 years, declined through the next quarter of the study, and disappeared completely in the last quarter due to natural succession. Initially, the forest was mature and characterized by a dense, fairly closed canopy with an open subcanopy and a low, dense shrub layer. At the end of the study, it was more open with a patchy canopy with a denser and taller shrub and subcanopy layer and a sparser low shrub layer. It remained in an adjacent area that had been damaged by a hurricane for 10-15 years after disappearing from the plot (Holmes and Sherry 2001). In a Connecticut woodlot over a 59-year period, there was a progressive shift to larger trees, a sparser shrub layer, and a less diverse tree canopy dominated more by oaks and maples. There was no change in its population despite the decline in shrubs (Buchanan et al. 2016).

The Wood Thrush nests in a variety of forest types in the northeast. In northern hardwoods, Noon et al. (1979) documented it in 80% of mature, undisturbed forests and 47% of disturbed and successional habitats. It nested in lowland hardwoods dominated by ash and basswood in New York (Samson 1979). It was rare in sapling-pole-size aspen-birch stands and absent in other stages of this forest type (Back 1979). In northeastern pine stands, it was absent in pitch pine and most pine stands but occurred in low densities in mature pine in 1 study (Capen 1979). It is absent or rare in upland balsam fir–spruce stands and lowland conifers but may use lowland white cedar stands, tamarack, and other conifers if there are deciduous species mixed among the conifers (Crawford and Titterington 1979; Dawson 1979). It is more common in mixed stands dominated by combinations of sugar maple, beech, yellow birch, hemlock, spruce, balsam fir, and pine (Temple et al. 1979).

Some authors considered the Wood Thrush a late-successional species (Speirs and Orenstein 1975) or to require mature forests (Temple et al. 1979). Sugar maple stands are climax forest types, so it is appropriate to term it a late successional species, but it is not typically associated with older

forests. In Pennsylvania, it occurred in 18.2% of old-growth forests compared with 91.2% of forests state-wide and 89.2% of forests on the Appalachian Plateau. Haney (1999) considered it to have negative old-growth forest affinities. Bond (1957) found that it was most abundant in intermediate-aged stands where the sapling layer was well developed. It occurred almost exclusively in mature bottomland forests in South Carolina and was rarely detected in younger stands of similar composition (Buffington et al. 1997).

In Virginia, Wood Thrushes tended to avoid areas dominated by oaks and pines. The oaks were associated with xeric soils and they may have been avoiding dry areas rather than the oaks and pines. It was positively correlated with worm biomass; worms were associated with moist soils close to streams. It appeared to prefer mesic areas within its home range, which also offered a high biomass of one of its preferred prey (Jirinec et al. 2016a).

Detailed vegetation analyses have been completed comparing characteristics around the nest to random areas in the territory. In Delaware, vegetative cover within 6 m of the nest was denser 1 m above the nest than at the same height of random non-nest sites (M.L. Evans et al. 2020). In Ohio, nest sites had a greater density of small deciduous and coniferous trees and a higher amount of coniferous canopy cover than perch sites. Nests were sometimes in small hemlock trees but foraging areas were almost exclusively in surrounding deciduous woodlands. Densities of trees per m^2 were: in 1-m radius plots, 1.42 at nests and 0.58 at perches; in 5-m radius plots, 0.90 at nests and 0.43 at perches; and in 11.3-m radius plots, 0.55 at nests and 0.31 at perches. The Wood Thrush did not exhibit a preference for any size of nesting microhabitat, but nests were often in microhabitat patches of about 5-m radius (Petit et al. 1988b). In Pennsylvania, nests were in areas that had higher densities of trees, higher canopy heights, higher density of shrub stems, and higher average shrub height than randomly selected points. It selected areas that had taller trees and shrubs than generally available (Hoover and Brittingham 1998).

The Wood Thrush may nest throughout forests, but is more likely to occur at forest edges. It is more likely to use forest edges bordering on service corridors and agriculture than those along roads. Growth rates of nestlings may be faster on edges than in the interior, probably due to more abundant food resources (Kaiser and Lindell 2007). In small woodlots in Pennsylvania, it spent more than 80% of its time within 20 m of edge. Use of edge habitat was significantly more than expected based upon its availability (MacIntosh et al. 2011). In Maine, it was most abundant within 100 m of Interstate 95 and was negatively correlated with increasing distance from the highway (Ferris 1979). Hayden et al. (1985) considered it an edge species in Missouri. In Tennessee, it was more abundant near a hydro corridor through large forests than distant from the edge (Kroodsma 1984). In Maryland, Gates and Giffen (1991) studied edge effects at a forest-stream ecotone. The Wood Thrush was most abundant near the stream and edge of the forest. The forest canopy was dominated by hemlock and had hemlock and rhododendrons in the understorey. Its presence was negatively associated with deciduous cover. In New York, it used edges in the habitats it occupied (Dilger 1956).

In Ontario, the Wood Thrush is not particularly area sensitive and regularly breeds successfully in woodlots as small as 3-4 ha (Friesen et al. 1999a; Wyatt 1998). In the Ottawa area, its abundance was best predicted by forest size; the amount of surrounding forest cover was not a significant factor. Density of thrushes decreased with increasing forest size (Lee et al. 2002). In southwestern Ontario,

its probability of detection was positively correlated with the amount of forest 100 m from edge and negatively correlated with woodlot size, the amount of forest within 2 km, and the amount of regional forest cover. Only the latter 2 relationships were significant (Austen et al. 2001). In Pennsylvania, Keller and Yahner (2007) classified it as area sensitive and associated with increasing forest size. M.L. Evans et al. (2020) stated that it was more likely to occur in larger woods, but that it may nest in 1-ha fragments and semi-wooded residential areas and parks. In Maryland, its abundance declined significantly once forest size declined below 10 ha. Robbins (1979) considered its critical forest size to be 100 ha. In the mid-Atlantic states, the forest area at which its probability of observation reached its maximum was 500 ha; probability was reduced by 50% at 1.0 ha. The 3 smallest woodlots where it was detected were 0.8, 0.8, and 0.2 ha. There was a 70% chance of detecting it in a 10-30-ha woodlot (Robbins et al. 1989). In Illinois, its presence was correlated with forest size (Blake and Karr 1987). In Wisconsin, it was at least 50% more common in large than small woodlots. Frequency of occurrence was 2.3 in 6.1-14.2-ha woodlands, 11.5 in 16.2-32.4 ha, and 20.0 in woodlots larger than 32.4 ha. In mesic stands, it occurred almost exclusively in large woodlands (Bond 1957). In Iowa, Stauffer and Best (1980) considered the Wood Thrush restricted by habitat patch size. It was absent in woodlands less than 145 m wide. In Missouri, the minimum forest size it was found in was 341 ha; the minimum size threshold reported in New Jersey was only 0.8 ha (Hayden et al. 1985). In Maryland, its probability of observation was 18% in a 0.1-ha forest, reaching a maximum of 80% at approximately 150 ha (Lynch 1987). In Rhode Island, Golet et al. (2001) examined its abundance in differently sized red maple swamps. The swamps were not isolated and were bordered by upland forest. It occurred in 5.6% of swamps smaller than 1 ha, 1.2% of those 1-5 ha, 0.5% in 6-10 ha, and 1.4% in 11-20 ha. There was no significant relationship between swamp size and its abundance. In Maryland and Delaware, its probability of occurrence in riparian forests increased significantly as corridor width increased. Its probability of observation was 76% in 50-m wide corridors, 84% in 100 m, 93% in 200 m, 97% in 300 m, and 100% in 800 m (Keller et al. 1993).

In southern Ontario, the probability of a smaller woodlot being occupied by the Wood Thrush was significantly correlated with proximity to large woodlands that were a source of thrushes. Occupancy rates were highest close to large woodlands and declined with distance. The occupancy rate adjacent to large woodlands was 30%, declining to 20% at approximately 7.5 km, and less than 10% at 20 km. Occupied fragments were mostly less than 14 km from large forests and much closer on average. There was no significant relationship between regional forest cover and percent occupancy of small fragments (Nol et al. 2005). In southeastern Ontario, the amount of forest cover within 2 km was positively correlated with its density and nesting success, but negatively correlated with pairing success (Richmond et al. 2012). In New York, it selected landscapes that were 82-100% forested (Cunningham and Johnson 2019). The Wood Thrush sings more frequently in continuous forests than in forest fragments. Birds in smaller forests or where densities of thrushes are lower are more likely to be undetected than those in large contiguous forest blocks. This may affect survey results and conclusions regarding area sensitivity, density, and overall abundance (McShea and Rappole 1997).

Several studies examined habitat partitioning between the Wood Thrush and other thrush species. In New York, the Wood Thrush had no positive associations with other thrush species'

habitat, but it was least negatively associated with the Veery (Dilger 1956). James et al. (1984) stated that none of the other thrush species occurred where the Wood Thrush occupied its average habitat. The Wood Thrush and Veery were most similar in their habitat requirements.

Noon (1981) found that the distribution of the Veery was very similar to that of the Wood Thrush on an elevational gradient, with both most abundant at low elevations and reaching their upper limit together at the lowest ecotone where sugar maple and beech disappeared and spruce and yellow birch increased. The Wood Thrush occupied the lowest gradient but the Veery did not appear until mid-elevation. The 2 species had almost exclusive ranges with only about 300 m overlapping. In New York, the Wood Thrush selected mature deciduous forests with high canopy height and cover dominated by a few large trees. The Veery occupied similar habitats but occurred in more open or disturbed areas where shrub coverage was significantly higher (Dilger 1956). In Tennessee and North Carolina, Wood Thrush habitat differed from that of the Veery in having a taller canopy and more tree species present. Most differences in their locations were due to spatial separation with the Veery occupying higher altitudes. The 1 factor that consistently separated the Wood Thrush and Veery was their differential response to shrub density, with the Wood Thrush selecting lower shrub density. When both species are present, the Wood Thrush may be competitively constrained by the Veery from using habitats with a particular structural configuration. It responded by expanding its habitat niche to include additional habitat types where the Veery was nesting at higher altitudes. The Wood Thrush had the lowest niche breadth of the thrushes studied, suggesting that it is a habitat specialist. In Maine, the Wood Thrush colonized an area inhabited by the Veery and Hermit Thrush. The Wood Thrush occupied both deciduous and coniferous areas that were moister than those used by the Hermit Thrush and drier than those used by the Veery. The Wood Thrush was not found in any habitats to the exclusion of the other 2 thrush species although it occupied young white pine–alder sites almost to the exclusion of the other species. In 2 cases, a Wood Thrush used essentially the same territory that had been occupied the previous year by a Veery or Hermit Thrush and therefore appeared to be socially dominant to both species. The Wood Thrush may be able to establish territories upon spring arrival even in areas that are already occupied by the Veery or Hermit Thrush (Morse 1971a). James et al. (1984) concluded that the Wood Thrush had similar habitat requirements to the Veery except that the Wood Thrush was more restricted to closed canopy forests. In Connecticut, the Wood Thrush preferred lower shrub density, less early- and late-successional habitat, less moisture, and less exposed soil than the Veery, but selected areas with taller canopy. Successional stage appeared to be the main difference between Wood Thrush and Veery territories, with the Veery appearing earlier in succession. Plants significantly more common in Wood Thrush territories than those of the Veery were typical of more mature forests and drier sites, and included American chestnut, flowering dogwood, large-toothed aspen, chestnut oak, red oak, black oak, and sassafras; plants in Veery territories were typical of early successional and wetter areas. The Wood Thrush was associated with flowering dogwood in mature forests compared with striped maple for Veery. Shrub coverage was the single-most important factor reflecting the absence of Wood Thrush in thickets and early successional areas. The Wood Thrush appeared to require 1 or more trees at least 12 m tall, possibly for song perches; the Veery usually sang at heights of 2-8 m (Bertin 1977). In West Virginia, the Wood Thrush and Veery nested at different heights (higher than 1.6 m for Wood Thrush and lower than 1.6 m for Veery). Some Veery nests had less than

2.5% woody debris on the ground; other Veery nests and Wood Thrushes had more than 2.5% woody debris. Some Veery nests had more than 222.5 saplings; Wood Thrush and some Veery nests had fewer than 222.5 saplings in the vicinity. Wood Thrush and Veery nests were separated by percent canopy cover, with more than 42.5% for Wood Thrush and less than 42.5% for Veery. There was more woody debris ground cover, fewer saplings, and more canopy cover at Wood Thrush than Veery nests. The Wood Thrush nested at the lowest altitude and the Veery at intermediate altitudes; the Wood Thrush was isolated in the lower portion of its range. Wood Thrush nests were usually higher and in a crotch; Veery nests were lower in epicormic branches. The Wood Thrush did not nest in raspberries, greenbriers, or roses, but the Veery did. In summary, the Wood Thrush and Veery have similar habitat preferences but the Wood Thrush prefers higher canopy, taller trees, drier areas, less dense shrub coverage, and more ground coverage by plants and woody debris than the Veery (Dellinger et al. 2007).

Both the Swainson's Thrush and Hermit Thrush are separated from the Wood Thrush through their preference for coniferous cover versus deciduous cover for the Wood Thrush. On elevational gradients, both the Swainson's Thrush and Hermit Thrush occur at higher altitudes than the Wood Thrush. There is typically no overlap in habitat used by the Swainson's and Wood thrushes, but the Wood Thrush and Hermit Thrush overlap in the upper portion of the Wood Thrush's range and the lower portion of the Hermit Thrush's range. The Wood Thrush nests in moister areas than the Hermit Thrush. Wood Thrush nests averaged more than 2.8 m from edge; Hermit Thrush nests were closer than 2.8 m to edge (Dellinger et al. 2007; Morse 1971a; Noon 1981).

The Wood Thrush and American Robin occasionally occur together in woodlands in agricultural or natural settings but co-occurrence is greatest in urban woodlots. The robin is most common in areas with intermediate canopy closure and limited understorey. The Wood Thrush prefers a more closed canopy and a well-developed shrub or sapling layer. The robin tends to nest closer to edge (less than 2.8 m) than the Wood Thrush (more than 2.8 m). The Wood Thrush is dominant to the robin and is usually successful in driving it out of its territory (Dellinger et al. 2007; James et al. 1984; F.G. Weaver 1939).

In Virginia, average nocturnal roost height of males was 6.8 m (range 2.0-26.5 m). The Wood Thrush usually used different roosts on different nights. Roosts were located twice 12 days apart; the mean distance between roosts was 158 m (range 2-607 m). This excluded an outlier of 1,301 m where a male relocated to a new territory. Only 8% of males roosted in the same location on both nights. Roosts were distributed throughout the daily home range and 31% were located outside it. The mean distance of external roosts to the edge of the daily home range was 91 m (range 9-322 m). Roosts within the daily home range were not in areas of high diurnal use. The mean distance of roost sites from peak diurnal use areas was 140.4 m for yearlings and 70.2 m for older males. Roosts were in areas with significantly higher vegetation density than random sites, approximately 7% denser at roosts than random sites. Females with active nests roosted exclusively in the nest; males roosted an average of 121.8 m away (range 72.6-204.2 m). Once nests failed or young fledged, the mean distance between roosts of the sexes was only 10.6 m (range 2.2-51.9 m). In most cases, members of the pair roosted side by side within the daily home range (Jirinec et al. 2016b).

All Ontario nests were above ground in living saplings (52.8% of nests), in trees (22.0%), in shrubs (22.8%), and on tops of dead stubs (2.4%). Deciduous trees and shrubs (83.5% of nests) of 17 species were used for nesting compared with 16.5% of nests in 6 species of conifers. Species selected most frequently for nesting were 54.2% maples, 18.3% beech, 12.2% hawthorns, 8.4% hemlock, and 6.9% white cedar. Nests were randomly situated from the lowest part of a tree or shrub to its top, and were on lateral branches (52.0% of nests) and in crotches or forks (48.0%). Nests were at or near the trunk (61.0% of nests) or distant from it. Distances from the trunk ranged from 0.3 to 4.5 m, but mostly 1.2-3 m. Nests were 0.3-9 m from the ground, with most 1.8-3 m up (Peck and James 1987, 1998a). Red elderberry is an important nesting shrub in early spring. This is one of the first woody species to leaf out and it provides good concealment for nests (Savignac 2012b). Friesen et al. (1999b) reported the average height of Wood Thrush nests in Waterloo Region to be 3.1 m (range 1.2-6.4 m). Reuse of nests has rarely been reported (Craves 1998). Two nests in Waterloo Region were reused during the same breeding season. Five of 61 nests (8%) survived the year intact and 2 were reused the following year. One nest was reused to fledge 2 broods within the same breeding season (Friesen et al. 1999c; Wyatt 1997).

Throughout its range, the Wood Thrush nests in shrubs, saplings, and deciduous trees and, to a lesser extent, coniferous species. Growth characteristics of the tree or shrub are probably more important than the species. It has nested in elms, tree-of-heaven, spicebush, witch-hazel, tartarian honeysuckle, black cherry, black gum, maple-leaved viburnum, sassafras, multiflora rose, white ash, white mulberry, southern arrowwood, flowering dogwood, oaks, blue spruce, snowball bush, privet, juneberry, basswood, locust, and grapevines. Spicebush was important for nesting in many areas. In North Carolina and Tennessee, 84% of nests were in hemlocks and 11.3% were in rhododendrons. Eighty-four percent of nests were in trees with a DBH less than 10 cm. There were significantly more shrubs at nest sites than non-nest sites. Hemlock comprised more than 51% of the shrubs or small trees at nest sites but only 33% at non-nest sites. It nested in hemlock more than its availability (Farnsworth and Simons 1999). Nests in Maryland were all on the lowest available branch, in forks in saplings, or saddled on a horizontal branch either near or distant from the trunk. Nests may be 0.3 m to more than 20 m above ground, but most are lower than 6 m, with about half 1.5-4 m up. There is 1 report of a nest on the ground. Individual birds do not favour any particular characteristics for nest-site placement. Subsequent nests may be placed very close to the previous one and the exact site of a previous nest may be selected. Subsequent nests of individuals may vary greatly in height, whether they are in a shrub or tree, whether they are in a fork or on a branch, and by species selected (Brackbill 1943, 1950a, 1958; M.L. Evans et al. 2020; Graber et al. 1971; Hoover and Brittingham 1998; Newell and Kostalos 2007; Nolan 1974; Stouffer and Best 1980; F.G. Weaver 1939; Weaver in Bent 1949). In Pennsylvania, mean nest concealment was 86% laterally and 82% from above and below, but there was a large range in values. Average nest site characteristics were: nest height, 2.2 m (range 1.0-6.5 m); 61.3 m to edge (range 1-300 m); supporting vegetation DBH 4.8 cm (range 0.8-55.9 cm); 7.6 cm from the nest to the main stem (range 0-182.9 cm); 13.8% horizontal exposure (range 0-65%); 17.5% vertical exposure (range 0-70%); and 15.0% total exposure (range 0-60%; Hoover and Brittingham 1998). Nests may be occur the interior of forests to the very edge, or in shrubby areas beyond the edge (Brackbill 1958; M.L. Evans et al. 2020; Hoover and Brittingham 1998; A.F. Riggs 1947; F.G. Weaver 1939).

The Wood Thrush is territorial but may trespass frequently in adjacent territories. In Algonquin Park, it occupied areas from the ground to a height of approximately 11.9 m, about 30 cm below the bottom of the canopy (Martin 1960). In Illinois, territories were 0.8-2.8 ha in 1 area; another study reported average size of territories as 1.2 ha (range 0.7-1.7 ha). In New York, territories ranged from 0.08 to 0.8 ha. In suburban Baltimore, territories were 0.8-1.1 ha. These territories included an entire city block, excluding areas where paved driveways and close spacing of buildings reduced the amount of lawns and shrubbery. In Kansas, 1 male sang over an area of 5.1 ha, but only small portions of this area were used. The territory consisted of 2 separate parcels that were several times longer than wide. The combined area was about 0.6 ha (0.4 and 0.14 ha), with both patches along woodland edge with an intervening 45-m wide field. In Pennsylvania, territories averaged 2.4 ha (range 1.5-4.0 ha). Mean nearest neighbour distance was 90 m with a range of 50-150 m (Brackbill 1943; Evans et al. 2008; Fitch 1958; Graber et al. 1971; F.G. Weaver 1939). In Virginia from May until late July, the median home range size of 37 males was 10.4 ha (Jirinec et al. 2016a).

The Wood Thrush may maintain the same territory for its second brood of the season, or move considerable distances. In Waterloo Region, all females stayed in the same woodlot to raise their second brood except one that moved across a highway to another woodlot. Distances between successive nests in a season averaged 72.6 m (range 0-400 m). Fifty-one percent of second nests were within 50 m of the first. In Delaware second nests averaged 35 m apart if the first nest was successful and 50 m if the first nest failed. In Virginia, the same numbers were 67 m for successful nests and 122 m for unsuccessful nests, excluding 2 long-distance movements of 1.5 and 4.3 km (Brackbill 1943; M.L. Evans et al. 2020; Friesen et al. 2000; Nolan 1974; Vega Rivera et al. 1998; Wyatt 1997). In Georgia, birds occasionally wandered long distances from the nest. Maximum recorded distance from the nest was 624 m for males and 539 m for females, but both sexes were found within 100 m of the nest on 50-60% of observations. The probability of a female staying the entire breeding season within a 400-ha area was less than 20%. Sixty-three instances of emigration of males and females from study areas were documented with the mean distance travelled between nests or after the end of the breeding season being 3,353 m. Thirty percent of adults moved less than 1 km and 20% moved 1-2 km. Some moved from a 14,000-ha contiguous forest to small, fragmented woodlots or residential areas. Within a breeding season, females moved 1-17,388 m (median 251 m) between nest sites; 80% travelled less than 1 km. Females renesting after successful nests did not move as far as those with previous failed nests (424 m compared with 1,130 m), but this difference was not significant (Lang et al. 2002). In Pennsylvania, 4 of 12 females (33.3%) with unsuccessful first nests moved a mean of 418 m (range 250-628 m) for their renesting attempt. Three of 11 females (27.3%) with successful first broods moved a mean of 381 m (range 250-558 m) for their second broods. There were more significant movements to nest sites with few large trees, short canopy height, high percent canopy cover, and high percent ground cover. This occurred for both birds that remained in territories and those that moved off territories. Dispersal was not influenced by female age, success of the first nest, or clutch size. Overall, 30% of females dispersed to different territories during the breeding season; this appeared to be solely to upgrade their habitat (Gow and Stutchbury 2013a).

In Pennsylvania, males, females, and pairs frequently made off-territory forays. Foray distances were more than 250 m for 17% of lone females, 17% of pairs, and 3% of lone males (range 300-2,200 m). All long-distance forays occurred after a recent nest failure. In 60% of cases, the foraying birds returned to breed in their original territory, but 2 females (40%) disappeared from the study area. Most forays during active nesting were shorter and to adjacent territories (Evans et al. 2008). In small woodlots in Delaware, more than half of pairs had only 1 nest and left the site after that attempt, which was typically a failure. New birds continued to arrive throughout the breeding season suggesting that they had attempted a previous nest in another location. Birds that emigrated from these woodlots did not appear in a 15-ha forest 1.6 km away, nor did emigrants from the larger forest appear in the smaller woodlots. This suggested that emigrants may move considerable distances. None of the birds that emigrated from any of the woodlots were found in other forests within 10 km. Two males that remained residents throughout the breeding season in the large forest were recovered 4 and 43 km away indicating that extensive movement may occur within the breeding season (Roth and Johnson 1993; Weinburg and Roth 1998). In Virginia, 56% of males relocated their home ranges during the breeding season at least once. Birds moved as far as 4.29 km from their original territory (Jirinec et al. 2016b). In Pennsylvania, Wood Thrushes nesting in woodlots smaller than 5 ha occasionally moved outside the territorial woodlot. Eighty-two percent of males and 33% of females made at least 1 foray outside their resident woodlot. In 2 cases, unmated males acquired a mate midway through the breeding season, but in different woodlots 50 and 700 m distant. Most forays by males were more than 150 m 1 way, with a maximum of 392 m. Males crossed open gaps as wide as 615 m, but most gaps were less than 100 m across. Most female forays were less than 150 m (range 40-1,400 m); they crossed gaps of 30-300 m. For females, the incidence of gap-crossing decreased significantly with gap width. Males in small woodlots spent more time off their territory (23.5%) than those in contiguous forest (4.8%) and travelled further (392 m compared with 9.9 m; MacIntosh et al. 2011).

The rate of natal philopatry may be 0% in some areas and fair high for a passerine species in other areas. Brackbill (1958) banded 26 nestlings in Maryland and 0 returned. In Delaware, 13 females and 21 males banded as young returned to breed, with an overall return rate of 5%. These included 4 females and 1 male that did not return until their second year after fledging. Over 8 years, 0 or 1 young returned in most years, with annual return rates varying from 0% to 12%. The maximum number returning in a year was 7, 4 of which hatched the previous year and 3 2 years previously. Yearlings and 2-year-olds were captured 1.3-4.2 km from the natal site, except for a female that was recovered 39 km away. Annual return rates of fledglings may vary and some may not return until 2 years after fledging (Roth and Johnson 1993). In New Jersey, 5 of 74 fledglings (6.8%) returned to breed the following year (Suthers 1988).

Adult site fidelity may vary geographically and annually at individual sites. Schlossberg (2009) estimated adult site fidelity at 41% based on 456 birds in 3 different studies. In Maryland, 4 of 10 (40%) males and 1 of 10 (10%) females returned (Brackbill 1943). In Delaware, mean return rates were 49% for females and 59% for males. Rates of return varied considerably year to year (Roth and Johnson 1993). At the same area, 64% of 39 females present for their third consecutive year returned the next year and 71% of 28 males that had been present for 4 years returned. For females, 64% of

4-year birds and 75% of 5-year birds returned. One female nested in the same 0.2 ha in 5 consecutive years with 1 male and then with another male in the same area for an additional 3 years. It was assumed that there was strong site fidelity and that return rates equalled survival rates (M.L. Evans et al. 2020). In New York, 1 male used the same territory in 3 successive years (F.G. Weaver 1939). In Illinois only 19.2% of 26 adults returned the following year even though 67-79% of all adults were captured in subsequent years. These data suggest a high turnover rate, but Robinson (1992) acknowledged that low return rates may have been due to net or territory shifts, or birds becoming net-shy.

Studies in the Ottawa area (Villard et al. 1992, 1995) provided insight into the variability of fidelity rates that have been reported. They studied the presence-absence of Wood Thrushes over 2 years in all woodlots in a 10 x 10 km square. Size of woodlots ranged from 3.0-129.8 ha (median 11.8 ha). There were local extinctions and recolonizations in 16-28% of the forest fragments. Extinctions and recolonizations even occurred in fairly large woodlots (25.3-53.3 ha). Although the woodlots that supported Wood Thrushes changed each year, the number of woodlots occupied within the larger study area remained constant. This has important implications because a single-year survey may conclude that a given woodlot does not support the Wood Thrush and is therefore unimportant to it. The same woodlot may have the potential to become recolonized and contribute to the metapopulation.

Limiting Factors

Eggs have been found in Ontario nests from the beginning of May until early August, with most present in the first 3 weeks of June (Peck and James 1987, 1998a). In Waterloo Region, 44% of nests had egg dates in July and early August. The average first egg date for double-brooded birds was 24 May (range 13 May to 7 June) for first nests and 1 July (13 June to 16 July) for second nests. First broods in Ontario fledge around 20 June. The first egg of second broods was laid an average of 13.4 days after young had fledged from the first nest (range 7-31 days; Friesen et al. 1999a, 1999c, 2000).

Nest construction takes 3-8 days but mostly 5 days or less. Three or 4 days may elapse between nest completion and initiation of egg laying. Eggs are laid at 1-day intervals. Incubation begins consistently with laying of the penultimate egg, although short periods of incubating may occur as soon as the first egg is laid. The incubation period at 8 Ontario nests was 10-12 days. Elsewhere, incubation periods of 11-14 days have been reported; average incubation periods at 3 different study areas were 12.7-12.75 days. Young leave the nest when they are 12-15 days old. It takes approximately 51 days from nest building to fledgling independence (Anders et al. 1997; Brackbill 1943, 1958; M.L. Evans et al. 2020; Longcore and Jones 1969; Nolan 1974; Peck and James 1987, 1998a; Vega Rivera et al. 1998, 2000: F.G. Weaver 1939; Weaver in Bent 1949).

The Wood Thrush typically attempts to raise 2 broods per season and very rarely 3. Double broods were suspected in Ontario based upon egg dates (Friesen et al. 1999a; Peck and James 1987, 1998a) and were confirmed by Wyatt (1997) and Friesen et al. (2000). Over 2 years, 74% of females in a Waterloo study area initiated a second clutch after successfully raising a first brood: 64% in the first year and 86% the following year. It was likely that some nests were missed, so the incidence of double brooding may have been close to 100% (Friesen et al. 2000). A similar rate of double brooding was reported in Pennsylvania, with 74% of birds that successfully raised a first brood

attempting a second (Gow and Stutchbury 2013b). Friesen et al. (2001) confirmed triple brooding in Waterloo Region and all 3 nests successfully produced young. The triple-brooded pair did not initiate nesting earlier than other birds (15 May) and the fledging date of their last brood (19 August) was only 2 days later than for several other pairs. Over 3 years, only 1 of 73 females (1.3%) was triple brooded. In Pennsylvania, 1 female successfully raised 3 broods (Gow and Stutchbury 2013b). Throughout the Wood Thrush's range, 2 broods are typically raised, but occasionally only 1 and rarely 3. About half of females are successful in raising a second brood. It is a persistent renester and may make several nesting attempts. In Waterloo, 2 females fledged a first brood and made unsuccessful attempts to raise a second; 13% of females did not attempt a second brood. Of females that were unsuccessful in raising the first brood, 35% renested in the study area and 65% were not encountered again (Brackbill 1958; M.L. Evans et al. 2020; Friesen et al. 2000; Longcore and Jones 1969; Powell and Knutson 2006; Powell et al. 1999; F.G. Weaver 1939). Clutches of 2-5 eggs have been reported in Ontario with most containing 4 eggs (Peck and James 1987). Clutches of 1-5 eggs have been documented throughout its range with 3 or 4 eggs typical. Single-egg clutches are usually in late nests or nests that have been parasitized by the Brown-headed Cowbird. In Delaware, mean clutch size for first nests was 3.7 eggs (range 1-5), 3.0 for second clutches (range 1-4), 2.8 for third nests (range 2-3), and 2.6 for fourth nests (range 2-3). Modes for successive nests were 4 eggs (72% of clutches) for second clutches, 3 eggs (83%) for third clutches, and 3 eggs (60%) for fourth clutches. In another Delaware study, mean clutch size was 3.7 eggs in May, 2.8 in June, and 2.8 in July with an overall mean of 3.3 eggs. In Maryland, all clutches smaller than 3 eggs followed a disturbance such as nest loss or parasitism (Brackbill 1958; M.L. Evans et al. 2020; Graber et al. 1971; Longcore and Jones 1969; F.G. Weaver 1939; Weaver in Bent 1949). The number of young fledged in a season is strongly related to when the moult is initiated. The most productive individuals moulted about 3 weeks later than average (Gow and Stutchbury 2013b).

The age at first breeding is 1 year, and the Wood Thrush nests annually thereafter. The mating system is monogamous, although polgyny rarely occurs. One male in Delaware had nests 50 m apart with 2 different females. The first female successfully raised 2 broods; the second female raised 1 fledgling in the first brood but her second nest failed. The low productivity of the second female may have been because the male seldom fed her young. In Delaware, polygynous males were detected 6 times in 945 nestings (0.6%). One male was a bigamist in 2 non-consecutive years. Two other males were bigamists for 2 nesting periods within a single season. The pair bond is typically maintained throughout a breeding season regardless of the number of nesting attempts or if the pair moves between successive nests. Divorce does occur; 13 of 417 females (3.1%) and 17 of 416 males (4.1%) renesting the same year did so with another mate. Most returning birds have a new mate annually, but 3-8% of pairs may be of birds that were mated the previous year. One pair is known to have stayed together for 5 breeding seasons (Brackbill 1943, 1958; M.L. Evans et al. 2020; R.K. Johnson et al. 1991; Lang et al. 2002). In Pennsylvania, 9 of 151 young (6%) were extra-pair; 7 of 51 nests (14%) contained extra-pair young. All 151 nestlings were related to their mother suggesting that intraspecific parasitism does not occur or is rare. Two extra-pair fathers occupied an adjacent territory 200-250 m away; another's territory was 650 m away. In Ontario, the rate of extra-pair paternity was 40% (45 of 112 nestlings). Twenty-four of 36 pairs (67%) had extra-pair young. The 2 extra-pair males that were identified each held territories adjacent to those containing nests with

their extra-pair young. Densities of Wood Thrushes were similar in Pennsylvania and Ontario, but the rate of extra-pair young in Ontario was 6.7 times that in Pennsylvania (Evans et al. 2008, 2009).

Young from early nests typically forage on the ground, often along logs. Later-fledging birds depend heavily on fruit for food and spend most of their time foraging 5-10 m high in trees. Upon first arrival at the breeding grounds, adults may feed from the foliage of newly leaved trees but later forage mostly on the ground. The Wood Thrush mostly probes and gleans and occasionally hovers or hawks insects and fruit that cannot be reached from the ground. It may also use bill swipes or pick up leaves to expose prey. In urban areas, it may forage on lawns in a manner similar to that of the American Robin (M.L. Evans et al. 2020; Vega Rivera et al. 2000; Weaver in Bent 1949). Dilger (1956) studied the foraging tactics of closely related thrushes in New York. The Wood Thrush and Hermit Thrush were primarily ground foragers in edge habitat. The Veery and Swainson's Thrush were predominantly arboreal foragers, occasionally flycatching, and occurred in forest interior.

The mean length of food given to young increases gradually with age: 9.8 mm in days 3 and 4 and 12.3 mm in days 8 and 9. Nestlings are fed caterpillars, earthworms, ants, spiders, soldier beetles, millipedes, cankerworms, and moths. Fruit provided to young includes red and white mulberries, honeysuckle berries, and black cherries. By days 7-9, young are fed more ants, spiders, soldier bugs, earthworms, and millipedes than at days 3-6, probably reflecting either selectivity by adults or different prey availability. In addition to these foods, fledglings may be fed Japanese beetles and June beetle larvae (Brackbill 1943; M.L. Evans et al. 2020; Lagassé and Ryder 2016; Powell et al. 1996; Vega Rivera et al. 2000; Weaver in Bent 1949).

Adult Wood Thrushes feed mostly on soil invertebrates with greater use of fruits in late summer and autumn (M.L. Evans et al. 2020). They also eat small salamanders, snails, and some arboreal insects. The diet of 22 birds in Illinois consisted of 71% insects and 19-21% fruit. It was exceptional among the thrushes in the number of millipedes it consumed (13% of the diet) and it also fed heavily on ants (15%) compared with other thrush species. Beetles were important, comprising 18% of the diet, mostly ground and scarab beetles, click beetle larvae and adults, and weevils. Other food items included 12% crane and march fly larvae, 1% spiders and harvestmen, 1% molluscs, and 1% bugs. Another study in Illinois found that bugs were more important, comprising 10-20% of the diet. In autumn, it has fed on fruits of spicebush and pokeweed (Graber et al. 1971). Beal (1915b) examined 171 stomachs taken throughout its breeding range. The diet consisted of 59.6% animal matter and 40.4% vegetable matter. The greatest amount of animal food was eaten during the month after arrival in spring and the least in October during autumn migration. Beetles were the most prevalent animal food at 20.4%, including scarab beetles (10.2%), ground beetles (2.2%), weevils (2.2%), click beetles (2.1%) and occasionally Colorado potato beetles. Caterpillars comprised 9.4% of the diet, with most taken in July (16.3% of that month's food items). Ants averaged 8.9% for the season, beginning with 18.1% in April, gradually declining through the summer and disappearing from the diet in October. Other hymenopterans were eaten regularly but in small quantities (3.9%). Other animal prey included 2.7% flies (mostly crane flies), 1.3% bugs, 2.3% grasshoppers, less than 1% other insects, 8.5% spiders and millipedes (which comprised 20-94% of April food, but gradually decreased in importance through September), and 1.8% isopods, snails, and earthworms. More than 90% of the vegetable matter eaten was fruit, predominantly wild fruit (33.5%), but some domestic fruit was

consumed (3.7%). Fruit comprised only 1.2% of the diet in April and gradually increased to 87.2% in October. Dominant fruits in the diet included blackberries and raspberries, mulberries, chokecherries, blueberries, spicebush, frost grapes, and dogwoods. In addition to fruit, it ate a few seeds and rose haws. In Illinois over 3 years, frugivory comprised 71-83% of foraging attempts; 74% of fruit foraging was in forest gaps created by treefalls and other disturbances. The percentage of fruit consumed was 3% elderberries, 58% Virginia creeper, and 39% spicebush in year 1; 20% grapes and 80% spicebush in year 2; and 8% grapes, 9% Virginia creeper, and 83% spicebush in year 3. Malmborg and Willson (1988) considered it an understorey-foraging species that foraged significantly more for fruits in gaps and for insects in forest interior. It favoured clumped areas of fruit when feeding in gaps rather than single stems. In Pennsylvania, it was rarely seen on red elderberry bushes despite being detected at 80% of elderberry sites during surveys. It was detected foraging at 5.9% of elderberry sites on only 0.9% of visits (Stutchbury et al. 2005a). Other fruits it eats include holly, jack-in-the-pulpit, and black gum (M.L. Evans et al. 2020). In Delaware, Ladin et al. (2015) used stable isotopes to determine the diet of adult and nestling Wood Thrushes. They compared diets of nestlings in nests with and without a Brown-headed Cowbird nestling. The diet of adults was composed largely of protein-rich and calcium-rich foods (51-62%), including snails, isopods, and myriapods, as well as spiders (23-33%). They ate 7 times the snails, 4 times the spiders, and 17 times the isopods than expected by availability, and 7.1% of the available insects and 5.9% of the available caterpillars. Earthworms and myriapods were consumed at expected frequencies. Nestlings without cowbirds in the nest ate snails, spiders, and myriapods at expected frequencies but only 20% of available insects and 12.5% of available caterpillars. Nestlings with cowbirds ate snails, spiders, isopods, and caterpillars at expected frequencies and 33% of available insects. Nestling diets where cowbirds were absent contained a greater proportion of calcium-rich foods and spiders compared with those accompanied by cowbird nestlings. Brood parasitism affects nestling diet and may have negative effects on development through nutritional stress that may subsequently affect survival and fecundity.

The Wood Thrush is commonly parasitized by the Brown-headed Cowbird. Parasitism rates generally decline with distance from the cowbird's historic range west of the Mississippi River. Hoover and Brittingham (1993) defined 3 general regions: the Midwest region, which in Ontario is approximately the area west of Rossport; the mid-Atlantic region, which extends from Rossport to the Toronto area; and the northeast region, which is east of Toronto in Ontario. Parasitism rates were 42.1% in the Midwest, 26.5% in the mid-Atlantic, and 14.7% in the northeast. The Ontario range of the Wood Thrush does not extend to the Midwest region. The percentage of parasitized nests was positively correlated with the number of cowbirds detected on Breeding Bird Survey (BBS) routes and negatively correlated with the number of Wood Thrushes detected. In Delaware, parasitism rates were 60% or more 1985-87 but 0% 1989-91 with no apparent reason for the change (M.L. Evans et al. 2020). Parasitism rates in a large Pennsylvania forest varied significantly annually with values of 0-23% (Hoover et al. 1995). In Ontario, 110 of 384 nests (28.6%) were parasitized (Peck and James 1998a). Parasitism rates vary geographically across the province and with woodland size. On the Niagara Escarpment, 41% of nests were parasitized, with no significant difference in parasitism rates by year. There was a significant difference in parasitism rates in large (8%) and small (57%) woodlots (Friesen and Campbell 2002). In Waterloo Region, Friesen et al. (1999a) reported an overall parasitism

rate of 47% and no significant difference in rates between large and small woodlands. Phillips et al. (2005) reported parasitism rates of 26-46% at Peterborough over 4 years and 20-39% at Ottawa over 3 years. Woodlands with houses in them had significantly higher parasitism rates than those with no nearby development or those with adjacent houses. In south-central Ontario, Burke and Nol (2000) reported parasitism rates of 4.4% in small woodlands and 2.8% in large woodlands. Wyatt (1998) reported on the outcome of 338 nests in Waterloo Region, Port Severn, and the Halton Region portion of the Niagara Escarpment, each with different amounts of forest cover (14%, 29%, and 48%, respectively). Parasitism rates were 14% in Waterloo, 12% in Severn Sound, and 28% on the Niagara Escarpment. Parasitism was most severe in woodlands smaller than 50 ha: 39% in 4-14-ha woodlots; 61% in 20-50 ha; 23% in 140-440 ha, and 0% in woodlands larger than 1,300 ha. In Norfolk County, 47 of 186 nests (25.3%) were parasitized. Nest concealment was not correlated with parasitism rates. Nests in 11-69-ha forests were parasitized at a significantly higher rate than those in 162-500-ha forests (Israel et al. 2023). Increased parasitism rates in smaller woodlots have been documented in Delaware (Weinberg and Roth 1998), Pennsylvania (Hoover et al. 1995), Missouri, Minnesota, and Wisconsin (Donovan et al. 1995). There was no relationship between forest area and parasitism rates in Indiana, with rates ranging from 58% to 100%. This may have been because the area is saturated with cowbirds (Fauth 2000). In Illinois woodlots, all nests were parasitized and nests contained 4 times as many cowbird as thrush eggs (Robinson 1992). Where the cowbird is very abundant, amount of forest cover and forest size are not significant due to the overall high rate of parasitism. Most studies found no relationships between parasitism rates and distance from forest edge. In Michigan, parasitism rates were higher along abrupt edges such as roads than along gradual edges such as wetlands and utility rights-of-way. In Virginia, where parasitism rates were 29%, parasitism increased with the percent of agricultural land and road density within 500 m (Etterson et al 2014; Kaiser and Lindell 2007; Simons et al. 2000). Occasionally parasitism rates may be inexplicably low, even when cowbirds are present and parasitism rates are high in the general region. In 1 Delaware woodlot, there was no parasitism of Wood Thrush nests, but nests of Red-eyed Vireos, Eastern Towhees, Common Yellowthroat, and Kentucky Warbler were parasitized (Artman and Downhower 2003; Hahn and Hatfield 1995; Longcore and Jones 1969). The Wood Thrush generally accepts cowbird eggs, although nests may occasionally be abandoned and there are accounts of it ejecting eggs or imbedding them in the nest (Brackbill 1958; M.L. Evans et al. 2020; Weaver in Bent 1949). It is a larger host and can raise its own young in parasitized nests. The incubation period of the 2 species is similar so that the cowbird does not have a competitive edge by hatching sooner, and the Wood Thrush can renest and increase its chance of successful reproduction. Parasitism has no effect on Wood Thrush nestling growth. Numerous studies demonstrated that the percentage of nests successfully fledging a Wood Thrush is not significantly affected by parasitism (Burke and Nol 2000; M.L. Evans et al. 2020; Farnsworth and Simons 1999; Fauth 2000; Friesen and Campbell 2002; Hoover and Brittingham 1993; Hoover et al. 1995; Kaiser and Lindell 2007; Lowther 1997; Phillips et al. 2005; Roth and Johnson 1993; Simons et al. 2000; Weinberg and Roth 1998). Although parasitism may not greatly affect nest success, the number of thrushes produced per nest declines as a result of parasitism. The cowbird frequently removes thrush eggs and these are not replaced, resulting in smaller clutch sizes. Presence of a cowbird egg may also inhibit the Wood Thrush from laying a full clutch. In Waterloo Region, parasitized nests produced significantly fewer thrushes than

unparasitized nests, and this relationship was also observed on the Niagara Escarpment. In the Peterborough area, parasitized nests produced almost 17% fewer thrush fledglings per nest (2.3) than unparasitized nests. In Missouri, Wisconsin, and Minnesota, parasitized nests fledged significantly fewer Wood Thrushes than unparasitized nests (Brackbill 1958; Donovan et al. 1995; M.L. Evans et al. 2020; Friesen and Campbell 2002; Friesen et al. 1999a; Phillips et al. 2005; Wyatt 1998).

Predation appears to be the greatest limiting factor to the Wood Thrush. In most areas, about half of nests fail and produce no young. Predation is the main cause of nest failure and accounts for 66-100% of losses in different study areas. Ontario studies reported nest success rates (fledging of at least 1 young) of 47-51%, with 74-85% of losses due to predation. These rates appear to be fairly typical for North America, but success rates as low as 37.6% and as high as 60.3% have been reported. The high rate of predation may be sufficient to result in a woodland being a sink area rather than a source in many cases. On the Halton section of the Niagara Escarpment, there was no difference in predation rates between small (20 ha) and large (1,300 ha) woodlands but the predation rate was 58.3% in small central Ontario woodlots compared with 27.8% in large woodlots. In woodlots in Waterloo Region, predation risk decreased with increased urbanization. The abundance of alternative food sources associated with humans may divert the attention of predators from bird nests. In Tennessee and North Carolina, high rates of predation were associated with areas with only 20% forest cover; predation rates were lower in contiguous forest. The lack of difference in predation rates between nests in large and small forests in some areas may be because large contiguous forests may support a more diverse and abundant predator community. In West Virginia, the southern flying squirrel was the most common predator. This species is restricted to large forest patches, particularly those with abundant mast, and may potentially be a greater predator than raccoons and cowbirds in large, contiguous forests. In Delaware, predation rates in small forest fragments were 1.88-2.28 times those in larger forests. Most studies found that predation rates are not affected by edge, with nests in forest interior having similar predation rates as those on edges, but in Pennsylvania, predation rates decreased significantly with distance from edge. Results of this study may have been somewhat confounded by the fact that thrushes nesting in forest interior nested an average of 2 m higher than those on edges, and higher nests were more successful than lower ones. In Virginia, elevated predation rates occurred within 50 m of agricultural edges; nest predation rates increased with increasing nest height. There may often be no difference in predation rates in relation to edge but the type of edge may influence predation. In Michigan, nests near abrupt edges such as roads and marshes were more likely to be depredated than those near gradual edges such as clear-cuts and hydro rights-of-way. The species of predators present may also influence predation rates at different distances from edge and at different nest heights (Artman and Downhower 2003; Burke and Nol 2000; Etterson et al. 2014; M.L. Evans et al. 2020; Farnsworth and Simons 1999; Fauth 2000; Friesen and Campbell 2002; Friesen et al. 1999a, 2013; Hoover and Brittingham 1998; Kaiser and Lindell 2007; Longcore and Jones 1969; Newell and Kostalos 2007; Phillips et al. 2005; Richmond et al. 2011; Simons et al. 2000; Weinberg and Roth 1998; Williams and Wood 2002).

Forest fragmentation has been considered to be highly detrimental to the Wood Thrush, but results may vary significantly geographically. The general pattern is less reproductive success in

small forests, in less forested landscapes, and in the Midwest than the east, but there are many exceptions to this (M.L. Evans et al. 2020). In the eastern United States, almost 35% of Wood Thrushes detected on BBS routes were in fragmented habitats (Donovan and Flather 2002). Studies undertaken in Ontario demonstrated that there are geographic differences within the province and much smaller woodlands than generally reported support viable populations. In Waterloo Region, which has approximately 14% forest cover, pairing success was essentially 100% in woodlots ranging in size from 3 to 12 ha. Nesting success was sufficient in these small patches that they acted as sources. A pair successfully reared 3 broods in a year in a 1.8-ha woodlot. Nest success and productivity were not affected by forest size or nest location relative to edge. Even in the smallest woodlands in an agricultural matrix, Wood Thrushes nested successfully. It was concluded that severe reproduction impairment is not a general phenomenon of all settled landscapes (Friesen and Campbell 2002; Friesen et al. 1997, 1999a, 1999b, 2001; Wyatt 1998). In Norfolk County, Wood Thrushes nesting in small fragments were not subject to strong negative effects on body condition, reproductive success, or timing of the last nest of the season. Annual survival was not linked to breeding fragment size and autumn migration was not delayed for birds nesting in small fragments (Boyd et al. 2023; Hayes et al. 2023). In central Ontario, woodland size was the most important factor affecting reproductive success. The amount of forest cover in the local landscape had no significant effect. Small forests were sinks and large ones were sources. Only 1% of the locally available forest fragments were sources (larger than 200 ha). The source areas occupied less than 30% of the total forest cover (Burke and Nol 2000). Nesting success rates from elsewhere are less than 18% in Illinois in 14-65-ha woodlands, about 25% in Missouri in 181-1,872-ha woodlands, 28% in Pennsylvania in 10-30-ha woodlands, 30% in Wisconsin in 181-1,872-ha woodlands, 41% in Missouri in 26,000-ha woodlands, about 60% in Wisconsin in 29,000-ha woodlands, and about 85% in Pennsylvania in a woodland larger than 10,000 ha. In rural Pennsylvania, nesting success in forests smaller than 80 ha was usually below the sustainable level. In central Illinois with 10% regional cover and Missouri with 31% forest cover, forest fragments 25-1,600 ha were population sinks. A 15-ha urban woodlot in Delaware was a source and nesting success there was equal to or greater than in the Smoky Mountains, the largest contiguous forest in the eastern United States. In Missouri, Wisconsin, and Minnesota, forest fragments had higher daily nest mortality due to predation and parasitism than contiguous forest. The primary reasons for decreased productivity in some forest patches are increased parasitism and predation. Predation and parasitism rates may vary annually, such that some woodlots are sinks some years and sources in others. Another factor that may affect reproductive success in small woodlots is that the return rate of experienced birds may be much lower than in large woodlands. Small woodlands may be regarded as inferior habitat and be populated by less experienced breeders (Anders et al. 1997; Donovan et al. 1995; M.L. Evans et al. 2020; Fauth 2000; Friesen et al. 1999a; Hoover et al. 1995; Roth and Johnson 1993; Weinberg and Roth 1998).

Forest fragmentation creates edge. The effects of edges on the Wood Thrush are variable. In Waterloo Region, Friesen et al. (1999b) found no edge effects, with nests on edges as successful as those in forest interior. In Michigan, nestlings in nests near gradual edges grew faster than those at abrupt edges and in forest interior. There was no difference in survival rates between nests in the interior and on edges (Kaiser and Lindell 2007). Nest success increased significantly with distance

from edge in Pennsylvania. Nesting success was 46% within 50 m of edge, 67% 50-100 m from edge, and 79% more than 100 m from edge (Hoover et al. 1995). In Illinois, reproductive success of Wood Thrushes nesting near an agricultural corridor was less than in contiguous forest (Ford et al. 2001). In an extensive forest in Pennsylvania, Wood Thrushes nesting near agricultural disturbances had lower success rates than those nesting near disturbances caused by forestry practices. The difference may have been related to greater abundance of predators within the agricultural land (Rodewald and Yahner 2001). In New Jersey, it was significantly more abundant near unpaved roads than paved roads or power lines. The widths of these corridors were 8, 16, and 23 m, respectively. Its abundance was significantly reduced along edge corridors 16-23 m wide, but not along 8-m wide corridors (Rich et al. 1994). In contiguous forest in West Virginia, the Wood Thrush avoided roads and pipelines and was significantly more abundant distant from them (Farwell et al. 2019).

In the Missouri Ozarks, the Wood Thrush shifted its breeding territories so they were closer to large openings such as clear-cuts. This resulted in high breeding densities around clear-cuts and low densities distant from clear-cuts. In large forests, there was an increase in mortality as juveniles became independent and wandered through the forest looking for suitable postfledging habitat. Wood Thrushes inhabiting forest fragments in Missouri did not have to wander far to find shrubby habitat and did not experience a similar increase in mortality. It may have lower annual reproductive success when it nests far from thickets and other habitats required by the young after independence. The growing maturation and homogeneity of deciduous forests in the east, where mature forests next to clearings have become increasingly rare, is leading to a decline in the Wood Thrush. In New Hampshire, it has disappeared from mature forests but is still present in forests near second growth or clearings (Ahlering and Faaborg 2006). Near Ottawa, its density declined with increasing forest size, supporting the theory that nesting density is greater at forest edges (Lee et al. 2002).

Hames et al. (2002) demonstrated that acid rain plays an important role in declines of birds, particularly in areas with low pH soils. Decreases of calcium in the soil may alter the quantity and quality of available prey, lead to toxicity due to release of heavy metals, and substantially decrease the biomass of prey in the litter (especially snails and slugs). Acid precipitation may be a limiting factor to the Wood Thrush in the Canadian Shield area of Ontario where soil pH is naturally low.

Nest success may vary depending upon vegetative characteristics around the nest, nest height, and how well the nest is concealed. In Delaware, nests initiated later in the breeding season were more likely to be successful than early nests. Spicebush and black gum were most often associated with successful nesting. Red maple and spicebush were used for nesting mostly early in the season, black gum was used most in mid-season, and arrowwood in July. Success was lowest in red maple, possibly due to the high average height of nests in this species, the early use of this species, and that these nests were highly conspicuous until foliage developed. Success was inversely proportional to nest height. Greatest nest success (53%) occurred below 1.6 m and was least (15%) at 5.0-7.6 m (Longcore and Jones 1969). In Pennsylvania, nesting success was highest where shrub density was lowest. The only factor affecting nest success was visibility of the nest from above and below, with better concealed nests having lower predation rates (Hoover and Brittingham 1998). In another Pennsylvania area, successful nests averaged more than 1 m higher and had approximately

a third fewer small stems surrounding the nest than unsuccessful nests. Success was 20% higher for nests placed above the median nest height of 3 m. High shrub density around nests was associated with high rates of predation. Nest concealment, forest canopy trees, or percent urban land use in the surrounding landscape did not affect nest success. Predators in this area were predominantly ground-foraging mammals and snakes, which probably explains why higher nests were more successful. Lower nests may be more successful in areas where avian predators are prevalent (Newell and Kostalos 2007). In Delaware, better nest concealment reduced predation. The plant used most frequently for nesting was southern arrowwood which could not support the weight of most mammalian predators (Johnson 1977).

In the Kawartha Lakes area, Wood Thrush nest success was positively correlated with invertebrate biomass. Nests in sites with higher prey biomass were more likely to succeed, but only in areas with low squirrel abundance. Squirrel density was positively associated with housing density within 100 m of the site perimeter; raccoon density increased with housing density within 2 km. Forests with greater amounts of less intensive agriculture (hay, old field, and pasture) nearby supported a higher biomass of invertebrate prey (Richmond et al. 2011).

In southeastern Ontario, density and productivity of the Wood Thrush was negatively correlated with housing density (Richmond et al. 2012). At Peterborough, the number of fledglings produced 1 year was significantly higher in undeveloped woodlots (2.7) than those with embedded (1.8) or adjacent (1.7) houses, but differences were not significant in other years or overall. When results for woodlots with embedded and adjacent (within 100 m) houses were combined, they had significantly lower productivity (2.6 fledglings per female) than undeveloped sites (4.0 fledglings per female). Decreased productivity was due to an increase in brood parasitism and nest predation in woodlands affected by development. Near Ottawa, Wood Thrushes in developed woodlands produced fewer fledglings than those nesting in undeveloped woodlots. Parasitism rates increased with development but there were no significant differences in predation rates. Phillips et al. (2005) concluded that the effects of housing developments appear to be region-specific and may depend on other factors influencing the overall abundance of cowbirds and rates of parasitism. Impacts of residential development appeared to be more significant in Waterloo Region, which has less forest cover than the Peterborough and Ottawa areas. Presence or absence of the Wood Thrush in Waterloo Region was estimated in 3 development classes (1-3 houses, 8-15 houses, and more than 25 houses) and 3 forest-size classes (3-4 ha, 8-15 ha, and 20-50 ha). It exhibited the most dramatic response of all species. Over 2 years, it was found in 43-67% of small woodlots with no development, 0-33% of small woodlots with 1-3 houses, 33% of small woodlots with 8-15 houses, and 0% of small woodlots with more than 25 houses. In medium-sized woodlots, it was present in 37-100% of woodlots with no development, 57-83% with 1-3 houses, 33-50% with 8-15 houses, and 0% with more than 25 houses. The same numbers for large forests were 83% with no development, 100% with 1-3 houses, 17-67% with 8-15 houses, and 0-40% with more than 25 houses. Friesen et al. (1995) considered it virtually absent in urban forests in Waterloo Region and concluded that cats and gray squirrels may have been factors. A more recent study in Waterloo Region found that the degree of predation did not differ in urban and rural areas. The probability of predation was unaffected by forest size or percent forest cover, but this may have been because all study woodlots were fairly

small and the regional forest cover was low. Nests in woodlots within areas of higher urban pressure were less likely to be depredated than those in rural areas, possibly because of abundant alternate food sources for predators (Friesen et al. 2013). In Waterloo Region, its historical abundance was almost 3 times greater than 20 years later. The decline was steepest (79%) in woodlots that had experienced housing development within 1 km since the first survey. The decline in woodlots without recent nearby development was 57%. There was no decline in daily nest survival over time with or without development. Urbanization near breeding habitat contributed to a decline in the Wood Thrush (Heidi et al. 2023). In Pennsylvania, there was no difference in nest success rates along an urban to forested gradient. The amount of urban area within the surrounding landscape was not a factor. Highest success rates occurred at suburban sites. At 1 contiguous forest, success was 2 times as high for interior nests than for those along an edge adjacent to a small housing development. This may have been due to increased predation by raccoons along suburban forest edges (Newell and Kostalos 2007). In North Carolina, it declined with density of buildings within 200 m (Lumpkin and Pearson 2013). In a residential area in Delaware, variables that were significant in predicting presence of the Wood Thrush were dense tree canopy, a shrubby understorey, wet soil, and amount of leaf litter. Parameters for having more than 50% chance of providing nesting habitat for it in residential areas included a minimum of 0.08 ha of tree cover, preferably contiguous and with at least 70% canopy closure, under which the natural leaf litter, native shrubs, and moist soil were maintained (Roth 1987).

Activities that remove overhead canopy or result in thinning of shrubs or saplings could be detrimental to the Wood Thrush. Removal of understorey growth is a common practice on cottage lots and this may affect habitat suitability (Stauffer and Best 1980). One factor that may affect the suitability of suburban and urban woodlots is the lack of management. Once development occurs, they are usually preserved with no harvesting of timber or firewood cutting. Over time, these woodlots become more park-like with very limited understorey, thereby making them unsuitable for the Wood Thrush.

The effects of forest management on the Wood Thrush vary considerably, with impacts on shrub density being most important. There appears to be a fine line between having an adequate number of shrubs and too high a density of shrubs. Selective thinning or fuelwood cuts that create small openings in forests are beneficial. More intensive management (diameter cuts, removal of a percentage of merchantable timber, and clear-cuts) may be deleterious. Forests that are retained with no management tend to become very close-canopied with minimal shrubs and become unsuitable. In Waterloo Region, the small woodlots studied by Friesen et al. (1999b) were lightly logged and managed for firewood and maple sugar production. These provided ideal habitat. In the Boreal Forest Region of Ontario, there was no effect on the Wood Thrush when 30% of trees were removed, but it declined when 50% or 70% of trees were removed (Vanderwel et al. 2009). In the Carolinian Forest Region in Ontario, it greatly preferred woodlots that had been thinned to those that were uncut. Heavy treatments, such as diameter-limit cuts, were preferred to woodlots that were thinned using standard techniques (Holmes et al. 2004). In Illinois, Robinson and Robinson (1999) created 0.02-0.04-ha openings within a 2,000-ha forest. This had no effect on the Wood Thrush; it was equally abundant in recently cut areas (1-5 years), older cuts (10-15 years), and in uncut

forest. In Pennsylvania where snags were retained in thinned forests, Wood Thrushes were present; none were recorded where snags were not retained. Woodlands where snags were retained had a more patchy and open canopy and significantly more woody vegetation 0-1.5 m from the ground (Stribling et al. 1990). In New York, Webb et al. (1977) examined the effects of removing 25%, 50%, 75%, and 100% of merchantable timber from woodlands. Populations of Wood Thrushes were significantly lower in the 25%, 75%, and 100% treatments than in uncut areas, but there was no significant difference in abundance in the uncut areas and the 50% cut. Presence of the Wood Thrush was an indicator of undisturbed forest conditions. It was negatively and equally affected by all levels of this type of logging. In Quebec, 10% fewer Wood Thrushes occurred in sugar maple forests affected by dieback than in healthy forests. In the affected woodlots, 78% of trees were affected favouring the development of more abundant regeneration (DesGranges et al. 1987). In Minnesota, it declined in riparian areas when adjacent upland forests were clear-cut, and it also declined when riparian areas were thinned (Hanowski et al. 2005).

Georgia forests that were thinned and burned resulted in adults using managed areas less than those that remained unmanaged (Lang et al. 2002). In Ohio, Artman and Downhower (2003) studied the effects on the Wood Thrush of prescribed burning in mixed oak forests. In unburned areas, there were few differences in vegetation parameters at nest sites compared with random sites. In burned areas, it selected sites with higher leaf litter, lower coverage by bare ground and grasses, higher densities of large shrubs and saplings, and lower density of snags than available at random sites. Nests were higher from the ground and in taller and larger diameter trees and shrubs in burned than unburned areas. In unburned areas, nests were more frequent in intermediate and mesic areas and less frequent in xeric areas than expected. In burned areas, nests were more frequent in mesic areas and where burn intensity was low or moderate. Nest success rates were similar in burned and unburned areas. In both unburned and burned forests, successful nests were higher and in lower density of shrubs and seedlings than failed nests. Successful nests in unburned areas had high coverage by ferns; the opposite was true in burned areas. Successful nests in unburned areas had lower tree and snag densities, with the opposite in burned areas. Low-intensity fires in closed-canopy forest appeared to have no adverse effects.

In New Jersey and Pennsylvania, hemlock declined from 56% of the total basal area to 46% due to the hemlock woolly adelgid; the amount of deciduous understorey increased. The Wood Thrush exhibited one of the most positive associations with hemlock decline, increasing due to the increased deciduous understorey (Toenies et al. 2018).

Overbrowsing by white-tailed deer reduces shrub and sapling density and impairs habitat for nesting Wood Thrushes. In Rondeau Provincial Park, there was limited recruitment of small trees and declines in basal area of species that were sensitive to browsing. Wood Thrush numbers were very low in the park when there were 55 deer per km^2. Following deer control efforts that reduced deer densities to 7 per km^2, thrush numbers increased in response to a modest increase in understorey regeneration (Savignac 2012b). In Delaware, Tymkiw et al. (2013) compared Wood Thrush abundance within areas of low (10 or fewer per km^2), moderate (11-19 per km^2), and high (20 or more per km^2) deer densities. Its abundance was significantly higher in areas of low and high deer

density than in areas of moderate deer density. It was very common in this area may be better adapted to using exotic shrubs than most species.

In Georgia, Crawford (1986) compared the amount of rainfall received in April and May with the number of singing males and found a positive correlation. The amount of spring rainfall could affect abundance of breeding Wood Thrushes. Dry springs could possibly limit opportunities to find mud for nest construction.

DesGranges and Morneau (2010) considered the Wood Thrush sensitive to climate change in Quebec.

Status

The Wood Thrush was formerly a much less common breeding species in Ontario and occupied a smaller range. McIlwraith (1894) knew it only as a migrant in the Hamilton area. Fleming (1907) considered it a rare breeder in the Toronto area, with only 3 records. In Niagara, Sheppard et al. (1936) had no breeding records for the Wood Thrush. It was recorded from the Kingston area dating back to 1858 (Weir 2008). In Elgin County in 1891, it was a fairly abundant summer resident; in 1954, it was a fairly common summer resident that nested mostly in larger woodlands; and in 2000 it was a common but declining breeder (Lancaster et al. 2004). Baillie and Harrington (1937) considered it a common breeder only in the extreme southwestern portion of the province. Elsewhere, it was found in small numbers from Lakes Erie and Ontario north to Parry Sound District and Ottawa. There were records of it from Sault Ste. Marie, Lake Nipissing, Nipissing District, and Manitoulin Island. MacLulich (1938) stated that it was an uncommon summer resident in Algonquin Park, where it was near the northern extent of its range. It was regular and moderately common in the Hamilton area in the 1930s and 1940s and is now a ubiquitous breeder (Curry 2006). A major range expansion of the Wood Thrush in Ontario started in the 1950s (M.L. Evans et al. 2020). During the first atlas, its breeding range was further north than indicated by Godfrey (1986). It occurred in almost every square north to approximately Lake Nipissing; the most northerly record was from near Kapuskasing (Sadler in Cadman et al. 1987). James (1991) considered the Wood Thrush a common summer resident north to about Georgian Bay and Ottawa, becoming rare north to Sault Ste. Marie and Sudbury. There were records north to Rainy River, Thunder Bay, Wawa, and Cochrane.

The second atlas revealed that there had been no significant change in the distribution of the Wood Thrush since the first atlas. It was found in virtually every square south of the Canadian Shield, including large urban areas such as Toronto and Ottawa. It continued to be widespread in the Shield north to the Lake Nipissing area, with another pocket of abundance around Sault Ste. Marie. It occurred north to New Liskeard and along the northern shoreline of Georgian Bay and eastern Lake Superior to Wawa. A small isolated population was present near Lake of the Woods. Its probability of observation did not change significantly since the first atlas. A significant decline occurred in the southern Shield that may have been due to the effects of acid precipitation or forest maturation. It was most abundant south of the Shield, although there were pockets of high abundance in the southern portion of the Shield. A large area of eastern Ontario was struck by a severe ice storm in 1998. This devastated many forests that are now regenerating. This region had the most extensive area of high-density Wood Thrush populations in the province (Friesen in Cadman et al. 2007).

From 1989 to 2014, Wood Thrush frequency of occurrence in the Canadian Shield of Ontario was high and stable. It occurred in 72.3% and 75.5% of forest fragments during the 2 sampling periods. Local extinction rates were 21.2% in the Shield and 2.5% south of the Shield. The probability of continuous detection increased with the amount of forest within an atlas square in the Shield, but this trend was much weaker south of the Shield. The probability of continuous detection increased with forest cover within 1 km. It was almost 2 times as abundant south of the Shield as in the Shield. It decreased at annual rates of 1.75% south of the Shield and 3.75% in the Shield (Torrenta et al. 2022).

BBS results indicate that the Wood Thrush decreased at annual rates of 2.69% in Canada and 2.33% in Ontario 1970-2021. The trends 2011-21 were annual decreases of 0.353% in Canada and 0.45% in Ontario. The long-term trends were highly reliable; the short-term trends were of medium reliability (A.C. Smith et al. 2023).

The Wood Thrush has been designated threatened nationally and special concern provincially.

POSTFLEDGING PERIOD

Fledglings may be fed by adults until they are 25-32 days old, but may start feeding themselves at age 17-20 days. For first nests, the brood remains together and individual young are fed by both parents. The second brood is often split with each adult caring for half the brood. In 1 case where there were only 2 fledglings, the male left and the female raised the young. In 1 case where there was only 1 fledgling, the female left. Young are usually independent when they are 31-32 days old, although some are independent as early as 21-28 days (M.L. Evans et al. 2020).

In Missouri, juveniles dispersed 3 weeks after fledging. They moved from forest-interior natal territories into areas of denser vegetation, such as mature wooded riparian habitat, young deciduous and pine forests (clear-cuts), and forest-field edges. Two different movement types were used by family groups prior to dispersal. Five of 7 broods had stationary home ranges centred around the nest site and 2 broods had drifting home ranges where adults and young moved progressively further from the nest. Mean brood home range was 4.46 ha for stationary home ranges and 19.5 ha for drifting home ranges, with an overall range of 2.6-24.8 ha. Siblings remained together until dispersal and moved separately from their natal areas. Mean dispersal distance was 2.08 km (range 0.21-4.65 km). Juveniles took an average of 4 days (range 1-9 days) to move to the post-dispersal home range. Habitats used by juveniles after dispersal were early successional oak-hickory or pine forests resulting from clear-cutting, with dense stands of saplings and shrubs; mid-successional pine forests with dense patches of oak, hickory, and sassafras in the understorey with continuous shrub coverage; high-graded oak-hickory forest with large, open patches supporting dense growth of understorey; mature riparian sycamore and black walnut forest with continuous ground cover; abrupt forest–old field and forest-pasture edges with dense canopy, understorey, and ground cover where juveniles were always under forest cover; and mature oak-hickory forests where juveniles selected dense stands of 3-4-m tall understorey trees along drainage courses or dense patches of ground cover 0.5-2 m high. Each juvenile settled into one of these habitats. Its post-dispersal home range occurred entirely within that habitat with areas of denser undergrowth or shrub and sapling coverage selected more than their availability. Mean dispersal home range size was 1.53 ha. Two juveniles moved to second post-dispersal areas and had home ranges of 0.21 and

0.26 ha. Post-dispersal home ranges were occupied for 4-30 days. In all habitats, juveniles remained on or near the ground within dense vegetation. Dense cover provides protection from predators and abundant food in the form of insects and raspberries (Anders et al. 1997, 1998). In Virginia, fledglings 12-15 days old were able to climb shrubs but were incapable of sustained flight. During this time, they perched quietly 1-5 m above ground. The distance the brood and adults moved from the nest after fledging and before independence varied depending upon whether parents remained in the nesting area to moult (104 m) or moved elsewhere (332 m). After independence, most fledglings dispersed 1.5 km from natal sites and joined flocks of conspecifics. Young either remained at the distant site or moved further away (Vega Rivera et al. 2000). In Georgia, the average pre-dispersal movements of fledglings were 131, 208, and 117 m over 3 years. Juvenile dispersal occurred between 3 and 4 weeks after fledging, although 1 fledgling did not disperse in each of the 3 years. The average dispersal distance for juveniles was 2,189 m; probabilities of dispersing different distances were 35% for 0-1 km, 30% for 1-2 km, and 20% for 4-5 km. After dispersal, most fledglings remained within 172, 360, and 390 m of their initial dispersal locations, but 3 juveniles made a second long-distance movement of about 5 km 18-20 days after dispersal. The longest distance travelled by a juvenile was 6,524 m; the average daily distance travelled was 140 m. No second-year birds were recaptured in their juvenile dispersal areas. Juveniles preferred a moderate overstorey taller than 2 m in 11-30% coverage, and avoided sparse (0-10%) overstorey. Of the 3 most common midstorey trees and shrubs, juveniles used areas with dogwoods more frequently than expected. Juveniles dispersed in random directions and not to a juvenile grouping site (Lang et al. 2002).

In Norfolk County, 93 of 119 juvenile Wood Thrushes (78.2%) made premigratory flights greater than 5 km. Ninety percent of movements were at night. The age of first detection more than 5 km from the natal woodlot varied. Birds that fledged in June were first detected distant from the natal woodlots 24-93 days postfledging. Later-fledging birds tended to disperse at a younger age postfledging and there was less variation in the timing. The average maximum distance juveniles were detected from the natal woodlot was 21.8 km, with 21 of 93 (22.6%) detected more than 30 km away. One moved 85 km from the natal site but returned prior to autumn migration. The direction of movements was random and not small-scale migration movements which would be southerly in orientation. Most premigratory dispersal occurred during the 2 weeks before departure on autumn migration (Hayes et al. 2024).

In Ohio, both juvenile and adult Wood Thrushes were frequently caught in regenerating clear-cuts during the postfledging period. Capture rates were more than 6 times as high in nets 4.5 m from the ground than those 2.5 m up. It was the sixth-most abundant forest-breeding bird captured in clear-cuts. Capture rates were 2.5 times higher in small (4-9 ha) than large (13-18 ha) clear-cuts. Capture rates in differently sized clear-cuts were significantly different for juveniles but not for adults. There were no differences in habitat characteristics, vegetation density, arthropod abundance, or fruit abundance between small and large clear-cuts. Birds were more abundant 50 m or more from the edge of clear-cuts than closer to adjacent forest habitat. There were no differences in habitat associated with distance from edge; birds may avoid edges if predators are concentrated along them (Vitz and Rodewald 2006, 2007).

In Minnesota, Streby et al. (2011b) captured no Wood Thrushes in regenerating clear-cuts during the breeding season, but caught 10 adults and 2 fledglings during the postbreeding season. In Virginia and West Virginia, Marshall et al. (2003) captured adults, juveniles, and a family group in regenerating clear-cuts. It was one of the most abundant forest-breeding species captured in clear-cuts. During the postfledging period in Pennsylvania, Stoleson (2013) captured 5 adults and 10 fledglings in clear-cuts compared with 4 adults and 0 fledgling in mature, closed-canopy forests with a dense understorey. Its capture rate was significantly higher in clear-cuts than in forests. Shrub density was not significantly different between clear-cuts and forests, but birds captured in clear-cuts were in significantly better condition. Clear-cuts supported high densities of fruit-bearing shrubs that may have provided a superior food source. In Missouri, Porneluzi et al. (2014) netted birds during the postfledging period in an oak-pine-hickory forest 2-15 years after it was clear-cut. The Wood Thrush exhibited a nonsignificant trend of gradually increasing to a peak about 6-9 years after harvest followed by a gradual decline.

In Georgia, adult males used all forest overstorey types available during the fledgling stage, but were most often present in sparse or moderately dense vegetation (Lang et al. 2002). In Virginia, males may move long distances (300, 400, and 855 m) from the nesting area with the brood and then either return to the nesting area or immature deciduous woods to moult (Vega Rivera et al. 2000). Of 30 birds in Virginia that remained to moult, 11 moulted where they nested and 19 moulted in different areas. Of birds that moved, 4 males used deciduous sapling stands near their territory and 15 (4 females, 11 males) used moulting sites an average of 2,015 m from their nesting territories (range 545-7,291 m). The moult began 1-4 days after young reached independence and lasted an average of 52.0 days (53.2 days for males and 49.2 days for females). Birds could barely fly for 10 days. During the moult, birds hid on the ground in the densest available vegetation, frequently among branches of fallen trees. Once the moult started, birds moved less (67 m compared with 114 m) and had smaller (1.4 ha compared with 2.6 ha) home ranges than during nesting. After moulting, most adults maintained similar movement patterns and remained in the moulting area. Others had different movement patterns: 1 moved 500 m to a site not visited before, remained there for 2 days, then returned to the nesting territory; 2 moved 4.4 km and 500 m back to their nesting areas and then left the study area; and 4 males that moulted in sapling stands adjacent to their territory moved back into the forest prior to autumn migration departure. None of the birds that returned to their nesting area exhibited any territoriality. These birds restricted their activities to sites characterized by the presence of at least 1 tree species with ripe fruit (black gum, flowering dogwood, and sassafras). The density of woody stems, understorey vegetation, and saplings was much higher in moulting areas than in nesting areas and provided cover from predators when birds' flight abilities were impaired. Large forested areas with a mix of forest types and ages may provide nesting and moulting habitat. Fragmented landscapes may provide nesting habitat but not moulting habitat. The time available for nesting is constrained by the requirement to moult prior to migration (Vega Rivera et al. 1998, 1999). In New York, 18 of 46 birds (39.1%) moulted on their breeding territory, 15 (32.6%) moulted off territory within the study area, and 13 (28.3%) moved more than 1 km from the study area. Moulting habitat differed significantly from nesting habitat by having a low percent canopy cover, more shrubs shorter than 60 cm, and more fruiting trees. Females were more likely to moult off territory than males and first-year breeders tended to moult off territory more than older

birds (86% compared with 52%), but these differences were not significant (Gow and Stutchbury 2013a).

Vitz and Rodewald (2012) examined the diet of several Wood Thrushes in 6-10-year-old clear-cuts in Ohio. There was no evidence that they had switched from a diet consisting of arthropods to one dominated by fruit.

In Indiana, Vernasco et al. (2018) examined the effects of cowbird parasitism, drought, amount of forest cover, understorey vegetation density, and nestling condition on postfledging survival of the Wood Thrush. Brood parasitism and nestling condition were not strongly linked to fledgling survival. Decreases in survival occurred during a year of drought and were most pronounced in fledglings 0-3 days out of the nest. During drought years, birds in areas with lower forest cover exhibited the steepest decline in survival. Fledglings of the same age in more forested habitats had similar survival rates in drought and non-drought years. In non-drought years, survival declined as the amount of forest cover increased, possibly because growth rates are higher closer to forest edge. Nestlings were in significantly poorer condition in parasitized nests and in drought years but were unaffected by vegetation parameters. Nest vegetation structure and parasitism had little effect on fledgling survival but forest cover and breeding season precipitation interacted to affect fledglings.

The breeding and postbreeding habitat requirements of the Wood Thrush are complex. Due to local extinctions and recolonizations, woodlots may support breeders some years but not in others. Although most pairs remain in the same woodland to raise their second brood, others may move several kilometres between successive nests within a breeding season. These within-season movements may occur in large, contiguous forests as well as in small fragments. Once they are independent, fledglings move to areas with dense understorey vegetation, often where there is limited overhead canopy. Many of these habitats would not support breeding pairs of Wood Thrushes, but are essential to fledglings. Adults also move to areas of thick cover during the moult. Many smaller forest fragments may not provide all the essential habitats for Wood Thrushes throughout the breeding season. They may still contribute young to the metapopulation or provide habitat for fledglings or moulting adults even if they are not used for breeding.

MIGRATION

The Wood Thrush migrates at night, except at the end of trans-Gulf flights (M.L. Evans et al. 2020). Early in the season, males arrive on the breeding grounds 2-3 days before females. Later in spring, arrivals of both sexes overlap (Dilger 1956; M.L. Evans et al. 2020; Weaver in Bent 1949). Most birds arrive in early May in southern Ontario with most on territories by mid-May; migrants may occur as early as mid-April. In the southern Shield, most arrive in mid-May and start moving south in August with migration continuing until early September and late birds persisting until the end of September. Autumn migrants may occur in the south as early as mid-July and move through in low numbers until early October (Black and Roy 2010; Curry 2006; LaForest 1993; Mills 1981; Tozer 2012; Weir 2008). In Norfolk County, the average departure date for juveniles was 19 September (range 25 August to 15 October). Juveniles that fledged by 22 June departed on autumn migration 9 days earlier than those that fledged later (Hayes et al. 2023).

During migration, the Wood Thrush may occur in both forested and shrubby habitat. In Pennsylvania, it was captured significantly more often in shrub than forested habitat during spring migration. Invertebrate biomass was higher in shrub habitats than in forest (Smith and Hatch 2008). During autumn in Pennsylvania, its highest abundance was in forest-agricultural edge habitat, where it was significantly more abundant than all other habitats except suburban forest. Abundance in shrub-sapling-stage forest was greater than in pole-stage forest, but the differences between these habitats as well as suburban forests were not significant. No Wood Thrushes were encountered in forest interior (Rodewald and Brittingham 2004). In Minnesota and Wisconsin during spring migration, it was detected in upland forests but not in floodplain forests (Kirsch et al. 2013).

The Wood Thrush is vulnerable to striking windows and tall towers and buildings during migration but may be less vulnerable than many migrants. Sixteen were killed at the Lennox generating station near Kingston. In Illinois, it represented 0.5% of birds killed at towers in autumn (Graber et al. 1971; M.L. Evans et al. 2020; Weir 2008). In the United States it was much more vulnerable to striking residences than average. It was 41.0 times more likely to strike residences 1-3 stories tall than the average for all birds (Loss et al. 2014).

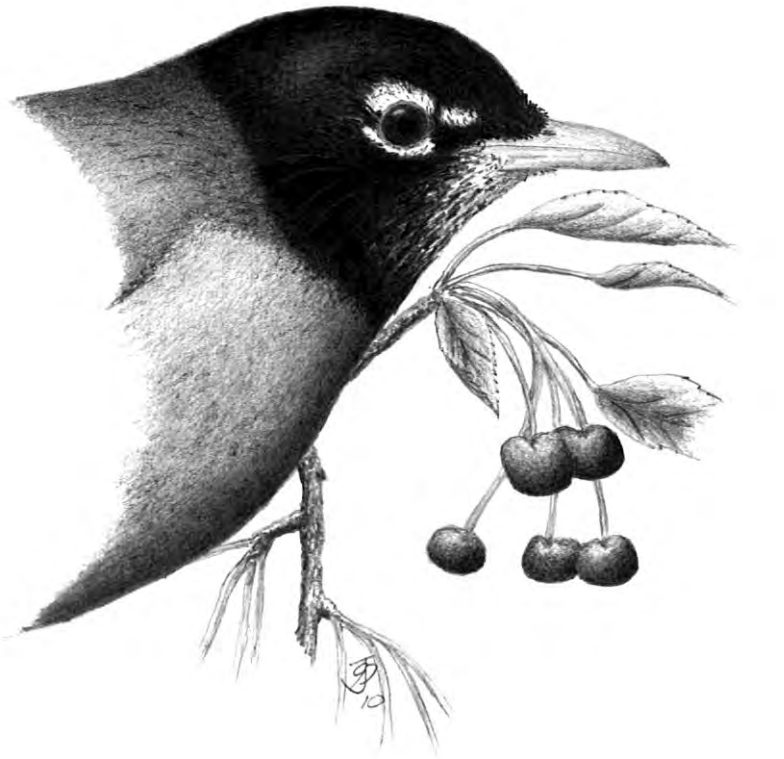
In New York, Zelt et al. (2017) compared spring arrival dates, autumn departure dates, and length of the breeding season for 1888-1939 and 1967-2012. There was little climate change during the first period but significant warming during the second period. The Wood Thrush departed significantly later in autumn during the second period, but there were no significant differences in its spring arrival dates or length of the breeding season. In Concord, Massachusetts, it arrived later in warm years, averaging 1.3 days later for each 1°C increase in temperature (Ellwood et al. 2010).

The Wood Thrush is a common migrant in Ontario (James 1991), although it is an uncommon migrant in Elgin County (Lancaster et al. 2004). Although it is common during migration, large numbers seldom occur.

Hussell et al. (1992) noted a significant decline of migrating Wood Thrushes of 6.0% 1966-88 at Long Point Bird Observatory. Rates of change during different periods were: 1961-70, −9.4%; 1970-70, −0.6%; and 1978-88, −15.0%.

American Robin

Turdus migratorius

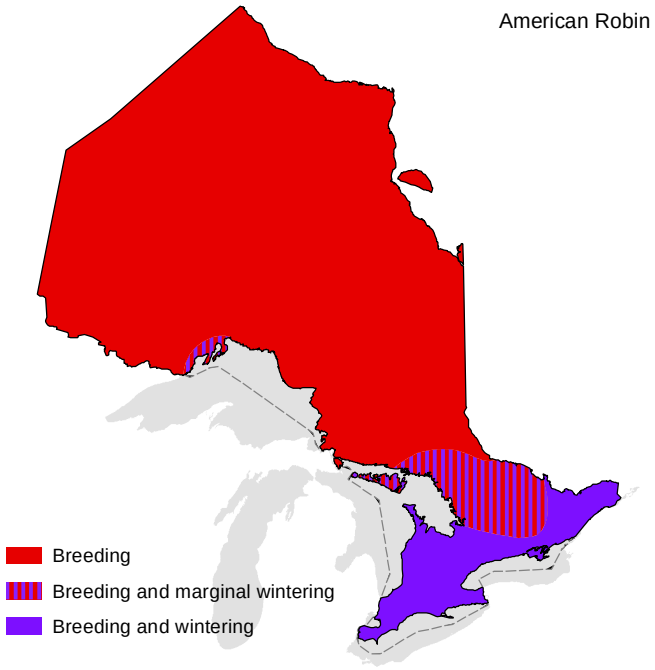


BREEDING SEASON

Habitat Requirements

In Ontario, American Robin nests have been found in urban, rural, and wilderness areas. Habitats where nests have been found include residential gardens, buildings, and tree-lined streets (38% of nests); open areas, including farm fields and orchards, roadsides, campgrounds, and mine buildings (35.1%); woodlands and swamps (25.1%); and bogs, marshes, and beaver ponds (1.8%). Coniferous forests were preferred for nesting and supported 50.2% of nests compared with 22.8% for deciduous woods, 21.4% for mixed stands, and 5.6% for treed swamps. It greatly preferred dry sites for nesting (90.0% of nests) over wet sites (Peck and James 1987).

In the Hudson Bay Lowland, Wilson and McRae (1993) recorded the robin at all forested sites they examined, but it was most abundant in and near Moosonee. Along the west James Bay coast and the southern Hudson Bay coast, it nested inland along forest edges in drier locations and was particularly plentiful around settlements. It also nested in willow thickets along the Moose River (Manning 1952).



In the Ontario portion of the Clay Belt, the robin occurred in all forest types except for a few black spruce–jack pine, jack pine, and trembling aspen stands (Welsh and Lougheed 1996). In Quetico Park, it was most abundant in early successional forests (1-23 years old), occurred at lower density in mature stands, and was not recorded in intermediate-aged or old-growth stands (Apfelbaum and Haney 1985).

In the Great Lakes–St. Lawrence Forest Region in the Canadian Shield, the robin nests in mature and old-growth white pine stands (Kirk et al. 2012). Near Gogama, it was rare in areas forested with jack pine and absent in older pine and mixed stands except at edges. It was most abundant in young plantations where there was open ground suitable for foraging (James and Peck 1995a). It was present in most open jack pine stands mixed with deciduous cover in Parry Sound District (James 1979a). In Algonquin Park, it was common near settlements and scarce in contiguous mature forest (MacLulich 1938). In Algonquin Park, Martin (1960) found it in most forest types but it was most abundant in edge habitat. In Muskoka District and Haliburton County, singing posts were in areas of low canopy volume, low tree density, and low amounts of understorey. It was associated with lawns. Its ability to nest on buildings and ledges and its preference for foraging in the open allowed it to be successful where most natural vegetation had been removed (Clark et al. 1983).

Near Kingston, upland white cedar stands provided quality breeding habitat (McLeish and Robertson 1997). Tozer (2002b) reported a robin nesting in a large cattail marsh associated with the Beaver River in Durham Region. It occurred in all habitats sampled by Speirs and Orenstein (1975) in Durham Region and did not show any special affinity for conifers or any particular level of succession.

In southern Ontario, the robin was more abundant on conventional than organic farms. It was positively associated with hedgerows, pasture, amount of riparian and upland woods, and row crops. It was significantly negatively associated with grassy strips between fields that often included a fence (Kirk et al. 2011).

The American Robin is the most widespread thrush in Canada and North America, breeding throughout except for a few areas north of the treeline and in the extreme south. It may be found in almost every habitat type. It is most frequent in urban and suburban areas, rural residential areas, and where there are wooded areas suitable for a nest site adjacent to open areas that provide foraging habitat. The most commonly used type of these habitats is small, isolated woodlots in agricultural settings but natural or anthropogenic openings in forests may be used including clear-cuts and burns. It may nest in any forest type, but prefers deciduous and mixed stands to pure

coniferous stands. Densities are considerably lower in large contiguous forests than in isolated stands in fragmented landscapes. It may nest in riparian and upland forests and treed swamps and, less frequently, in thicket swamps, but tends to be more common in upland habitats. Nesting may occur in old fields regenerating with trees and shrubs, hedgerows, plantations, Christmas tree farms, oak savannahs, pine and oak barrens, orchards, lightly grazed pastures, and alpine meadows. Other habitats it may nest in occasionally include marshes dominated by cattails or common reed, fens, bogs, and on low cliffs in treeless areas. Active agricultural land may not be used for nesting, but adjacent hedgerows and woodlots frequently are and the open fields may be important foraging habitat. In the Yukon, its abundance was positively correlated with density of trees and shrubs (Back 1979; Beals 1960; Bielefeldt and Rosenfield 1994; Bock and Lynch 1970; Campbell et al. 1997; Capen 1979; Crawford and Titterington 1979; Crozier and Niemi 2003; Dawson 1979; Erskine 1977; Gentry et al. 2006; Golet et al. 2001; Graber and Graber 1963; Graber et al. 1971; Grundel and Pavlovic 2007a; Hoffman 1989a, 1989b; Howell 1942; Hudson 1994; Hughes and Hudson 1997; Inman et al. 2002; Noon et al. 1979; Mossman 1988; Mossman and Hoffman 1989; Mossman et al. 1991; Rotenberry and Wiens 1980; Rumble and Gobeille 1998; Samson 1979; Shirley 2005; Sinclair et al. 2003; Suthers 1988; Tardif and Lanoue in Gauthier and Aubry 1996; Taylor and Taylor 1979; Temple et al. 1979; Turner 2013; Tyler in Bent 1949; Walk et al. 2011; Wood et al. 2013).

The robin is most abundant in cities, suburban areas, towns and villages, and rural residential areas. In southern Illinois, 80% of the population nested in towns and cities compared with 60-70% in the northern portion of the state. Overall, 75% of the population was associated with residential areas and farmyards (Graber and Graber 1963; Graber et al. 1971). In urbanizing areas of Washington State, it was most abundant in forested neighbourhoods and forest patches where squirrels were uncommon. It avoided areas within forest patches where a single predator was abundant or where there were several species of predators (Marzluff et al. 2007). In suburban areas of Massachusetts, its abundance was correlated with the amount of coniferous tree volume in the 1.5-6.1-m height range and the amount of deciduous volume 3.4-6.1 m from the ground. The number of gardens and distance to the nearest fallow field were significant predictors and were probably related to suitable foraging sites (Thomas et al. 1977). In 2 Nevada cities, nest success was positively correlated with the amount of canopy cover within 20 m of the nest (Becker and Weisberg 2015).

The American Robin is an edge species that forages mostly in open habitats. Some authors considered it an obligate edge species, but it also occurs in forest interior and in contiguous forest at much lower densities. In Wisconsin, 75.9% of nests were at the edge of white cedar plantings, and a tree directly on the edge was frequently selected for nesting. In West Virginia forests, nests tended to average less than 2.8 m from edge, including roads and skid trails. Nesting close to edge separated the robin from all other thrushes except the Hermit Thrush. Robin nests had fewer than 2-5 medium-sized trees around nest sites; the Hermit Thrush had more. In California, the robin was more common in open burns than adjacent unburned forest. It nested in residual trees in the burn or the edge of forest and foraged in the burn. Despite a preference for edge, its abundance was negatively correlated with the complexity of the shape of the habitat patch (Bock and Lynch 1970; Campbell et al. 1997; Crozier and Niemi 2003; Dellinger et al. 2007; Suthers 1988; Young 1955). Erskine (1977) considered the robin one of the most common species along edges in the Boreal Forest Region.

The robin is more common in fragmented landscapes than contiguous woodlands. In southern Ontario, its probability of detection was significantly negatively correlated with woodlot size, amount of forest within 2 km, and regional amount of forest. It was also negatively correlated with the amount of forest habitat 100 m or more from edge but not significantly (Austen et al. 2001). In Vermont, it was significantly more abundant in Christmas tree farms surrounded by agriculture than those encompassed by forest (Hughes and Hudson 1997). In Saskatchewan, it was more common in small forest fragments and areas with a low percentage of forest cover (Hobson and Bayne 2000). In Quebec boreal forest, its abundance was significantly correlated with poorly forested landscapes (Drolet et al. 1999). In Newfoundland, its presence was not correlated with the amount of forest within 2.5 km, but was negatively associated with the amount of forest and shrub areas within 150 m (Taylor and Krawchuk 2006). In Pennsylvania, there were no correlations between robin abundance and the amount of fragmentation or patch size (Keller and Yahner 2007).

In North Dakota in 400-m landscapes with less than 30% tree cover, the robin increased with increasing tree cover within 100 m. The response in wooded landscapes was somewhat similar but much weaker (Cunningham and Johnson 2016). It preferred areas with 52-75% forest cover in North Dakota and 44-92% in New York. In North Dakota, there were no areas with more than 75% tree cover (Cunningham and Johnson 2019).

Virtually all studies concur that the robin prefers small to large forests. In North Dakota aspen stands, its probability of observation was approximately 35% in 1-ha woodlots and almost zero in 1,000-ha woodlands (Grant and Berkey 1999). In Maryland and Delaware, it was more likely to occur in narrow riparian forests than wide ones. Its probability of detection was 83% in 50-m wide forests, 79% in 100-m wide, 70% in 200-m wide, 59% in 300-m wide, and 11% in 800-m wide forests (Keller et al. 1993). In the mid-Atlantic states, its probabilities of detection were 78% in 0.3-ha woodlots, 50% in 10-ha woodlots, 35% in 100-ha woodlands, and 20% in 3,200-ha woodlands (Robbins et al. 1989). Blake and Karr (1987) reported that the abundance of the robin was negatively correlated with forest size.

Most authors reported that the robin is more likely to be found in young than old stands, but some (Morgan and Freedman 1986; Rumble and Gobeille 1988; Speirs and Orenstein 1975) reported it equally common in all age classes; Temple et al. (1979) considered it a late-successional species in mixed-wood forests. Erskine (1977) considered the robin associated with young stands in the Boreal Forest Region. Crawford and Titterington (1979) reported that it was common in young upland spruce-fir stands in the northeast, but sparse in mature forests. In western boreal areas, it was absent in stands younger than 10 years and in mature stands, common in stands 15-20 years old, and uncommon in older-growth forests. It was associated with younger than older stands (Kirk et al. 1996). In Newfoundland and Wisconsin it was associated with young clear-cuts (Hoffman 1989b; Taylor and Krawchuk 2006). In Pennsylvania, its presence was negatively correlated with old-growth forest. It occurred in 36.4% of old-growth forests compared with 99.1% of forests statewide and 98.7% of forests in the Appalachian Plateau (Haney 1999). In New Jersey old fields, Suthers (1988) found it in equal numbers in fields aged 10, 20, and 40 years. In New York, Brooks and Bonter (2010) surveyed a regenerating field, forest, and Christmas tree plantation over a 35-year period. Over this

time, the number of robins declined significantly in the regenerating area but did not change in forest. Numbers increased in the plantation where the trees were allowed to grow taller.

In New York, water was usually present in robins' territories (Dellinger et al. 2007; Howell 1942) and in many British Columbia habitats it tends to nest near streams, marshes, or ponds (Campbell et al. 1997). In Rhode Island, McKinney and Paton (2009) studied birds associated with small (less than 0.1 ha) seasonal pools that dried up in summer. The robin was 1 of 3 species detected most often. It was more abundant at urban seasonal pools suggesting that it may take advantage of the available resources in the absence of competition from non-tolerant species. Seasonal pools were surrounded by denser shrub coverage, possibly providing enhanced food resources and shelter. Presence of water is important to the robin due to its need for mud to construct the nest.

A number of microhabitat requirements have been identified for the robin. In Indiana savannahs, it was most abundant in areas with a high proportion of low ground cover and a low proportion of high ground cover. Increased fire frequency increased the density of vermivores, with the robin dominating this guild (Grundel and Pavlovic 2007a, 2007b). In northern mixed forests, it increased with increasing abundance of sugar maple and yellow birch (Temple et al. 1979). In the northeast, it was associated with a low density of trees and saplings and a high density of shrubs (Niemi and Pfannmuller 1979). In western boreal forests, it preferred open areas. It was associated with slightly drier than average stands with a low nutrient status (Kirk et al. 1996). In the mid-Atlantic states, its abundance was positively correlated with percent canopy closure but negatively associated with the number of trees and percent canopy coverage by conifers (Robbins et al. 1989). In Wyoming, its abundance was negatively associated with shrub density indicating an affinity for a more open understorey (Finch 1991a).

In balsam fir stands in the Boreal Forest Region of Quebec, the robin was observed almost exclusively in riparian areas near water (LaRue et al. 1995). It was ubiquitous in balsam fir–white cedar stands in Newfoundland, occurring in both riparian and non-riparian stands (Whitaker and Montevecchi 1997, 1999). In British Columbia coniferous stands, it was associated with riparian habitat during winter and spring and autumn migration, but it was not significantly associated with riparian stands during the breeding season (Wiebe and Martin 1998).

Communal nocturnal roosts are used by the robin year-round and are frequently shared with European Starlings and Common Grackles. Less frequently, it roosts with Brown-headed Cowbirds, Red-winged Blackbirds, Eastern Kingbirds, Baltimore Orioles, Cedar Waxwings, and Brown Thrashers. Adult males roost together during the breeding season and adult females join them once nesting is complete. Juveniles of both sexes join a roost as soon as they are capable of flying, and all birds roost communally during winter. During spring and early summer, small roosts near the breeding territory are used, but robins move to more protective habitat (from lawns to forests) in preparation for the moult in August and September. It selects roosts primarily for their proximity to a good food source, especially once the diet becomes dominated by fruit. Breeding-season roosts in Massachusetts were typically in low-lying swampy woods. Most roosts are in deciduous trees, but it has roosted in pines and white cedar. Night-roosting has been reported from a hayfield dominated by bluestem in Kansas. In 1 case, 400-500 roosted in lilacs near a house. In New York, the mean distance of breeding-season roosts from the centre of the daily activity centre was 0.48 km. The

mean distance moved between sightings on consecutive days was 0.36 km. Four of 7 robins moved their daily activity centres 7-9 km at the end of the breeding season and also switched roosts. Roosts were switched 12.3% of the time, but only 4 of 56 birds (7.1%) moved more than 2 km. Roosts may contain as many as 250,000 robins but 20-200 birds is more typical. Large roosts may be used year after year. In winter, nocturnal roosts provide both foraging and antipredator benefits. During winter, flocks of roosting birds may break up in the day and fan out over an area of more than 1,100 km², then gather again to roost in trees (Applegate 2001; Dunn and Tessaglia-Hymes 1999; Graber et al. 1971; Hirth et al. 1969; Howell 1942; Morrison and Caccamise 1990; Pitts 1984; Tyler in Bent 1949; Vanderhoff et al. 2020). Common (1947) reported a male that roosted singly in an apple tree near the nest.

Ontario nests were in trees, shrubs, and vines, and on stumps, fallen trees, and roots (78.8% of nests); on or in buildings and other human-made structures (21.0%); on cliff or quarry ledges (0.1%); and on the ground (0.1%). Of nests in trees, 70.7% were in crotches and 29.3% were on horizontal branches 0.2-6 m from the trunk, with most 0.9-2 m from the trunk. There was a tendency for nests to be near the midpoint of the nest tree. Nests were placed equally often in deciduous and coniferous trees. Tree species used most often were spruce (338 nests), white cedar (234), hawthorn (217), pine (182), maple (182), and apple (123). Four nests were in tree cavities. Most tree nests were over ground, but some were over water. Heights of nests ranged from 0 to 21 m, with most 1.4-3 m up. Some nests were reused, and old nests of Eastern Phoebe, Barn Swallow, Blue Jay, Gray Catbird, and Common Grackle were used (Peck and James 1987). Savard and Falls (1981) examined nest-site selection of robins in Toronto. Nests were found in more than 30 species of trees. Of 171 nests, 105 were in deciduous trees, 57 in conifers, and 9 on human-made structures. Norway maple was the most common deciduous species used and blue spruce was the most common conifer used which was probably a reflection of the abundance of these trees. In May, 63% of nests were in conifers compared with 15% in June and 4% in July. Nests were at heights of 1.52-13.41 m (average 5.00 m). Nest height was similar to that reported from other urban areas, but higher than in non-urban areas, probably due to the scarcity of low vegetation in urban areas. Most nests were in the layer of foliage just below the layer with the largest volume. Average nest height was significantly lower in conifers (3.82 m) than in deciduous species (5.57 m). Taylor (1959) reported a nest in a tree cavity in Toronto. In Muskoka and Parry Sound districts, nests were in dead and alive trees, on stumps, and on buildings at heights of 0.15-15 m (Mills 1981). Dance (2008) reported 2 Ontario nests in black alder. Woodliffe (1996) found a nest on the ground at the base of a black oak tree at Rondeau. At that time, only 3 of 6,358 nests (0.05%) reported to the Ontario Nest Records Scheme were on the ground. Tozer (2002b) reported a nest in a cattail marsh in Durham Region.

Nest-site selection by the robin is variable. Most nests are in trees or shrubs, but it may nest on a wide variety of human-made structures. Almost any species of tree or shrub may be used for nesting. Individual birds may have successive nests that are in different species and at different heights. In some areas, it has shown a preference for particular tree species, but often tree species are used in proportion to their availability. In Minnesota shelterbelts, spruce was selected over maple and ash. In Maine, 62% of nests were in conifers although they represented only 45% of available trees. In Christmas tree farms in Vermont, 4 times as many nests were in spruce than fir trees. In

Manitoba, about half of nests were in Manitoba maple but it was 25% of available trees. Peach-leaved and sandbar willow were 55% of available trees but supported only 25% of nests. In Nevada, trembling aspen was used less than expected for nesting and pine was used more than expected. In Colorado, spruce was preferred and cottonwood was avoided. In Iowa riparian habitat, all nests were in deciduous trees and none were in conifers, saplings, or shrubs. In most areas, coniferous trees are selected early in the spring but deciduous species are used predominantly later on. In Nevada, there was no seasonal change in usage of deciduous and coniferous trees. Most nests are near the centre of the tree at 50-60% of the tree height. Nests in trees are usually in a fork or on a horizontal branch. Half or more are at the trunk and the remainder are distant from the trunk. In Colorado Springs, 345 of more than 500 nests were on tree branches overhanging streets, alleys, and driveways; 107 were on branches over sidewalks; and 54 were in vertical forks. For nests overhanging streets and sidewalks, the lower branch was usually selected, 4.6-7.2 m from the ground. Nests have been reported on the ground to a height of 24 m, but most are 2-4 m up. In Illinois, rural nests averaged 2.1 m in height compared with 3 m in urban areas; Vancouver nests averaged 3.8 m from the ground, higher than the provincial average. Ground nests are rare even where trees are almost absent. Nests in wooded areas tend to be within 5 m of an opening or edge and are frequently near water, even if it is a temporary source such as a puddle. Most studies found that nest orientation is random, but nests in Minnesota and Nevada faced between south and east, presumably to take advantage of the morning sun. The Cornell Nest Record Scheme revealed that only 1 of 16,000 nests was in common reed. Ten nests in a marsh in Boston were supported by common reed and were 0.9-1.8 m from the ground. Other unusual nesting locations include under plants in a garden; at the base of trees, shrubs, or logs; on exposed roots at road cuts; on leaves on the ground with no evidence of a nest; in a knothole in a tree; in old woodpecker cavities where the top or side had broken off; within a split in a stump; on top of nests of Baltimore Oriole, Northern House Wren, Red-winged Blackbird, Western Kingbird, Gray Catbird, and hornets; on a slight shelf on the bare trunk of a maple tree; in crevices of rock walls and caves; on fallen trees leaning against other trees; and on witch's-brooms (Brackbill 1947a, 1950a; Campbell et al. 1997; Common 1947; Graber et al. 1971; Howe 1898; Howell 1942; Hoyt 1948; Hudson 1994; Hughes and Hudson 1997; Klimstra and Stieglitz 1957; Knupp et al. 1977; MacKenzie et al. 1982; Mousley 1916a; Stauffer and Best 1980; Tyler in Bent 1949; Vanderhoff et al. 2020; Warkentin et al. 2003b; Webb 1946; Weber 1975; Yahner 1983; Young 1955). The robin may nest on or in buildings anywhere there is a flat surface to support the nest. It has nested on arms of utility poles, on top of bird nest boxes, in the hub of a wagon, in a smoke pipe, on a railway tank car that was occasionally moved, on fence rails and posts, on a chandelier at the entrance to a library, at the intersection of 3 cables of a trolley line with trolleys passing every few minutes a few centimeters below the nest, on a gate that frequently swung back and forth, on the arm of a railway signal that was raised 50 times a day, on a steel crane that was constantly swinging to load railway cars, on a figure over a grave, in old horse carriages; in woodpiles, on a set of antlers hung over a frequently used garage door, on ornamental vines growing on trellises, on bridges, on abandoned equipment, in underground parking garages, in tunnels, on billboards, on steps of a ladder, on boards in lumber piles, and in hanging bird feeders and flower baskets (Campbell et al. 1997; Eiserer 1976; Howe 1898; Howell 1942; Leighton et al. 2002).

The robin defends a small territory from which other robins are expelled, but foraging and roosting occur in undefended areas outside the territory. Peck and James (1987) reported a group of about 25 pairs nesting on steel beams beneath a concrete bridge over a river suggesting coloniality. Nests were often separated only by the thickness of the steel, but birds could not see others while they were on their nests. R.G.B. Brown (1972) reported what he termed a colony of robins breeding at Vineland. A total of 13-14 pairs bred in 15.4 ha of cedar hedge and cherry orchard. There were only 8-13 pairs in the remaining 27.1 ha of the farm, which was similar habitat. In Quebec, robin territories were evenly spaced in forested habitat, with no evidence of grouping (Bourque and Desrochers 2006). Territory sizes vary inversely with population density and habitat quality, with most territories 0.1-0.3 ha. Reported territory sizes are 0.11-0.21 ha in New York, 0.04-0.24 in Wisconsin, 0.12-0.84 ha in Tennessee, and 4.00 in spruce forest in Maine. In Tennessee, 1 male had territories of 0.43 and 0.50 ha during 2 nestings within a season. Another had territories of 0.53 and 0.48 ha in the same territory in consecutive years. The mean size of territories in this population was 0.42 ha, larger than reported from most locations. Habitat was less than ideal because there were a limited number of suitable nest trees. Nests were rarely at the centre of territories and usually near the edge. Nests of neighbouring females may be as close as 5 m to each other and in 1 case nests were touching each other. In Tennessee, overlapping of territories occurred in 5 of 7 years. The amount of overlap was 0.03-0.08 ha with the largest overlap being 21% of the smaller of the 2 territories involved. In Algonquin Park, depth of territories in white birch–poplar forest was 0-10.7 m, corresponding to the area from the ground to the top of the canopy. Neighbours may join together to attack an intruder (Bourque and Desrochers 2006; Howell 1942; Martin 1960; Morse 1977; Pitts 1984; Vanderhoff et al. 2020). Home ranges are larger than the territory. Most birds have to leave the territory to find sufficient food and nocturnal roosts are typically outside the territory. Birds may feed and roost as far as 400 m from the territory (Howell 1942; Pitts 1984).

Few juveniles return to their natal site to breed, but a high proportion return to the general vicinity. In British Columbia, 0 of 35 fledglings returned; 4 of 90 juveniles (4.4%) returned to a New Jersey study area. In New York cherry orchards, return rates of juveniles depended upon the quality of the cherry crop. After a good crop year, 17 of 61 nestlings (27.9%) returned; only 6% returned the following year after a poor crop. In Massachusetts, 4 of 250 nestlings (1.6%) returned. In North Dakota, 33 of 368 young (9.0%) returned to breed. None nested in their natal shelterbelt. Mean distance of first nests from the natal area was 3.5 km (range 0.1-9.4 km). In Massachusetts, 61 nestlings were recovered; 54% were found within 1.6 km of their natal nest and an additional 20% were found 1.6-16 km away (Campbell et al. 1997; Haas 1995; Hirth et al. 1969; Johnson et al. 1976; Suthers 1988). Farner (1949) analyzed 428 recoveries of breeding robins that were banded as young east of the Mississippi River from Pennsylvania northward. Of 422 breeding record returns, 387 (91.7%) were 0-40 km from the natal site, 13 (3.1%) 40-80 km away, 10 (2.4%) 80-160 km away, 10 (2.4%) 160-320 km away, and 2 (0.48%) more than 320 km away. Some were found 233-684 km from the natal site and they had dispersed in all compass directions. Of 121 birds, 120 (99.2%) were retrapped at the banding location. Of birds found dead, 387 of 428 (86.9%) occurred within 40 km of the banding area. This figure increased to 89% if doubtful breeding records were removed. Of 115 recovered away from the original banding site, 75 (65%) were found within 40 km of the natal site, or 69% when doubtful breeding records were removed. These data suggest that juveniles tend

to return to the same general area and may return to breed in the last place they occupied prior to autumn migration. Older adults return sooner which may prevent first-year birds from establishing territories in their natal areas. Weir (2008) reported that 10.5% of robins banded at Prince Edward Point returned 1 year later to nest, 3.3% returned 2 years later, and 1.3% returned 3 years later.

Adults typically return to the same area to breed every year. There are several records of distinctly plumaged birds nesting in the same territory for as many as 6 years (Farner 1945; Graber et al. 1971; Howell 1942). In Vancouver, 14 of 20 adults (70.0%) returned to breed, 5 of 11 (45.5%) returned in New York, and 11 of 22 (50.0%) returned in Tennessee; 93 of 100 (93.0%) were rediscovered in a North Dakota study area, although not all birds returned to the same breeding area. Some birds nest in the identical spot each year and may build a new nest on top of the old one. In 1 case, 7 nests were built on top of each other (Brackbill 1952; Campbell et al. 1997; Haas 1998; Howell 1942; Pitts 1984). In Tennessee, several birds that did not return to the same nesting area were found nesting nearby; some skipped a year before returning to nest again (Pitts 1984). In Maryland, 1 male returned to his previous territory, but moved a considerable distance away a month later (Brackbill 1952a). In New York, females returned to the general location of their previous territory; males returned to the same territory (Howell 1942). Of returning robins in North Dakota, 56% returned to the same shelterbelt and 75% of these used the same nest site, 18% moved to woody draws between shelterbelts, and 7% moved to a different site. Return rates were dependent upon breeding success the previous year. Return rates for successful birds were 46% for males, 43% for females, and 44% overall. Return rates for birds whose nests failed due to natural causes were 12% for males, 27% for females, and 22% overall; and for experimentally induced failures, 20% for males, 17% for females, and 18% overall. Distances moved between nests in successive years were 0-1,300 m. Means were 66 m for successful birds, 152 m for natural failures, and 125 m for induced failure. Distances moved between successive nests within a breeding season were 0-1,200 m, with means of 42 m, 71 m, and 125 m for successful, naturally unsuccessful, and experimentally failed nests, respectively. The relationship between nesting success and dispersal distance was significant only for within-season movements (Haas 1995, 1998).

Limiting Factors

Eggs have been found in Ontario nests from early April until the third week of August, with most present in May and the first half of June (Peck and James 1987, 1998a). In Algonquin Park, nests are under construction from mid-April to mid-June, eggs are present from late April to late July, nestlings are present from mid-May to early August, and dependent fledglings have been observed from early June to mid-August (Tozer 2012). Nesting in late autumn and in very early spring or late winter has been documented elsewhere. In Iowa and Illinois, late dates for nest establishment were 3, 9, and 26 August (Klimstra and Stieglitz 1957). In Virginia, Bedell (1999) found a dead nestling in February and a newly constructed nest that was estimated to have been initiated on 31 January. Winter nesting by the robin is rare, but has been reported from Pennsylvania (nest with eggs on 4 January [Berger 1966]), Ohio, and North Carolina; all these attempts were unsuccessful. In Missouri, Gardali and White (2003) reported a nest that fledged young on 12 and 15 October. They reviewed 11,113 Cornell University nest records for the robin and found 15 records for September and 3 later than September. Most September records were in the later stages of nesting, but 3 of 5 from Alaska

contained eggs. The 3 later nests were 3 October in Massachusetts, 18 November in West Virginia, and 8 January in Ohio. About 23,000 nest records for Canada yielded only 2 records from September, 1 each from Quebec and Manitoba.

Nest construction may take as little as 1 day or as long as 20 days, with average times reported as 3-6 days, 7 days, and 3.5 days. Nest construction takes longer early in the season. Work may be halted for a few days during periods of snow or other adverse weather. Second or third nests are usually built in 2-3 days. Initiation of nesting is delayed by 3 days per degree of increasing latitude in the east, but there is no difference in timing in the west (Common 1947; Graber et al. 1971; Howe 1898; Howell 1942; Klimstra and Stieglitz 1957; Tyler in Bent 1949; Vanderhoff et al. 2020; Young 1955). Egg laying may begin the day after the nest is completed or be delayed as long as 15 days. The time elapsed between nest completion and initiation of egg laying is 1-4 days. The egg-laying interval is approximately 1 day. Most females begin incubation with the laying of the last egg, but some start with laying of the first egg resulting in a wide range of reported incubation periods. In California, nocturnal incubation began with laying of the first egg and the amount of time spent on the nest increased with each egg that was laid, with full incubation beginning with laying of the last egg. The incubation period of 109 Ontario nests was 9-15 days (average 11-13 days). There was only 1 record of a 9-day incubation period. In British Columbia, the incubation period was 11-16 days (median 13 days); mean incubation periods at 1 site over 2 years were 12.7 and 13.1 days. Of 233 nests reported to Cornell University, most eggs hatched in 10-12 days. The incubation period is longer earlier in the nesting season. There is a nonsignificant tendency for the incubation period to increase with latitude; the incubation period decreases with increasing clutch size. In the Yukon, the incubation period averaged 11 days; that study concluded that the incubation period decreased with latitude. Eggs hatch over a 2-3-day period (Brackbill 1977; Butcher 1988; Campbell et al. 1997; Graber et al. 1971; Howe 1898; Howell 1942; Klimstra and Stieglitz 1957; Morton and Pereyra 2010; Peck and James 1987; Tyler in Bent 1949; Young 1955). Young may leave the nest when they are 10-21 days old, but mostly in 12-15 days. In British Columbia, the nestling period ranged from 11 to 21 days (median 15 days). Young usually stayed in the nest longer earlier in the season or during periods of inclement weather. The mean nestling period at 1 site over 2 years was 13.2 and 13.5 days; it was 14 days at another site. In the Yukon, the nestling period was only 11 days. All young leave the nest on the same day even though there may be 1 or 2 days difference in their ages. The time for a nesting cycle from initiation of nest building to fledging of young is 33-49 days, but mostly about 37-39 days (Campbell et al. 1997; Graber et al. 1971; Brackbill 1947b; Howell 1942; Turner et al. 2017; Tyler in Bent 1942; Young 1955).

The American Robin typically raises 2 broods and occasionally 3. In Ontario, 8 double broods and 1 triple brood have been confirmed. In British Columbia, 2 broods are reared except in the north near the Yukon boundary where only a single brood is raised; 3 broods are occasionally reared in the south. In New York, 4 of 27 pairs (14.8%) raised 3 broods. A new nest is usually built for subsequent clutches 15-60 m from the first nest. Occasionally the first nest is used to raise a second brood and there is 1 record of a pair using the same nest to raise 3 broods in a season. The first egg is laid in the second nest 37-43 days after laying the first egg in the first nest; second broods fledge about 5 weeks after the first. Renesting is common if a nest fails, with an average of 1.2 days elapsing

between nest failure and the start of the next nesting attempt. A full clutch may be completed 9-16 days after loss. Although the robin will nest repeatedly after failures, it can make no more than 5 attempts (Campbell et al. 1997; Graber et al. 1971; Howe 1898; Howell 1942; Nickell 1957; Peck and James 1987; Pitts 1984; Sinclair et al. 2003; Vanderhoff et al. 2020; Young 1955). Clutches of 2-8 eggs have been found in Ontario with most containing 3 or 4 eggs (Peck and James 1987). Overall, clutches of 1-8 eggs have been reported, but 1-egg clutches have usually been partially depredated. Clutches larger than 5 eggs are likely due to the efforts of more than 1 female. Throughout its range, the robin typically lays 3 or 4 eggs per clutch, and 2 or 5 much less frequently (3-4% of clutches). Clutch size declines with season but increases with latitude. In Illinois, 74% of April and May clutches had 4 eggs and 23% had 3 eggs; in June and July, 46% had 4 eggs and 48% had 3. After mid-May, more 3-egg than 4-egg clutches are laid in New York. If a third clutch is laid, it almost always contains 3 eggs. In Illinois, the mean clutch size was 3.17 eggs; it was 3.44 in Iowa, and 3.16 in Maine. In Quebec, first nests had a mean clutch size of 3.7 eggs compared with 3.2 for second nests. Clutch sizes in the Maritime provinces (3.0 in Prince Edward Island, 3.2 in Nova Scotia, and 3.3 in New Brunswick) are significantly lower than those in the remainder of the east. This may be due to the later springs and resulting poorer food supply (Campbell et al. 1997; Eiserer 1979; Graber et al. 1971; Howard 1967; Howe 1898; Howell 1942; Klimstra and Stieglitz 1957; Knupp et al. 1977; Tardif and Lanoue in Gauthier and Aubry 1996; Tyler in Bent 1949; Vanderhoff et al. 2020; Young 1955).

The age at first breeding is 1 year and breeding occurs every year thereafter. The mating system is monogamous although there are a few anecdotal incidents that suggest polygyny. Birds typically remain mated throughout a breeding season but mates are quickly replaced if one dies. Divorce occasionally occurs during a breeding season. Returning members of a pair usually do not reunite, but remating in subsequent years occurs occasionally. In Wisconsin, only 1 pair of 18 (5.6%) remated the following year. Both returned in the third year but selected different mates. None of 18 pairs returning to the Kingston area remated. In Maryland, 1 of 8 returning pairs remated. To remate, both birds need to be faithful to their previous territory and arrive at approximately the same time in spring (Brackbill 1952a; Howell 1942; Vanderhoff et al. 2020; Weatherhead and McRae 1990; Young 1955). Over 2 seasons in Illinois, 62% and 72% of broods contained at least 1 offspring from an extra-pair copulation, and as many as 48% of young were the result of an extra-pair fertilization (Vanderhoff et al. 2020).

Young begin to peck at the ground at age 20 days but are not effective in obtaining food. By age 24-30 days, juveniles are capable of capturing prey. Adults move less, spend less time foraging in shaded areas, and capture more worms on wet surfaces and after rain than juveniles. Adults were more successful at capturing arthropods than juveniles. Juveniles only captured worms in the most saturated soils. Both age groups spent more time foraging in the most saturated soils: 59.3% for juveniles and 45.5% for adults. In Kentucky, juveniles were successful in picking mulberry fruit only 23% of the time compared with 69% for adults (Brackbill 1947b; Vanderhoff and Eason 2008a, 2008b). The robin exploits 3 primary food resources: invertebrates on the ground, fruit in trees and shrubs, and invertebrates in trees and shrubs. While foraging on arthropods in foliage, it tends to sit and wait to observe and capture prey. On the ground, it wanders and actively seeks prey. It may bill-sweep to move litter to find prey. Lawns are a preferred foraging substrate where it captures

earthworms visually. Progressively less time is spent foraging on lawns as the grass grows taller. Robins consistently selected short grass when offered a choice between tall and short lawns (Clark 1983; Eiserer 1980; Heppner 1965; Morton 1968; Paszkowski 1982). It selects larger fruit; mean widths of fruits consumed were 3.7-9.0 mm in diameter, all below the main gape width of the robin (White and Stiles 1991). In a laboratory, the robin selected fruits with the highest percentages of protein. It significantly preferred fruits of autumn olive and multiflora rose to those of native plants. Some fleshy-fruited invasive plants may receive more dispersal service from the robin than native plants with similar fruits (Lafleur et al. 2007). There are 2 groups of fruits: those that are high in sugars relative to lipids and those high in lipids relative to sugar. Sugar-rich fruits are common throughout the fruiting season and lipid-rich fruits are common from late summer through early winter. It selected sugar-rich fruits in both summer and autumn. There was only a slight (6%) increase in the consumption rate of sugar-rich fruits from summer to autumn but a more substantial (46%) but nonsignificant increase in consumption of lipid-rich fruits. Energy assimilation did not change seasonally for sugar-rich fruits but increased for lipid-rich fruits from summer to autumn. Birds obtained more energy from the same fruit in autumn than earlier which may be important in preparation for migration. Robins tended to prefer red to purple fruits in summer and had no colour preference in autumn (Lepczyk et al. 2000). The nutritional value of fruit may be increased by selecting those that are infested with insects (Vanderhoff et al. 2020). The robin may defend food resources when they are scarce. A single robin successfully defended a crabapple tree against flocks of 2-15 Cedar Waxwings and also a Purple Finch and Blue Jay over a 2-week period in spring. Later, when the waxwing flock increased to 30-36 birds, the robin was no longer capable of defending the food supply (Pietz and Pietz 1987).

Adults split the territory roughly in half when collecting food for nestlings. They tend to bring young larger prey items than they consume themselves. Near Kingston, the percentage of food provided to nestlings in May was 38% worms, 33% caterpillars, 11% beetles, 5% millipedes, 4% hymenopterans, 3% odonates, and 2% each for snails, isopods, and spiders. The percentages in June were 37% caterpillars, 22% beetles, 14% worms, 12% orthopterans, 6% hymenopterans, 4% spiders, 3% odonates, and 2% millipedes. In some areas, nestlings are fed mainly cutworms. In Illinois, food brought to nestlings consisted of 50% caterpillars, 29% earthworms, 7% ants, 6% flies, and small percentages of adult lepidopterans, beetles, and millipedes. In New York, young were fed earthworms, grubs, fruit, caterpillars, grasshoppers, cutworms, June beetles, crickets, insect larvae and adults, and spiders as well as large numbers of crane flies and ripe cherries. The food of 15 young aged 3-35 days consisted of 70.2% animal matter and 29.8% plant matter. Animal food consisted of 44.1% insects, 15% earthworms, 3.1% millipedes, 2.3% spiders, 1.7% isopods, and a trace of pseudoscorpions. The insects included 24.7% caterpillars, 11.6% beetles (ground, soldier, click, pill, darkling, and scarab beetles plus weevils), 4.9% short-horned grasshoppers, 3.2% ants and ichneumonid wasps, and 0.5% bugs. Plant material consisted of 19.5% grass blades, stems, and roots; 3.2% mulberries; 2.4% honeysuckle seeds; 0.5% aster family seeds; and traces of strawberry seeds, clover leaves, and plantain seeds. The grasses may be brought along with other food and ingested incidentally. Nestlings 5-7 days old were fed exclusively green darners (a large dragonfly) in 1 afternoon. Earthworms were scarce in this area which may have explained the unusual diet. Nestlings in an October Missouri nest were fed hawthorn fruits. There are several accounts of young

being fed small garter snakes and a red-bellied snake; adults have been seen consuming a 20-25 cm ribbon snake and attacking a red-bellied snake (Burton 1963; Gardali and White 2003; Graber et al. 1971; Gullion 1950a; Howell 1942; James 2011; Johnson et al. 1976; Keast 1990; Kilham 1958; Richmond 1975; Tyler in Bent 1949; Vanderhoff et al. 2020; Whitford 1998).

Beal (1897a) analyzed the contents of 330 robin stomachs collected in the United States. The diet consisted of 42% animal matter and 58% vegetable matter, predominantly small fruits or berries. Nineteen percent of the diet consisted of beetles and about one-third of them were ground beetles. Grasshoppers constituted 10% of the annual diet but over 30% of the August diet. Caterpillars represented 6% of the diet. The remaining animal food consisted of a variety of insects with a few snails, spiders, and earthworms. Of the 58% plant material in the diet, 47% was wild fruit and 4% was cultivated fruit. Cultivated fruit was eaten predominantly in June and July; wild fruits were consumed year round. Forty-one species of fruit were eaten with the most important being 4 species of dogwoods, 3 of cherries, 3 of wild grapes, 4 of greenbriers, 4 of sumacs, and 2 of elderberries, plus cranberries, huckleberries, blueberries, juneberries, and hackberries. It also ate some seeds. Wheelwright (1986) summarized contents of robin stomachs in 3 geographic areas. The eastern area included the Atlantic states and coast westward to Ontario and Minnesota in the north and Louisiana in the south. The robin was documented eating fruit of at least 51 genera and 28 families; 34% of fruit consumed belonged to the rose family. Twenty percent of food items consisted of cherries; 5% were raspberries. Also important were sumac and poison ivy (10%), grape (6%), and dogwood (5%). Invertebrates were represented in the diet by 107 families and 14 insect orders. Beetles occurred at a frequency of 40%. Important beetles were ground beetles (10%), weevils (8%), and scarab beetles (7%). Beetles were followed in frequency by lepidopterans (13%) and hymenopterans (9%), with these 3 orders accounting for more than half of food items. Lepidopteran prey was almost exclusively caterpillars. Adults were most frequently eaten in other orders, although it occasionally ate larval scarab beetles. Caterpillars and earthworms were likely under-represented in the samples due to their rapid digestion. In the northeast, fruit from at least 37 plant genera and 12 families was eaten and the robin preyed upon invertebrates of 72 families and 12 orders of insects. The most common fruits eaten were those of the rose (43% of fruit records), dogwood (12%), heath (19%), and sumac and poison ivy (7%) families. Invertebrates most commonly consumed were ground beetles (9% of invertebrates), ants (8%), weevils (7%), scarab beetles (6%), and click beetles (6%). Fruit and sumac was eaten in every month. Sumac was most prevalent in the diet in spring, fruits of the rose family dominated the fruit diet in mid- to late summer and were replaced by dogwoods and grapes in autumn. Within the rose family, cherries and raspberries were commonly eaten in June, July, and August; hawthorn fruits were eaten in late autumn and again in spring. During autumn and early winter, 80-99% of the diet consisted of fruit; the change in diet was abrupt, climbing from less than 10% to more than 80% in 1-2 months. Fruit was most commonly eaten in autumn (96%), followed by winter (93%), summer (66%), and spring (6%). Four to 6 taxa of fruit occurred in the diet during the breeding season compared with 2-3 in winter. There was no difference in the diet of the sexes. Stomachs of juveniles contained a higher proportion of fruit than those of adults. Stomachs contained different proportions of fruit depending upon habitat. The proportion of fruit consumed was highest in orchards (96.0%), native fruiting trees (90.0%), and forests (80.0%) than in agricultural lands (10.5%). Birds in meadows and edge habitats ate

intermediate amounts of fruit: 60.0% and 31.0%, respectively. Habitat differences in fruit consumption were greatest in spring and early autumn. In August, the amount of fruit eaten began to become similar among habitats and by October birds collected in all habitats ate 80-99% fruit. Beetles were eaten most frequently in open habitats (fields and lawns) and infrequently in edge habitats; the reverse was true for hymenopterans and lepidopterans. It preyed upon bugs more than expected in forested habitat and less than expected in open habitats. In Illinois, the robin fed almost exclusively on invertebrates in spring. The most frequent prey items were earthworms and march fly larvae early in the spring. Later in spring, cutworms, tussock moth egg masses, ground beetles, and click beetle larvae became prevalent in the diet. It also ate cankerworms and cicadas. In June, it switched to a predominantly fruit diet, and fruit was important through summer and autumn. Dominant fruits in the diet in late summer and autumn were grape, black cherry, Virginia creeper, hackberry, dogwood, multiflora rose, pokeweed, elderberry, and red cedar. Other fruits commonly eaten were those of mountain-ash, sumac, barberry, bittersweet, holly, snowberry, pear, apple, and greenbrier (Graber et al. 1971). Breiding (1946) reported the robin eating Canada moonseed fruit. In a New York residential area, Hamilton (1940) analyzed 700 fecal samples collected from late June to early July. The frequency of occurrence was 80.1% for animals and 73.1% for plant material. Animal matter consisted of 74.1% insects including 38.4% hymenopterans (mostly ants), 11.3% beetles (mostly weevils and leaf beetles), 6.9% lepidopterans (mostly cutworms), 5.6% orthopterans, 0.7% lacewings, 0.7% bugs; 3.4% spiders; 3.3% molluscs; 0.6% earthworms; and 0.4% centipedes. Frequency of fruits consumed was 58.2% chokecherry, 40.0% Allegheny blackberry, 21.1% red raspberry, 17.0% pin cherry, 11.7% black cherry, 8.3% honeysuckle, 5.9% nightshade, 2.4% Canada juneberry, 1.3% strawberry, and 1.1% red currant. In Nova Scotia and eastern Canada, the robin is considered the most important consumer of lowbush blueberries (Crossland and Vander Koet 1996). In an Illinois forest, 100% of robins ate fruit, and all fruit was consumed in forest gaps. In the first year, 58% of frugivory was on grapes and 42% was on Virginia creeper; the following year, 81% was on grapes, 13% on pokeweed, and 6% on Virginia creeper. It was not observed feeding on elderberries, poison ivy, greenbrier, moonseed, or spicebush. It strongly favoured isolated grape plants for foraging and was the most important species for dispersal of grape (Malmborg and Willson 1988). Stutchbury et al. (2005a) studied its frugivory on red elderberry in forest gaps in Pennsylvania. It was observed foraging at only 5.9% of sites on 1.9% of visits. The low level of frugivory probably reflected the low abundance of the robin in the study area. In New Jersey, it commonly fed on the fruit of winged sumac, red cedar, multiflora rose, fox grape, spicebush, black gum, apples, pears, and viburnums (White and Stiles 1991). Near Ithaca, New York, preferred fruits were those of northern arrowwood and spicebush. Changes in fruit consumption occurred seasonally even for captive birds when offered constant food quality and abundance (Wheelwright 1988). Jung (1992) offered captive robins choices between white mulberry, bella honeysuckle, and red-osier dogwood. Thirty-five birds ate 318 mulberries, 150 dogwood fruits, and only 28 honeysuckle berries. Some birds showed a preference for 1 species of fruit: 15 ate mostly mulberries, 2 ate mostly dogwood, and 0 ate mostly honeysuckle. Unusual food items that have been reported in the robin's diet include skinks, snakes, mice, shrews, trout fry and other fish, and damselfly nymphs (Eiserer 1976; Tyler in Bent 1949; Vanderhoff 2007; Vanderhoff et al. 2020). In New Brunswick, there was no relationship between the abundance of the robin and spruce budworm numbers (Morris et al. 1958). Over 2 years in Maine,

spruce budworm larvae and pupae constituted 23.7% and 29.1% of the robin's invertebrate diet (Mitchell 1952).

The American Robin and Cedar Waxwing eat many of the same fruits, but the robin consistently eats less fruit throughout the year. Cherries were the most common fruit in the diet of both species in summer and autumn and the relative consumption of cherries was also similar. During winter and spring, robins ate fewer red cedar berries than waxwings, and waxwings did not eat sumacs. In autumn, 4 species of dogwoods were prominent in the robin's diet, but the waxwing ate only flowering dogwood berries. The 2 species showed strong differences in their selection of insect orders and ate different families of beetles and bugs. The most terrestrial insects eaten by robins, stink bugs and ground beetles, were not eaten by waxwings (Witmer 1996a). In Michigan, robins visited cherry orchards less frequently than waxwings (on 6% of days compared with 21% of days for waxwings). Robins visited orchards a mean of 2% of daylight hours compared with 5% for waxwings. The difference in times spent within orchards by the 2 species was probably a reflection of their diets. Robins consume larger proportions of invertebrates and prefer lipid-rich fruits; waxwings prefer sugary fruits such as cherries (Eaton et al. 2016).

The reported percentage of robins' nests that are parasitized is very low but the robin is a known rejecter of cowbird eggs. The female cowbird typically removes a robin's egg when laying one of her own. Even if the robin ejects the egg, there is a decrease in productivity because robins do not replace single eggs that are lost. When a cowbird successfully parasitizes a nest, robins are usually capable of fledging their own young as well as those of the cowbird. In Ontario, 17 of 6,004 nests (0.3%) were parasitized and 0.1% of 4,522 British Columbia nests were parasitized. Other reported parasitism rates are 0.25% in Illinois, 0.8% in Ohio, 0.5% in Louisiana, 4.3% in Oklahoma, and 40% in Kansas. The sample size was only 5 nests in Kansas, but parasitism rates are higher there than reported elsewhere (Campbell et al. 1997; Graber et al. 1971; Hodges 1949b; Howard 1967; Howell 1942; Leighton et al. 2002; Lowther 1991; Peck and James 1998a; Rasmussen et al. 2009; Rothstein 1975; Vanderhoff et al. 2020; Wolfe 1994).

The robin is vulnerable to the effects of a wide range of environmental contaminants and can be useful as an indicator of chemical pollution. Starting in the 1950s, severe die-offs and reduced reproductive success occurred due to spraying of DDT in an attempt to control Dutch elm disease. DDT was also widely used in orchards until the late 1960s. It takes 10-17 years for robin populations to return to pre-DDT levels. The robin is poisoned primarily by residues in earthworms. DDT may continue to cycle from the soil through earthworms to robins for as long as 30 years after a single application. In New York orchards where DDT had been applied as recently as 7-8 years previously, robins produced significantly smaller clutches and raised fewer nestlings than robins from the same area during the pre-pesticide era. Robins did not forage in areas that had received direct spray, possibly due to the scarcity of earthworms. In British Columbia orchards, robin eggs contained 18-3,500 times more DDT and 4-100 times more DDE than eggs of other species. Orchard-nesting robins had significantly higher concentrations of trans-monochlor, heptachlor epoxide, and PCBs than robins nesting in other habitats. Earthworms appeared to be the major source of contamination. Contaminant levels in the Niagara Peninsula of Ontario are lower than those in British Columbia, probably due to the species of earthworms that are present. One of the dominant

earthworms in Ontario is the common earthworm which burrows as deep as 1 m and thereby dilutes contaminant burdens. Despite high levels of contaminants in British Columbia orchard-dwelling robins, they were capable of surviving and successfully rearing broods. DDT was sprayed on a Wisconsin university campus from 1959 to 1961. More than 340 dead birds were collected during this period, and at least 232 were robins. Mortality occurred mostly in birds with a minimum of body fat and those that ate highly contaminated food. Birds collected later in spring had higher fat reserves and tolerated higher levels of contamination before succumbing. In Maine where DDT was used to kill spruce budworms, arriving birds contained burdens of DDT accumulated on the wintering grounds and most also carried mirex which was used to control fire ants in the south. Of 20 birds sampled in sprayed areas, only 2 did not carry higher burdens of DDT than those in unsprayed areas. Females transferred a significant amount of their contaminant burden to the eggs. Contaminated food in sprayed areas maintained residue levels in females but residue levels declined in females in unsprayed areas. Residues in eggs (14.8 µg) were passed on to nestlings (9.6 µg) and fledglings (7.7 µg) in unsprayed areas. In sprayed areas, residues accumulated significantly from eggs (23.9 µg) to nestlings (29.5 µg) to fledglings (110.4 µg). No influence of pesticides on reproduction was noticed. Adults collected in August from the sprayed area had about the same amount of residues as spring migrants. The rapidity at which pesticides were eliminated when uncontaminated food was available was important. DDT was sprayed on the Iowa State University campus in an attempt to control Dutch elm disease. This resulted in a gradual loss of breeding robins. Annual production declined to a total of 1-3 fledglings, although there were originally as many as 47 nests on campus. Following a switch from DDT to methoxychlor, a significant increase in number of nests and young was observed, although some mortality continued. In Illinois, 85-90% of a population was eliminated following an application of heptachlor. The following year, the population had only recovered by 5% but was back to 75% the second year. Spraying of dieldrin in Illinois resulted in high mortality, probably due to consumption of dead earthworms. Robins in urban areas tend to accumulate higher levels of lead than those in rural areas, but at levels lower than those considered toxic. This difference may not be so great since leaded fuel has been banned. In 1972, 10,000 robins were killed in a field that had been treated with Azodrin® near Homestead, Florida. Treatment of Quebec lawns with insecticides (chloropyrifos) resulted in decreased productivity. Other chemicals known to cause robin mortality are carbofuran, hydrogen sulphide, furadan, famphur, nemacur, cyanide, dursban, fenthion, chlordane, and carbamate and organophosphate pesticides (Elliott et al. 1994; Graber et al. 1971; Hunt 1969; Johnson et al. 1976; Knupp et al. 1976; Tardif and Lanoue in Gauthier and Aubry 1996; Vanderhoff et al. 2020; Weller 1971).

Late spring storms may cause mortality of robins, even when there is sufficient food available. A late storm in the spring of 1933 in the Mackenzie Delta killed virtually all robins, and it was still scarce 2 years later. Snowstorms early in spring may cause mortality even in more southern locations, such as Illinois. Periods of prolonged or heavy rain may kill nestlings. During a severe Michigan cold front in March, robins fed on frozen earthworms stuck to concrete and on a moribund luna moth (Graber et al. 1971; Johnson et al. 1976; Porsild 1943; Royall 1995).

First nests are only about half as successful as second nests. In New York, 32% of first nests fledged young compared with 55% for second nests. There are a number of inter-related factors

that lead to lower success early in the season. The robin selects coniferous trees over deciduous trees early in spring, but nesting success is much lower in conifers: 18% in conifers compared with 52% in deciduous trees in Maine. Coniferous trees are more likely to attract red squirrels, a nest predator. In Minnesota shelterbelts, nest success was 40% where squirrels were present and 67% where they were absent. Other factors that may contribute to low success rates of early nests are relative scarcity of food and weather that may result in nests falling or mortality of nestlings. Many early nests are conspicuous prior to leaf-out and may be more susceptible to predation. In Iowa and Illinois, nest success was 69.0% in rural areas and 32.7% in urban areas with the difference apparently due to predation by cats (Graber et al. 1971; Howell 1942; Klimstra and Stieglitz 1957; Knupp et al. 1977; Yahner 1983).

Habitat loss is currently not a limiting factor for the robin. Forest fragmentation, selective logging, clear-cutting, fires, and urbanization are all beneficial. It is one of few species that thrives in urban areas where it may occur at higher densities than in natural habitats. In North Carolina, its abundance increased significantly with increasing numbers of houses and buildings within 200 m of the centre of the forest patch (Lumpkin and Pearson 2013). Along the Michigan shoreline of Lake Superior, it was significantly more abundant on developed cottage lots than in contiguous forest on the other side of the road (Ford and Flaspohler 2010). Although the robin thrives in urban areas, modern subdivisions may be marginal habitat or even unsuitable for it. Houses are built at very high densities with tiny lawns and few trees, so nest sites and foraging areas are limited.

In deciduous forests in southeastern Ontario, robin density, pairing success, and nest success were unaffected by habitat characteristics within 100 m of nests. The amount of forest cover within 2 km was positively associated with its productivity and the amount of intensive agriculture within 2 km was positively correlated with its density and productivity. Early in spring, it was often observed foraging for earthworms and other arthropods in bare soils in agricultural land. The amount of intensive agricultural land surrounding forest fragments could influence where males establish territories by providing them with an early spring source of food (Richmond et al. 2012).

In many studies on the effects of selective timber harvesting, there were no significant differences in abundance of the robin in uncut areas and where varying degrees of harvesting had taken place. In Vermont, the robin occurred equally in forests and adjacent clear-cuts. In Newfoundland, it was insensitive to the effects of clear-cutting; 63% of robin captures were in clear-cuts. In the Boreal Forest Region, a 50% increase in its abundance resulted when as many as 70% of trees were removed. In northern hardwoods near Sault Ste. Marie, it was more abundant in forests that had been selectively thinned than in uncut forests. In the Carolinian Forest Region, it preferred recent cuts in forests over old cuts, with heavier cuts most preferred. In British Columbia, it often increases after clear-cutting or fires, with numbers increasing once tree heights reach 1 m and declining once trees become 10 m tall. In South Dakota, density of breeding robins was 6.0-19.8 times higher in very small fragments of woodlands than in large riparian forests and there were no differences in survival rates in fragmented and contiguous forests (Campbell et al. 1997; Gentry et al. 2006; Hanowski et al. 2003, 2005; Holmes and Pitt 2007; Holmes et al. 2004; Howell 1942; Lent and Capen 1995; Medin and Booth 1989; Vanderwel et al. 2007; Whitaker et al. 2008). In the Ontario Canadian Shield, there was no difference in its abundance in early and mid-successional clear-cuts

compared with similarly aged stands after fire. It was equally abundant in mid-successional and mature stands but significantly more abundant in early successional than mature stands (Zimmerling et al. 2017).

Forest fragmentation is generally beneficial to the robin, but it may promote invasion by nonnative shrubs. Nests built in common buckthorn and nonnative honeysuckles experienced higher predation rates than those in native shrubs (hawthorns and viburnums) and in native trees. Increased predation rates in nonnative shrubs may be due to a combination of lower nest heights, absence of sharp thorns, and perhaps a branch architecture that facilitates predators. Invasion by nonnative shrubs may result in a decrease in nest success (Schmidt and Whelan 2000). In Chicago, its abundance was positively correlated with litter and negatively correlated with cover by nonnative honeysuckle species and invasive shrub stem density (Schneider and Miller 2014).

In Pennsylvania and New Jersey over a 15-year period, hemlock declined from 56% of the total basal area to 46% due to the hemlock woolly adelgid, and the coverage by deciduous shrubs increased. The robin increased in these woodlots, probably due to the increased shrub coverage and more open canopy (Toenies et al. 2018).

The common house mosquito preferentially feeds on robins. This mosquito is the vector for the West Nile virus. Robins are a key reservoir for the disease and are responsible for spreading it in the summer months. Regional declines in the robin in Massachusetts, Maryland, and Minnesota may be due to the West Nile virus.

The robin responds to light pollution by initiating singing earlier in the morning, as early as 255 minutes before civil twilight in the brightest areas. The consequences of earlier singing in brightly lit areas were uncertain. The longer period of singing could potentially reduce survival if energy demands or predation risks were elevated. Conversely, light pollution might increase productivity if robins can forage or seek mates during longer periods of time. Nestling growth rates might also be enhanced due to the longer feeding period (Miller 2006).

In Alberta, the robin was equally abundant at noisy compressor stations and quiet well pads. It exhibited no response to chronic noise (Bayne et al. 2008). It was significantly more abundant along pipelines and at well pads than in adjacent forest interior; it was equally abundant along seismic lines and in adjacent forest interior (Bayne et al. 2016). In West Virginia, it was significantly more abundant at well pads, access roads, and pipelines than distant from these features (Farwell et al. 2019).

The robin is vulnerable to being killed on roads by vehicles. In British Columbia, it is one of the most road-killed species. It is also vulnerable to flying into windows when flocks feed in vegetation near windows (Campbell et al. 1997; Vanderhoff et al. 2020).

Bird feeders that are maintained during the breeding season have the potential to reduce the reproductive success of the robin. Ohio neighbourhoods with at least 15 feeders had 2.7 times more American Crows and 3.2 times more Brown-headed Cowbirds than neighbourhoods with 3 or fewer feeders. In neighbourhoods with the most feeders, fewer than 1% of nests were expected to survive until fledging compared with 34% in neighbourhoods with few feeders (Malpass et al. 2017).

Becker and Weisberg (2015) studied the effects of spring temperatures on the robin in Nevada. Nest success was significantly correlated with temperature, with nestling survival increasing by 12% for every 1°C above baseline temperatures. Moderate warming of spring temperatures as a result of climate change may be beneficial to the robin.

Status

The robin has always been abundant in Ontario. McIlwraith (1894) reported that great numbers nested throughout the province. Baillie and Harrington (1937) considered it one of the most common and widely distributed bird species in Ontario. It nested everywhere in the province north to at least Moose Factory and the Severn River but was uncommon between latitudes 53-54º N along the Manitoba border. It was most common near habitation and comparatively scarce in large areas of northern Ontario. During the first atlas, it was found in virtually every square in southern Ontario and in most blocks in the north (James and Long in Cadman et al. 1987). James (1991) considered the robin abundant in residential and agricultural areas and uncommon in forested areas throughout the province.

The second atlas demonstrated that the distribution of the robin had not changed since the first atlas; in essence, it inhabits the entire province. It was confirmed as a breeder in every square in the Carolinian Forest Region and most squares in the Great Lakes–St. Lawrence Forest Region. Probable or confirmed breeding was reported from every block in the Boreal Forest Region and the Hudson Bay Lowland. Its probability of observation did not change province-wide between atlases, but significant increases were recorded in the Boreal Forest Region and Hudson Bay Lowland. It was most abundant south of the Canadian Shield. Densities were much lower in the remainder of the province, with localized areas of higher density associated with towns, cities, and agricultural areas (Burke in Cadman et al. 2007).

The robin is probably many times more abundant in Ontario and North America now than it was prior to European settlement. Forest clearing, fragmentation, and urbanization created better habitat. In addition to modifying habitat to the benefit of the robin, settlers inadvertently introduced earthworms and a new food supply (Graber et al. 1971; Pitts 1984; Tyler in Bent 1949; Vanderhoff et al. 2020).

Breeding Bird Survey data indicate that the robin increased at an annual rate of 0.051% in Canada and decreased at an annual rate of 0.503% in Ontario 1970-2021. From 2011 to 2021, it decreased at annual rates of 0.569% in Canada and 3.07% in Ontario. All results were highly reliable, except for the long-term Canadian results which were of medium reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Usually young cannot fly when they leave the nest, but are able to fly about 2 days later. Fledged young are dependent on the adults for 3-4 weeks after leaving the nest. In Maryland, young first attempted to feed themselves 20 days after fledging, but remained partially dependent until 28-31 days after fledging (Brackbill 1947b; Howell 1942; Young 1955). Near Kingston, adults commonly cared for some young more than others. Males were associated with fledglings more than females because the female typically initiated another clutch. By 3 weeks after nest departure, both adults were largely free of caring for the young, although some young were fed 26 days after fledging. The

female provides care to the young until she starts incubating the next clutch (Weatherhead and McRae 1990).

In Wisconsin, maximum distances from the nest by time after fledging were: 0 days, 46 m; 1 day, 69 m; 2 days, 73 m; 3 days, 119 m; 10 days, 160 m; 14 days, 389 m; 28 days, 1.46 km; and 31 days, 1.65 km. One young was seen near the study area 89 days after leaving the nest (Young 1955). Near Kingston, some young flew in excess of 50 m 2 days after fledging, but most only showed a gradual expansion of their range (Weatherhead and McRae 1990). In Massachusetts, most juveniles were still near their parents' territory or within 160 m of the nest 3 weeks after fledging. Between 4 and 6 weeks, most had moved only 320 m from the nest. After 8 weeks, 27% remained within 320 m of the nest; 33% had moved 800 m or further away. Young stayed an average of 14.5 days near the nest (range 5-32 days). Time spent near the nest may vary by individuals within a brood. In 1 brood, 2 young left after 13 days and the third remained 32 days. In another brood, 3 young remained 8, 11, and 22 days. In this area, 63% of robins captured in a cherry orchard were juveniles; 90% were juveniles in an area of blueberry plantings. Juveniles concentrated in orchards where there were cultivated cherries, blueberries, and wild blackberries; and a tree nursery with cultivated blueberries and wild tartarian honeysuckle and black cherry. The presence of these food sources may have limited dispersal distances of birds. The 2 feeding areas were 1.1 km apart; only 7.1% of fledglings were observed at both sites. Foraging sites each had an area adjacent to them that was suitable for loafing during hot days. Loafing sites were in small stands of coniferous or deciduous trees with a closed canopy and very little undergrowth. Flocks of fledglings remained intact as long as the food source persisted. There was very little interchange of individuals among flocks. After the fruit was depleted, some young remained, others disappeared entirely, and a few were seen 1.6 km away. Seven of 106 fledglings (6.6%) were seen more than 1.6 km from the nest during the summer. One traveled 9.0 km but the remainder moved less than 4 km. Only 6% of 93 juveniles and adults were seen at more than 1 roost. The average distance from the nest travelled by 9 juveniles in October was 500 m. Two were within 160 m and 1 moved 3.7 km (Hirth et al. 1969). In Washington State, juveniles consistently used heavy- to medium-developed urban and residential areas more than expected by availability. Forest cover was used less than expected. Areas with high road densities were used significantly less than expected by fledglings and more than expected by juveniles. High use of urban habitats was most pronounced in landscapes where urban cover was least common. Urban habitat may be preferred because of the abundance of worms in lawns. Of the species studied, the robin had the largest home range of 259 ha, the highest proportion of urban cover (46%), and the highest road density (0.4 m/m^2) in its home range (Whittaker and Marzluff 2009). In Michigan, Akresh et al. (2009) captured 100% of juveniles in riparian forest and none in upland forests. In Ohio, Vitz and Rodewald (2007) captured 32 juvenile robins in regenerating clear-cuts suggesting that they may seek out dense cover in the postbreeding period. In Minnesota, Streby et al. (2011b) captured only a single robin in regenerating clear-cuts during the breeding season, but captured 9 adults and 9 fledglings during the postbreeding period.

In the postbreeding period, adults may seek denser cover. On a Tennessee university campus, birds moved out of the study area in mid-August to moult in more heavily wooded areas (Pitts 1984). In Ohio, Vitz and Rodewald (2006, 2007) reported adult robins in regenerating clear-cuts. Home

ranges of adults increased in the postbreeding period near Kingston. Adults foraged in an average area of 1,472 m² during the nestling period and 8,080 m² during the fledgling stage. Adults and their fledglings had broadly overlapping home ranges during the fledgling stage even though fledglings from the same nest were seen together on only 23% of observations (Weatherhead and McRae 1990).

MIGRATION

The robin is predominantly a diurnal migrant but some nocturnal migration occurs. In spring, there are more morning than evening flights; the reverse is true in autumn. Of 533 recoveries of Ontario and Quebec robins, 85% were re-encountered within these provinces, with nearly all recoveries between March and October and 76% between April and July. Birds banded or encountered from December to February were nearly all found in the Carolinas and Gulf Coast states east of Texas. A single record from Mexico and 2 from Texas indicate that a few Ontario and Quebec birds winter further west. Recoveries in the Detroit to Chicago area suggest that robins may cross in the Sarnia area (Brewer et al. 2018; Graber et al. 1971; Speirs 1953; Vanderhoff et al. 2020). Since the 1990s, more robins have adapted a nonmigratory strategy and travel less than 100 km from their breeding areas, possibly in response to climate change (Vanderhoff et al. 2020).

In spring, the robin tends to follow the advance of the isotherm of average daily temperature of 2.8ºC. Males arrive before females who may join the males within a week (Graber et al. 1971; Howe 1898; Howell 1942; Tyler in Bent 1949). In the south, the first spring migrants usually appear in late February or early March with a few arrivals in mid-February. Migrants continue to move through in late April and early May, even after local birds have been nesting for some time. In the southern Shield, average arrival is around the third week of March. By early to mid-September, robins are migrating south in the Hudson Bay Lowland. Most pass through central Ontario in late September and the first half of October, but it is often seen into mid-November; some occasionally persist into December or beyond. In the south, migration peaks in October and most are gone by 15 November except for those that overwinter. Autumn migration is conspicuous along the Lake Erie shoreline at Elgin County hawk watches, where peaks occur near the end of October (Curry 2006; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008; Wilson and McRae 1993).

During migration, the American Robin occurs in a wide variety of habitats and is more likely to be detected in fragmented than contiguous habitat. In spring, it forages mostly in grasses; it inhabits woody areas much more in autumn. During spring migration in Pennsylvania, it was 4 times more likely to be observed in shrubs than in forest. During migration in the Yukon, it is especially common in wetlands. Spring migrants there forage on mudflats alongside flocks of shorebirds and waterfowl. In British Columbia, migrants occur primarily in fields, open woodlands, edges, and rural and suburban areas. Flocks occur in almost any open, grassy, or bare-soil area that provides foraging opportunities. It also forages on intertidal mudflats during low tide. Favoured habitats include pastures, fields, park lawns, golf courses, open swamps, meadows, school yards, beaches, agricultural areas, suburbs, logged and burned areas, along open riverbanks, and in open forests along lakeshores and marshes. During spring migration in Minnesota and Wisconsin, it was observed more frequently in floodplain forests than in upland forests, but the difference was not significant. In Kansas, where it is warm in autumn, robins congregated on cooler, moister, northern slopes where

grapevines were more abundant. While the weather was warm and deciduous trees still retained leaves, it tended to stay in well-shaded areas in thick woods (Campbell et al. 1997; Fitch 1958; Graber et al. 1971; Keller and Yahner 2007; Kirsch et al. 2013; Sinclair et al. 2003; Smith and Hatch 2008).

Food preferences during migration typically dictate what habitats are used. In spring, lawns and short grassy areas are selected because they provide earthworms and a variety of other arthropods. In New York, robins foraged on rotten apples in an orchard during spring migration. In autumn, areas supporting large amounts of fruit are selected such as orchards, open fields and edges with pokeweed and grapes, vineyards, commercial blueberry farms, and residential areas with fruit-bearing ornamental shrubs. In British Columbia and the Yukon, important fruits during autumn migration include mountain-ash, juneberry, balsam poplar buds, holly, arbutus, and crabapples. In Algonquin Park, fruits of wild raisin and winterberry holly are important. During autumn migration in New York, approximately 13% of fecal samples contained bella honeysuckle fruits; 37% contained common buckthorn fruits. Fruits of red-osier and gray dogwood were available but apparently not consumed. It has been documented eating sunflower seeds and grubs in a household compost pile (Campbell et al. 1997; Fitch 1958; Johnson et al. 1976; Mudrzynski and Norment 2013; Sinclair et al. 2003; Tozer 2012).

McClure et al. (2013b) created a phantom road by playing traffic noise in an undisturbed forest during autumn migration. Abundance of the robin declined with noise intensity. Eight robins were present on average when the noise level was about 36 dB(A) compared with 1 at 57 dB(A). Robins appeared to be avoiding the noise, and it was assumed that they would be less frequent near roads than in quieter areas. In Alberta, robins exhibited no response to noise (Bayne et al. 2008).

The robin is an abundant migrant in Ontario, with many daily counts of 1,000-10,000 (Curry 2006; James 1991; LaForest 1993; Lancaster et al. 2004; Weir 2008).

WINTER

Speirs (1953) examined the winter distribution of the robin east of the Rocky Mountains. Recoveries of Ontario birds in winter were predominantly south of latitude 37ºN. Its greatest abundance occurred between latitudes 30-35ºN, with extensions into eastern North Carolina and central Tennessee, and south into the Florida peninsula and wooded regions of southeastern Texas. Most occurred between the 4.4ºC and 15.6ºC isotherms with only about 6% of the population north or south of this area. The 4.4ºC isotherm corresponds well with the northern boundary of the region in which fewer than 15 days per winter have continuously freezing weather. In this area, it can probably find unfrozen ground and animal food. Robins from all latitudes of the breeding range winter in the same average latitude of 32ºN. Root (1988) stated that it avoids areas where the average minimum January temperature drops below –15ºC and areas that receive less than 20 cm of precipitation annually.

During winter, the robin inhabits areas with more trees and denser cover than at other times of the year, and presence of abundant fruit is a requirement. In Presqu'ile, it favours dense brush in winter, such as stands of white cedar or where fruits of common juniper or red cedar are abundant (LaForest 1993). Smith (2003) analyzed Ontario Winter Bird-Population Study results. Densities of robins per km^2 by habitat were 6.9 in urban natural areas with water, 2.1 in urban natural areas

without water, and 0.1 in small urban natural areas. It was not documented on counts in farm or rural habitats. Doherty and Grubb (2000) studied winter use of forest fragments (0.05-6.01 ha) by robins in Ohio. Density decreased from early to mid-winter and as woodlot edge increased, as shrub coverage increased, and with increasing connectivity to other woodlots. In 1906-07, the primary habitats used by wintering robins in Illinois were picked cornfields (with the stalks remaining), forests, and orchards. In 1956-58, the habitats used most frequently were shrubby areas, forests, and pastures (Graber and Graber 1963). In Arkansas, Kentucky, and Mississippi, it was less common in row-crop fields with buffers of native grasses and forbs than in fields without buffers, but not significantly (Evans et al. 2015).

Winter roosts are important and are often in evergreens such as junipers, small pines, cedars, and magnolias (Speirs 1953). Tyler (in Bent 1949) reported winter roosts in common reed in marshes in Missouri. Curry (2006) reported an early winter or late autumn roost on the south shore of Cootes Paradise (supporting 614 birds), but did not specify the habitat.

The robin may be territorial in winter, but food resources are defended rather than a fixed area. Flocks of robins may defend fruit supplies against other species such as Northern Mockingbird and Cedar Waxwing. The robin is nomadic in winter; once a supply of fruit has been depleted it moves elsewhere (Vanderhoff et al. 2020).

The winter diet is comprised almost entirely of fruit, especially grapes in Illinois, but berries of cedars and junipers may be important. Fruits of common hawthorn are a staple in the western United States. In Maryland, hundreds of robins were observed feeding on holly berries in late winter. It uses a number of cues in foraging, in descending order of importance: fruit crop size, fruit size, and fruit pulpiness. Once a plant has been selected, larger fruits are selected over smaller ones. Fruit abundance defines the local abundance of robins. When fruit is abundant, robins may be common, but they may be absent in the same location during poor crop years (Chavez-Ramirez and Slack 1996; Graber et al. 1971; Petrides 1942; Vanderhoff et al. 2020). Riverbank grape and common buckthorn berries are staples of the winter diet in the Cambridge area (personal observation).

The robin occasionally visits winter bird feeders. Favourite feeder foods are fresh and dried fruit and water. Infrequent choices are mixed seeds, millet, black oil and striped sunflowers, safflower, cracked corn, milo, hulled peanuts and hearts, suet, peanut butter mixes, bird puddings, and baked goods. Occasionally, it eats pet food, meat scraps, and popped corn (Dunn and Tessaglia-Hymes 1979). One bird overwintering in the Yukon ate raisins at a feeder (Sinclair et al. 2003).

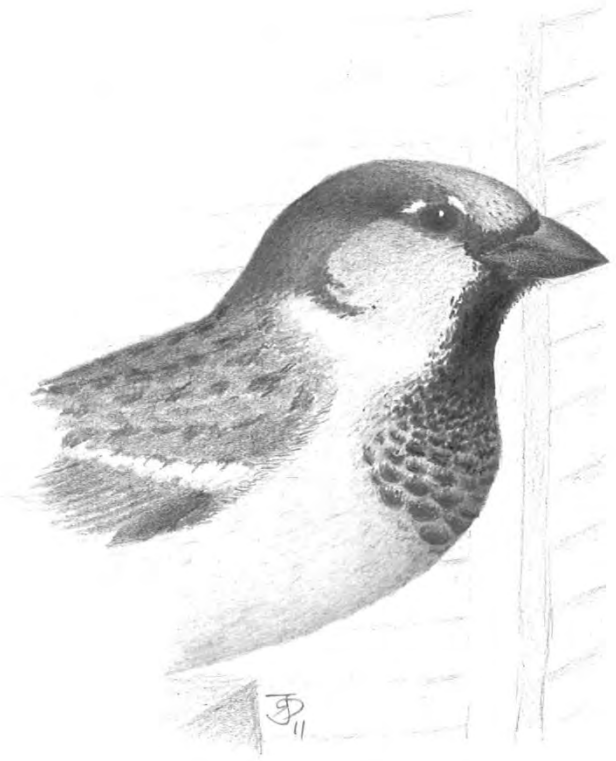
In winter in Colorado, the robin was positively influenced by the density of housing within 100 m and the height of understorey vegetation, but was negatively affected by percent canopy cover and percent cover of understorey vegetation (Miller et al. 2017).

The robin may die in winter during extreme cold coupled with precipitation even if ample food is available. After severe winter weather in Illinois, robins moved from upland to bottomland forests. The number of birds per km² before and after the storm were 26.2 and 36.5 in bottomland forest (a 40.0% increase), 151.4 and 14.8 in upland forest (a decline of 90.2%), and 0 and 35.1 in urban residential. A few dead birds were observed (Graber and Graber 1963; Vanderhoff et al. 2020).

The robin has always occurred in winter in Ontario. McIlwraith (1894) stated that it occasionally spent the winter in sheltered hollows. James (1991) considered it a rare to locally uncommon winter resident in the south and occasional and rare north to Thunder Bay and Kirkland Lake. Speirs (1953) reported that the most northerly winter locations for robins in Ontario at that time were Thunder Bay and Ottawa, and that fewer than 10 per party were recorded on Ontario Christmas Bird Counts (CBCs). Freedman and Riley (1980) analyzed CBC data for southern Ontario. Numbers remained stable from 1929 to about 1961 after which an irregular but large increase occurred, with peaks in 1972 and 1976. They speculated that increases might have been due to increased winter food supplies such as plantings of fruit-bearing shrubs. CBC trends for Ontario were annual increases of 6.17% 1970-2021 and 3.17% 2009-21 (National Audubon Society 2022).

House Sparrow

Passer domesticus



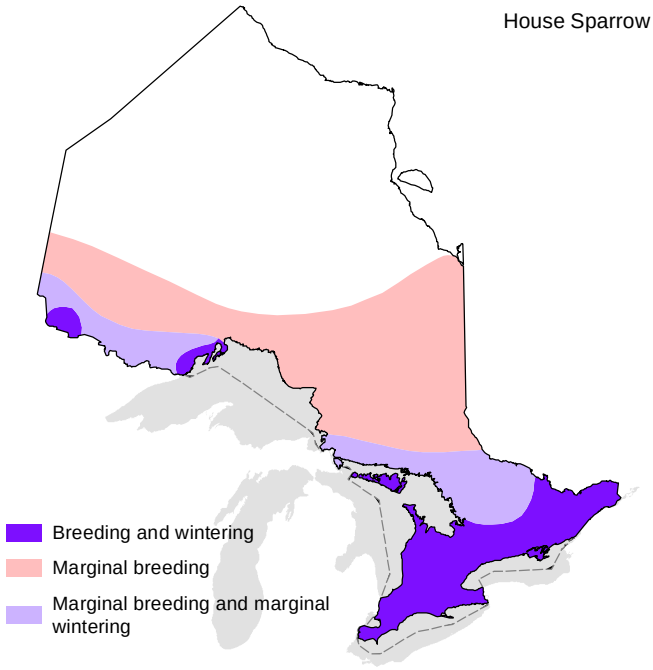
BREEDING SEASON

Habitat Requirements

Ontario House Sparrow nests were typically associated with human buildings and structures, with much less use of natural habitats. Of 1,234 nests, 56.4% were in urban and rural residential and commercial areas, including buildings, gardens, and cemeteries; 30.5% were in farmland, including farmyards, roadsides, hedgerows, fields, and pastures; 3.5% were in wooded areas including mixed and deciduous woods, orchards, and plantations; 3.2% were in river courses; 3.1% were in cottage and camping areas; 2.0% were in treed sand dunes; 0.9% were in wetlands, including swamps, meadow marshes, and dykes; and 0.4% were on railway rights-of-way. Wooded areas that were used were usually open, or nests were at clearings. Wet habitats were apparently chosen only because of the presence of suitable nest sites (Peck and James 1987). Even in natural habitats, it often nests in nest boxes or other artificial sites.

In Ontario, the House Sparrow is restricted to areas where there is human habitation such as urban centres, suburbs, villages, and scattered countryside dwellings. In rural areas, it favours areas with livestock and small grains and is rarely found in natural areas (Lancaster et al. 2004; MacLulich

1938; Mills 1981). It was equally abundant on southern Ontario organic and conventional farms. Its abundance was significantly correlated with the presence of farmsteads. It was also positively correlated with pastures and negatively with hedgerows and spring grain, but these relationships were not significant (Kirk et al. 2011).



In North America, the House Sparrow is associated with human settlements and agricultural lands with grain crops. It is absent in extensive woodlands, grasslands, and deserts. In the far north and arid west, it is present only in the immediate vicinity of human habitation. In large areas of desert, small colonies are present at every isolated ranch, gas station, and roadside rest areas, but none occur away from human-made structures (Lowther and Cink 2020). MacGregor-Fors et al. (2017) investigated its density relative to land use and location relative to an urban centre and urban intensity in Mexico and California. They studied its usage of 5 land uses: intra-urban areas with high urbanization (average of 77.3% built cover), intra-urban areas with low urbanization (average of 13.4% built cover), periurban areas with high urbanization, periurban areas with low urbanization, and agricultural areas. In Los Angeles and Mexico City, it was significantly more abundant in the intra-urban high urbanization habitat than in other land use classes. In Mexico City, there were also high densities in the periurban high urbanization class with only a few or 0 in the remaining classes; no birds occurred in agricultural areas. In Los Angeles, its abundance was positively correlated with maximum building height and high urbanization in urban areas. In Mexico City, its abundance was correlated with high urbanization and pedestrians. In all areas, its abundance was negatively correlated with trees. In urban areas, it can take advantage of a wide range of resources because most other species are absent due to lack of habitat or urban-related hazards. Its density and abundance are determined by variables unique to different cities and urbanization densities. In Illinois, densities were highest in high-density urban areas followed by low-density urban areas, with densities in developed open space dropping to less than 30% of densities in developed urban areas. Densities dropped another 50% in wheat and another 50% in grazed grass with very low densities in corn, soybeans, oats, alfalfa, savannahs, and grass mowed for hay. It was not detected in upland forests, floodplain forests, shrubs, idle grasslands, or marshes (Walk et al. 2011). In Manitoba, it used nest boxes in sites that had the highest percentage of long grass and the lowest percentage of forest and wooded pasture of the secondary cavity-nesters that were studied. Used sites had 8.0% wooded pasture and 41.4% long grass compared with 12.7% and 30.9% for unused sites, respectively; these differences were significant. It was significantly more likely to use nest boxes in disturbed areas and where utility lines were present. It was strongly associated with sites less than 400 m from buildings

but used boxes as far as 800 m from buildings (Munro and Rounds 1985). In Quebec, nests are usually near a food source in an open area such as a park, garden, or greenspace, or near a dwelling or building (Aubry in Gauthier and Aubry 1996). In Alberta, it nested in rows of blue spruce on a farmstead (McGillivray 1980a). In British Columbia, the House Sparrow is a resident of most human settlements and farmland areas where it concentrates near buildings and anthropogenic food sources. It occurs in highly urbanized commercial and industrial sites to sparsely settled rural and farmland areas. It is most abundant in residential areas followed by apartment residential areas, commercial areas, older residential areas, woody residential areas, and industrial areas; it is absent in mixed woodlands. It occurs regularly around railway yards, grain elevators and grain-shipping facilities, livestock barns and feedlots, poultry pens, and landfill sites. In cities, it often frequents fast-food restaurants, sidewalk cafes, bakeries, concession stands, and parks. Its distribution within residential areas is strongly influenced by the location of feeding sites. In Vancouver, numbers drop sharply when total vegetative cover reaches 60%. Nests are almost always close to buildings (Campbell et al. 2001). On a university campus in Mississippi, it nested in a group of 4 magnolia trees, a horse barn, an equipment shed and orchard, and a cluster of buildings associated with a pig feedlot (Sappington 1977). In rural areas of Oklahoma, it nested in boxes in open fields with scattered trees (Pogue and Carter 1995). In Iowa, it nested naturally in trees in riparian habitats, including herbaceous meadows, savannahs, scrub, wooded edges, and floodplain and upland woodlands (Stauffer and Best 1982). In suburban areas of Massachusetts, its abundance was positively associated with 4 variables: volume of structures, building density, cats, and humans. It was positively associated with distance to fallow fields and woodlots, indicating a preference for built-up areas. It was negatively associated with low volume of both conifers and deciduous trees and shrubs. It was positively correlated with high canopy, particularly coniferous volume 17-21 m from the ground, but was probably responding to the presence of nest sites in buildings rather than vegetative features. Suburban areas are ideal habitat because they provide buildings for nesting and grassy cover and open ground for feeding, dusting, and gathering nest material. It was observed on 61.7% of plots in suburban areas. In Florida suburban areas, it comprises more than 50% of the total breeding bird population (Thomas et al. 1977).

Nocturnal roosts are an important component of the House Sparrow's habitat year-round. In spring and summer, communal roosts in urban areas may support thousands of birds. In Oklahoma, roosts consisted of 1 or several trees, with roosts distributed throughout the city but not close to each other. Roosts were in maples, oaks, elms, sycamores, and cottonwoods. The main factors determining suitability for a roost were tree height and foliage density, with tree species probably not important. Trees at least 6 m tall with dense foliage were preferred. It seldom roosted closer than 3 m to the ground. There often was a congregating site near the roost where birds gathered 30-60 minutes before entering the roost. In 1 case, this was a clump of shrubs about 45 m from the roost. At another site, birds congregated on telephone wires, then flew down into shrubs, then to the roost which consisted of 3 large cottonwoods. The largest roosts in Stillwater, Oklahoma supported about 1,000 birds. In Iowa, birds roosted in Boston ivy on the walls of a hospital. In Philadelphia, thousands roosted in a single 12-m tall tree, with birds huddling as close together as possible. Additional birds roosted on an adjacent store covered with Boston ivy and Virginia creeper. In Boston, 3,000 birds roosted in 5 trees; 2 adjacent trees were devoid of sparrows. Roosts are occasionally shared with

other species, particularly the European Starling (Bent 1958; Bergtold 1921; McAtee 1950; North 1973). It is probable that rural birds roost in barns and other outbuildings but this does not appear to have been documented. While nesting, the female spends the night on the nest.

In Ontario, 44.2% of 1,198 nests were in bird boxes; 35.1% were on or in buildings; 10.4% were in trees; 5.1% were on hydro poles, traffic lights, or signs; 4.5% were on bridges; and 0.8% were in fence posts and other posts. One nest was near the ground in a fallen fence post. Nests were either concealed in cavities or recesses of trees and human-made structures or exposed in trees and vines on human-made structures. Concealed nests were in both single- and multiple-unit bird houses, with many in Purple Martin and Eastern Bluebird houses; in or on buildings in eaves and eavestroughs, holes, beams, roofs, canopies, ledges, fixtures, walls, and air conditioners; in trees in natural cavities and old woodpecker and chickadee holes; in or on signs, traffic lights, and hydro and telephone poles; on beams or in holes of bridges and culverts; in holes in posts; and in mail boxes. Exposed nests were in tree crotches, on beams of bridges and buildings, on hydro transformers and lines, in ivy on building walls, on silo ladders, on top of pillars, and on light and other outdoor fixtures. Of 109 nests in trees, 56.0% were in 12 species of deciduous trees and 44.0% were in 5 species of conifers. Species selected most frequently for nesting were spruce (29 nests), white cedar (16), maple (11), and willow (11). The House Sparrow sometimes built on top of or otherwise used old nests of Barn Swallows (25 nests), Cliff Swallows (24), American Robins (4), and Common Grackles (1). Nest boxes intended for Purple Martins, Tree Swallows, Northern House Wrens, and Eastern Bluebirds were usurped or used. Nests were occasionally built into the sides of occupied raptor nests, including 2 of the Red-tailed Hawk and 1 of the Bald Eagle. Nests were often close together with groups of 2-12 nests occurring together. Three nests between 2 billboards were 0.3 m apart and there were 6 occupied nests on the same bridge railing. Heights of nests in trees ranged from 1.2 to 23 m, with most 3.7-7.6 m up. Heights of nests in human-made structures, excluding nest boxes, were 0.9-15 m, with most 2.7-5.5 m up. Nests may be reused for as long as 4 years (Peck and James 1987). In Toronto, Savard and Falls (1981) characterized House Sparrow nest heights in 8 neighbourhoods representing the main types of residential development. House density ranged from 6.2 to 27.3 per ha; 4 plots contained 1-storey houses and 4 plots contained 2-storey houses. The average nest height was 5.29 m (range 1.5-11.9 m). Nests were equally abundant in 1- and 2-storey houses. Nest height depended on the height of the eavestroughs which was determined by the number of storeys; 6.5 m at 2-storey buildings and 3.86 m at 1-storey buildings. Fifty-one percent of nests were in openings around eaves and eavestroughs. It also nested in vent holes of attics, behind window shutters, and in decorative boxes over drain pipes. In plots with 1-storey houses where human-made structures were scarce, it frequently nested in conifers. Nests in trees were significantly higher than those on buildings in the same plot. In 2 plots, average nest heights in trees were 6.29 m and 5.65 m from the ground compared with 2.97 m and 4.13 m for nests on buildings. Where they were abundant, human-made structures were preferred. In 1 plot, tall conifers were present but all nests were on buildings. All tree nests were in dense foliage indicating a preference for cover. Height was also selected for in conifers. Coniferous shrubs were abundant in both plots but were not used for nesting. Nests in conifers averaged 5.95 m from the ground (range 3.05-9.14 m).

Throughout its range, the House Sparrow prefers to nest in cavities such as nest boxes and openings and crevices in buildings and other human-made structures. Occasionally, it nests in natural cavities in trees or old woodpecker holes. Less frequently, nests may be exposed and placed in trees or vines on buildings. Nests in trees may either be in forks of branches or among dense branching. Nests are always elevated and have been reported at heights of 0.2-32.2 m. Occasionally it uses old nests of other species as a platform or cavity for nests, including those of the Eastern Phoebe, Bank Swallow, Cliff Swallow, Barn Swallow, Northern House Wren, American Robin, and European Starling. In Bank Swallow colonies, it occupies the lower rows of nests. It readily uses nest boxes built for it and those intended for Tree Swallows and bluebirds. Similar to Ontario, nests have been reported in active raptor nests, including those of the Osprey, Bald Eagle, Swainson's Hawk, and other hawks. Unusual nest sites include tunnels into hay bales that were accessed from cracks in the boards below them and on oil pumps that were in constant motion, moving up and down approximately 60 cm every 3 or 4 seconds. One pair nested in an old hornet's nest. In British Columbia, 93% of nests were in cavities or crevices or on partially enclosed ledges and 7% were non-enclosed globe-shaped nests in trees, vines, hedges, or shrubs. Only 4 of 620 nests (0.6%) were in natural or excavated tree cavities. Forty-six percent of nests were in nest boxes, 35% were in building structures (houses, garages, sheds, barns, roof shelters, commercial or industrial buildings, and grain elevators), and 6% were in other human-made structures, including utility poles, street lights, signs, traffic lights, marine pilings, and bridges. Most non-cavity nests were in thick ornamental spruce or in vines on walls sheltered by a roof overhang (Bent 1958; Campbell et al. 2001; Kalmbach 1940; Leighton et al. 2002; Lowther and Cink 2020; Morejohn 1953; Rand and Rand 1952; Tatschl 1968; Werler and Franks 1975). In Vancouver, nest height ranged from 1.5 to more than 9 m (mean 5.1 m); most were 3-4.6 m from the ground. Of 56 nests, 51 were in buildings, 3 were in bird boxes, 2 were in deciduous trees and vines, and 0 were in conifers. The habitat included high- and low-density residential areas and apartment buildings. Of 44 nests in Hope, British Columbia, 38 were in buildings, 5 were in bird boxes, and 1 was in an old Cliff Swallow nest (Weber 1975). In Iowa riparian habitat, 46% of nests were in snags, 23% were in dead limbs, and 31% were in live trees. In snags, the House Sparrow nested predominantly in soft and intermediate-density snags with lesser numbers in hard snags. Nest height averaged 10.7 m in trees averaging 16.4 m tall with a diameter of 18.5 cm at the cavity; it nested high in small structures (Stauffer and Best 1980, 1982). In Alberta, McGillivray (1980b) studied clumping of nests in 2 rows of blue spruce 80 m apart. Ninety-seven percent of nests were against the tree trunk. Nests in 1 row were spaced evenly with only 2 trees with more than 2 nests. Nests in the other row were clumped with a maximum of 14 nests in 1 tree and 10 nests within a 1-m radius. In the row with dispersed nests, the mean number of nests within 1 m was 0.76 and the mean distance between nests was 1.52 m. In the row with clumped nests, the mean number of nests within 1 m was 3.43 and the mean distance between nests was 0.66 m. Dispersed nests had significantly more clutches and number of young hatching than clumped nests but fledging success was nonsignificantly higher in clumped nests. Grouping of nests may be associated with synchronous clutch initiation that may increase postfledging survivorship by providing flock mates. Clumping of nests may minimize the detrimental effects of adverse weather. Nests may be very close together; as many as 4 nests may be joined together into a communal structure. Birds may steal nesting materials from other nests, but not from their immediate

neighbours. Nests may be reused within and between seasons, but not necessarily by the same birds (Lowther and Cink 2020; McGillivray 1980a). In Kansas, nestlings did not imprint on their natal nest type, with the nest type they selected for nesting unrelated to their natal nest type. Males showed no preference for cavity nests or tree nests, but females showed a preference for cavity nests. Males advertising from tree nest sites may be at a disadvantage in attracting a mate (Cink 1976).

In Purple Martin houses, the House Sparrow was significantly less abundant in colonies with gourds only than in colonies with houses only or with both houses and gourds. There was higher occupancy of wooden than aluminum houses, but not significantly. Presence of some shrubs at the base of the pole appeared to favour occupancy and it preferred houses that received some sun, but not in the afternoon. On average, it occupied 20.4% of apartments in house colonies. Several factors had no influence on whether a Purple Martin house was occupied by the House Sparrow: type of house, its exterior and interior colour, whether it was cleaned out in spring, habitat (urban business, urban residential, suburban, rural), whether water was nearby, whether there was a neighbouring Purple Martin house, whether there were nearby utility wires, the amount of time that the house was in shade, and how many years the structure had been present (Jackson and Tate 1974). Other studies examined factors affecting nest box use. In Manitoba, used boxes had the largest internal area, the smallest entrance hole, and were higher above ground and closer to buildings than those used by other species. Four parameters differed significantly for boxes that were used and unused, respectively: box area, 263 and 259 cm^2; hole diameter, 39.3 and 41.7 mm; height above ground, 138.6 and 130.1 cm; and distance from building, 467.0 and 1,040.8 m. It selected boxes less than 800 m from buildings with box entrances of 30-38 cm. Boxes facing roads were used significantly less than expected. It did not select for exterior colour of nest boxes (Munro and Rounds 1985). In Tennessee, it preferred boxes with white interiors, but used boxes with dark interiors. White interiors may allow adults to detect predators (snakes) in the box easier and see the nestlings easier (Pitts 1977). In Ohio, there was a significant positive relationship between box usage and distance to the nearest tree. The mean distance of used boxes from a tree was 9.17 m compared with 3.07 m for unused nests (Horn et al. 1996). Lowther (2012) determined that there was a significant correlation between clutch size and area of the bottom of the nest box. The mean clutch size was 4.49 eggs in small boxes (112 cm^2) compared with 4.77 eggs in large boxes (221 cm^2). Nest-box size did not influence hatching or fledging success, egg mass, or nestling condition. There was no evidence that adults selected either large or small nest boxes.

The House Sparrow defends a small area around the nest. Experienced males may remain in the vicinity of the nest site year round, but it is defended strongly only during the breeding season. In Alberta, there were agonistic encounters between birds nesting in boxes 3 m apart, but birds nesting in blue spruce were more tolerant of each other. The foliage may have screened visibility, but birds nesting in trees were still more tolerant of each other than those nesting in boxes. Pairs of birds with nests in the same tree perched side by side without antagonism. Birds nesting within 1 metre were accepted, but strangers were attacked aggressively. A male that constructed a nest within another active nest was initially chased by a neighbouring male. Once the intruder attracted a mate and they began to nest, they were accepted by their neighbours (Lowther and Cink 2020;

McGillivray 1980a; Morrison et al. 2008). Breeding birds tend to remain within 1-2 km of the nesting area (Lowther and Cink 2020).

The House Sparrow is a highly sedentary species that does not migrate. Only 3 banded birds in Canada were recovered more than 25 km from the banding site: 33, 43, and 175 km. All these records were in southwestern Ontario (Brewer et al. 2018). Despite its sedentary nature, natal philopatry rates may be low due to dispersal during the postfledging period and high mortality. In Michigan, 7 of 187 fledglings (3.7%) from artificially enlarged broods returned; 7 of 99 control fledglings (8.1%) returned. There was no difference in the return rates of fledglings of second broods of females that laid 3 clutches (5.7%) and those that did not attempt a third brood (2.7%; Anderson 1998). In Kansas, Fleischer et al. (1984) studied colonies at 7 farms and checked for banded birds at 9 other farms, all within an area of 12 km^2. Only 63 of 3,360 nestlings (1.9%) were recaptured and 23 of these (36.5%) dispersed: 47.8% of females and 30.0% of males. Dispersal rates of females were significantly higher than for males. For both sexes, dispersers came more frequently from nests that had greater fledging success. Breeding success and population size may affect philopatry. On the farm with the lowest productivity per female and lowest population, 0 of 13 nestlings subsequently captured there had hatched there. All 5 recoveries of birds hatched there occurred at surrounding farms. Another farm about 1 km distant had the second highest breeding success and population. Of 90 birds captured there, 28 (31.1%) had been banded there as nestlings and only 8 (8.9%) were recovered at other farms, a highly significant difference. Brood size and hatch date had no effect on dispersal rates. Sixty-two percent of first-year autumn birds dispersed compared with 32% of adults; this difference was significant. Most or all dispersal occurred in late summer and early autumn. In Ohio, Dexter (1949) banded 668 House Sparrows; only 2 juveniles (0.3%) returned. In Kansas, 24.7% of treatment fledglings that had been moved to another nest box and 30.7% of control fledglings returned the following year (Cink 1976). In Illinois, 89 of 1,785 birds of unspecified age (5.0%) returned; 2 were banded as nestlings and 15 as fledglings. Random movements as far as 700 km have been reported and these represent dispersal by juveniles. Such movements are undertaken by a very small proportion of the population (Will 1973). North (1973) concluded that juveniles do not necessarily return to their original home range, but become dispersed over a large area. Few juveniles returned to the area in the Oklahoma town where they had hatched; instead they dispersed into new home ranges. Lowther and Cink (2020) reported that 1 bird banded as a nestling travelled approximately 26 km.

The House Sparrow is wary of traps and difficult to catch. Adults in particular are likely to avoid traps if they have been caught previously. Consequently, rates of natal philopatry and especially adult site fidelity may be underestimated. In Kentucky, 109 of 244 males (44.7%) that used nest boxes returned to nest in the subsequent year. Seventy of the returning males (64.2%) returned to the same nest box, 17 (15.6%) returned to a different box on the same barn, 4 (3.7%) returned to a box on a different barn, and 18 (16.5%) did not defend a box in the following year. Forty-two males lost their nesting box in the middle of the season and only 2 (4.8%) were seen at a box later in the season. Both defended a box on the same barn. Nine of the 42 males (21.4%) were seen in subsequent years: 3 returned to defend a nest box and 3 did not occupy a box. Sixty percent of males that were box owners for 2 or more years used the same box and 76% returned either to the same box or same

barn (Morrison et al. 2008). Another Kentucky study determined that fewer than 25% of birds survived long enough to breed in more than 1 season (Stewart et al. 2006). At a Michigan site, overwinter returns of females were less than 40%. There was no difference in return rates of females that raised 3 broods (36.0%) and those that raised 2 broods (28.3%; Anderson 1998). In Mississippi, 125 of 156 birds (80.1%) nested at the location where they were banded, but not necessarily in the same nest box where they bred the previous year. Eighty-six percent of males occupied the same box for the entire season, significantly more than those that used multiple boxes. There was no difference in the number of females using a single box (45%) or multiple boxes (55%) within a season. In subsequent breeding seasons, only 6 of 60 breeding males (10.0%) returned to their previous nest sites. Nest-site tenacity may have been affected by humans tearing down old nests and others deteriorating due to weather (Sappington 1977). In Kansas, adults dispersed significantly less than juveniles, with only 1 of 15 adult recoveries (6.7%) occurring at another farm. Adult males that dispersed were significantly larger than those that did not disperse, suggesting that smaller dispersing males had lower survival rates. Nineteen percent of males recovered as adults dispersed compared with 50% of yearling males; females of both age classes dispersed at equal rates (Fleischer et al. 1984). In Ohio, 11 of 668 birds (1.6%) were recovered and 9 were adults (the number of adults banded was not specified). Two recoveries were 1.2 and 1.6 km from the banding location (Dexter 1949). In Illinois of 1,785 banded birds of unspecified age, 4 adults returned. The longest movement was 3.2 km; only 3 birds moved as far as 1.6 km. One was an adult male that moved 2.4 km daily between its autumn feeding and roosting areas. Most movements occurred in late summer, autumn, and winter; many movements may have been within the daily flight range. Only 23.6% of birds were recaptured more than 30 m from where they were banded (Will 1973). In Oklahoma, most birds spent their entire lifetime within a very small area. Fifteen percent of birds (721 of 4,805) were subsequently recovered. Movement generally occurred in autumn. At 1 barn where no birds were collared, 1.0% of birds there in September were collared and this increased to 3.1% in October and 5.2% in November. Some birds were found 6.4 km distant and 2 were recaptured 11.3 and 109 km away, all in a northwesterly direction (North 1973).

Limiting Factors

Peck and James (1987) reported eggs in Ontario nests from the beginning of April until mid-August, with most present from mid-May to mid-June. Peck and James (1998b) reported nestlings on 3 November which would indicate a later egg date. They also reported nest building on 3 February and 4 March which may indicate earlier nesting. Early nests may take more than a month to construct, and adults may continue nesting most of the year (Weaver 1943), so it is difficult to predict when these nests might have held eggs. An egg was found in an Ottawa nest on 18 January (Kalmbach 1940). Young were found in a Utah nest on 1 January when temperatures averaged around −17°C and dropped to as low as −25°C. The young fledged successfully, but 1 or both adults were on the nest at all times and both spent the night in the nest box (Bent 1958; Weaver 1943). Although the House Sparrow may rarely nest very early or very late in the year, nesting typically occurs from April to August or early September, or slightly earlier further south. Murphy (1978) compared the timing of nesting initiation and termination in Kansas and Alberta. Breeding began later but at cooler temperatures in Calgary, so breeding initiation was not strongly tied to photoperiod or temperature; breeding continued longer in Calgary. Cessation of egg laying was

related to cooler temperatures in late summer in Calgary and high temperatures and dry weather in midsummer in Kansas. At both sites, cessation of egg laying was probably due to decreased insect abundance.

Nests built early in the season are constructed very leisurely. One British Columbia nest initiated in late February took 42 days to build. No information is available on how long it typically takes to build a nest. Peak periods of nest building tend to be followed by intensive egg laying within a week. One egg is laid per day and incubation usually begins with the laying of either the third or penultimate egg; occasionally incubation begins with the laying of the final egg. The incubation period of 15 Ontario nests was 9-14 days. Elsewhere incubation periods of 10-17 days have been reported, with most eggs hatching in 11-13 days. The longest-reported incubation period of 17 days was at a nest where a Barn Owl near the nest site inhibited nest attentiveness. Hatching may be synchronous in small clutches and those where incubation did not start until the last egg was laid. Hatching may take place over 2-3 days in broods where incubation started before the clutch was complete. The nestling period has been reported as 9-23 days but most nestlings fledge at age 14-17 days. Earlier departures are often associated with nest disturbance and the longest period was associated with the presence of the Barn Owl (Anderson 1994, 1997, 1998; Bartlett et al. 2005; Campbell et al. 2001; Cink 1976; Hegner and Wingfield 1987; Kalmbach 1940; Lowther 1990; Lowther and Cink 2020; Peck and James 1987; Sappington 1977; Weaver 1943).

The House Sparrow typically raises 2 or 3 broods in the northern portion of its range and as many as 4 in the south. Triple brooding has been confirmed in Ontario and British Columbia and was common in Michigan. There are reports of more than 4 broods per year but these may be erroneous. Individual nest boxes may be used by as many as 3 different females within a season; researchers that assume the same birds are using a nest may report an inflated number of broods. Yearling females are capable of rearing 3 broods, but significantly fewer (43.8%) did so compared with adult females (68.8%) in Michigan. Females raising large second broods of 7 or 8 young were significantly less likely (42.9%) to raise a third brood than those with normally sized second broods (72.7%). Thirty percent of females moved to a different nest box to raise their next brood. The distance between successive nests was 2-89 m, but 66.7% of females had their next brood within 10 m of the previous nest; the median internest distance was 5.9 m. The interval between fledging of the previous brood and laying the first egg of the next clutch is usually about a week, but ranges from −8 to 49 days. Females may lay eggs in nests still containing young of the previous brood and sometimes initiate egg laying in another nest before young leave the previous nest. In New York, the interbrood interval increased significantly with the number of fledglings in the previous brood. The interbrood interval averaged 7.0 days for broods that were experimentally reduced, 7.1 days for control broods, and 11.3 days for experimentally enlarged broods. The House Sparrow is a persistent renester if nests are lost and may lay as many as 8 clutches in an attempt to raise a brood (Anderson 1994, 1998; Campbell et al. 2001; Hegner and Wingfield 1987; Kalmbach 1940; Lowther 1979; Lowther and Cink 2020; Mitchell et al. 1973; Peck and James 1987; Peck and Peck 2010; Sappington 1977; Weaver 1943). Clutches of 3-7 eggs have been reported in Ontario (average 4.66 eggs). Four- and 5-egg clutches were most frequent, with more nests containing 5 than 4 eggs (Peck and James 1998b). Elsewhere, clutches of 1-9 eggs have been reported, but the normal range is 3-7 eggs.

Clutches of 5 eggs are most abundant, followed by 4 and 6 eggs. Clutch size is strongly correlated with latitude, with mean clutch sizes of 2.0-3.3 in Central America to more than 5 eggs in Alberta. The size of subsequent clutches in a season is negatively correlated with the size of the previous clutch. In New York, mean size of second clutches was 5.4 eggs for females whose first clutch had been experimentally reduced, 4.3 eggs for control females, and 3.6 eggs for females whose clutches had been experimentally enlarged. Some studies observed no seasonal decline in clutch size; others reported that clutch size declines with season. In Kansas, clutch sizes increased to a maximum in midseason, the only time when 7-egg clutches were present. In Illinois, clutches initiated in March and April averaged 4.46 eggs, significantly larger than 4.17 eggs for clutches initiated in July and August (Anderson 1994, 1998; Baker 1995; Bartlett et al. 2005; Bent 1958; Campbell et al. 2001; Hegner and Wingfield 1987; Kalmbach 1940; Lowther 1990; Lowther and Cink 2020; Mitchell et al. 1973; Sappington 1977; Weaver 1943; Will 1973).

Both sexes are capable of breeding when they are 1 year old. In many populations, some birds of each age and sex class do not breed, possibly because of limited nest sites. In Kentucky, male nest-box holders were more likely to be older birds. Those that were nest-box owners in previous years and yearlings that had hatched in a box at the site were more likely to become nest-box owners. Sixteen of 51 males (31.4%) that were hatched in on-site boxes became a box owner compared with 10 of 100 yearlings (10.0%) that had hatched elsewhere (Morrison et al. 2008). In Mississippi, 82.6% of adults bred, including 78.4% of males and 86.7% of females (Sappington 1972).

The House Sparrow is monogamous with no cases of polygyny reported. Mate fidelity is variable. In Missouri, only 60.5% of pairs remained together for the entire season, although the number of males having a single mate was significantly higher than those having multiple mates in a season. There was no evidence of pairs remaining together for more than 1 season (Sappington 1977). In Missouri, females that were removed were replaced within 1-20 days, with most replacement females appearing in an average of 12.2 days (mode 5-8 days). Replacement females began to lay eggs as soon as 1 day after arrival. Replacement birds were mostly yearlings that had not bred previously and older females that had not been at the colony the previous year (Anderson 1990).

In Kentucky, 45 of 419 nestlings (10.7%) were extra-pair and 33 of 126 broods (26.2%) contained extra-pair young. Yearlings were as likely as adults to be sires; size had no influence on whether a male was a sire of extra-pair young. Sires included neighbours, males breeding at the same barn, and some that may have been breeding some distance away. Adult males tended to have more extra-pair young in their broods than yearlings. Yearling females had more extra-pair young in their broods than adults. Later broods were more likely to contain extra-pair young, probably because some females stop breeding after the second or third clutch, freeing their mates to seek extra-pair copulations. There was no relationship between nesting density or breeding synchrony and the rate of extra-pair copulations, but significantly fewer extra-pair young occurred in larger broods (Stewart et al. 2008). Rates of extra-pair young reported elsewhere include 1%, 7%, 10%, 14, and 20% (Stewart et al. 2006; Wetton et al. 1987).

In Delaware, 8 of 94 clutches (8.5%) showed evidence of intraspecific parasitism. Parasitism was confirmed by electrophoresis. Other signs of parasitism were unusually large clutches, odd-coloured eggs, and 2 eggs appearing in the nest in a single day. Kendra et al. (1988) artificially parasitized

some nests and hosts had 3 different responses. One female removed 3 eggs that had been inserted after she laid her first 3 eggs, 2 of the 17 manipulated nests (11.8%) were abandoned after an egg was added, and at 3 of the manipulated nests (17.6%) the host female failed to lay an egg on the day following egg addition. Eggs were removed from some nests, demonstrating that the House Sparrow was an indeterminant egg layer until the clutch size reached 3 eggs after which total egg production appeared to be limited to 4-6 eggs. Females could increase their fecundity by laying parasitic eggs before they laid 3 eggs in their own nests. Parasitism may be detrimental to the host, suffering reduced fecundity and diluted resources for her own clutch. If an egg is inserted before the host lays 3 eggs, the parasitic egg may halt egg production, reducing the host clutch size by 1 egg. If parasitism occurs after the third egg, the host may have an oversized clutch that can result in decreased food deliveries to each young and decreased survival. It was uncertain what occurred when the host female skipped a day in egg laying after parasitism. It is possible that she laid her egg parasitically in another nest.

The House Sparrow forages mostly on the ground for seeds. In grain fields, it alights on the stalks and plucks the seeds from the fruiting heads, or shakes them to the ground to be picked up later. It pursues low-flying beetles through the air and captures them on the wing; it is one of the heaviest predators of the Japanese beetle. It catches insects by flycatching and hover pouncing, follows lawnmowers to catch moths, kleptoparasitizes earthworms from robins, pierces flowers to obtain nectar, and picks insects out of grills of stopped cars. It flushes prey from trees and shrubs by shaking the leaves or twigs with its feet while vigorously flapping the wings. Moths and other prey flushed by this method were captured in flight. In Connecticut, it captured larvae of the elm leaf beetle by creeping around trees in nuthatch fashion as high as the first limbs to intercept descending larvae. It captures black locust leafminers by systematically searching the curled-up edges of leaves. It responds to outbreaks of geometer moth caterpillars, crickets, and locusts. It has eaten salt from salt blocks in barnyards and foraged at night on insects at floodlights (Bent 1958; Brooke 1973; Brooks 1951; Brown 1971; Calhoun 1945; Campbell et al. 2001; Guillory and Deshotels 1981; Lowther and Cink 2020; Wilmot 1917). The House Sparrow is highly vigilant while foraging, with flocks frequently flying from the food source to adjacent cover. Food resources in locations where sparrows cannot adequately detect predators may not be used. In Wisconsin, Popp (1988a) studied their selection of horse pats for foraging. Pats were in grassy pasture grazed to within 5 cm of the ground and weedy areas where many of the plants were taller than 0.5 m. Visibility for the House Sparrow was good and bad in these habitats respectively. Over 2 years, 88.7% and 92.2% of foraging visits to horse pats were in the grassy area. Birds preferred to forage at pats where 2-4 birds were already present. These pats were approached more than expected by chance; pats with no birds present were approached less than expected. Pats with 1 or 5 or more sparrows already present were approached with the expected frequency. Foraging in taller vegetation would put sparrows at risk of predation, especially by cats, due to low visibility. Joining a small flock at a pat could provide benefits from the selfish-herd effect and from reduced vigilance rates. Presence of other sparrows might also be indicative of a good foraging location. At a Saskatchewan site, House Sparrows comprised about 65% of the breeding season diet of the Merlin, which increasingly took juveniles rather than adults from May to July. Approximately 70% of adults and 80% of juveniles foraged within 1 m of cover. In June, all juveniles were in or near cover. In July, juveniles occurred at almost every distance from cover, but

more juveniles were close to cover than adults. As juveniles aged, they became more proficient at detecting predators and ventured further from cover (Sodhi 1992). In Pennsylvania, sparrows feeding on a flat roof initially congregated on the wall prior to descending to feed. When alarmed, they retreated to 2 adjacent trees, but mostly to a hemlock that offered better cover than a red oak. Each sex was equally likely to initiate a feeding flock, but 71.6% of birds remaining after a disturbance were males, significantly more than expected. Males are subordinate to females and may be excluded from the best foraging areas so they may risk predation to get better access to food (Breitwisch and Hudak 1989). Other studies demonstrated that females are dominant to males (Jawor 2000; Johnston 1969), but males in northern latitudes may be dominant in certain seasons.

Young House Sparrows subsist predominantly on insects but switch to a diet of seeds as they age. At age 11 days, nestlings ate live flies and puppy food when it was offered but showed no interest in millet and canary seeds. At age 16-17 days, they abruptly switched from a strong preference for insects to a complete refusal of insect offerings. By age 25-30 days, they fed on seeds almost exclusively and ignored the puppy food (Mueller 1986). Kalmbach (1940) analyzed the stomach contents of 2,819 nestlings from all months. The diet consisted of 68.13% animal food and 31.87% vegetable matter. Nestlings consumed significantly more animal food than adults (3.39%). The animal food consisted of 15.17% weevils, 4.01% scarab beetles, 0.46% click beetles, 2.65% ground beetles, 0.29% leaf beetles, 1.43% other beetles, 25.24% orthopterans, 11.16% caterpillars and moths, 1.34% bugs, 2.88% flies, 1.34% hymenopterans, 0.16% other insects, 1.79% spiders and other arachnids, and 0.21% other animal material. Vegetable matter consisted of 29.76% agricultural feed, 0.19% oats, 0.95% wheat, 0.03% corn, 0.01% other grain, 0.17% grass and weed seeds, 0.11% mast and wild fruit, 0.11% cultivated fruits and vegetables, and 0.54% other vegetable matter. The amount of animal food consumed declined as nestlings aged, with a decrease in the amount of weevils, caterpillars, fly larvae, and spiders. The percentage of animal food in the diet was 90.15% for nestlings 1-3 days old, 65.1% for nestlings 4-6 days old, and 49.13% for nestlings older than 7 days. Other animal foods in nestlings' diet included lacewings, mayflies, dragonflies, millipedes, earthworm cocoons, snails, and fragments of hens' eggs. Judd (1901) reported that 50 nestlings had consumed 65% insects, 2% weed seeds, and 33% grains. The insect food consisted of 49% grasshoppers, 8% beetles (mostly weevils), 4% lepidopterans (armyworms, cutworms, fall webworms, and tussock moth caterpillars), 3% ants and other hymenopterans, and 1% bugs. Almost all the grasshoppers were short-horned grasshoppers, but nestlings also ate crickets and long-horned grasshoppers.

In Ontario, adults have been observed eating cicadas (Luft 2000). In Hamilton, McIlwraith (1894) reported that they depredated the grapes in his yard by eating the fruit buds. Judd (1901) examined 82 stomachs collected throughout the year in eastern and Midwestern states. The diet consisted of 2% animal matter and 98% vegetation, which consisted almost entirely of seeds. Insects were consumed mostly in May and June when they comprised 10% and 8% of the diet respectively. It has been observed capturing nymphs of twelve-spotted skimmers (a dragonfly) that had just emerged from the water. Other animals consumed included small bees, ichneumonid wasps, parasitic wasps, weevils, dung beetles, June beetles, leaf beetles, soldier bugs, leafhoppers, aphids, scale insects, and cicadas. The vegetable matter consisted of 7% grass seeds (wild rice, panic grass, foxtails, and

crabgrass), 17% weed seeds, and 74% grain, which comprised 90% of the diet from June to August. Seeds consumed included those of lamb's-quarters, black bindweed, sweet clover, knotweed, field mustard, smartweed, climbing false buckwheat, dandelion, sunflower, and ragweed. Kalmbach (1940) analyzed the contents of 4,848 adult stomachs. The diet consisted of 3.39% animal matter and 96.61% vegetation. Most animal food was consumed in May, with a decrease through summer and autumn. The animal food consisted of 3.32% insects and 0.07% arachnids, crustaceans, and miscellaneous invertebrates. Weevils were an important component of the insect diet, with most eaten in May and June. It regularly visited alfalfa fields to feed on alfalfa weevils. Other beetles commonly consumed included bark beetles, which were also fed to young, and June beetles and other scarab beetles. Urban birds ate more beetles than rural birds. Other beetles that occurred in the diet included click, ground, leaf, lady, long-horned, tiger, darkling, rove, and clown beetles. Orthopterans were eaten from April to September with a peak in August, but comprised only 0.57% of the annual diet. These were predominantly short-horned grasshoppers, but it also ate crickets, locusts, and long-horned grasshoppers. Lepidopterans comprised 0.23% of the diet; only in July did they comprise more than 1% of the diet. It most frequently ate owlet and geometer moth caterpillars and adults and occasionally consumed cabbage white butterflies, fall webworm caterpillars, forest tent caterpillars, and gypsy moths. Bugs were insignificant in the diet and were consumed from April to September with a peak in April. It ate ebony bugs, stink bugs, lace bugs, treehoppers, leafhoppers, planthoppers, aphids, scale insects, and cicadas. Flies were consumed from March to September but mostly in April; overall they comprised 0.10% of the diet. These were predominantly crane flies and house flies taken chiefly from manure. Hymenopterans comprised 0.31% of the diet and were eaten every month except February and December with a peak in September. They were mostly ants but some ichneumonid and parasitic wasps were consumed. The amount of other insects consumed was trivial and included termites, lacewings, mayflies, odonates, and stoneflies. In addition to spiders, it ate millipedes, earthworms and their cocoons, snails, and fat and meat fibres that were human garbage. One pecked out the eyes and fed on the brains of a dead House Sparrow that was in the same trap. Vegetation comprised 96.61% of the diet and constituted less than 90% of the diet in only May. It ate feed picked up in chicken coops and yards and barnyards and it was the dominant food, representing 59.5% of the annual diet. Grains were important in the diet, including 14.37% oats, 2.70% wheat, 0.43% corn, and 0.58% other grains. Other vegetation consumed included 16.97% grass and weed seeds, 1.39% mast and wild fruits, 0.2% cultivated fruits and vegetables, and 0.58% other vegetable matter. Those consuming the greatest amounts of feed were collected in the vicinity of poultry runs, with maximum consumption in February. Oats were eaten in sheaves, stubble, and from granaries and horse manure, but mostly from village streets and barnyards. Other grains consumed included sorghum, rice, barley, and millet. Grass and weed seeds were eaten every month with greatest consumption in October and the least in June. Dominant seeds consumed were those of ragweed and crabgrasses, and smartweed seeds were also prevalent in the diet. Other seeds included those of lamb's-quarters, amaranths, foxtails, panic grasses, paspalum, barnyard grass, Johnson grass, annual bluegrass, timothy, flatsedges, common chickweed, plantains, sheep sorrel, catnip, bedstraws, white clover, and sunflowers. Mast and wild fruits were eaten every month but mostly in June and July. Elm seeds were most prevalent, but it also ate mulberries, blackberries, strawberries, and fragments of rose hips. Cultivated fruits and vegetables it consumed included

cherries, peas, and beans. It also eats cultivated strawberries, raspberries, blueberries, gooseberries, currants, grapes, mulberries, plums, peaches, apples, pears, and tomatoes. It feeds on buds of fruiting trees. In spring and early summer, it feeds on the tender sprouting leaves of peas, beans, lettuce, peppers, cabbage, beets, asparagus, and other vegetables and on those of certain flowering plants such as pansies and carnations. It feeds on the flowers of vegetables such as peas and beans. From April to August, it fed on the foliage of clover obtained from lawns. Gavett and Wakely (1986) compared the diets of 218 urban and 267 rural House Sparrows in Pennsylvania. In the country, 97.3% of birds consumed cereal grains and 94.3% ate insects that were mostly beetles. These 2 food items were the most important for rural birds. In the city, 93.1% of birds ate insects, 81.2% ate seeds, and 82.6% ate commercial bird foods. By volume, cereal grains were most important for rural birds and bird seed was the most important for urban birds. The most important grains in the diet of rural birds were corn (eaten by 49.4% of birds), oats (4.1%), and wheat (3.7%). The most important seeds for urban birds in bird seed included milo (consumed by 14.7% of birds), millet (9.6%), and sunflowers (1.4%). Urban birds consumed elm seeds (18.3% of birds) but these were not eaten by rural birds. Urban adults ate significantly more bird food than rural birds and urban juvenile birds. Urban birds consumed other seeds significantly more frequently than rural birds. Rural birds tended to eat more plant fragments than urban birds; urban birds were more likely to eat spiders and other arachnids than rural birds. Other miscellaneous foods consumed by House Sparrows included seeds of wood-sorrel and panic grasses, springtails, flies, bugs, aphids, insect eggs, cestodes, bird lice, fleas, and mites. The significant differences in the diets of urban and rural birds probably reflect differences in food availability. Beetles were the most important insects in the diet of both urban and rural birds. The significant difference in the amount of other seeds consumed by urban and rural birds was due to the preponderance of elm seeds in the diet of urban birds; these trees were common along city streets. In urban areas, it was often seen feeding on discarded food and other refuse, but this was probably digested too quickly to show up in the results. Most food consumed by both urban and rural birds came from humans. Urban birds have been documented feeding on chicken drumsticks and other human waste food (MacGregor-Fors et al. 2020). Howell and Clements (2019) documented it depredating brown anoles in Florida. Both sexes caught the lizards, bashed them against the ground, and pecked off and consumed small pieces.

The House Sparrow is a rare host of the Brown-headed Cowbird. This is probably because the House Sparrow either nests in cavities or builds a globular nest with a side entrance whereas the cowbird prefers open-cup nests. No parasitized nests have been reported in Ontario. There are fewer than 20 records of cowbird parasitism of House Sparrows, but they include 2 cases where they successfully fledged a young cowbird. In British Columbia, 1 of 359 nests (0.3%) was parasitized and there is a single record of a House Sparrow feeding a fledgling cowbird. A 1951 report of a parasitized nest in Maryland was the fourth known case of parasitism at that time (Brackbill 1951; Campbell et al. 2001; Lowther and Cink 2020; Peck and James 1998b).

Food availability is probably the greatest limiting factor for the House Sparrow. It has declined significantly in response to reductions in the amount of available food. The invention of the internal combustion engine had an indirect but highly significant impact. Prior to then, horses were used for transportation and harvesting crops and sparrows fed heavily on grain in horse droppings. Horses

were widely replaced by tractors and automobiles. Bergtold (1921) provided evidence of a decline in House Sparrows in Denver, Colorado, and attributed it to the decline of horses in the city. Previously, hundreds of sparrows were present in the business section but they were absent by that time. In the downtown area, it fed almost exclusively on grain in horse manure. There was a 66% decrease in horse droppings from 1911 to 1919. By 1919, there were enough tractors in Colorado to displace 16,000 horses. Immediately following World War 2, cars became abundant and horses essentially disappeared from urban areas, resulting in further declines in the House Sparrow. In urban areas, food from garbage decreased due to better sanitation methods (Bent 1958; Erskine 2006; Holder 2003; Lowther and Cink 2020). Although there has been an increase in bird feeding in urban areas, this occurs predominantly in winter and many people do not offer the oats, cracked corn, and feed mixes that it prefers. Urban areas also support more predators than they did previously, especially domestic cats, but also raptors such as Sharp-shinned Hawks and Merlins. In the Maritime Provinces, urban areas no longer provide a favourable habitat for the House Sparrow and it may disappear from cities there within a few decades (Erskine 2006).

Several factors have contributed to less food availability for the House Sparrow in rural areas, resulting in lower populations. The number of farms has decreased, livestock numbers have declined and they are managed differently now, methods of harvesting crops have changed, and the crops that are grown have changed. Beginning around the 1950s, marginal farmlands were retired and often reforested or allowed to undergo natural succession. This resulted in less habitat for the House Sparrow due to fewer barns and outbuildings and less land in agricultural production.

The number of cattle declined in Ontario. This decline continues, with 2.141 million cattle in Ontario in 2001 and 1.624 million in 2016 (Statistics Canada 2018), a decrease of almost 25%. Until the mid-20th century, each farm typically had a few cattle that grazed outside in pastures. Now, fewer farms have cattle and they are often kept and fed within barns where their feed and manure is unavailable to sparrows. Manure was formerly stored outside in barnyards and spread on fields as fertilizer. Farmers are now required to have manure management systems that often consist of sewage lagoons that offer no food for sparrows. Earlier most farms had a small flock of chickens that was kept in a coop and fed in an enclosure outside the coop. Sparrows were able to feed on the food that was intended for the chickens. Most chickens are now raised and fed inside barns where sparrows cannot access their food.

Prior to the 1950s and 1960s, grain was harvested using a binder that tied the grain into sheaves. Sheaves were stooked together in the field to dry for a few days before they were taken to the barn to be threshed. This method of harvesting left considerable waste grain in the fields, and sparrows could also feed on the grain heads while they were drying. Now almost all grain is harvested with combines that leave little waste grain, and the harvested grain is transported immediately into barns.

The crops that are grown in Ontario have changed significantly and these changes have been detrimental to the House Sparrow. Originally, most crops were designed to support livestock and included pastures and hayfields for forage and small grains to supplement their diet, particularly oats but also wheat and some barley. The pastures with their livestock and the extensive fields of small grains provided abundant food for the House Sparrow. As the number of livestock declined, pastures were converted to croplands and corn and soybeans began to be the dominant crops.

Wheat became the dominant small grain grown rather than oats. In Ontario, corn production increased over 3,000% from 1947 to 1987, mostly at the expense of oats and mixed grains. The area of cropland planted to corn and soybeans continues to increase. In 2001, there were 909,922 ha planted to soybeans compared with 1,126,419 ha in 2016; there were 810,595 ha planted to corn in 2001 and 874,932 ha in 2016. During the same period, the area planted to oats declined from 41,144 ha to 33,268 ha (Statistics Canada 2018). The changes in crops are significant because oats are the preferred grain food of the House Sparrow. Full-sized corn kernels are too large for it to handle efficiently although it readily consumes cracked corn. It is unknown whether it eats soybeans at all. Erskine (2006) identified many of these same factors as contributing to the decline of the House Sparrow in the Maritime Provinces. In Illinois, Graber and Graber (1963) reported that populations declined in the southern portion of the state but increased in the north from 1907-09 to 1957-58. They attributed this to changes in crops. The amount of land planted to oats increased in the north where sparrow populations also increased, whereas the area planted to wheat increased in the south.

The number of available nest sites has declined in both urban and rural areas. In cities, most of the ornate architectural fashions on eaves that provided abundant nest sites have disappeared. More significantly, most modern buildings have eaves constructed of aluminum and many older structures are being retrofitted with aluminum eaves. Eaves of houses were formerly an abundant source of nest sites, but these sites are largely gone. In rural areas, the number of wooden barns and outbuildings has decreased significantly and continues to decline. Modern barns are typically built of steel and provide no nest sites.

Researchers had varying opinions on whether the House Finch had an adverse effect on the House Sparrow in eastern North America. It is agreed that House Sparrows were declining before the introduction of the House Finch so it was not fully responsible for the decline, with changes in urban and agricultural practices being more important. Most studies conducted at large scales determined that the decline of the House Sparrow was accelerated in the northeast where the House Finch was abundant. In the southeast and in Indiana where the House Finch population is not as great, presence of House Finches did not influence House Sparrow population trends. This suggests that competition influences are not manifested unless the House Finch density is high. Beginning in 1994, disease significantly reduced House Finch populations. In the northeast, the House Sparrow declined significantly in winter when the House Finch was increasing, but no longer declined after the House Finch decreased. Trends in summer were similar but nonsignificant. It appears as though high densities of House Finches can depress House Sparrow populations, but this may no longer be a significant limiting factor now that the House Finch is declining (Bennett 1990; Cooper et al. 2007; Hamilton and Wise 1991; Holder 2003; Kalinowski 1975; Kritcher 1983; McClure et al. 2011; Wootton 1987).

The House Sparrow is host to a variety of parasites, viruses, and bacteria that can have adverse effects on individuals or populations. It is occasionally infested by gapeworms and adults with severe symptoms such as gasping for air have a reduced probability of survival (Holand et al. 2014). Nestlings are involved in the amplification of the western encephalitis virus. They circulate the virus for several days in their bloodstream at concentrations high enough to infect vector mosquitoes

(Mitchell et al. 1973). Sparrows nesting in Cliff Swallow colonies may become infected with the Buggy Creek virus (BCRV). This virus was typically associated only with the Cliff Swallow and is transmitted by the ectoparasitic swallow bug. BCRV has little effect on adult House Sparrows but only 9% of infected nestlings fledged in Nebraska. The bugs prefer Cliff Swallows as hosts, so the closer a House Sparrow nest is to a Cliff Swallow nest, the more likely it is to fledge young. Cliff Swallows have become immune to BCRV and rarely show any symptoms of infection. It was considered unlikely that House Sparrows would develop immunity due to low site fidelity, lack of imprinting on nest sites by young, and limited maternal transmission of antibodies (O'Brien and Brown 2012). Die-offs of House Sparrows due to salmonellosis have occurred in Prince Edward Island and transmittal of it may have been aided by increased transportation between urban centres (Erskine 2006).

Severe weather may have adverse effects on the House Sparrow. High mortality may occur when sudden storms arise at night while birds are roosting (Kalmbach 1940). High winds may cause extensive damage to nests in trees (Mitchell et al. 1973) and nests may be deserted late in the season due to hot dry weather (Will 1973).

Traffic noise does not appear to have significant effects on the House Sparrow. Brischoux et al. (2017) played recordings of traffic noise at nest boxes. Noise did not influence nestling growth. Those chronically exposed had a reduced resting metabolic rate, the opposite of the expected effect.

Status

Originally native to Europe, Asia, North Africa, the Middle East, India, and Burma (Myanmar), the House Sparrow was introduced widely so that it now has a cosmopolitan range. With the exception of Antarctica, it may occur almost everywhere that humans reside. Where it was introduced, densities initially increased in urban areas and spread to suburban areas and then rural areas, especially where small grain crops were grown or where there was livestock. In North America, its spread was hastened by the network of railway tracks. Birds travelling in grain cars established colonies at most settlements along railway corridors. A small population in Churchill is associated with the railway and grain elevator, but there are no other populations within several hundred kilometres (Erskine 2006; Jehl and Smith 1970; Kalmbach 1940; Lowther and Cink 2020).

The House Sparrow was introduced to New York City predominantly from England but some German birds were also introduced. The rationale for its introduction was three-fold: it was believed that it would control larvae of the elm spanworm moth, some European immigrants wanted to see familiar birds from their homeland, and others wished to introduce to North America all bird species that were mentioned in Shakespeare's works. Its initial successful establishment in New York was met with enthusiasm. People were paid to feed them, nest boxes were erected for them, legislation was enacted to protect it, and bounties were put on shrikes and hawks that might prey upon them. It spread rapidly and the enthusiasm quickly turned to annoyance. The legislation protecting it was repealed and bounties were placed on House Sparrows and removed from the predatory species. In a few days in 1899 in Boston, 6 men filled 5,000 nest holes, destroyed 4,000 nests, and broke 1,000 eggs. A sparrow shooting contest was held in Streetsville, Ontario in 1902 with the successful team

bagging approximately 3,000 (Curry 2006; Judd 1901; Lowther and Cink 2020; Robbins 1973; Walk et al. 2011).

The first introduction of the House Sparrow to North America consisted of 6 pairs that were released in Brooklyn, New York in the spring of 1851. These birds did not survive. In 1852, approximately 100 were brought from England. Fifty were released upon arrival and 50 were released the following year. These became successfully established and the rate of spread from the release site was a radius of 40 km in 5 years, 80 km in 10 years, and more than 160 km in 15 years. The public clamored for more releases and at least 19 shipments were released in the next year and liberated from New England to Utah. Numerous undocumented releases were made throughout the continent from stock that had already become established. It spread further by travelling in train boxcars and established populations at most settlements along railways. By 1886, its range included most of the eastern United States, southern Ontario, southwestern Quebec, and New Brunswick, with extensive thriving colonies in major cities in the western states. The eastern population peaked around 1890 and has been declining since (Bennett 1990; Kalmbach 1990; Robbins 1973).

The first successful introduction in Canada was in Quebec City. The House Sparrow appeared in Montreal around 1870 and was abundant by 1896 (Aubry in Gauthier and Aubry 1996). It was established in the Maritime Provinces in the 1880s (Erskine 2006). Around 1870, 10 pairs were released in Ottawa and an unknown number were released in Hamilton in 1872. It was first observed on the streets of Hamilton in 1875 and 2,000 were observed on a single day in 1943 (Curry 2006; McIlwraith 1894). Its early distribution and abundance is difficult to trace because it was held in such contempt that many people refused to acknowledge its presence. It was not included in the annotated checklists of the birds of Elgin County in 1891 or 1954, but would certainly have been abundant during both periods (Lancaster et al. 2004). Sheppard et al. (1936) reported that it was very abundant in Niagara Region. Populations appeared to be stable in rural areas but declining in cities and villages. In the Toronto area, its numbers increased or decreased depending upon the severity of the winter but the general trend was an increase in population (Fleming 1907). It was first reported during the breeding season in Algonquin Park in 1912 and bred sparingly in small settlements, particularly those along the railroad. The last confirmed nesting in the park was in 1967; by the 1970s, most villages had been abandoned and dismantled (MacLulich 1938; Tozer 2012). By the late 1880s, it was established at North Bay (Mills 1981). It was not reported in Sudbury in 1889 but occurred there in great numbers in 1901 (Baillie and Hope 1947). It has variously been reported in small numbers or absent in Moosonee and Moose Factory and first appeared there in 1911. It is likely that birds do not survive the winter but that new colonists occasionally arrive on the train (Barlow 1966; Manning 1952; Schueler et al. 1974; Weaver 1943). The most northern record for Ontario was a female collected in June 1940 at Fort Severn; it appeared to be the only House Sparrow that was present (Barlow 1966). Baillie and Harrington (1937) concluded that the House Sparrow was very common in suitable habitat throughout the province, and that it probably nested wherever it occurred. They had no breeding records for areas north of Lake of the Woods or Kapuskasing, where it was a common breeder in 1928. R.L. Weaver (1939) described its distribution in Ontario and concluded that it extended northward regularly as far as there was systematic cultivation. In northern areas, it was restricted to areas near railways, roads, and cultivated crops. The northern

boundary of successful establishment appeared to be the Great Lakes–St. Lawrence Forest Region from Lake Nipissing to Lake of the Woods. At that time, it was considerably less abundant in Toronto than it had been 30 years previously. The first atlas revealed a slightly more extensive northern range. It occurred in the Moosonee area, in the Lake Nipigon area eastward to the Quebec border at the same latitude, and north to Red Lake north of Lake of the Woods. It was absent in heavily forested landscapes of the southern Canadian Shield. It was reported in every square south of the Shield except for the extreme tip of the Bruce Peninsula and portions of Manitoulin Island; these areas are predominantly forested. It was a common to abundant resident south of the Shield. In the north, it was absent or rare to locally common depending upon remoteness, winter severity, food abundance, and winter shelter (Barlow in Cadman et al. 1987). James (1991) considered the House Sparrow a common to locally abundant permanent resident north to Georgian Bay and Ottawa, becoming increasingly uncommon and local to Red Lake and Moosonee, and a vagrant to the north coast.

The second atlas revealed no significant change in the breeding distribution of the House Sparrow since the first atlas. There were some contractions in the northern extent of its range, but many of these probably represented populations in isolated settlements. Its probability of observation declined significantly province-wide and in the Carolinian and Great Lakes–St. Lawrence forest regions. It also declined in the Boreal Forest Region and the Hudson Bay Lowlands but not significantly. The decline was most evident in the Shield portion of the Great Lakes–St. Lawrence Forest Region, probably due to an increase in forest cover. It was common only south of the Shield. It was most abundant in areas of intense agricultural operations and high human population. These included Ottawa and farmlands to its southeast, the Toronto and Hamilton area, the Niagara Peninsula and Haldimand County, and the farmlands and urban centres in Perth, Waterloo, Wellington, Oxford, Lambton, Essex, and Chatham-Kent (Lang in Cadman et al. 2007).

Breeding Bird Survey (BBS) results may underestimate declines of the House Sparrow because routes typically avoid urban areas. It is also possible that some surveyors did not include it in their counts in earlier years. BBS data for 1970-2021 indicate that it decreased at annual rates of 3.08% in Canada and 3.32% in Ontario. For 2011-21, the annual rates of decrease were 2.38% in Canada and 2.47% in Ontario. All results were highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Young are capable of more or less sustained flight when they leave the nest, unless they are disturbed and fledge prematurely. Fledglings are typically cared for by the male and remain with him 7-10 days after leaving the nest. After this, juveniles congregate together into foraging and roosting flocks (Lowther and Cink 2020; McGillivray 1984).

Both juveniles and adults are most mobile during the postbreeding period, which extends into late autumn. Fledglings are being produced by May and by June they begin to gather in flocks. By then, food may be scarce in urban areas. These flocks move into rural areas where they feed on small grain crops. Flocks of juveniles are joined later by adults when they cease to breed. These flocks may number in the thousands of birds, but start to break up in October. In Oklahoma, birds returned to urban areas in October and remained there until the following June (Kalmbach 1940; Lowther and Cink 2020; North 1973).

Communal nocturnal roosts are important during the postfledging period. The House Sparrow establishes flyways between roosts and feeding areas and there is a general movement out of urban centres as the season progresses, especially by juveniles. In Oklahoma, 7.5% of birds in fields were adults compared with 48.8% in the urban centre. Birds left the roost in the morning in small flocks of 2-25 birds, but returning flocks may contain more than 100 birds. Specific flight lines were used. Early in the season, routes were more indirect, becoming increasingly direct with continued use. In early May, flocks foraged in pastures and cut hayfields close to the city and began feeding in standing and harvested grain in June. At this time, few birds fed more than 800 m from the city. In late July, sorghum fields were visited and were used into October. Few birds travelled further than 3.2 km between roosts and feeding areas, but some moved as far as 4.8 km. When returning to the roost, birds often stopped in feeding and staging areas at the edge of the city. These had a supply of food and trees and shrubs for cover. Communal roosts tended to be in areas of the city where buildings protected trees from the wind. There were no roosts in or near the field where birds fed daily. Roosts were abandoned late in autumn once the leaves dropped. At this time, birds moved to more numerous, smaller, and more sheltered roosts for the winter (Kalmbach 1940; North 1973).

M. Brown (1972) described what appeared to be migratory behaviour in October on an island in New Jersey. He observed numerous flocks of 10-30 House Sparrows flying at a height of about 30 m. He estimated 400 in 30 flocks within a half hour, but more could have passed through. They appeared to be doing a reverse migration to the mainland. The birds that were moving may have come from densely populated areas further north. When the tourists leave, there is a critical shortage of food and the House Sparrow must move or perish. This is the only report of possible migration in North America, but it appeared to be a local response to food shortage rather than true migration.

WINTER

Winter habitat for the House Sparrow is the same as the breeding habitat, consisting of urban areas and rural sites where there are livestock or small grains. Most birds remain in the same area year round, but some may move from urban areas to rural areas for the winter or vice versa depending on which areas provide the most food (Root 1988). In Toronto, it was least abundant in January and started increasing in February to a peak in September, falling to winter levels in October (R.L. Weaver 1939). In Muskoka and Parry Sound districts, it is found only locally and mostly in larger cities in winter but occasionally occurs around active farms (Mills 1981). In southern Ontario, Smith (2003) used results of Winter Bird-Population Studies to characterize its habitat. It was recorded exclusively in cities and urban natural areas. Densities per km^2 were 150.3 in city commercial or residential areas, 46.2 in urban natural areas smaller than 10 ha, 8.4 in urban natural areas with water, and 0 in cultivated fields with hedgerows and mixed rural areas. Nonetheless, it does occur in rural areas near farms or feeders (personal observation). In Kansas, large flocks frequented almost every farmyard and it was common wherever grain was grown or livestock was kept. Flocks often occurred in thorny trees and shrubs that bordered grain fields or were close to farm buildings (Fitch 1958). Along an urban gradient in California, it was significantly correlated with structures and negatively correlated with trees (Kalinowski and Johnson 2010). In Illinois, it was absent in bottomland and upland forest and occurred solely in urban residential areas; agricultural lands were not surveyed (Graber and Graber 1979).

Roosts are even more important in winter because they help the House Sparrow conserve energy. In more temperate areas, individuals may roost in nest boxes or other nest sites. Where winters are more severe, it constructs feather-lined structures in nest boxes and crevices in buildings. Birds may huddle together in cold temperatures and huddle closer as the temperature drops. Near the northern extent of its range, it may select heated areas for nocturnal roosts including inside grain elevators, attics, soffits, livestock barns, and structures such as light fixtures, street lights, and electric signs. In Missouri, it roosted in a subterranean transformer vault. Birds entered through a grate and roosted under the concrete roof about 1 m underground (Anderson 1998; Burns et al. 2013; Campbell et al. 2001; Jehl 2004; Jehl and Smith 1970; Kalmbach 1940; Marti 1974).

Adults may defend their former nest sites during the winter and also use them as roosts. In winter, juveniles visit multiple nest boxes or other potential nest sites to prospect for nest sites (Lowther and Cink 2020; Sánchez-Tójar et al. 2017).

The House Sparrow is highly vigilant and skittish when feeding in winter. As the number of birds in a flock increases, the amount of time spent scanning for predators decreases and the amount of time feeding increases (Studd et al. 1983). Dominant males with larger bibs spend less time being vigilant and more time feeding (Boujja-Miljour et al. 2018). Of 305,087 House Sparrows foraging events at feeders, white proso millet was the dominant seed consumed (by 70% of birds), followed by black oil sunflowers (5%), cracked corn (5%), 0.3-mm sunflower chips (3%), and 0.5-mm sunflower chips (2%). It did not eat niger seed, red milo, safflower, striped sunflowers, or whole peanuts. Factors such as presence of a hull on the seed, protein content, fat and fibre content, seed volume, and ratio of bill to seed volume were not good predicators of food choice (Johansen et al. 2014). It preferred tube feeders over platform and hopper feeders (Horn et al. 2014). The House Sparrow is a common and consistent visitor to feeders all winter. It is less likely to visit rural feeders but is equally abundant at rural and urban feeders. Flock size declines steadily as winter progresses. Favourite feeder foods include mixed seeds, millet, black oil and hulled sunflowers, cracked corn, milo, baked goods, popped corn, and barley. Infrequent choices include canary seed, striped sunflowers, whole corn, wheat, niger seed, hulled peanuts and hearts, canola, pet food, peanut butter mixes, bird puddings, dried fruit, and sugar water (Dunn and Tessaglia-Hymes 1999).

Severe winters may result in extensive mortality. Heavy snow cover in rural areas may cover food and result in widespread starvation. Cold weather may cause mortality even when there are sufficient food resources. From the Sudbury and Algonquin Park areas northward, local populations may be extirpated in winter and this has been documented in numerous other northern locations (Campbell et al. 2001; Erskine 1977, 2006; Jehl and Smith 1970; Kalmbach 1940; MacLulich 1938; Root 1988; R.L. Weaver 1939). Large females and small males have lower survival fitness and are less likely to survive the winter (Johnston and Fleischer 1981).

Most surveys conducted in winter demonstrated that the House Sparrow population is declining in Ontario. Freedman and Riley (1980) analyzed results from Christmas Bird Counts (CBC) in southern Ontario 1929-77. Numbers were relatively stable over this period. Both the CBC and Project Feeder Watch (PFW) results for Ontario 1977-97 indicated a significant decline. The PFW abundance index averaged about 9 1977-89, dropped to 3-4 in 1990 and 1991, and was down to 1 by 1997. Over the same period, the CBC abundance index dropped from 40 to less than 5 (Lepage

and Francis 2002). Curry (2006) reported that the Hamilton CBC peaked at 3,900 in 1966 followed by a sharp drop to 1,717 in 2005 with a 10-year average of 2,064. CBC results for Ontario indicate that it decreased by 6.15% annually 1970-2021 and 3.54% 2009-21 (National Audubon Society 2022).

American Pipit

Anthus rubescens

BREEDING SEASON

Habitat Requirements

Ontario American Pipit nests were on dry tundra areas on raised gravel ridges or beside tundra ponds (Peck and James 1987). In Ontario, it breeds only in the Tundra Region and Hudson Bay Lowland, predominantly on coastal tundra. Preferred habitat is relict gravel and boulder-strewn beach ridges within 20 km of the Hudson Bay coast. It also occurs locally inland on extensive, open palsa plateaus (Sutherland in Cadman et al. 2007). Manning (1952) reported that it bred at Little Cape where it was observed most frequently among driftwood and boulders near the top of the coastal storm beach.

The American Pipit typically nests in arctic or alpine tundra which differ from each other and the gravel ridges that are inhabited in Ontario. In the arctic, it usually avoids flat areas, although flat areas are occasionally used. Nesting has occurred on the Iqaluit airport on Baffin Island. Preferred habitats in the arctic are moss-grown slopes with southern exposures, sunny ravines cut into bluffs, rocky slopes near streams, sheltered meadows on south-facing slopes, high rocky ridges along Hudson Bay near Churchill, and granite ridges. It is very common in rocky habitat and absent in wet tundra with no granite outcrops. The extensive lowlands of Baffin Island are less suitable than the rugged slopes and support a much smaller population; it was infrequent in the high plateau-like interior. Favoured areas were completely free of wind even in adverse weather and warm when the sun was

out. Insects and spiders tend to be common in these areas even when it is windy. Mosquitoes were often a good indicator of suitable pipit habitat. The pipit is closely correlated with the most mesophytic vegetation and areas with the highest diversity of plant species. Many nesting areas are slowly watered by melting snow from above, contributing to development of mesic plant communities, often dominated by mosses, lichens, heather, and horsetails, and creating habitat suitable for mosquito breeding (Bray 1943; Drury 1961; Freeman 1970; Jehl and Smith 1970; Manning et al. 1956; Parmelee et al. 1967; Soper 1946; Sutton and Parmelee 1954; Wynne-Edwards 1952).

In alpine habitats above the treeline, the pipit breeds in the Rocky Mountains as far south as New Mexico. In these areas, it nests in mesic meadows, barren lava flows with scattered dead or dying trees and minor amounts of herbaceous vegetation growing in cracks and crevices, sparsely vegetated alpine tundra, heath meadows, more richly vegetated meadows, boulder fields, scree slopes with scattered vegetation between rocks, cliff ledges, and gravelly streambeds. Territories in Wyoming alpine areas included fell-fields (at least 40-50% rock and soil with most vegetation shorter than 2 cm, but with scattered plants as tall as 15 cm) and wet meadows, on level to steeply sloping ground, and on bare to well vegetated surfaces. The 2 main habitat requirements were that a site must become ice-free soon enough for nesting and it must have some rough features such as tussocks, tilted rocks, or eroded spots for nest sites. In British Columbia, most nests were in well vegetated sites, usually on sloping hillsides where there were overhanging clumps of vegetation, sod, and stones for nest sites. In California, nesting occurred in exposed gravel shorelines around alpine lakes (Anderson 1989; Campbell et al. 1997; Hendricks and Verbeek 2020; Miller and Green 1987; Norris and Morgenson 1982; Sinclair et al. 2003; Verbeek 1970).

Pipits typically arrive at the breeding area before all the snow has melted. The first birds occupied snow-free areas in Wyoming, but frequently abandoned these areas before the good weather set in (Verbeek 1970). In Washington, territories consistently had snow in them. As the snow melted, these areas became more hydric and supported taller vegetation than other areas. Territories may not be selected for the snowfields themselves, but for the vegetation that the melting snow provides (Norvell and Creighton 1990).

Ontario nests were cups sunken into the sides of heath and lichen hummocks. One had a short tunnel entrance overhung by a heath plant, and this appears to be the only reported nest with a tunnel. Another nest was overhung by a clump of earth (Peck and James 1987).

Throughout its range, the pipit always nests on the ground and the nest typically has a recognizable entrance. Nests are rarely exposed from above, but most are under overhanging rocks, sod, or vegetation. Nests are frequently built into the side of a tussock with vegetation overhanging the nest, but they may be under rocks or in fissures in rocks. The female scrapes out a small depression in the ground prior to building the nest, or rarely builds the nest over the entrance of a small mammal burrow. In alpine areas south of Canada, most nests are oriented northwest to northeast. In these areas, temperatures may become very hot so nests are orientated to avoid direct sunlight and prevent discomfort to the incubating female. Nests in the arctic, including areas as far south as the Belcher Islands, face southward, presumably to take advantage of the warm sun in colder climates. Old nests are occasionally reused. When this occurs the female may remove the old nesting material or simply add to it (Bent 1950; Campbell et al. 1997; Drury 1961; Freeman 1970; Hendricks and Verbeek 2020; Johnson 1933; Norris and Morgenson 1982; Pickwell 1947; Sinclair et al. 2003; Soper 1946; Sutton and Parmelee 1954; Verbeek 1970, 1981; Wynne-Edwards 1952).

The American Pipit defends a territory and may be aggressive to Horned Larks, Pine Siskins, and Brewer's Blackbirds. Silent pipits that are feeding may sometimes intrude into neighbours' territories without fights. At other times, intruders may be attacked. Almost everywhere throughout its range, large areas of suitable habitat are unoccupied. This allows pipits to feed outside their territory without being accosted. Most foraging occurs within 150 m of the nest, but some birds travel as far as 300 m to forage. In Wyoming, 5 territories averaged 0.18 ha (range 0.16-0.36 ha). Larger territories have been reported elsewhere, but the foraging area outside the defended area may have been considered part of the territory. In California, the territory of 1 bird was several 100 m in diameter, but consisted mostly of snow with small meadows of heather and grass. The average territory size in Utah was 0.7 ha; territories were 1.7-2.1 ha in the Rocky Mountains in Colorado (Drury 1961; Hendricks 1987a; Hendricks and Verbeek 2020; Pickwell 1947; Verbeek 1970).

Natal philopatry rates appear to be very low, although there are limited data. In Wyoming, 1 of 222 nestlings (0.5%) returned to breed the following year (Verbeek 1970).

Hendricks (1991a) banded 32 nesting females in Wyoming and 4 (12.5%) returned the following year; 1 returned a second year. Two returning birds nested 34 m and 37 m from their previous year's nest. The female that returned in 2 years had her final nest 24 m and 38 m from her earlier nests. It was uncertain whether the low return rate of females was due to dispersal or mortality. Also in Wyoming, 1 of 9 adult females (11%) returned and nested about 400 m from her previous nest (Verbeek 1970).

Limiting Factors

Eggs are most likely to be present in Ontario nests during the first 3 weeks of June (Peck and James 1987). An average of 5.1 days elapse from when the female excavates the nest hollow until the first egg is laid. The interval between nest completion and laying of the first egg is 1-3 days. Initiation of egg laying appears to be related to air temperature. Initiation of egg laying in Wyoming occurred after 4 days with an average temperature of 7.3-8.2°C. It takes 4 days for the female to develop an egg and once she has, she is committed to laying. Eggs are normally laid at the rate of 1 per day, but occasionally a day is skipped. Size variation in broods of 6 suggests that incubation may begin before the clutch is complete, at least in large clutches. On Baffin Island, the incubation period was just a

few minutes less than 12 days. In Wyoming, the average incubation period was 14 days 10 hours (range 13 days 18 hours to 15 days 19 hours). It has been suggested that reported incubation periods of less than 13 days were likely in error, but it is possible that arctic-breeding birds have shorter incubation periods. On Baffin Island, the nestling period was 12-14 days; the mean nestling period in Wyoming was 14.0 and 14.2 days (range 12-15 days). The entire breeding cycle takes about 50 days from nest building until independence of the young (Hendricks and Verbeek 2020; Johnson 1933; Sutton and Parmelee 1954; Verbeek 1970; Wynne-Edwards 1952).

A single brood is raised annually. In the arctic and alpine habitats where the American Pipit breeds, the breeding season is too short to raise a second brood. Renesting may occur if a clutch is lost, but renesting often does not occur, particularly if losses occur late in the season. The female may continue laying in a nest if an egg is lost, but not if the first egg is lost. After nest loss, many females abandon the territory and general area. Those that renest build a new nest, usually within the same territory or in undefended areas adjacent to the original territory. Four replacement nests were an average of 36.8 m from the first nest. The first egg in replacement clutches appeared an average of 5.5 days after the first nest was lost. Two replacement clutches had the same number of eggs as the first, 1 had 1 less egg, and 1 had 1 more egg. Clutches or broods of 4-6 have been reported from Ontario. The overall clutch size is 3-7 eggs with 5 or 6 eggs most frequent. In Wyoming, the mean clutch size remained stable in June but declined around mid-July. The mean clutch size increases significantly with latitude. In Wyoming, 5 eggs was the most frequent clutch size and 6- and 7-egg clutches were rare. On Baffin Island, all clutches contained 5-7 eggs. The larger clutch sizes in the north are unrelated to daylength and are because birds in arctic areas initiate nesting earlier than those in more southern alpine areas (Bent 1950; Campbell et al. 1997; Hendricks 1991a, 1991b, 1997; Hendricks and Norment 1992, 1994; Hendricks and Verbeek 2020; Peck and James 1987; Verbeek 1970, 1981; Wynne-Edwards 1952).

The age at first breeding is 1 year. It is likely that most birds are monogamous, but 1 Wyoming male attended 2 nests concurrently that were 120 m apart (Hendricks 1987a; Hendricks and Verbeek 2020). Intraspecific parasitism appears to be rare. Four Wyoming nests were apparently parasitized by other female pipits, with 2 fresh eggs occurring within them in a single day (Hendricks and Verbeek 2020).

Most foraging occurs by walking through thick moist vegetation, often along stream banks, in meadows at the crests of bluffs, on frost-heaved barrens on slopes, on south-facing slopes, on mud and pebble shorelines of lakes, on snowfields, on drifted sea wrack along the coast, and in salt or brackish marshes along tidal streams. The American Pipit tends to forage at the edge of vegetation, weaving in and out of open and vegetated areas. It forages mostly by walking often simply walking from the nest to forage, but it may run to capture food. It occasionally makes short flights from the ground or boulders to pursue prey. Less frequent foraging techniques include wading in shallow water to capture aquatic invertebrates and perching in branches of tall plants growing in shallow water and reaching for insects among heads of plants. Birds in a flock were observed flying 0.9-1.2 m above ground capturing moderately sized flying beetles then dropping back to the ground. In Ungava Bay, birds fed on maggots at whale carcasses. During the breeding season, birds forage alone. Members of a pair leave the nest in different directions and forage in different areas to avoid

competition for resources. In Wyoming, the area used for foraging by 6 pairs averaged 6.7 ha (range 3.3-10.1 ha); 5.3 ha (range 1.8-10.1 ha) for males and 3.6 ha (range 2.2-6.6 ha) for females. Each foraging area contained portions of all 4 major habitats that were present. Males tended to visit tundra meadows and snowfields more than females. Females tended to visit fell-fields and stony areas more than males. In alpine areas, snowfields offer a unique foraging substrate. Thermal winds carry insects up from lower altitudes and deposit them on snow where they are abundant, easily detected, and often moribund and easy to capture. Despite the abundance of suitably sized prey, snowfields are used considerably less than their availability for foraging. In Washington, 89.9% of birds were seen on snow-free surfaces. In Wyoming, 19.6% of time was spent foraging on snowfields, 19.6% on fell-fields, 17.7% in rocky meadows, 31.4% in grassy meadows, 6.5% in shrub growth, and 1.3% in treed areas. During summer snowstorms, the pipit feeds in snow-free pockets on the leeside of rocks, hummocks, and shrubs. Peak visitation to snowfields corresponds with the maximum density of arthropods in this habitat which is in mid-July and in mid- to late afternoon when updrafts are most likely to be depositing invertebrates. Avoidance of snowfields may be because foraging pipits are conspicuous on snow and may be more vulnerable to predation (Bent 1950; Drury 1961; Hendricks 1987a, 1987b; Hendricks and Verbeek 2020; Norris and Morgenson 1982; Norwell and Creighton 1990; Pickwell 1947; Verbeek 1970).

In Wyoming, most food supplied to nestlings was 5-10 mm long. In California, the mean length of food provided to nestlings was 8.05 mm (range 2-22 mm). Two percent of nestling food items were less than 3 mm in length, 86% were 3-6 mm, and 12% were longer than 6 mm. In Wyoming, stomach contents of 25 nestlings 4-14 days old consisted of insects and grit; grit was absent in stomachs of nestlings younger than 4-5 days. Vole and squirrel molars were found in nestlings' stomachs. The mammal teeth were probably picked up from the ground and do not indicate that these animals had been eaten. In another Wyoming study, of 62 prey loads delivered to nestlings, lepidopterans were identified in 71.0% of deliveries, flies in 19.4%, spiders in 6.5%, grasshoppers in 1.6%, and flying ants in 1%. In Labrador, nestlings ate mostly flies and small larvae, including 1 large grub. In California, 95% of nestlings' diet consisted of flies plus aphids, seed bugs, and jumping plant lice. During the breeding season, adults eat almost 100% insects plus a few seeds, small snails and crustaceans, and wild berries. In Wyoming, the diet of adults consisted of 58.3% flies, 11.1% bugs, 11.1% moths, 2.1% millipedes, and 0.7% snails. Other arthropods eaten during the breeding season included emerging stoneflies, crane flies, mayflies, lacewings, dragonflies, caddisflies, and spiders. The diet in Colorado consisted of 10.0% orthopterans, 9.7% bugs, 6.0% beetles, 25.1% lepidopterans, 25.1% flies (10.7% crane flies, 7.5% stilleto flies), 1.9% ants, 14.7% mites and spiders, and 8.2% miscellaneous. Along marine shores, the American Pipit may forage in tidewater pools where it feeds on marine worms and crustaceans (Bent 1950; Hendricks 1987a, 1987b; Hendricks and Verbeek 2020; Johnson 1933; Pickwell 1947; Verbeek 1970; Wynne-Edwards 1952).

The most significant limiting factor to the American Pipit is snowstorms and other adverse weather during the breeding season. A severe thunderstorm on Baffin Island killed at least 1 adult and most nestlings perished from exposure, starvation, or both. A July snowstorm in Wyoming covered nests with 15-30 cm of snow. The researchers dug out all the nests, but a high percentage of young still perished. Without human intervention, probably all young would have been lost.

Nestlings younger than 11 days probably died of exposure; older birds died of starvation. Prolonged periods of wet, windy, or foggy weather may reduce insect availability and result in death of nestlings due to starvation or exposure (Drury 1961; Hendricks and Norment 1992; Hendricks and Verbeek 2020; Sutton and Parmelee 1954).

High temperatures are injurious to developing embryos. Exposure of eggs to direct sunlight when the female is off the nest can kill embryos even if temperatures are fairly low. In Wyoming, there was a correlation between the incidence of addled eggs and unusually warm weather at a subalpine site (Hendricks and Norment 1994).

Status

Breeding evidence for the American Pipit in Ontario was first established when Manning (1952) collected recently fledged young near the mouth of the Sutton River in 1947. He concluded that it nested in small numbers in a few locations along the Hudson Bay coast. The first nest was found at Cape Henrietta Maria on 29 June 1948. Other early breeding and nest records were from Fort Severn and radar sites 415 and 416. It was concluded that it probably nested all along the Hudson Bay coast (Baillie 1962; Peck 1972; Peck and James 1987). Wilson and McRae (1993) concluded that it nested at Shagamu. During the first atlas, 16 breeding records were obtained, all from coastal tundra from the Manitoba border east to Cape Henrietta Maria, again indicating that it nests in suitable habitat all along the Hudson Bay coast (Peck in Cadman et al. 1987). James (1991) considered it a common summer resident along the Hudson Bay coast.

The second atlas revealed that there had been no significant changes in the distribution or probability of observation of the pipit since the first atlas. Prior to this atlas, all breeding records had been within 20 km of the Hudson Bay coast, but breeding evidence was found in 4 squares 38, 38, 53, and 65 km inland. It is likely that it breeds all along the Hudson Bay coast and along the northern James Bay coast as far south as latitude 54°N. Highest density appears to be in the vicinity of Cape Henrietta Maria where there are more extensive areas of suitable beach ridge habitat (Sutherland in Cadman et al. 2007).

Breeding Bird Survey data indicate that the American Pipit declined in Canada at annual rates of 3.16% 1970-2021 and 1.58% 2011-21, but results were of low reliability. No population trends are available for Ontario (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Some young are not capable of flying when they leave the nest but others may be able to fly short distances. The young appear to make no effort to feed themselves the first 2 weeks after fledging and are highly dependent upon the adults during this period. Young may be partially dependent for 6 weeks after fledging (Hendricks and Verbeek 2020).

In Wyoming, postfledging young were most likely to inhabit rock slides or strips of rock (Vermeer 1970). In Labrador, 3 young with 1 or both their parents frequented an area about a woodpile and house approximately 300 m from the nest. They were seen there for 2.5 weeks after fledging. Another family was frequently seen in this area, but no brood mixing occurred (Johnson 1933).

MIGRATION

The American Pipit migrates during the day, usually in loose, straggling flocks of a few to several hundred. Single birds may also occur during migration. Autumn flocks are typically much larger than spring flocks. The timing of initiation of autumn migration is uncertain. In late summer, at least part of the local population moves and is replaced by other birds. Adults moult in mid-August and flocks at this time are comprised mainly of juveniles. By the end of August, adults flock with juveniles and flocking behaviour becomes stronger toward early September (Bent 1950; Hendricks and Verbeek 2020; Verbeek 1970).

In southern Ontario, spring migrants pass through from late March until the end of May (Speirs 1985). Wilson and McRae (1993) saw spring migrants at Longridge on 8 and 9 June, at Ekwan on 19 June, and at Shagamu from 28 May to 9 June. Manning (1952) reported that the pipit occurred all along the western James Bay coast during autumn migration and observed a large flock on 29 September several kilometres inland on the Hayes River above York Factory. Wilson and McRae (1993) saw migrants at Shagamu 20-30 August, at Ekwan on 12 September, and migrants were common at Longridge 4-13 September. In the southern Shield, most pass through between mid-September and mid-October with early arrivals in mid-August and stragglers until mid-November (Mills 1981; Tozer 2012). In southern Ontario, autumn migration is from mid-September until mid-November (Speirs 1985). There is often a noticeable peak in numbers at the end of October or early November. If there is no snow cover, some birds may linger into late December or January (Black and Roy 2010; Curry 2006; Fleming 1907; LaForest 1993; Lancaster et al. 2004; Weir 2008).

During migration, the pipit inhabits open areas that are often unvegetated. In Ontario, it is most often observed in freshly plowed fields, along the shorelines of Lake Ontario and Lake Erie, on rocky shores of islands in the Kingston area, in stubble fields in autumn, in forest clearings, in gravel pits, in moist meadows in open country, and on shores of ponds, creeks, and inland lakes (Curry 2006; LaForest 1993; Lancaster et al. 2004; McIlwraith 1894; Tozer 2012; Weir 2008). Similar migration habitat requirements have been reported elsewhere. It may prefer mudflats and river banks during migration, but significant numbers are found on beaches and plowed and stubble fields, and it has been recorded in gravel pits, landfills, short-grass pastures, along roadsides in forested areas, on river gravel bars, at airports, and on playgrounds. At Churchill, birds congregated around grain elevators to feed on waste grain (Bent 1950; Campbell et al. 1997; Falardeau in Gauthier and Aubry 1996; Hendricks and Verbeek 2020; Jehl and Smith 1970; Leighton et al. 2002; Sinclair et al. 2003).

The pipit usually feeds in loose flocks during migration and winter (Hendricks and Verbeek 2020). In Utah, Knowlton (1944) collected 103 birds that were foraging in alfalfa and wheat stubble fields and along roadsides. Of 3,450 food items, 56.3% were true bugs (47.5% seed bugs and 1.6% plant bugs), 16.3% beetles (12.2% weevils, 2.2% scarab beetles, and 1.0% rove beetles), 14.0% weed seeds, 6.0% soft-winged bugs (2.7% leafhoppers and 2.6% aphids), 3.1% lepidopterans, 1.7% hymenopterans (0.6% ants), 0.9% orthopterans (0.8% crickets), 0.9% flies, 0.6% springtails, 0.3% spiders, 0.1% thrips, and 0.1% bristletails. Two birds collected during autumn migration had eaten 10% vegetable matter (violet seeds) and 90% animal material: 37% beetles (ground beetles and weevils), 33.5% caterpillars, 8% plant bugs, 7.5% spiders, 2.5% flies, and 1.5% hymenopterans (Bent 1950).

Hendricks and Verbeek (2020) concluded that forest clearing probably improved habitat for migrating pipits, but that wetland drainage had the opposite effect. Less habitat is available as marginal farmland reverts back to forest or is converted to other uses.

The American Pipit is a rare to locally common spring migrant in Ontario and a common autumn migrant (James 1991).

WINTER

Root (1988) concluded that wintering pipits were most abundant where there is moist habitat along streams and ponds and also numerous irrigated fields. Wintering areas in the east are generally where the minimum January temperature is higher than −1°C, but it occurs in areas as cold as −7°C in the west. It is often found in fields containing very little vegetation. When snow covers fields, it often forages along plowed roads. Hendricks and Verbeek (2020) concluded that it avoided regions that had persistent snow on the ground, and that it used similar habitat in winter as during migration. Ontario is north of the typical wintering range of the pipit and is marginal winter habitat because of the snow cover. Keyser et al. (2023) considered it an avoider of snow that selected areas where there were frequent temporal changes between snow cover and bare ground.

In winter in North Carolina, the pipit was seen only in the largest hayfields, in winter-wheat fields, and in old cornfields where the corn stalks were all down. It was not observed in plowed fields. In Florida, it occurred in prairies, old fields, and marshes, and occasionally on sand dunes and sea beaches (Bent 1950). Campbell et al. (1997) reported usage of similar habitats by the pipit in winter in British Columbia. In addition, it occurred on golf courses and playing fields, at sewage lagoons and airports, and on tidal flats and river estuaries.

James (1991) reported that the American Pipit was an occasional and rare winter resident in the south, north to Peterborough. In the Hamilton area, there are only 3 records of birds overwintering, all single birds (Curry 2006).

CBC data for Ontario for 1970-2009 indicate that the American Pipit is rare in winter and that observations of it increased during that time. It was not recorded on any counts in the province in the 1970s. The 2000s were the first decade in which the pipit was recorded every year, but numbers observed were quite low. Ontario trends determined by CBC data indicated an annual increase of 7.28% 1970-21 and an annual decrease of 14.88% 2009-2021 (National Audubon Society 2022). It is probable that many birds observed on CBCs are late migrants rather than wintering birds.

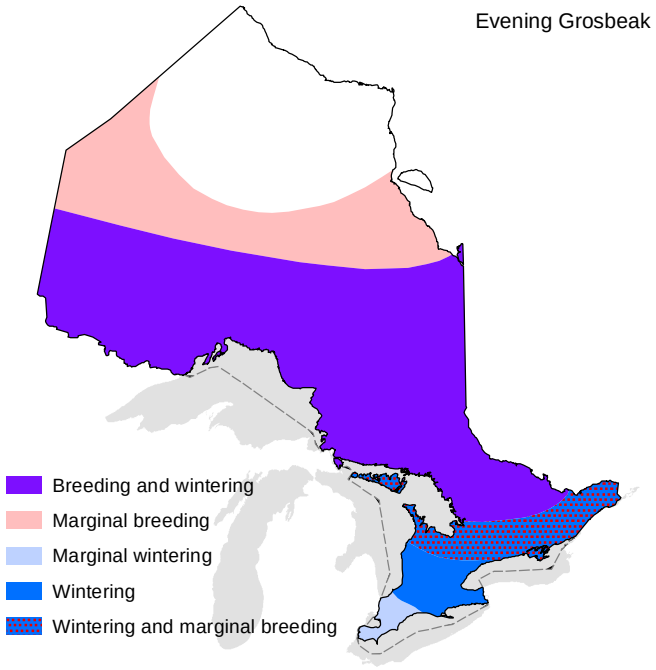
BREEDING SEASON

Habitat Requirements

Ontario Evening Grosbeaks breed in second-growth and mature forests. Five nests were in mixed-wood forests, 1 was in an open coniferous forest, and 3 were in unspecified forest types (Peck and James 1987).

In the Hudson Bay Lowland, Schueler et al. (1974) reported the Evening Grosbeak nesting near Moosonee in a spruce stand, the most northern record at that time.

In the Clay Belt in the Boreal Forest Region, the Evening Grosbeak was most frequent in white spruce stands followed by stands dominated by white spruce–balsam poplar, black spruce, jack pine, and tamarack–white cedar. It was absent in stands dominated by trembling aspen. It occurred in mesic to wet stands, but not in dry stands. It was present along the entire nutrient-richness gradient (Welsh and Lougheed 1996). Near Hearst, it occurred in upland mixed stands, including an unharvested stand and clear-cuts 3 and 17 years old (Welsh and Fillman 1980). Those detected in clear-cuts may have been foraging rather than nesting. Near Manitouwadge, it was absent in stands



1-21 years old, occurred in low density in stands 24-36 years old, and was 6.7 times more abundant in stands 60-223 years old (Venier et al. 2009).

In jack pine stands near Gogama in the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region, most observations of Evening Grosbeaks were of birds simply flying over. James and Peck (1995a) concluded that it could feed in any pine or mixed forest more than 10 years old, but would likely nest only in areas with mature trees. In Algonquin Park, it nested in a second-growth mixed forest of white pine, black spruce, white spruce, balsam fir, and white birch (Hope 1947). It was associated with coniferous forests in Algonquin Park, but not those dominated by white pine. Kingsley and Nol (1999) found it in all age classes of white pine forests, but many observations may have represented birds foraging distant from their nests. In white pine stands throughout the Shield portion of the Great Lakes–St. Lawrence Forest Region, it was 2.5 times more abundant in old-growth than mature stands. It was positively correlated with the mean patch size of pines (Kirk et al. 2012). Results from the Ontario Forest Bird Monitoring Program suggested that it was sensitive to the amount of habitat available at the 3.2- and 24-km scales (Savignac 2016).

At the landscape level, the Evening Grosbeak selects habitat based upon food availability. Its presence is highly correlated with outbreaks of spruce budworms or other tree defoliators. It is strongly associated with coniferous and mixed forests, particularly those dominated by white spruce and balsam fir because these are the main species attacked by the spruce budworm. In Quebec, it occurs at low frequency in northern, more boreal forests dominated by black spruce because spruce budworms are much less likely to be attracted to this species. The spruce budworm typically attacks only older stands and thus the Evening Grosbeak is associated mostly with mature and old-growth stands (Erskine 1977; Gillihan and Byers 2020; Vincent in Gauthier and Aubry 1996).

The Evening Grosbeak nests predominantly in mature mixed and coniferous stands throughout its range, and much less frequently in deciduous woods (mostly in the west). Most forests it nests in have a diverse structure and a fairly open canopy. In the east, these forests have a high proportion of balsam fir, white spruce, and trembling aspen. In the west, it may be common in mature and old-growth trembling aspen stands and mixed conifer–trembling aspen stands. In the Upper Peninsula of Michigan, it breeds in hardwood forests but moves to jack pine stands during spruce budworm outbreaks (Campbell et al. 2001; Flack 1976; Gillihan and Byers 2020; Savignac 2016; Scott and Bekoff 1991). In Quebec, Falardeau et al. (1999) detected it in low densities in strip-cuts, but it is most likely that it was feeding in this habitat rather than breeding. Dawson (1979) considered it locally common

in northeastern lowland conifers. It was absent in open bogs and shrubs with scattered conifers, uncommon in young or low black spruce, common in intermediate-aged to mature black spruce stands, and occurred in moderate densities in tamarack and white cedar stands. In the Prairie Provinces, it was in a guild associated with coniferous trees. It occurred on sites that were dry and rich in nutrients (Kirk et al. 1996). In Saskatchewan, it was most common in white spruce stands and mixed stands, and least common in trembling aspen stands, although the differences were not significant. It was more common than expected in contiguous forest (Hobson and Bayne 2000). In British Columbia, Campbell et al. (2001) considered it a habitat generalist that nested in a variety of coniferous, mixed, and deciduous forests. It made little use of black spruce–tamarack bogs or pine stands. In the south, presence of the western spruce budworm was an important predictor of its breeding patterns and densities. In the Yukon, it was most common in or at edges of old-growth white spruce stands. It inhabited stands that were structurally complex, with a lush shrubby understorey, standing dead trees, downed woody debris, and scattered old trembling aspens and balsam poplars (Sinclair et al. 2003). There is 1 record of a nest in an orchard (Speirs in Austin 1968).

In Oregon, nesting sites were significantly more open than unused areas, with fewer deciduous stem intersects, lower deciduous canopy cover, fewer large clumps of shrubs, and less shrub dispersion. Vegetation at nesting sites was less dense and more dispersed than in non-nesting areas. Open areas allow high visibility for detecting predators, allow easier departure and arrival at the nest, and allow better thermoregulation (Bekoff et al. 1987). Another Oregon study determined that this grosbeak's distribution was associated with beaked hazel. Forest openings where hazel and other deciduous species' buds occur may provide a food source (Gillihan and Byers 2020).

The Evening Grosbeak is typically associated with mature or old-growth forests. In boreal mixed-wood forests in Saskatchewan, its probability of detection was 0% in stands 50-60 and 80-90 years old, 20-49% in stands 100-110 years old, and 50-79% in stands older than 140 years; these differences were significant (Cumming and Diamond 2002). In the Prairie Provinces, it occurred only in stands 80 or more years old. It was 1 of only 4 species that was detected exclusively in old stands (Kirk et al. 1996).

Ontario nests were in living trees, with coniferous trees selected more than deciduous trees. Nest-tree species included white pine (2 nests), white birch (2 nests), and 1 nest each in white cedar, balsam fir, black spruce, and white spruce. Nests were in crotches of trees or forks of branches, often within 2 m or less of the top of the tree. An equal number of nests were against the tree trunk or 1-3 m distant from it. Nests were 7.5-16.8 m from the ground, with most 9.3-15 m up. Many were very well concealed and invisible from the ground (Devitt 1944; Hope 1947; Kendeigh 1947; Peck 1973; Peck and James 1987; Speirs in Austin 1968).

Nests reported elsewhere are similar to those described from Ontario, except that in the west it occasionally nests in shrubs and nests in deciduous trees are more frequent. Nests are typically well concealed and extremely difficult to find, but nests in trembling aspen near Edmonton were exposed because tent caterpillars had denuded the forest canopy. Two California nests were fully exposed in dead fir trees. Nests tend to be near the top of the nest tree or shrub; in Colorado, nest height averaged 60-80% of tree height. Tall willows appear to be the only shrubs that have been used for nesting. Nests have been found in trembling aspen, balsam poplar, white pine, red pine,

Douglas-fir, lodgepole pine, sugar maple, red spruce, Norway spruce, jack pine, balsam fir, black spruce, white cedar, white birch, elm, juneberry, silver maple, black oak, and tamarack. Nests may be either near the trunk or on a horizontal limb. In Colorado, nests averaged 1.5 m from the tree trunk at a height of 9.7 m. A Michigan nest was 7.6 m up in a red pine near the drooping end of one of the lowest branches. Nests have been reported 2.1-18.2 m from the ground, with many above 10 m (Bekoff et al. 1989; Campbell et al. 2001; Flack 1976; Gillihan and Byers 2020; Hoffman and Pletz 1988; Ligon 1923; Shaub 1954; Speirs in Austin 1968). In Colorado, there was no correlation between the relative abundance of tree species and the percentage of nests built in that species. Nests were predominantly in Douglas-fir and lodgepole pine with none in trembling aspen or fir. Nests were higher in trees and closer to the trunk than expected, and were nonrandomly oriented to the south. No nests were built between 271° and 360°; 60.9% were built between 91° and 180°. Placing nests on the south side of the tree may protect them from the prevailing winds. Placing them close to the trunk would shelter them from wind and rain and increase their stability (Bekoff et al. 1987, 1989). Of 64 nests in Colorado, none were used in subsequent years but 2 (3.1%) were used again in the same year for a replacement clutch (Bekoff et al. 1989; Gillihan and Byers 2020; Scott and Bekoff 1991).

The Evening Grosbeak is nonterritorial and tolerates other grosbeaks close to the nest. Avian predators, such as Canada Jay and Common Grackle, are chased away as are Hermit Thrush and American Robin. Because it is nonterritorial, loose groups of 10-12 pairs may occur in small areas, although pairs may be widely dispersed. North of Lake Nipigon, the closest other pair to a nest was 2.4 km distant. During nesting, adults may wander widely to obtain food, particularly males. In Algonquin Park, 1 bird routinely flew 3.2 km to obtain salt. In New York, birds travelled long distances in flocks to feed on pin cherries in clearings. During the incubation phase in Colorado, males often foraged within sight of the nest tree but also travelled as far as 1 km during foraging excursions. Unmated males are locally nomadic, wandering widely during the breeding season (Bekoff et al. 1987; Devitt 1944; Gillihan and Byers 2020; Hope 1947; Kendeigh 1947; Scott and Bekoff 1991; Shaub 1956; Speirs in Austin 1968). The facts that it is nonterritorial and may travel considerable distances to feed make it difficult to determine its breeding habitat. Most records of it in clear-cuts and younger forest stands probably represent foraging rather than breeding birds.

No information is available on natal philopatry. Because of the species' high nomodic tendencies, natal philopatry is probably very low or nonexistent.

Adult site fidelity is very low because the Evening Grosbeak nests wherever food is most abundant. In New York, 1 of 54 adults (1.9%) banded in summer returned to breed in the same general locality (Shaub and Shaub 1953). In Quebec, 0 of 500 adults returned (Blais and Parks 1964). Savignac (2016) reported that 8 of 10 birds banded during the breeding season dispersed as far as 950 km from the previous year's breeding site.

Limiting Factors

Eggs are most likely to be present in Ontario nests in the last 3 weeks of June (Peck and James 1987). In Algonquin Park, nests are under construction from mid-May to mid-June, eggs are present from late May to late June, nestlings are present from mid-June to mid-July, and dependent fledglings are present from early July to mid-August (Tozer 2012).

The large bisexual winter flocks break up in spring and form smaller groups of 4-10 birds; pair bonds are established within them. Where the Evening Grosbeak is absent in winter, birds are often paired when they arrive on the breeding grounds. Nest building occurs almost immediately and is timed to be synchronous with leaf-out of deciduous trees. In Colorado, nest building and egg laying took an average of 6.3 days, suggesting that it took 2-3 days to build the nest. One egg is laid per day. Incubation may start with the laying of the second egg. The incubation period averaged 13.4 days in Colorado (range 12-14 days). Because incubation begins before the clutch is complete, hatching may take place over 1-4 days (average 2.5 days in Colorado). The nestling period is 13-15 days (average 14.1 days in Colorado). It is well adapted to nesting in areas that often have severe weather, short growing seasons, and patchy food resources by devoting little or no time to prenesting activities, not establishing breeding territories, spending only a short time building nests, and producing fledglings that remain in the nesting area for only a short time (Bekoff et al. 1987, 1989; Gillihan and Byers 2020; Scott and Bekoff 1991; Speirs in Austin 1968).

The Evening Grosbeak raises a single brood in a year but may renest if the first clutch is lost. Clutches of 3-4 eggs have been reported in Ontario (mean 3.6 eggs). Elsewhere, clutches of 2-5 eggs have been reported but most contain 3 or 4 eggs. The mean clutch size in Colorado was 3.0 eggs (Peck and James 1987; Scott and Bekoff 1991; Speirs in Austin 1968).

The age at first breeding is unknown (Gillihan and Byers 2020), but is probably 1 year. The Evening Grosbeak is typically monogamous, with 63 of 64 mated pairs (98.4%) being monogamous in Colorado (Scott and Bekoff 1991). The other male was polygynous and attended 2 females nesting approximately 1.6 km apart; both nests were successful. Nest B lagged behind nest A by about 8 days. Polygyny may be facilitated when food is unusually plentiful (Fee and Bekoff 1986). Because nests are difficult to find and nests of females mated to polygynous males may be distant from each other, it is possible that polygyny is more common than has been documented.

During the breeding season, the Evening Grosbeak gleans insects from foliage, especially caterpillars and other larvae and pupae. Early in the season before insects are abundant, it feeds on buds and is particularly fond of sugar maple sap. It rummages among leaves on the ground to find fallen maple seeds, especially those of sugar, Manitoba, and mountain maples. It occasionally captures insects by aerial pursuit. From July into autumn, it feeds extensively on cherries, particularly those of the pin cherry. It discards the outer pulp, cracks open the pit with its bill, and eats the seeds within the pit. It may take cherries that have already had their flesh removed by Cedar Waxwings and seek out pits that have been voided by other vertebrates. When transporting food back to the nestlings or incubating female, it is stored in the back part of the throat or mouth so that a considerable quantity can be carried. It is strongly attracted to salt and ingests salty water and salt-impregnated earth. In northern Ontario near Wawa, many pools beside the Trans-Canada Highway have sodium concentrations as high as 100-160 ppm even in summer. Grosbeaks were attracted to these pools in June and the first week of July but were never observed at natural mineral licks, even though they had higher sodium concentrations. It is also attracted to roads where calcium chloride is used for dust suppression, so it is the chloride that it seeks. It eats ashes and soot from campfires and other sources, and presumably is attracted to recent wildfires. The soot and ashes are another source of minerals for it. It drinks copious amounts of water and eats much snow in winter (Brunton

1994; Campbell et al. 2001; Devitt 1944; Downs 1956; Fraser 1985; Gillihan and Byers 2020; Shaub 1956; Shaub and Shaub 1954; Speirs in Austin 1968). Benkman and Pulliam (1988) reported that the handling efficiency of the Evening Grosbeak increased as seed size increased. It needs to encounter a seed every 200-500 seconds to meet its midwinter energy requirements compared with 1-5 seconds for sparrows. Of the 6 species studied, only the Evening Grosbeak can survive on seed sizes larger than 90 mg. Its ability to feed on large seeds enables it to exist at low seed densities. It can also store seeds in its mouth and throat, allowing it to use seed resources that are patchily distributed.

The male brings the female most of her food while she is incubating. In Vermont, males initially offered females sugar maple buds followed by elm and cherry buds. Later, they provided salt-impregnated soil and sunflower seeds (Downs 1956). The most important food items provided to nestlings include masticated spruce budworm larvae and the contents of pin cherry pits. In British Columbia, a female fed 4 nestlings for 4 days on the aphid contents of galls on cottonwoods; they were also fed fruits of viburnums and buckthorns. In Winnipeg, nestlings were initially fed semi-digested food. After they were a week old, they were fed caterpillars and small soft green seeds (Bekoff et al. 1987; Brunton 1994; Hope 1947; Scott and Bekoff 1991; Shaub 1956; Speirs in Austin 1968).

Vegetation is important in the adults' diet in the early and late portions of the breeding season and in the nonbreeding season. Invertebrates are important during the peak of the breeding season. Buds are the most common food item upon arrival on the breeding grounds, and the Evening Grosbeak also eats tree flowers. It has eaten buds of maples, elm, willows, oaks, poplars, and lilac. Once insects become available, they dominate the diet. Where the spruce budworm occurs, this is the preferred prey. Several birds in New Brunswick had eaten large numbers of sixth instar larvae and pupae of the spruce budworm. In Quebec, it was present from 15 June to the end of the month once budworm larvae were large enough to eat. Prior to that, few grosbeaks were seen when the larvae were too small. It decreased after 15 July when spruce budworms were in the moth stage. Numbers of grosbeaks at this site were sufficient to effectively decrease the budworm population. It may eat larvae and pupae of other insects that may reach epidemic populations, such as cankerworms, western spruce budworms, jack pine budworms, larch sawflies, and aspen leafrollers. Other insects it may consume include beetles and aphids. As numbers of larvae decline, it switches back to a vegetable diet dominated by seeds and fruits. The most important of these is the seeds and pulp within pin cherry pits; it eats chokecherry and black cherry pits where they are available. Other fruits it eats include those of Russian olive, ash, crabapple, hawthorn, and juniper. Seeds are important in the diet, particularly those of sugar maple and Manitoba maple. Other seeds it consumes include those of ashes, apples (often while they are still on the tree), tulip tree, elm, pine, baldcypress, hawthorn, blackberry, blueberry, birch catkins, black locust, hickory, buffaloberry, snowberry, beech, sumac, and cotoneaster. It eats variety of seeds from nonwoody plants including those of sunflowers, docks, bindweeds, goosefoots, sedges, spotted geranium, buttercups, and violets (Bekoff et al. 1987; Blais and Parks 1964; Brunswig et al. 1983; Brunton 1994; Curry 2006; Fee and Bekoff 1986; Gillihan and Byers 2020; Ligon 1923; McIlwraith 1894; Mills 1981; Mitchell 1952; Savignac 2016; Shaub 1954, 1956; Speirs in Austin 1968). Gabrielson (1924) analyzed the contents of

127 stomachs collected in 14 states and Canada throughout the year. In winter, the diet consisted entirely of seeds and fruit. The summer diet consisted of 20.82% animal matter and 79.18% vegetation. In winter, the diet was comprised of 37.63% seeds of wild fruits, 37.96% winged seeds (maples and ashes), 14.5% conifer seeds, and miscellaneous seeds, mast, and rubbish. The most important wild fruits were cherries (17.48%), dogwoods (13.77%), mountain-ash (3.82%), and snowberry (1.77%). Fourteen birds had eaten juniper berries and 13 had eaten seeds of other conifers. In summer, the vegetation consumed was 37.87% seeds of wild fruits, 2.79% winged seeds, 28.45% conifer seeds, and miscellaneous weed seeds and rubbish. Additional wild fruits that were consumed included those of blackberry, apple, juneberry, sumac, New Jersey tea, mallows, nightshade, and elderberries. Beetles and caterpillars were the main animal foods, but it also ate small numbers of wasps, ants, bugs (chinch bugs), and spiders. The beetles consumed included ground, click, stag, darkling, and June beetles and weevils. June beetles that ate leaves of pine, willow, hickory, and other trees were the most abundant beetles consumed. Caterpillars comprised 11.49% of the overall diet.

Presence of the Evening Grosbeak is strongly correlated with outbreaks of the spruce budworm. Its highest frequencies during the first Quebec breeding bird atlas corresponded with the principal areas of spruce budworm infestations (Vincent in Gauthier and Aubry 1996). The same was true in Ontario during the second atlas (Hoar in Cadman et al. 2007) and probably during the first atlas although this analysis was not undertaken. Near Manitouwadge, the number of Evening Grosbeak territories per year mirrored those of the spruce-budworm specialists but with a steeper response to budworm populations. It was absent until the budworm outbreak occurred (Venier et al. 2009). In 1962 during a spruce budworm outbreak in Quebec, large flocks were seen daily and groups of 30-50 occurred daily at a feeder. In 1963 when budworms were absent or very scarce, a single flock of 7 was seen once (Blais and Parks 1964). In New Brunswick, numbers of grosbeaks responded directly but weakly to budworm numbers. Before the budworm outbreak, it was rarely seen in northern New Brunswick in summer, but large flocks were common throughout the infested area (Morris et al. 1958). Campbell et al. (2001) attributed high concentrations of Evening Grosbeaks in British Columbia to high populations of spruce budworms coupled with salty roadsides. Similar to the warblers that are considered spruce-budworm specialists, the population of the Evening Grosbeak is closely tied to the abundance of the spruce budworm and declines when the area affected by budworms decreases. Scarcity of spruce budworms can be a major limiting factor to the Evening Grosbeak.

The Evening Grosbeak is a rare host of the Brown-headed Cowbird, probably because the 2 species have different habitat preferences. There are no reports of parasitism in Ontario. An Edmonton nest contained 2 cowbird nestlings, 1 Minnesota nest was parasitized, there is 1 record of adults feeding a cowbird fledgling in New York, and 2 such records in British Columbia (Campbell et al. 2001; Gillihan and Byers 2020; Hoffman and Pletz 1988).

Selective thinning in mature and old-growth forests may be beneficial for the Evening Grosbeak because it prefers stands with open canopies. In Oregon, it was more common in thinned than unharvested stands but in Montana there was no difference in its abundance in selectively logged, mature second-growth, and old-growth stands (Gillihan and Byers 2020).

Forest management typically conducted within the range of the Evening Grosbeak in Ontario and Canada may be a significant limiting factor that affects the abundance of its habitat and food. The magnitude of the impacts of forestry does not appear to have been fully recognized. In the Committee on the Status of Endangered Wildlife in Canada status report it was concluded that threats from forestry were either low or negligible (Savignac 2016). Management practices such as fire suppression, clear-cutting, reforestation, and spruce budworm control all have negative impacts on its habitat and food availability.

Wildfires are routinely suppressed to protect forest resources. Areas that are burned provide an abundance of favoured food for the Evening Grosbeak. Most important of these are the pits of pin cherries, and chokecherries are also common in burns. The pin cherry does best after fire and is often called fire cherry; it disappears once the canopy closes over it. In Ontario, it was less abundant in early successional clear-cuts than in recent burns, but the difference was not significant. It was significantly more abundant in mid-successional burns than similarly aged clear-cuts. Regeneration rates may be slower in burns than clear-cuts due to removal of the litter layer and burning of organic soils, thus early successional species such as pin cherry and chokecherry may persist longer in burns. It was significantly less abundant in early- and mid-successional stands than mature stands (Zimmerling et al. 2017). Although younger stands may provide food resources, nesting typically occurs in mature stands. This study suggests that clear-cuts and younger stands resulting from harvest provide inferior habitat to burns and unharvested mature forests.

More than 20 million ha of boreal forest, mainly mature and old-growth stands, were harvested in Canada 1975-2010, and an additional 6 million ha were predicted to be harvested by 2020. Almost all this timber is harvested by clear-cutting with short rotation periods of 40-70 years. This does not allow forests enough time to become mature and develop a diversified structure (Savignac 2016). These perpetually young stands are suboptimal habitat for the Evening Grosbeak. In Saskatchewan, it was found significantly more frequently in stands older than 140 years old, but the rotation period was only 80-90 years. Cumming and Diamond (2002) concluded that some stands older than 120 years should be maintained to sustain species characteristic of older forests.

In eastern Canada, balsam fir stands are often harvested and replanted with faster-growing species such as black spruce and jack pine. These species are much less susceptible to spruce budworm outbreaks. Balsam fir stands are a preferred habitat by the Evening Grosbeak. Black spruce and jack pine stands are suboptimal habitat due to the lower numbers of spruce budworms they support. In northwestern Canada, mature mixed-wood stands are managed to reduce tree species diversity in favour of trembling aspen, thus decreasing habitat suitability for the Evening Grosbeak (Savignac 2016).

In eastern Canada, the spruce budworm has a population cycle of 25-40 years and this has a direct effect upon the abundance of the Evening Grosbeak. During the first atlas, the area in Ontario affected by spruce budworm outbreaks was 8,000,000-18,000,000 ha annually. By 1997, the area of outbreaks had declined to 53,000 ha but there were 2 moderate outbreaks of 200,000+ ha in 2003 and 2004 (Hoar in Cadman et al. 2007). Forest management is undertaken to reduce the extent and severity of spruce budworm outbreaks to the detriment of the Evening Grosbeak. Applications of Bt target caterpillars and a reduction in their population can have adverse effects on the development

and survival of nestlings. More importantly, remote sensing is being used to detect mature and old-growth balsam fir stands that are most likely to host spruce budworm outbreaks. Preventative logging will be undertaken before outbreaks occur. This will decrease the density of fir forests in the landscape and forest composition will be changed to produce habitat that is unsuitable for budworms. This will also reduce the amount and quality of habitat and food resources for the Evening Grosbeak (Savignac 2016).

In Colorado, Bekoff et al. (1989) compared characteristics of nest sites that were successful and unsuccessful in fledging young. Successful nests were started later in the season in the last 3 quarters of the building period, were in more open areas with less dense vegetation and a higher canopy, were 2 m or closer to the trunk, were oriented in a more southerly direction (average 179° for successful nests and 137° for unsuccessful nests), were in taller trees, and were further from the closest neighbouring nest (77.6 m for successful nests and 24.7 m for unsuccessful nests). This was a high-altitude site, so later nests were probably more successful due to weather influences. Areas with less dense vegetation could increase visibility from the nest, which could enhance predator detection. Nests nearer the trunk were better camouflaged, more stable, and more difficult to approach for avian predators. Large trees are more stable than smaller ones and provide more cover for the nest.

In eastern Canada, overbrowsing by moose and white-tailed deer may limit regeneration of suitable habitat (Savignac 2016).

Price (2004) concluded that the Evening Grosbeak could disappear as a breeding species in southern Ontario if the average summer temperature increased by 2°C. It is projected that there will be a significant range contraction of balsam fir which would be a direct loss of habitat for it and would also reduce the potential extent of spruce budworm outbreaks.

Status

Originally confined to the west, the Evening Grosbeak is a fairly recent breeder in Ontario. The first evidence of breeding occurred in 1920 when an adult with young was observed near Lake of the Woods. By 1940, there were 32 breeding records for the province, with the most notable range extension occurring from 1920 to 1929. At that time, its range extended from Lake of the Woods to Thunder Bay, from Sault Ste. Marie to the Lake Nipissing and Ottawa area, and around the Gananoque area (Baillie 1940, 1967; Baillie and Harrington 1937; Devitt 1944). Although it had been seen in Algonquin Park in 1929, breeding was first recorded there in 1932 (MacLulich 1938). Breeding first occurred in Muskoka District in 1927 (Baillie 1967). de Vos (1964) noted that it previously bred in a narrow belt across Ontario, but that there had been a recent widening and spreading of this belt. The first atlas indicated a much more widespread breeding distribution than previously known. It occurred in the eastern portion of the Hudson Bay Lowland to slightly north of Moosonee, in the Boreal Forest Region to north of Lake Nipigon and to Pickle Lake, and throughout the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region. It also occurred in scattered locations south of the Shield on Manitoulin Island, the Bruce Peninsula, and a band from Lake Simcoe to the Kingston area and north of the St. Lawrence River. It was concluded that it was a fairly common breeder and that it might be extending its range further south (Peck in Cadman et al. 1987). James

(1991) considered it a common summer resident north to Pickle Lake and Moosonee, south to Simcoe County and Brockville, and occasional and rare south to Haldimand and Norfolk counties.

Widespread planting of Manitoba maple was initially believed to be the reason for the eastward breeding range extension of the Evening Grosbeak into Ontario east to the Atlantic Coast. Early observers noticed that it fed extensively on the seeds of this species during winter (Baillie 1940; de Vos 1964). Although this explanation is still occasionally provided (Gillihan and Byers 2020), it appears implausible. Manitoba maple is rare in the Canadian Shield where most of the population breeds. The Evening Grosbeak occurred only 10 years after the initial plantings of Manitoba maple, which were confined to areas near human settlement, and would not have been old enough to develop seeds (Brunton 1994). More recently, the Evening Grosbeak has declined significantly, but Manitoba maple is much more abundant now than when it first colonized Ontario. The most likely explanation for its colonization of Ontario is outbreaks of spruce budworms coupled with extensive forest fires. Massive outbreaks of budworms occurred in 1910-20 and 1945-55, coincident with the flurry of early breeding records in the province. There were also major extensive fires in northern Ontario in 1910-20, resulting in shrubby regeneration that included one of its favourite foods, the pin cherry (Brunton 1994; Savignac 2016).

The second atlas revealed that there had been no significant change in the breeding distribution of the Evening Grosbeak since the first atlas. Its probability of occurrence declined significantly province-wide and in every region where it occurred. The decline was attributed to the decline of spruce budworms and the area affected by outbreaks of this species. High densities occurred in the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region and in the Red Lake and Pickle Lake areas. High concentrations in the southern Shield were probably a result of significant spruce budworm outbreaks in the Sudbury, North Bay, Bancroft, Arnprior, and Petroglyphs Provincial Park areas. During the second atlas, the Evening Grosbeak was considered an uncommon breeder in Ontario (Hoar in Cadman et al. 2007).

Cadman et al. (2016) reported that the Evening Grosbeak experienced the sixth greatest decline rate of 6.1% per year of Ontario species during 1983-2013. Declines are generally attributed to the reduction in spruce budworm numbers, although forest management may also be a factor. Breeding Bird Survey data for 1970-2021 indicate that it decreased at annual rates of 3.99% in Canada and 6.43% in Ontario. During 2011-21, it decreased at annual rates of 4.55% in Canada and 14.6% in Ontario. The long-term trends were highly reliable for Canada and of medium reliability for Ontario; the short-term trends were of low reliability (A.C. Smith et al. 2023).

A new major spruce budworm outbreak is projected to occur in eastern Canada early in the 21st century. As of 2016, the outbreak was occurring in 5 regions of Quebec and was expanding into New Brunswick and eastern Ontario. The Evening Grosbeak appears to be increasing in response to this new outbreak (Savignac 2016).

The Evening Grosbeak is designated special concern in Canada and Ontario.

POSTFLEDGING PERIOD

Fledglings remain near the nest for 2-5 days after leaving the nest. They separate when they leave the nest and often perch within 20 m of the nest tree. After 2-5 days, the young begin wandering

with their parents, visiting areas of high food concentrations, including feeders. At feeders, the adults shell sunflower seeds and feed the meat to the young. In the wild, fledglings are often fed the contents of cherry pits. It is unknown when juveniles become independent. Adults routinely feed young into August or early September and even into October (Campbell et al. 2001; Downs 1956; Gillihan and Byers 2020; Scott and Bekoff 1991; Shaub and Shaub 1953; Speirs in Austin 1968).

MIGRATION

The Evening Grosbeak migrates both nocturnally and diurnally (Gillihan and Byers 2020; Speirs in Austin 1968). In the east, it is an irruptive migrant with large flocks moving as far south as the Gulf Coast states in some years; it is scarce or even absent in other years. There is a high degree of synchrony in the irruptive pattern of boreal seed-eating birds, including the Evening Grosbeak, Red-breasted Nuthatch, Purple Finch, Redpoll, Red Crossbill, White-winged Crossbill, and Pine Siskin. Irruptions appear to be related to food availability and coincide with poor seed crops, particularly those of spruce, balsam fir, and birch. Some tree species set seeds only in alternate years or at longer intervals so irruptions are not entirely predictable but tend to occur every 2-3 years. Strongest irruptions occur when poor seed crops of all tree species coincide, including pines and white cedar. When the Evening Grosbeak was initially becoming established in Ontario, irruptions were very sporadic with as many as 35 years between irruptions. Once it became a common breeder, strong flights occurred regularly every 2-3 years, with some migrating south even in non-irruption years. Now that it is an uncommon breeder, it may be absent south of the Shield in some years but still occurs occasionally (Bock and Lepthien 1976b; Erskine 1977; Fleming 1907; Gillihan and Byers 2020; Kirchman and Van Keuren 2017; Prescott 1991; Yunick 1983a). Brewer et al. (2018) reported that birds wintering in Ontario had spent other winters in states from Michigan to the Atlantic coast as far south as North Carolina. Ontario birds have been recovered in Quebec and the Maritime Provinces.

Differential migration of the sexes occurs, with males wintering further north than females. In the east, the proportion of males in the wintering population was 65% in the north at latitude 50°N and 18% in the south at latitude 30°N. Males are larger than females. The more northern range of males is consistent with the hypothesis that larger birds are better able to withstand cold weather. Pairs become mated in early spring before reaching the breeding grounds, so males do not have to hurry to reach the breeding grounds to attract a mate or establish a territory because it is nonterritorial. The sole reason for males wintering further north appears to be that they are better adapted to colder weather. Females are subordinate to males and may migrate further south to avoid competition and colder weather (Balph and Balph 1976; Magee 1939; Mason and Shaub 1949; Prescott 1991, 1994; Shaub and Shaub 1950).

Even at the southern extent of its wintering range, the Evening Grosbeak begins its northward migration in mid-April (Prescott 1991). In Ontario, the timing of spring migration is difficult to ascertain because of the presence of wintering birds. In Elgin County, where it rarely overwinters, spring migration extends from mid-April to mid-May (Lancaster et al. 2004). In 1890 when it was rare, birds started to return to Hamilton in March and were present until mid-April (McIlwraith 1894). In the south, spring migrants may occur as late as mid- to late May, rarely into June (Black and Roy 2010; Curry 2006; LaForest 1993; Weir 2008). MacLulich (1938) reported that migrants occasionally returned to Algonquin Park before the end of February. In the south, autumn migrants may arrive in

mid-September or even August, but most arrive in mid-October (Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008).

During migration, the Evening Grosbeak may occur in any habitat that supports an abundant supply of food. It may be found in a variety of forest types and also anthropogenic areas with ornamental trees and shrubs and bird feeders. In spring, buds and seeds of maples are important food items and these trees may attract flocks. In autumn, conifers bearing seeds and berry-producing trees and shrubs provide important foraging habitat. Coniferous, mixed, and deciduous forests may be inhabited if the trees are bearing seeds, or there are openings or understories with maples, chokecherry, pin cherry, Saskatoon, or red-osier dogwood. In urban and rural areas, it frequents orchards and gardens where there are ornamental plants such as Manitoba maple, Chinese elm, white elm, apples, crabapples, cherries, or Russian olive. It also visits feeders, particularly those where sunflower seeds are provided (Campbell et al. 2001).

The Evening Grosbeak wanders widely during migration and exhibits no site fidelity. Once food resources are depleted at a site, flocks move in search of another food source. In New York, 0 of 1,933 banded migrants returned in a subsequent year (Gillihan and Byers 2020; Yunick 1983a).

There is a cost to migration, with increased risk to birds during this period. Survival rates are high in years with limited irruptive behaviour and low in years of major irruptions (Savignac 2016).

James (1991) considered the Evening Grosbeak a common to locally abundant migrant, although it is considerably less common now. It first appeared in southern Ontario during the irruption of 1854-55, with major irruptions in 1886-87, 1883-84, and 1889-90. Subsequent irruptions occurred with increasing frequency in 1901-02, 1903-04, 1910-11, 1915-16, 1916-17, and 1957-58 (Baillie 1940; Brunton 1994; Fleming 1907; Gillihan and Byers 2020; McIlwraith 1894). In the Kingston area, there were invasions in 30 of 60 years, but in only 3 of 17 years since 1990 (Weir 2008).

WINTER

The Evening Grosbeak is associated with snow in winter. It is least likely to occur where there are frequent changes from snow cover to bare ground and where there is frozen ground without snow (Keyser et al. 2023).

In non-irruption years, most of the Evening Grosbeak population remains in the breeding range. It tends to occur mostly in coniferous and mixed forests where conifer seeds are abundant, but may visit villages and other settlements if feeders and fruit- or seed-bearing trees and shrubs are available. South of the breeding range, it occurs in coniferous, mixed, and deciduous forests as well as urban and suburban areas and rural residential lots. Deciduous forests that are used are predominantly those that contain trees with winged seeds such as maples and ashes. In British Columbia, it appears to be highly localized in winter around human settlements, especially near feeders. In the Yukon, it is most frequent in open mixed forests around settlements with feeders. In urban areas of Massachusetts, it was most abundant in the smallest woodland size class of 1-5 ha, possibly because houses with feeders and other food sources were closer to smaller woodlots (Campbell et al. 2001; Gillihan and Byers 2020; Sinclair et al. 2003).

In winter, flocks of Evening Grosbeaks may roost together at night; birds may also roost singly. In Connecticut, flocks roosted in elms, maples, and oaks taller than 23 m. In Indiana, one roosted in small twigs in a pine in the lee of the 12.5-15 cm trunk, and one roosted on the ground where a ravine and roots of an apple tree provided protection. In Ontario, birds have roosted in a white pine at Mattawa, in white pine and white cedar in Toronto, in a large elm in a yard, and in rows of spruce trees in Mississauga (Parks 1947; Speirs in Austin 1968).

The Evening Grosbeak is not territorial in winter and occurs in gregarious flocks. These large social groups facilitate locating clumped food resources. Adult males are dominant over females and juvenile males, juvenile males are dominant over both age classes of females, and juvenile females are dominant over adult females. In Utah, females predominated at a large food tray (86 by 86 cm); males predominated at a 30-cm diameter tray. Easy recognition of status reduces agonistic interactions. This is advantageous given the large flock sizes and unstable flock membership (Balph and Balph 1976; Gillihan and Byers 2020).

Winter site fidelity is very low in the east, with typically less than 1% of Evening Grosbeaks returning to the same 10-minute block in subsequent years. In Connecticut, only 3 of 2,429 birds (0.1%) returned. It wanders extensively within winters and is unlikely to return to the same location in another year in the east. In Connecticut, 8 birds were recovered within a 24-km radius in a subsequent winter; 7 were recaptured 1 day later 8.0 km distant. In New York, 0 of 704 birds returned in a subsequent year and only 2.2% were recaptured as repeats in the same season. There were 14 recoveries of birds that had been banded elsewhere in a previous winter: from New York, Maine, Connecticut, Ontario, Pennsylvania, Ohio, Texas, North Carolina, Virginia, and Maryland. Birds banded in winter in Ontario have been recovered in subsequent years from Michigan east to the Atlantic Coast (Balph and Lindahl 1978; Gillihan and Byers 2020; Mason and Shaub 1949, 1952; Parks 1947; Savignac 2016; Yunick 1983a). Site fidelity is much higher in the west. In Utah, 15 of 107 (14.0%) returned the following winter, including 25.0% of males and 8.5% of females. This suggested that males are somewhat more site faithful than females or that females suffer higher mortality. Three returning birds were among the first to be seen at the feeders and each returned to the precise location where it had been banded. All but 1 bird remained until May whereas eastern birds appear to be constantly moving. Some returning birds did not arrive until late April or May and these tended to have been banded later in the previous season. They may have wintered elsewhere and did not return until migrating in spring, or they may have visited other feeders in the area until spring (Balph and Lindahl 1978).

Natural foods that the Evening Grosbeak eats in winter include seeds of silver maple, chokecherry pits, Norway maple fruits, catalpa seeds, mountain-ash seeds, Manitoba maple seeds, hackberry fruits, maple buds, apple buds, flowering dogwood buds, ash seeds, sumac seeds, fruits of multiflora rose, and red cedar berries (Downs 1958; Gillihan and Byers 2020; Mason and Shaub 1949, 1952; McIlwraith 1894; Parks 1947; Thompson 1890). There are 2 reports of an Evening Grosbeak killing a House Sparrow at a feeder and flying away with it (Babcock 1967; Cockwill 1986).

The Evening Grosbeak is a fairly regular feeder visitor within its breeding range, but its presence is unpredictable in other areas. It visits far more rural than urban feeders (Dunn and Tessaglia-Hymes 1999). Sunflowers are its preferred food at feeders and it eats both striped and black oil sunflowers.

It infrequently eats millet, mixed seeds, cracked corn, peanut hearts, bird puddings, suet, safflower, and milo. If water is available, it consumes great quantities and it also eats snow (Dunn and Tessaglia-Hymes 1999; Mason and Shaub 1949; Speirs in Austin 1968).

The Evening Grosbeak is strongly attracted to salt and therefore to roads and parked vehicles. Large numbers may be killed by vehicles. This may occur in all seasons because salt concentrations along roadsides remain high during the summer. In June and July of 1 year, it was estimated that more than 2,000 were killed by vehicles in a British Columbia park (Campbell et al. 2001; Parks 1947; Savignac 2016; Speirs in Austin 1968; Taylor 1997; Tozer 2012).

The Evening Grosbeak is vulnerable to diseases. In 1999, there was an outbreak of conjunctivitis in the Saguenay area and northcentral Quebec. At 14 feeding stations, 10-20% of birds were infected, which included more than 100 Evening and Pine grosbeaks. This disease affects the eyes, resulting in birds going blind (Iron 1999). In British Columbia, approximately 50 died due to salmonellosis, probably due to use of bird feeders (Campbell et al. 2001).

Occasionally, the Evening Grosbeak strikes windows at buildings that have feeders. It does not appear to be disproportionately susceptible to collisions with windows and was not listed among the more vulnerable species to building strikes in the United States. In New York, only 4 Evening Grosbeaks flew into window panes at a feeder where 2,429 were banded (Loss et al. 2014; Parks 1947; Savignac 2016; Speirs in Austin 1968).

At feeders, the Evening Grosbeak is vulnerable to being preyed upon by cats (Speirs in Austin 1968).

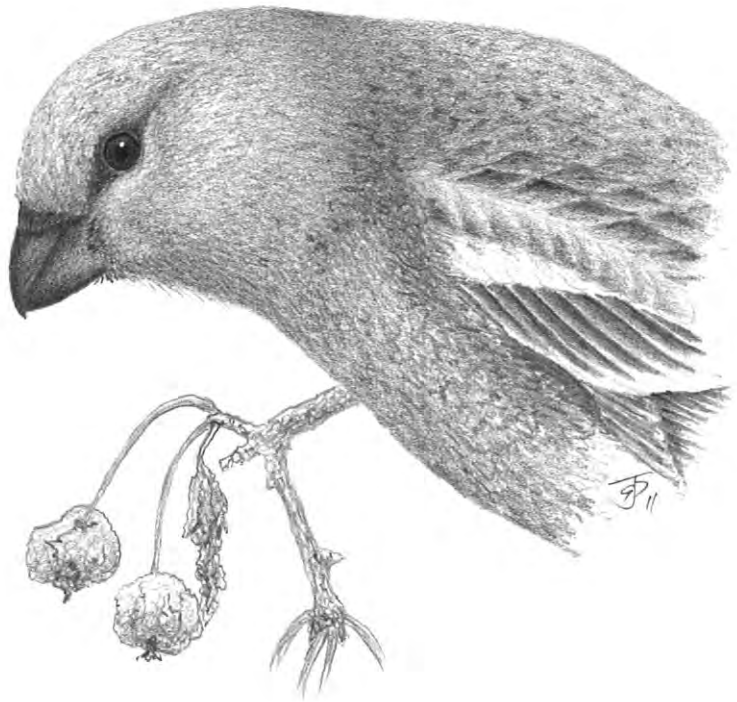
James (1991) considered the Evening Grosbeak a common winter resident in the south and uncommon in the northern breeding range, north to about northern Lake Superior. It has been detected at Moosonee in December (Schueler et al. 1974). In extreme southwestern Ontario, it has never been a common wintering species, although birds may move through during migration. There is only 1 record of an overwintering bird in Elgin County (Lancaster et al. 2004).

Winter populations of the Evening Grosbeak have mirrored those of the breeding season. Initially it was absent in the province. Periodic and intermittent winter invasions started in the mid- to late 19th century followed by a great increase in numbers and regular invasions at 2-3-year intervals, with birds present in the south even in non-invasion years. This was followed by a significant decline when few were seen in the south during winter. Freedman and Riley (1980) summarized the results of southern Ontario Christmas Bird Counts (CBC) for 1929-77. It increased greatly during that period, with erratic peaks beginning about 1960 at intervals of 2-3 years. The number of birds seen per observer was 0 to 1 in 1929-60 and peaked at 10 in 1972. The increase in the number of bird feeders during the same period probably contributed to its increase in the south (Brunton 1994; de Vos 1964). Winter numbers were high in southern Ontario until the early to mid-1980s, followed by a sharp decline. In Algonquin Park, the last time large numbers were present was in 1984-85 when 1,474 were counted on the CBC. On 6 of the last 10 counts, 0-3 were reported (Tozer 2012).

CBC results for Canada indicate a significant decrease of 1.1% per year for 1970-2012; results for Ontario indicate a significant decrease of 11.9% per year for this period (Savignac 2016). In North America, CBC results indicate a significant decrease during the period 1980-98, with the most serious decline in the Great Lakes region (Cadman et al. 2016). CBC results for 1970-2021 indicate an annual decrease of 2.84% in Ontario; there was an annual increase of 1.20% 2009-21 (National Audubon Society 2022).

Pine Grosbeak

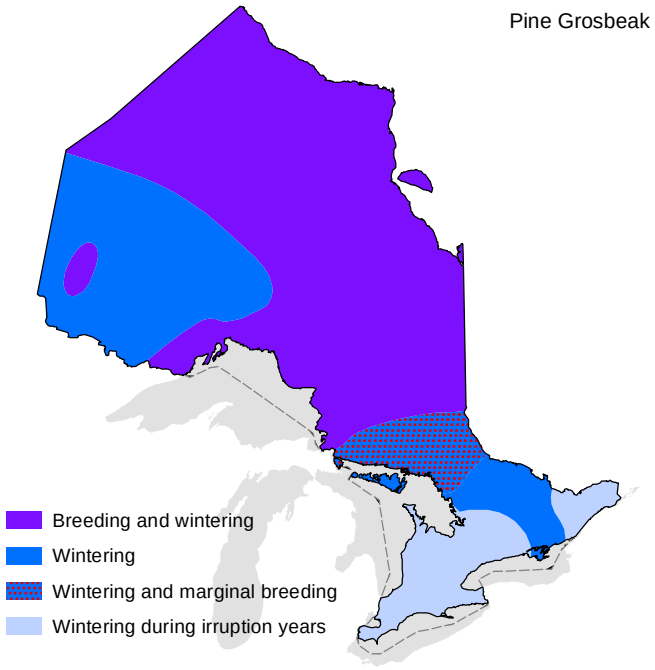
Pinicola enucleator



BREEDING SEASON

Habitat Requirements

In Ontario, the Pine Grosbeak is usually associated with open coniferous stands but may also occur in mixed stands. The first documented nest for the province was north of the Swan River on the coast of James Bay. It was in an open white spruce–tamarack forest with an understorey of willow and alder on a beach ridge. It was less than 10 m from a small stream. The ground cover consisted of a thick bed of lichens and mosses (Peck et al. 2004b). Wilson and McRae (1993) found a recently fledged young at Ekwan. This area consisted of spruce-lichen woodland and spruce forest on beach ridges. In the Clay Belt portion of the Boreal Forest Region, it was most abundant in stands dominated by white cedar–tamarack, followed by those dominated by black spruce, balsam poplar, and white birch–trembling aspen. It occurred mostly in wetter stands and those that were nutrient-poor, but to above half way on the richness scale (Welsh and Lougheed 1996). It is possible that some records in deciduous stands were of foraging rather than breeding birds, or that they contained scattered conifers. In Algonquin Park, it was extremely rare in summer, occurring in pine and spruce forests in the northern portion of the park (MacLulich 1938). The validity of these records has since been questioned and it is no longer considered a summer resident in the park (Tozer 2012).



Throughout its range, the Pine Grosbeak nests predominantly in open coniferous forests and less frequently in mixed forests. Because it prefers open stands, it is most abundant in taiga, in subalpine areas, and in forests opened up by logging. Nesting habitat may consist of widely scattered stunted conifers. Where forest is close-canopied, it nests in or near small openings and at forest edges. Within the Boreal Forest Region, it has no clear association with any particular forest type, but tends to be most common in those dominated by spruce and balsam fir (Breton in Gauthier and Aubry 1996; Campbell et al. 2001; Erskine 1977; Ray 1912; Taylor and Taylor 1979; Young and Adkisson 2020). In the Great Whale Region of Quebec, highest densities occurred in black spruce–lichen woodlands. In the Eastmain River area, highest densities were in shoreline scrub, jack pine stands, and recent burns. In northern Quebec, it occurs mainly in wooded valleys, isolated stands of conifers, and isolated patches of forest spared by fire. During the first Quebec breeding bird atlas, it was found mostly in the northeastern portion of the south, especially where balsam fir was abundant. Frequency of occurrence was very high in regions dominated by balsam fir–black spruce and also high in the balsam fir–yellow birch and balsam fir–white birch regions. At the turn of the 20th century, large numbers nested in white spruce stands on the Magdalen Islands (Breton in Gauthier and Aubry 1996). In Newfoundland balsam fir stands, Whitaker and Montevecchi (1997, 1999) considered the Pine Grosbeak a habitat generalist. It occurred in equal abundance in riparian edges and forest interior but was absent within 30 m of edges adjacent to clear-cuts or other non-forest edges. Also in Newfoundland balsam fir stands, it was significantly more abundant in stands 40 years old than those 60 or 80 years old. Younger stands were characterized by a well-developed small-tree layer that had a relatively high (6%) deciduous component of white birch and pin cherry. These species gradually disappeared as forests aged and many have provided a food source (Thompson et al. 1999). Austin (1968) reported that it nested in a spruce-tamarack swamp in Nova Scotia and in balsam fir in an open pasture in Maine. In northeastern Manitoba, it was equally abundant in coniferous forest with an understorey, coniferous scrub, and mixed scrub. It was not detected in deciduous or mixed forests, coniferous forest without an understorey, deciduous scrub, heath, or tundra (McLaren and McLaren 1981). At Churchill, it occurred most frequently in spruce forests (Jehl 2004; Jehl and Smith 1970). In northeastern Manitoba, it nested in stands dominated by white spruce–tamarack, white spruce–black spruce–tamarack, and white spruce–jack pine–tamarack. It was much less abundant in similar stands bordering on open tundra and absent in a riparian strip of willow (Gillespie and Kendeigh 1982). In British Columbia, most nesting occurs in subalpine areas, but it nests in lower hemlock-fir forests in

Haida Gwaii. It is widespread throughout the Engelmann spruce–subalpine fir forest zone and the spruce-willow-birch region of the higher elevations of the boreal white spruce–black spruce zone. It occurs in young or open subalpine coniferous forests. Habitats include older burns or clear-cuts, selectively logged areas, subalpine parkland or krummholz, and forest edges along meadows, avalanche chutes, beaver ponds, and lakeshores. The burns it used were 15-60 years old and several had a deciduous component of willow. In Engelmann spruce–subalpine forests, it avoided clear-cuts 5 years or less in age and remnant forest patches 0.4 ha or smaller within recent clear-cuts. It preferred young seral forests, edge habitats, and open subalpine areas (Campbell et al. 2001). In the Yukon, the Pine Grosbeak nests mostly in lodgepole pine forests, but also in black spruce bogs, white spruce forests, and mature black spruce forests mixed with white spruce and shrubs (Sinclair et al. 2003). In Alaska, it nested in lowlands dominated by black spruce and other spruces, on hills and bluffs dominated by deciduous forests, and in subalpine forests. It was not documented in floodplains or alpine areas (Handel et al. 2009). It breeds in alder thickets beyond the treeline in Alaska (Young and Adkisson 2020). In the Rocky Mountains in the western United States, it nests predominantly in Engelmann spruce–subalpine fir forests where there are numerous gaps in the canopy. It is absent or rare in dense coniferous forest and aspen forest (French 1954; Young and Adkisson 2020).

The first nest described for Ontario, found on 12 June 2003, was 2.36 m from the ground in a 6-m tall spruce with a diameter at breast height of 7 cm. It was not particularly well hidden and was placed atop 3 horizontal branches against the tree trunk (Peck et al. 2004b).

Very few nests of the Pine Grosbeak have been described. All were in conifers, mostly in spruce but also in fir and hemlock. Young and Adkisson (2020) stated that nests are well concealed in dense vegetation, but many were in plain view and those that were concealed were usually visible from below. Nest trees are often short or stunted but it may also nest in taller trees. Nests have been reported 0.6-10.7 m from the ground, mostly 1-4 m up. Nests may be either against the trunk or as far as 2.4 m distant from the trunk at the end of a bough. The nest is not attached to the supporting substrate and simply rests on branches (Austin 1968; Campbell et al. 2001; French 1954; Ray 1912; Young and Adkisson 2020).

Young and Adkisson (2020) stated that the Pine Grosbeak is strongly territorial during the breeding season. Although this may be the case in Eurasia, North American birds are probably nonterritorial. Young and Adkisson (2020) concluded that the facts that males approached playbacks of their songs and that captive males and occasionally females often fight with same-sex birds in adjacent cages was evidence of territoriality. Other evidence for North America suggests that the Pine Grosbeak is nonterritorial. In Utah, French (1954) stated that the diameter of 1 territory was 365 m or approximately 10.5 ha. On 2 occasions, strange Pine Grosbeaks were tolerated by a nesting pair. Another pair fed with the resident pair less than 30 m from the nest tree and another strange male joined the pair as they fed in a meadow about 45 m from the nest. This male was tolerated until it flew within 0.9 m of the female, at which time the resident male drove him away. It seems more reasonable to consider the area occupied by this pair a home range rather than a territory. At the Ontario nest, Peck et al. (2004b) saw a second singing male in a nearby tree and later a second female foraging in nearly the same location. Erskine (1977) stated that the finches were

predominantly nonterritorial. It seems most likely that the Pine Grosbeak is nonterritorial in North America.

No information is available on natal philopatry, but it is probably very low.

Information on adult site fidelity is scarce and may be different in the west and east. In the west, seasonal movements, if any, are typically short distance and altitudinal. In the east, irruptive long-distance south-north movements may be undertaken. Young and Adkisson (2020) stated that there was strong evidence of summer site fidelity, but most banding and recovery information was documented at the 10-minute-block scale. Of 28 North American recoveries, there were 5 cases of breeding season birds being captured 1-4 years later. In Colorado, 8 of 24 birds (33.3%) returned 1-3 years later and all were within 500 m of the original banding site. Near Churchill, numbers varied annually suggesting that there were regular turnovers in populations (Jehl 2004). It is possible that eastern birds are more nomadic, nesting only where food is most abundant.

Limiting Factors

At Churchill, nesting appears to start when fresh buds become available. No information is available on how long it takes to build a nest or if there is an interval between nest completion and the initiation of egg laying. Eggs are laid at the rate of 1 per day. Incubation begins with the laying of the last egg; the incubation period is 13-14 days. The eggs usually hatch within 1 day or at most 2 days. The nestling period is typically 20 days, although it has been reported to be as short as 13-14 days (Austin 1968; Campbell et al. 2001; Jehl 2004; Ray 1912; Young and Adkisson 2020).

There is no evidence that the Pine Grosbeak raises more than a single brood in a breeding season. Late clutches are presumed to be replacement clutches. Clutches of 2-5 eggs have been reported, but most contain 3 or 4 eggs. The single Ontario nest had a full clutch of 3 eggs (Austin 1968; Campbell et al. 2001; Peck et al. 2004b; Ray 1912; Young and Adkisson 2020).

Captive yearlings are capable of breeding so it is probable that first-year birds breed in the wild. Pair formation may take place in late winter when birds are still in flocks. Apparent pairs have been observed in mid-March in Michigan and Colorado. The mating system appears to be monogamous, but limited study has been conducted on this subject (Young and Adkisson 2020).

Foraging occurs on the ground and also in shrubs and trees from near the ground to the upper canopy. The Pine Grosbeak takes buds and newly grown conifer needles from the tips of branches. It spends much of its time on the ground in forest openings eating unripe seeds and developing ovaries of forbs. Fruits and seeds too high to reach by stretching are sometimes reached by biting and bending the main stalk. It captures some insects by flycatching in forest openings. On herbaceous plants, it bites flower heads open and shakes the seeds out (French 1954; Peck et al. 2004b; Young and Adkisson 2020). Both sexes develop gular sacs for a brief period during the breeding season when they are feeding young. This allows them to store food and carry large quantities back to the nest. The male feeds the female as part of the courtship ritual, during incubation, and for 3-4 days after the chicks hatch (Austin 1968; Cross 1952; French 1954; Jehl 2004; Peck et al. 2004b).

Young appear to be fed mostly insects and spiders, often mixed with vegetation. Adults eat predominantly vegetable matter. Early in spring and summer, the Pine Grosbeak eats a variety of buds and fresh growth of conifer needles; in summer, it eats insects, unripe seeds, and fruits; and buds and fruits are eaten in autumn and winter. It eats mountain-ash berries and other species with hard seeds by biting through, discarding the pulp, and crushing the seed. In late summer, unripe fruits of forbs are crushed in the beak and the flower part is discarded. It drinks water or eats snow on at least a daily basis. It eats cranberries, willow buds, moss campion seeds, salt and grit, ovaries of glacier lilies, raspberry seeds, juneberry seeds, mountain holly seeds, and terminal buds and seeds of spruce, pine, and fir (Austin 1968; Cross 1951; French 1954; Peck et al. 2004b; Ray 1912; Sinclair et al. 2003; Young and Adkisson 2020). In a Maine spruce–balsam fir stand in the first year, spruce budworms comprised 10% of the volume of the food and other insects and invertebrates comprised 79%; the remainder was vegetable matter. In the second year, spruce budworms constituted 79% of the diet compared with 11% other insects and invertebrates and 10% plant material (Mitchell 1952). Gabrielson (1924) analyzed the contents of 394 stomachs collected from 14 states and 5 provinces. He completed a literature review revealing that the Pine Grosbeak has a fondness for buds and eats mountain-ash berries, black ash seeds, maple seeds, red cedar berries, conifer seeds, frozen apples, birch and alder seeds, fruit buds of apples and pears, apple seeds, tree-of-heaven seeds, alder fruits, honeysuckle fruits, maple buds, ash buds, and Norway spruce and other coniferous buds. Nearly all these items were found in the stomachs he examined, suggesting that it feeds locally on different plants and plant parts, probably depending upon availability. It tends to eat 1 variety of seed or fruit until it is exhausted or the birds are disturbed. Stomachs from New Hampshire contained little but blackberry seeds and staminate flower buds of pines. Usually the gizzard was filled with one of these foods and the gullet with the other. The diet between April and September consisted of 83.3% vegetation and 16.17% animal matter. The vegetable matter differed from that taken in the winter chiefly in the absence of maple and ash seeds and in a higher percentage of fruit. Raspberry seeds and pine flower buds, the winter staples, were found in 7 of 29 stomachs (24.1%) and constituted only 7.0% of the summer diet. Seeds of conifers, especially spruce, accounted for 12.37% of the summer diet. Weed seeds constituted 19.97% of the diet, wild fruits contributed 32.8% to the summer diet, and deciduous tree buds, mast, and miscellaneous vegetable matter formulated the remainder of the vegetable diet. Miscellaneous seeds consumed included those of sedges, greenbriers, irises, smartweeds, docks, amaranths, mustards, currants, strawberries, juneberries, cherries, smooth sumac, buffalo-berry, wild sarsaparilla, bunchberry, nightshade, ragweeds, dandelions, hawkweeds, and Lapland rosebay. The animal food was very finely ground up; most of it could not be specifically identified. Grasshoppers, ants, spiders, and caterpillars constituted the bulk (15.08%) of the summer animal diet; small flies and beetles comprised the remainder. In New Brunswick, it exhibited no response to spruce budworm numbers (Morris et al. 1958). In Alaska, it fed on blueberries, rose hips, and cranberries until snow covered the ground. After mountain-ash berries were depleted, it ate berries of devil's club and highbush cranberry and buds of willows and alders. In June, it ate dandelion seeds and in July it fed on caterpillars on young alder buds and also ate weed seeds (Austin 1968).

The effects of forest management on the Pine Grosbeak are uncertain. Vanderwel et al. (2009) summarized the effects of partial harvesting of stands in the Boreal Forest Region in Ontario. They

stated that it should increase when 30%, 50%, or 70% of the forest cover was harvested but acknowledged that the reliability of their data was low. In British Columbia, Campbell et al. (2001) reported that 1 study found no change in its breeding abundance following selective logging that opened up the forest. Young and Adkisson (2020) and Herbers et al. (2004) concluded that large-scale clear-cutting was likely to negatively affect populations.

Status

The first breeding evidence for the Pine Grosbeak in Ontario was obtained in 1935 when an adult with young was seen on an island in the Temagami Forest. It had been observed there during the breeding season since 1922 and a nest was found in July 1940. In late August of the same year, a nest containing young was found near Sundridge. These nests were not described, so it was considered a hypothetical breeder. A female collected at Hawley Lake in 1958 had a brood patch and a fully formed egg without a shell in its oviduct. As of 1940, there were only 32 summer records, west to Sioux Lookout, north to Fort Severn, and south to Southampton in Bruce County, Mary Lake in Muskoka District, the Little Nipissing River, Combermere in Renfrew County, and Cross Lake in Frontenac County (Baillie 1960). Mills (1981) considered it sparsely distributed in Parry Sound and Muskoka districts. He was aware of only 4 or 5 breeding season records and some of these were questionable. During the first atlas, breeding records were obtained from the Lake Nipissing and Sudbury area north through the eastern Boreal Forest Region and at scattered sites throughout the Hudson Bay Lowland. No records were obtained from the western portion of the Boreal Forest Region except for 1 record north of Pickle Lake. In 1985, adults were observed feeding fledglings near the headwaters of the Black Duck River, approximately 10 km from the Manitoba border. No nests were found during the first atlas. Breeding season records were very spotty. Helleiner (in Cadman et al. 1987) concluded that it was an uncommon breeder in Ontario; it appeared to be fairly common along the north shore of Lake Superior in the Sault Ste. Marie area. James (1991) considered it a rare to uncommon summer resident across northern Ontario. Wilson and McRae (1993) concluded that it probably bred throughout the Hudson Bay Lowland in varying numbers.

The second atlas indicated limited change in the Pine Grosbeak's distribution since the first atlas. It was infrequently detected in the southern Lake Nipissing area, and records were again concentrated in the eastern portion of the Boreal Forest Region and the Hudson Bay Lowland. It was somewhat more widespread north of Lake Superior, extending westward to Thunder Bay. There were also some records in Rainy River District. There were significant declines in the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region and the Boreal Forest Regions, but significant increases in the Hudson Bay Lowland resulted in a nonsignificant increase for the entire province. Greatest concentrations appeared to be in the Kapuskasing area, with low abundance and apparent absences throughout the rest of its range (Peck and Coady in Cadman et al. 2007).

Breeding Bird Survey data indicate that the Pine Grosbeak decreased at annual rates of 2.23% in Canada and 2.37% in Ontario 1970-2021. Trends 2011-21 were annual decreases of 0.182% in Canada and 1.52% in Ontario. All results were of low reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

As soon as the fledglings are able to fly, they follow their parents, even when they forage on the ground distant from thick cover. Shortly after leaving the nest, birds gather in small flocks that may

represent family groups. In British Columbia, the earliest breeders occasionally move to lower elevations in small family groups as early as mid-May. In most years, they do not appear at lower elevations until late October or early November (Campbell et al. 2001; French 1954; Young and Adkisson 2020).

MIGRATION

In many years, the Pine Grosbeak is nonmigratory and remains within the breeding range. Even in these years, it may wander during the postbreeding and migration periods. Near Churchill, it seems to disappear in mid-October. In the Yukon, it moves out of contiguous forest habitat and occurs in human settlements from October to April. Its presence and habitat use appear to be directly related to food distribution and abundance. In western areas, it remains in subalpine habitats all winter if food is plentiful, but moves to lower altitudes when food is scarce. In the east, it makes long-distance irruptive movements far south of the breeding grounds in years when food resources are low in the breeding grounds. Migratory movements appear to occur during the day (Austin 1968; Campbell et al. 2001; Jehl 2004; Sinclair et al. 2003; Young and Adkisson 2020).

Peak numbers occurred in the Toronto area in years following maximum abundance of food in the north. Speirs (1939) concluded that there was no evidence to suggest that lack of food on the breeding grounds drove birds south. Austin (1968) noted that southward movements were unrelated to weather conditions. The Pine Grosbeak was absent in the south in some of the severest winters and present in some warm winters. Bock and Lepthien (1976b) compared the timing of irruptions of several boreal seed-eating birds and found that they were highly synchronous, although the Pine Grosbeak did not irrupt as frequently as some other species. Most trees set seeds every other year, but some do so at greater intervals. Largest irruptions occurred when seed crops of all tree species were poor. It is now generally accepted that southward irruptions are a response to low food supplies in the northern breeding grounds. When irruptions occur, the Pine Grosbeak may winter as far south as Arizona (Root 1988; Young and Adkisson 2020).

The frequency of southward irruptions is irregular. At times the Pine Grosbeak appears on a regular cycle, but then the intervals between irruptions may change or there may be long periods without any wintering birds south of the breeding grounds. McIlwraith (1894) reported that it was common in the winters of 1882-83 and 1883-84 then none were seen until the large influx in 1889-90 (Thompson 1890). Using Christmas Bird Count (CBC) data for 1929-77, Freedman and Riley (1980) concluded that irruptions in southwestern Ontario appeared to be cyclic, occurring at intervals of 3-5 years (mostly 3 years). Since 1950, peak numbers of Pine and Evening grosbeaks were highly synchronous. In the Toronto area, peaks occurred at intervals of 5-6 years, usually 6 years (Speirs 1939). In Niagara Region, influxes occurred irregularly prior to 1966, with peaks every 3 years, but occasionally with intervals of 4, 5, or 6 years (Black and Roy 2010). In the Hamilton area, it occurred at least every other year from 1950 to the late 1980s, or often every winter. Only 2 irruptions occurred during 1996-2005 (Curry 2006). In the Kingston area, irruptions occurred in 21 of 61 years 1948-2008, an average of about every third year (Weir 2008). Intervals between irruptions are irregular in other areas as well. In Massachusetts, the interval between irruptions was normally 2-6 years but with some longer intervals. In New York, intervals were as long as 18 years and 25-year intervals have been reported elsewhere (Austin 1968; Young and Adkisson 2020).

In the extensive winter invasions in the winters of 1882-83 and 1883-84, McIlwraith (1894) reported that Pine Grosbeaks first appeared in early January and remained into April. During the winter of 1889-90, when numerous birds were reported from Kingston, Toronto, southern Peel Region, and Hamilton, the first birds seen on 1 January (Thompson 1890). Parker (1973) tracked the 1971-72 irruption into southern Ontario and New York using CBC data. From 18-22 December, numbers per party-hours were more than 20 on the Canadian Shield to southern Georgian Bay, 6-20 in a very narrow band east and south of that, and 1-5 or 0 in the remainder of the south. During 23-28 December, there were more than 20 from southern Georgian Bay eastward, 6-20 from Toronto to the Port Elgin area and along the north shore of Lake Ontario, and 1-5 in the remainder of the south. During 29 December-2 January, there were more than 20 from Goderich to Toronto eastward to Quebec, a narrow band with 6-20 south of that, and 1-5 in the remainder of the south. Spring departure varies from early March to early April, with stragglers into late April. Autumn arrival is typically late October to early November (Black and Roy 2010; Curry 2006; LaForest 1993; Mills 1981; Tozer 2012; Walker 1989; Weir 2008). In Thunder Bay, it started to arrive in October or November. The population peaked around Christmas or early in January and decreased as mountain-ash fruit became depleted. A minor upsurge in numbers occurred in late February or early March (Austin 1968).

WINTER

In winter, the Pine Grosbeak is strongly associated with snow. Important predictors of its presence are length of the snow season and absence of frozen ground without snow (Keyser et al. 2023). Winter and migration habitats are essentially the same. Even in populations that do not migrate, winter habitat may differ from breeding habitat. It appears wherever food is most abundant and may use habitats in winter that are not used during the breeding season. During winter irruptions, it may occur in open coniferous forests provided that seed crops are abundant. It is more likely to occur where fruits and seeds of deciduous trees and shrubs are available and may be attracted to bird feeders, although it tends to prefer natural foods. It may occur around dwellings, in shade trees, in orchards, in deciduous woods where seeds of maple or ash are abundant, and along roadsides. Two locations where it may be abundant in winter in Ontario include Thunder Bay, where it is attracted by showy mountain-ash fruit, and the arboretum at the University of Guelph where it is attracted by crabapples. In winter in Alaska, it usually inhabits low ridges sparsely treed with birch and spruce, but retreats into willows in the severest weather (Austin 1968; Campbell et al. 2001; Earley 2009; Young and Adkisson 2020). In British Columbia, highest densities of wintering Pine Grosbeaks occurred at the highest elevations in subalpine spruce and spruce–fir forests. It was rare or absent in low-elevation ecosystems, although it occasionally moves to lower-altitude areas. It was one of few species adapted to wintering in the severe climate of subalpine areas (Herbers et al. 2004).

In winter, the Pine Grosbeak roosts in dense conifers, and birds tend to roost close to each other (Young and Adkisson 2020).

The Pine Grosbeak often occurs in small flocks of 5-10 birds suggesting that families and groups of families remain together. It may also occur singly or in much larger flocks. It may be loosely associated with other species that are attracted to the same food resources. In 1890, mixed flocks of

Pine and Evening grosbeaks were common, but each species also occurred in discrete flocks. Other species that may occur at the same food sources include Bohemian Waxwing, Evening Grosbeak, House Finch, Purple Finch, Redpoll, Red Crossbill, and Pine Siskin (Campbell et al. 2001; Thompson 1890; Young and Adkisson 2020).

Information on winter site fidelity is scarce. It is probable that western birds that tend to migrate only altitudinally have higher rates of site fidelity than eastern irruptive populations. There are 12 cases of wintering birds being recovered in the same 10-minute block 1-5 years later. One bird banded in Michigan was recovered 4 years later approximately 100 km south of the banding location (Young and Adkisson 2020).

In the Hamilton area and along the north shore of Lake Ontario, the Pine Grosbeak was usually seen feeding on mountain-ash berries. The crops and gizzards of those that were collected were full of black ash seeds (Thompson 1890). McIlwraith (1894) stated that it occurred wherever mountain-ash or red cedar berries were available. In Thunder Bay and many other locations in the province, mountain-ash berries are the most important food. Its abundance is directly correlated with abundance of this fruit in Thunder Bay. It initially feeds in the trees and later on the ground when melting snow reveals more fruit. The next favourite foods were lilac seeds and ornamental crabapples. Stragglers remaining later in spring fed on black ash seeds and occasionally on highbush cranberry, Manitoba maple, and white birch. It splits lilac seeds to obtain the insides (Austin 1968). In Parry Sound, it fed on mountain-ash, lilac, white pine, honeysuckle, maples, apples, and tamarack (Mills 1981). In Newmarket, it ate seeds of riverbank grape and American bittersweet (Dance 1986). At Deep River, it fed on crabapples; this is the predominant food eaten at the University of Guelph arboretum, where it also consumes mountain-ash berries (Earley 2008; Walker 1989)). In Algonquin Park, it has eaten buds of aspen, willow, balsam fir, white pine, sugar maple, and juneberry. It is attracted to salt and sand on roads and, in some winters, few are seen until these materials are applied to the highway (Tozer 2012).

Winter foods that the Pine Grosbeak has consumed elsewhere include seeds of ashes, lilacs, mountain-ash, roses, pines, birches, tamarack, balsam fir, grasses, hemp, burdock, ragweed, lamb's-quarters, tulip tree, wild grapes, northern wild raisin, greenbrier, privet, and cultivated honeysuckles; fruits of snowberry, crabapple, mountain cranberry, barberry, red cedar, black alder, hawthorn, buckthorn, sumac, bittersweet, apples, and nightshade; buds of apples, elderberries, pear, willow, poplar, birch, and alder; and pitch pine twigs (Austin 1968; Campbell et al. 2001; Crumb 1981; Taylor 1996; Young and Adkisson 2020). In Alaska, its diet was similar to that of Redpolls: seeds and buds of birch, alder, and willow, and sometimes tender spruce needles (Austin 1968). The Pine Grosbeak needs water in winter and commonly eats snow. In Alaska, a bird flew from a perch in a tree to hover briefly to take a drop of water from an icicle hanging from the roof of a cabin. This behaviour was repeated 5-10 times within 5 minutes (Crumb 1981; Wolfe 1996). It is readily attracted to salt, particularly in winter along roads. When it feeds on natural foods, it tends to feed on 1 item until it is completely depleted and then moves to another food source (Young and Adkisson 2020).

Gabrielson (1924) analyzed the contents of 365 stomachs collected in winter and determined that the diet consisted of 99.1% vegetable matter. Raspberry seeds constituted 14.37% of the diet; coniferous buds comprised 24.22% of the diet. Almost all buds were staminate flower buds of pine,

although a few leaf buds and spruce buds were eaten. One or both of these foods occurred in 217 stomachs and they were eaten in every month. Other items constituted high percentages of the diet, but some comprised the entire content of a few stomachs from 1 locality rather than general use over a broad area. Snowberry constituted 17.3% of the diet and had been eaten exclusively by 69 birds from British Columbia. Weed seeds represented 7.67% of the diet; 7 stomachs from Ontario contributed half this total. Red cedar berries and other coniferous seeds amounted to 4.15% of the diet, mostly from Connecticut birds. Birds from Ontario and Massachusetts ate most of the maple (2.78% of the diet) and ash (1.25%) seeds. Wild fruits constituted 14.34% of the diet. The most abundant fruits consumed were those of hawthorn, dogwood, mountain-ash, huckleberry, blueberry, crowberry, and viburnums. Most fruits were probably taken for the seeds because little pulp was found, although fruit pulp of mountain-ash, crowberry, and blueberry were frequently taken. Mast constituted 5.66% of the diet and was mostly beechnuts or acorns. Buds of willow and maple comprised 4.72% of the diet and the remaining 2.64% of vegetable matter included bits of pine needles, wood, grass, and fragments of unidentified seeds. The 0.9% animal food consisted of fragments of small beetles and weevil larvae, hymenopterans, and flies. All these occur in coniferous buds so it is likely that they were ingested incidentally.

In British Columbia and the Yukon, the Pine Grosbeak is a common visitor to bird feeders and is among the top 10 species at feeders (Campbell et al. 2001; Sinclair et al. 2003). Overall, it is an uncommon user of feeders and is most likely to visit feeders where it is a year-round resident. It rarely visits feeders during southward irruptions but is a common visitor to feeders in northern Ontario. Until the late 1980s, it was a rare feeder visitor in the Shield portion of the Great Lakes–St. Lawrence Forest Region but may have increased the frequency of its visits. At Deep River, there was no correlation between the number of birds present and the number that used a feeder. Over 9 years when Pine Grosbeaks were present, visits to the feeder occurred in 7 years. In 1 winter, 30 birds were present for 2-3 months but only 2 visited the feeder on 4 occasions. The maximum number of birds that visited the feeder was 15; only 0.25-11.5% of the birds that were present used the feeder. Usage of feeders may be a learned behaviour which may explain why only a small proportion of birds use them. It may prefer natural foods to those provided at feeders. It may use feeders week after week and is much more likely to occur at rural and suburban feeders than urban feeders. The proportion of feeders visited increases until late winter than drops off markedly in February and March, at which time flock sizes also decrease (Crumb 1981; Dunn 1989, 1990; Dunn and Tessaglia-Hymes 1989; Pittaway 1989; Tozer 1990; Walker 1989). Its favourite feeder foods are striped and black oil sunflowers and water. In Algonquin Park, it prefers to take sunflowers that have fallen to the ground from the feeder. Infrequently consumed feeder foods include fine cracked corn, millet, wheat, oats, milo, suet, and fruit (Crumb 1981; Dunn and Tessaglia-Hymes 1999; Tozer 2012).

The Pine Grosbeak is subordinate to the Evening Grosbeak and may not visit feeders where it is abundant. Alternatively, visitation by the Pine Grosbeak may be deferred until late afternoon after Evening Grosbeaks have departed. It may decrease in numbers in winters when Evening Grosbeak numbers are high, both at feeders and in the wild (Dunn and Tessaglia-Hymes 1999; Pittaway 1989).

The Pine Grosbeak commonly strikes windows during winter, particularly at houses where there are feeders. In the United States, it was 12.4 times more likely than average to strike a building and ranked 15th in overall vulnerability (Campbell et al. 2001; Loss et al. 2014; Young and Adkisson 2020).

Because it is attracted to roadsides by salt and grit, the Pine Grosbeak is frequently struck by vehicles. Considerable numbers may be killed in this manner, particularly during irruption years (Campbell et al. 2001; Tozer 2012; Young and Adkisson 2020).

The Pine Grosbeak may be vulnerable to conjunctivitis, a disease that affects the eyes and ultimately results in blindness and death. Outbreaks in both Pine and Evening grosbeaks occurred in February 1999 in the Saguenay area of Quebec and in the northcentral region of that province. Ten to 20% of birds at 14 feeding stations were sick, representing more than 100 birds of both species (Iron 1999).

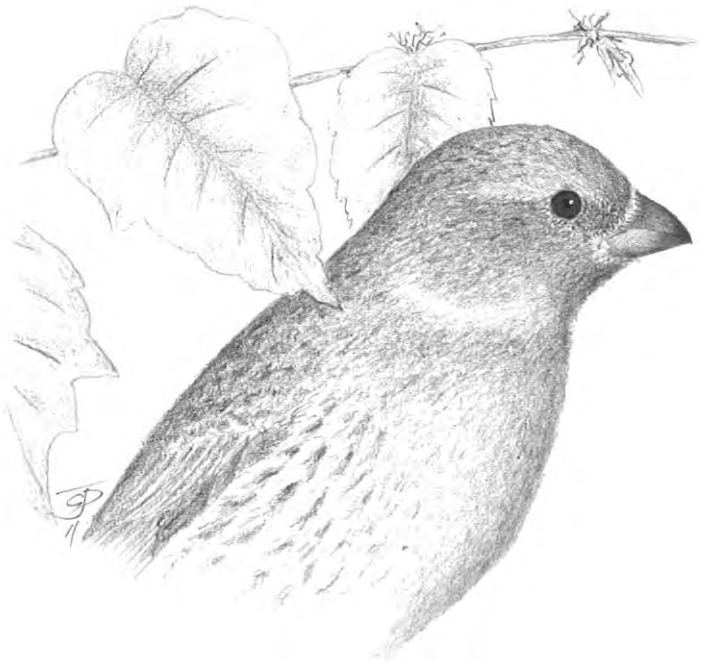
CBC data indicate that the Pine Grosbeak is consistently present north of latitude 50°N in North America. Highest concentrations occur in the Upper Peninsula of Michigan and along the north shore of Lake Superior in Minnesota and Ontario. High numbers also occur northeast of Georgian Bay (Root 1988; Young and Adkisson 2020).

There are no reliable trend data for the Pine Grosbeak in the core of its Ontario wintering range. South of the main wintering area, the frequency of irruptions appears to be declining and fewer birds occur during irruptions. This is the case throughout eastern North America as well as in Ontario. The reasons for this are unclear, but it has been suggested that wide-scale clear-cutting has lowered population levels (Breton in Gauthier and Aubry 1996; Young and Adkisson 2020). Although it appears to be declining, it is unknown if decreases of birds occurring south of the normal wintering area are representative of the trend of the entire population.

Freedman and Riley (1980) summarized CBC results for southern Ontario for 1929-77. There was a trend toward an increase in numbers beginning in 1960. The number of birds seen per observer was 0 to less than 1 until 1960, except that it was almost 3 in 1929. A regular cyclic pattern began in 1960 when numbers alternated between 0 and 2-3. In Elgin County, the high CBC counts were 149 in 1979 and 57 in 1977, but fewer than 10 are reported on most counts now (Lancaster et al. 2004). There are very few records after 1986 in Niagara Region (Black and Roy 2010). In the Hamilton area, it was detected in 8 winters during 1930-50 (38.1% of winters). From 1950 to the late 1980s, it occurred at least every other winter or often in every winter. Occurrences declined thereafter with only 2 winter irruptions during 1996-2005. Numbers reaching the area during irruptions also dropped (Curry 2006). In the Kingston area, typical flock sizes are 30 during moderate irruptions and as high as 400 during heavy irruptions (Weir 2008). In Muskoka and Parry Sound districts and Algonquin Park, the Pine Grosbeak is present almost every winter. In the park, it has been recorded on 34 of 38 CBCs (Mills 1981; Tozer 2012). CBC data indicate that the Pine Grosbeak increased in Ontario at an annual rate of 2.13% 1970-21 and decreased at an annual rate of 0.57% 2009-21 (National Audubon Society 2022).

House Finch

Haemorhous mexicanus



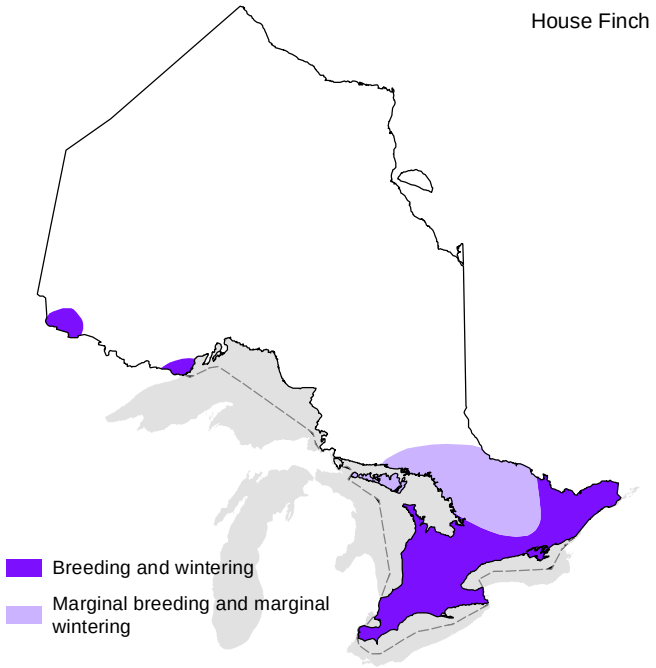
BREEDING SEASON

Habitat Requirements

In Ontario, most House Finch nests were near or on residences or buildings in both rural and agricultural areas. Three were in coniferous plantations, 3 were in woodlands in parks, 3 were in cemeteries, 2 were in abandoned pastures, and 1 was in a hawthorn meadow (Peck and James 1998b). It is strongly associated with humans and avoids areas of extensive forest. Consequently, its Ontario range is restricted predominantly to the urban and agricultural areas south of the Canadian Shield and in Rainy River District. It is absent from the Hudson Bay Lowland and the Canadian Shield except in larger urban centres (Leckie in Cadman et al. 2007).

The eastern population of the House Finch is nonnative, having been established by the release of California birds in New York in 1940. The 2 populations differ somewhat in their habitat preferences, although both are most abundant in urban and suburban areas with lesser numbers around rural dwellings and other buildings. The western population also nests in some natural habitats that probably represent its ancestral habitat prior to settlement by humans (Badyaev et al. 2020; Bergtold 1913).

Badyaev et al. (2020) concluded that the House Finch nested almost exclusively in settled areas in the east. It prefers areas with buildings, lawns, and small conifers but also occurs in urban centres



where it commonly nests on high-rise buildings. Smaller numbers occur in rural areas around houses and outbuildings on farms. It is rare in extensive coniferous and deciduous forests away from human settlement. It avoids mature pine stands and 20-30-year-old monoculture pine plantations. In Vermont, it nested in Christmas tree plantations planted in blocks of white spruce, balsam fir, and Fraser fir. Nests were more common in plantations surrounded by forest (0.67% of trees had nests) than those surrounded by agriculture (0.10% of trees had nests). Nests were 1.3 times more abundant in interior than edge trees. The House Finch exhibited the weakest preference of the species present for nesting in interior trees rather than those in rows at the perimeter of the plantations (Hughes and Hudson 1997).

In Colorado before human settlement, the House Finch nested primarily in treed floodplains of larger streams and along the base of the foothills, and, to a lesser extent, along streams up into the foothills. After settlement, it was the only species that was common around urban buildings until the introduction of the House Sparrow (Bergtold 1913). In the west, the House Finch is common in urban habitats where it prefers areas with ornamental shrubs, particularly conifers. It continues to breed in a variety of undisturbed habitats including deserts, desert grasslands, desert shrublands, oak savannahs, juniper–oak woodlands, riparian areas, open coniferous forests, and subalpine shrubs. It avoids dense coniferous stands but is common along their edges. It occupies open grasslands and short-grass prairies where abandoned farm equipment or buildings provide nest sites (Badyaev et al. 2020). Woods (in Austin 1968) concluded that it was always near a source of water in natural habitats. In California, it occupied oak savannahs at a higher rate than in montane hardwoods and oak woodlands, but not significantly. It was considered an oak–savannah affiliate. Its abundance was positively correlated with herbaceous cover and average tree diameter and negatively correlated with hardwood and shrub coverage (Wood et al. 2013). In British Columbia, it is closely associated with human-created habitats and most abundant around human habitation, particularly in suburban areas. It uses other anthropogenic habitats including city core areas, golf courses, semiopen parks, cemeteries, nurseries, airports, orchards, and vineyards. In Vancouver, it was most abundant in lightly wooded apartment and residential areas with 30% tree and shrub coverage, but avoided sparsely vegetated industrial and commercial areas. In open grassland landscapes, it is associated with shrub thickets in gullies and occurs around wetland margins. It avoids closed forest habitats and subalpine and alpine areas and is rarely observed in wilderness areas (Campbell et al. 2001).

Adults may roost singly in small groups in the canopy of trees or in cactus stands and occasionally in ivy under eaves of buildings, inside buildings, and under roof shingles. Occasionally the House Finch roosts with House Sparrows. When the female is incubating, the male roosts nearby, and the pair roosts together near the nest when it contains nestlings. Nest boxes are not used as roosts after nesting is complete. At 1 California site, males appeared to roost together as far as 2.4 km from their nest sites (Badyaev et al. 2020; Bergtold 1913; Evenden 1957).

All Ontario nests were elevated, mostly in coniferous trees, but also on or in buildings and in hanging flower pots. Tree nests were in spruce (44.9% of nests), juniper (35.5%), and white cedar (19.6%). They were usually near the tops of trees and most were against the trunk on horizontal branches. In larger trees, nests were occasionally distant from the trunk on a horizontal branch. One nest was on a rose trellis against a wall, 2 were under aluminum window awnings, 1 was on a verandah overhang, 1 was on an upright stud inside a garage, 1 was in a factory fan duct, and 1 was in a space between bricks on a building. Nests were 1-10 m from the ground with most 2.3-3.4 m up. Some were in old nests of Mourning Dove, Cliff Swallow, Barn Swallow, and House Sparrow. Some nests were used in 2 successive years or for more than 1 brood in a year (Peck and James 1987, 1998b). In St. Catharines, 1 nest was in a hanging flower basket and the remainder were in Chinese junipers and red cedars. Nests were 1.2-4.3 m above ground (average 2.6 m; Kozlovic 1988, 1998; James 1978b). Three nests in Rainy River were all in white cedars (Graham and Salvadori 1995).

Most nests reported elsewhere were on or in buildings or coniferous trees and shrubs adjacent to buildings. The House Finch commonly nests in ivy growing on the sides of buildings. In desert habitats, it commonly nests on cacti. The main requirements for nests in anthropogenic sites are a solid base and some overhanging structure that provides protection from the elements (Badyaev et al. 2020). In Vermont Christmas tree plantations where the trees were 1-3 m tall, it preferred to nest in trees that were 2.0-2.5 m tall. Mean height of nests was 1.1 m regardless of tree species. Nests were 95.2% shaded from above and 93.1% from the sides. It exhibited a strong preference for nesting in spruce with 9 times more nests per tree in spruce than fir. Shading was much higher in spruce suggesting that nest concealment may be important (Hughes and Hudson 1997). In British Columbia, 97% of nests were in human-influenced habitats; the other 3% were in forest, wetland, or grassland habitat. Human-influenced habitats included 46% suburban, 26% cultivated farmland, 10% urban, 7% rural, and 6% orchards. Sixty-two percent of nests were in trees and shrubs. Fifty-three percent were in conifers that were mostly ornamental species; only 8% were in deciduous trees or shrubs. Spruce was a preferred nest-tree species, including blue spruce. Eighty-three percent were in nonnative tree and shrub species and 9% were in vines or ivies that were usually growing on buildings. Eleven percent were in or on human-created structures including shed rafters, beams, shelves, under sundecks and carports, in window shades and wall vents, in covered street lamps, on porch light fixtures, on top of sliding garage doors, in an opening in a balcony railing, in bird feeders, in a coil of wire, in hanging flower baskets, and in nest boxes. Nests were 0-45 m from the ground with most 1.8-3.0 m up; the highest nest was on the 15th floor of a high-rise apartment building (Campbell et al. 2001). It occasionally nests on rock ledges and rarely in deciduous trees or shrubs or in cavities in trees. Unusual nest sites include in tin cans hanging on fence posts, on the ground, in old hats and stove pipes, in hollow limbs and woodpecker holes, and

in a haystack. Nests have been constructed in old nests of phoebes, Cliff Swallow, Barn Swallow, American Robin, towhees, blackbirds, and orioles (Badyaev et al. 2020; Bergtold 1913; Evenden 1957; Hamilton 1993a; Janssen 1989; Woods in Austin 1968). The House Finch nests in boxes built for it and in those designed for other species (Bergtold 1913). It also nests in Purple Martin houses and gourds intended for martins (Hill 1988b). Sometimes the first nest is used to raise a second or even third brood but just as often new nests are built for subsequent nests. In California, no nests were reused by a single pair within a breeding season but 7 of 24 pairs (29.2%) reused their nest from a previous year; 74% of all nests had been used previously. Old nests of other pairs may be refurbished and used and females frequently take material from old nests to build new ones. One nest in a haystack was used for more than 6 years, but probably not by the same individuals (Badyaev et al. 2020; Bergtold 1913; Campbell et al. 2001; Gill and Lanyon 1965; Hooge 1990; Woods in Austin 1968).

The House Finch is highly gregarious and tolerant of conspecifics. No resources are defended other than the immediate nest site. Close neighbours are tolerated and most aggression is directed to females that have nests more than 12 m distant. In urban areas, pairs commonly nest within 1 m of each other. In deserts, pairs often nest in loose aggregations 20-40 m apart. Two active nests on a barn beam were so close together that the nesting materials were interwoven on the adjacent sides. Both sexes guard their mates, presumably to reduce the incidence of extra-pair copulations (Badyaev et al. 2020; Kalinoski 1975; Woods in Austin 1968).

Natal philopatry tends to be lower in eastern populations, which may be partially migratory. In all populations, independent juveniles may wander considerably during the postfledging period, and this reduces natal philopatry even in resident populations. Juveniles that remain in an area for more than 2-3 weeks in late summer or autumn are likely to nest in that area in the following breeding season. In Michigan, 16 of 345 nestlings (4.6%) returned to breed. In Massachusetts, 12 of 45 juveniles (26.7%) did not leave the breeding area. In Arizona over 8 years, natal philopatry rates ranged from 7.9% to 13.2% (average 10%). In both Montana and Arizona, about 15% of birds did not leave their natal area and those that dispersed usually travelled less than 20 km. In California, a male nestling was recaptured the following year 12.2 m from its natal nest. In Montana, most newly arriving birds were hatched in other areas less than 20 km distant. In New York, 5 of 63 nestlings (7.9%) returned to the natal area. Others were recaptured as far as 24 km away in the spring of the following year. Of 16 nestlings in Colorado, 1 died shortly after banding, but 0 of the remaining birds returned (Badyaev et al. 2020; Bergtold 1913; Evenden 1957; Gill and Lanyon 1965).

In the west, the House Finch is predominantly a resident so birds tend to remain in the same area. Within breeding seasons, subsequent nest sites are usually within 10-20 m of the previous nest. In the east, 27.8% of males and 20.9% of females were recaptured at their previous breeding area; the mean distance between recaptures for 333 birds was 109 km. Within breeding seasons, eastern birds often move more than 1 km between nesting attempts (Badyaev et al. 2020).

Limiting Factors

Eggs have been found in Ontario nests from the third week of March until the first week of August. Most are present from the last week of May until the third week of June. At St. Catharines, 72% of breeding occurred from mid-May to late June. The timing of egg laying varied significantly, averaging 18 days earlier in a warmer spring than in more typical springs. Warm spring weather may

induce earlier egg laying, but the presence of nearby feeders may also be a factor (Kozlovic 1988, 1998; Peck and James 1998b).

Pair formation begins in winter flocks. Both sexes prospect and select potential nest sites. Nest prospecting may take as long as 2 weeks, usually 1-8 days. Pairs that return from the previous year only prospect for 1-2 days. First nests of the season take longer to build on average (10.4 days) than later nests (7.6 days). In Arizona, nest building took an average of 8.9 days (range 5-21 days). In Montana, nests took an average of 11 days to build (range 4-29 days): an average of 17.5 days for early nests and 4.5 days for later nests. In Colorado nest boxes, first nests took 3-6 days to build and later nests were completed within a day. In California, early season nests took 14-21 days to build; later nests were built as quickly as in 2 days. New York nests took 2-5 days to build, mostly 3 days. Early in the season, as many as 10 days may elapse between nest completion and the initiation of egg laying. In later nests, egg laying begins the day the nest is completed or the following day. Eggs are laid at the rate of 1 per day but occasionally 1 or 2 days are skipped. Incubation typically begins with the laying of the penultimate or final egg. When temperatures are lower than 4°C, incubation may begin with the laying of the first egg. The incubation period of 30 Ontario nests was 10-14 days, with 15 having incubation periods of 11-12 days. In St. Catharines, the modal incubation period was 13 days. Elsewhere, incubation periods of 11-18 days have been reported with most eggs hatching in 12-14 days. Shorter incubation periods are often associated with warmer ambient temperatures; colder temperatures may prolong the incubation period. The eggs may all hatch in 1 day but more frequently 2 hatch on the first day and the others follow at 1-day intervals. Eggs may also hatch at the rate of 1 a day with a noticeable size difference in the nestlings that carries over into the fledgling stage. The nestling period at 1 Ontario nest was 16 days. Elsewhere, nestling periods of 11-19 days have been reported. The median in British Columbia was 15 days and most studies report average nestling periods of 14-16 days. Young may leave the nest when they are only 11-12 days old if disturbed (Badyaev et al. 2020; Bergtold 1913; Campbell et al. 2001; Evenden 1957; Gill and Lanyon 1965; Kozlovic 1998; Peck and James 1987, 1998b; Woods in Austin 1968).

The House Finch regularly raises 2 broods in a season and some pairs raise 3 broods. Three broods have been confirmed in Ontario and many other locations. In California, birds that maintained their pair bond from the previous year raised significantly more clutches (2.5) than newly formed pairs (1.7 clutches). Seven of 9 returning pairs (77.8%) raised 3 broods. Renesting is common if a clutch is lost and nest building may begin within an hour of the loss of the previous nest. It has been known to attempt as many as 6 clutches within a season, but has never been documented raising more than 3 broods (Badyaev et al. 2020; Bergtold 1913; Campbell et al. 2001; Hooge 1990; Peck and James 1998b). Clutches of 2-6 eggs were reported in Ontario, with most containing 4 or 5 eggs (mean 4.39 eggs). Overall, clutches of 2-7 eggs have been reported with 70% or more of clutches containing 4 or 5 eggs. Mean clutch sizes tend to range from 4.2 to 4.5 throughout its range but may be as high as 4.75 eggs. In Indiana, most April nests contained 5 eggs; May and June nests contained 4 eggs. Clutch sizes of replacement nests tend to be smaller than those of first nests (Badyaev et al. 2020; Bergtold 1913; Campbell et al. 2001; Evenden 1957; Gilbert et al. 2005; Gill and Lanyon 1965; Hamilton 1993a; Peck and James 1998b; Woods in Austin 1968). The mean clutch size was significantly greater in the east (4.53 eggs) than in southern California (4.21 eggs) and the

northwest (4.35 eggs). Wootton (1986) concluded that larger clutch sizes in the east were probably because of higher predation rates and population densities in the west. Where predators are more abundant, birds may lay fewer eggs to conserve energy for renesting. Where densities are lower, the amount of available food is greater on a per individual basis. If higher clutch sizes in the east are due to predation rates, clutch sizes should remain high. If it is a result of lower densities, then clutch size should decrease as the population increases. It is possible that females reduce the clutch size when more than 5 eggs are present. In clutches of 5 or more eggs, 1 egg was often found outside the nest. Bergtold (1913) assumed that these eggs had been accidentally pushed out of the nest but it is conceivable that the female deliberately removed them to reduce the number of nestlings that had to be cared for. In Alabama, a female ate one of her own eggs from a clutch of 6 eggs. The proportion of single eggs disappearing from 6-egg clutches (2 of 12, 16.7%) differed significantly from the proportion disappearing from smaller clutches (1 of 205, 0.49%). This may have been a deliberate attempt to reduce clutch size but may have been a response to disturbance or a damaged egg (Gilbert et al. 2005).

Both sexes are capable of breeding in their first year. In all populations, the sex ratio is highly male biased so as many as 50% of males may not attract a mate. Brightly coloured males are more likely to attract a mate than dull-coloured males. The bright colours are a result of a rich diet and signal that the male may be superior in providing food to the female and nestlings. Brightly coloured males obtain mates sooner and nest earlier, possibly allowing time to raise an additional brood (Hill et al. 1994). In many populations, some yearling females do not breed (Badyaev et al. 2020; Gill and Lanyon 1965; Hill et al. 1994).

The mating system is monogamous. In Montana, loose behavioural interactions between 2 males and 1 female were observed in 5% of pairs, although only 1 male provisioned the incubating female and the nestlings. There is 1 case of a male with 2 females that laid a total of 10 eggs in a single nest. There are 2 records of a single female having 2 active nests only 5 m apart at the same time. Eggs were laid in the second nest during the incubation period of the first nest. It was presumed that the same male attended these nests but this was not positively confirmed (Badyaev et al. 2020; Evenden 1957; Woods in Austin 1968). In sedentary populations, the pair bond may be maintained throughout the nonbreeding season and into subsequent breeding seasons; 1 Montana pair remained together for 7 years. In California, the pair bond was maintained in 16 of 17 pairs (94.1%) when both members of a pair returned. The pair that did not reunite failed to produce young in the previous year and the male was the most promiscuous bird in the population, being responsible for most of the extra-pair copulations. Year-round maintenance of the pair bond allows pairs to nest earlier and raise more broods than newly established pairs. It also allows an individual to recognize the loss of a mate during the nonbreeding season and to find a replacement before the breeding season starts (Hooge 1990). Of 33 females observed for 2-4 consecutive years, 70% bred with the same male in at least 2 years. In another location where 18 pairs were followed for 2 years, 16 (88.9%) retained their mate. Of 56 breeding males observed for 2-5 consecutive years, 60% nested with the same female in any 2 consecutive years. In Michigan, approximately 10% of birds switched mates during the breeding season, almost always after nest abandonment by the female. Ninety-three percent of pairs remained together after the nest was depredated and 100% remained

together after nesting successfully. In Arizona, 16% of females switched mates during the breeding season, 43% after nesting successfully and 57% after nest predation or abandonment (Badyaev et al. 2020).

Intraspecific egg dumping is a rare reproductive strategy. Only 2 cases have been confirmed of more than 900 nests across the range of the House Finch (Badyaev et al. 2020). Both sexes engage in extra-pair displays. Females may display to a group of males followed by extra-pair copulations, often with more than 1 male. Most extra-pair copulations do not result in fertilization. In Michigan, 8.4% of nestlings in 14.3% of nests were fathered by a male other than the attending male. Nesting density was correlated with the incidence of cuckoldry. Factors such as plumage brightness, adult size, clutch initiation date, clutch size, and age of the male had no effect on the rate of cuckoldry (Hill et al. 1994). Overall, 6-10% of offspring are extra-pair. In pairs where both partners were local, nests contained 35% extra-pair young compared with 8% when at least 1 partner was nonlocal. In 3 Montana areas, the incidence of extra-pair young was 6.5%, 4.6%, and 9.0%. Occurrence of extra-pair young was associated with the total number of active nests in a local neighbourhood: 3 local nests resulted in 10% extra-pair young, 4 nests in 20%, 6 nests in 40%, and 7-10 nests in 50% extra-pair young (Badyaev et al. 2020).

The House Finch feeds on the ground or while it is perched on grasses, shrubs, cacti, or trees. In British Columbia, 60% of foraging occurred on the ground. Nearly half of foraging occurred in sparse grass or weed patches that represented less than 2% of available habitat. It feeds on herbaceous seeds either by picking them off the ground or by clinging to plants and picking seeds off flower heads. It frequently hovers at fruits and flowers and can feed and drink while hovering. In spring, it eats leaf and flower blossoms from shrubs and trees. It prefers to eat fruit that is still hanging on the tree. It sips maple sap from wounded branches and also visits hummingbird feeders. In the west, it is attracted to weeds and seed spillage along railroads; this is an important food source in winter. It is attracted to sodium and ingests salt where it is available. It also frequents calcium licks and soils and may make daily visits to calcium deposits throughout the breeding season (Badyaev et al. 2020; Bergtold 1913; Campbell et al. 2001; Woods in Austin 1968). In an aviary experiment, the House Finch was most efficient at handling seeds 25-65 mg. It needed to encounter a seed every 200-500 seconds to meet its midwinter energy demands (Benkman and Pulliam 1988). It strongly prefers fruits containing hexoses over those containing sucrose but is capable of assimilating both types of sugars. The preference for hexoses may be because these sugars are readily assimilated whereas sucrose must be hydrolyzed first (Avery et al. 1999). Avery (1996) treated oats, the preferred seed of adults, with a chemical so that they avoided oats. Adults that learned to avoid oats did not feed them to older nestlings and fledglings. Food preferences of adults can affect the diet of dependent young.

The male may courtship feed the female and feed her while she is incubating. In Arizona, 56% of males did not provision females during incubation. Females compensated by taking fewer off-nest bouts so that the incubation period was not prolonged (Badyaev et al. 2020). Young are fed regurgitated food for the first 1-3 days. In Colorado, nestlings were fed mostly dandelion seeds. When they were not fed dandelion seeds, nestlings were given the same types of seeds that the adults consumed. No animal food was found in crops or stomachs. In Michigan, nestlings were fed

buds from trees in April and early May (Avery 1996; Badyaev et al. 2020; Bergtold 1913; Evenden 1957; Gill and Lanyon 1965). Beal (1907) analyzed the contents of 46 nestling stomachs. The diet consisted of 2.4% animal food and 97.6% vegetable matter. The House Finch appears to be unique within its family, eating very little animal food and feeding nestlings mostly plant materials. Animal food consumed by nestlings consisted almost entirely of a minute beetle that lives on decayed fruit, a few aphids, and 1 grasshopper fragment. It is possible that most of the animal food was ingested incidentally with the plant material that the adults provided. Vegetation in the nestling's diet consisted almost entirely of seeds with the most important being sunflowers, poison oak, and 2 species that do not occur in the east.

In Colorado, House Finch adults ate almost any vegetable matter, but preferred seeds. In experiments, hemp seeds were preferred over others. It ate pieces of bread, apples, oranges, and almost any kind of table waste and will consume large quantities of fat, including suet. In arid areas, it drinks copious amounts of water (Bergtold 1913). Woods (in Austin 1968) reported that it ate watermelon pulp at a feeder. In British Columbia, it eats seeds from birches and bird feeders, and herbaceous seeds, and in spring it frequently eats fruit tree buds. It feeds on seeds of dandelions, yellow salsify, scotch broom, and goldenrods, and on the berries of crabapples, hawthorns, mountain-ash, apple, Saskatoon, blackberries, and wax myrtle. It occasionally damages blueberry and wine grape crop, but is considered a minor pest. Beal (1907) analyzed 1,160 adult stomachs of birds from the western population. The diet consisted of 2.4% animal food and 97.6% vegetable matter. The animal food was predominantly aphids, but it also consumed caterpillars and a few beetles that were mostly weevils. The vegetable matter consisted of 86.2% weed seeds, 10.5% fruit, and 0.9% miscellaneous. The most important seeds were those of knapweed, black mustard, prostrate knotweed, and stork's-bill. It rarely ate grain such as wheat, oats, and corn. Fruit attained a maximum of 27.4% of the diet in August. Favourite fruits were cherries, apricots, peaches, prunes, and pears and it also ate strawberries, elderberries, and blackberries. It pecks at larger fruits and may not eat them, or it may eat half of one and move on to the next. Only 63 stomachs (5.4%) did not contain plant seeds and 67% contained nothing else; 78.4% of stomachs contained no fruit. Badyaev et al. (2020) reported that chokecherry berries comprised as much as 70% of the diet some weeks in Montana. The House Finch may cause substantial damage to apple crops by consuming parts of the growing fruits. Large numbers may be attracted to ripe thistles in late summer and autumn. In the east, it eats ripe mulberries in the summer; seeds of amaranths may also be important in the diet. Elliott and Arbib (1953) reported that eastern birds ate mouse-ear chickweed seeds.

Parasitism by the Brown-headed Cowbird is rare in long-established House Finch populations but common in expanding populations. In Montana, the rate of parasitism peaked 5 years after a House Finch population was established; no parasitism occurred 15 years after establishment. In the core of the western population, parasitism is nonexistent or very rare. The probable reason for this is that the House Finch is a poor host for the cowbird. The finch feeds its nestlings an almost exclusive vegetable diet but cowbird nestlings need animal food to sustain themselves. Most cowbird nestlings die in the nest; a few fledge but these are considerably underweight. It is uncertain whether any cowbirds have been successfully reared to independence by House Finches. When finches expand into a new area, cowbirds parasitize them at a high rate because they are not

familiar with them and their nests are easy to find. Gradually cowbirds learn that few of their young are surviving in House Finch nests and the incidence of parasitism declines or even ceases (Badyaev et al. 2020; Evenden 1957; Woods in Austin 1968). In Guelph in the first Ontario study, Graham (1987) reported that 7 of 8 nests (87.5%) were parasitized; when nests found within the nestling stage were included, 10 of 13 nests (76.9%) were parasitized. Peck and James (1987) reported that 27 of 62 nests (42.2%) found in the province had been parasitized. In St. Catharines, Kozlovic (1998) reported that 33 of 82 nests (40.2%) were parasitized. van Twest (2001) did another study in Guelph and determined that 19 of 166 nests (11.4%) were parasitized. Peck and James (1998b) reported that 50 of 182 Ontario nests (27.5%) were parasitized. Since 1987, 23 of 95 nests (24.2%) were parasitized, a substantial decrease from the 42.2% they reported in 1987. Consistent with other colonizing populations, parasitism rates were initially very high in Ontario but have declined considerably. The cowbird has not yet learned to completely avoid House Finch nests as it has in many long-established western populations where the parasitism rate is 1% or less. In British Columbia where it first became established in 1935, 24 of 404 nests (5.9%) were parasitized (Campbell et al. 2001). In St. Catharines, the clutch size of parasitized nests (3.50 eggs) was significantly smaller than unparasitized nests (4.22 eggs). There were no differences in hatching rates, nestling growth, or fledgling rates in parasitized and unparasitized nests. The cost of parasitism was an average loss of 0.72 eggs per parasitized nest. Ninety percent of cowbird eggs hatched but all young cowbirds died in the nest. The House Finch began to nest about a week before the cowbird and many initiated nesting much earlier. Early nesting birds were able to avoid parasitism by completing their clutches before cowbirds started nesting (Kozlovic 1998). In Guelph, there was no significant difference in the clutch size of parasitized (4.4 eggs) and unparasitized (4.6 eggs) nests but unparasitized nests produced significantly more fledglings (3.7 compared with 1.8). Some nestling cowbirds survived for more than 3 days in the nest and this competition for food and space may have led to increased mortality of finch nestlings. Three cowbirds fledged but only one was encountered later; it is unknown if it survived to independence. Parasitized nests were abandoned at a higher rate than unparasitized nests, but not significantly (van Twest 2001). The House Finch often abandons nests that contain more than 2 cowbird eggs (Badyaev et al. 2020).

Diseases are the greatest limiting factor for the House Finch, with the most significant being mycoplasmal conjunctivitis. This disease causes swelling of 1 or both eyes. Diseased birds spend a larger proportion of their time feeding (86% compared with 28% for healthy birds), move at a lower rate (32% compared with 59%), feed singly more often, and associate with smaller flocks. Even when food is abundant, birds may lose weight and subsequently die. Due to reduced vision or blindness, diseased birds have reduced antipredator responses and are much more likely to be preyed upon than healthy birds. Heavily infected birds have difficulty seeing well enough to fly and spend most of their time on the ground. Prevalence of conjunctivitis is low in late spring and summer and increases in late summer and autumn, peaking in September or October each year. Juvenile females are most vulnerable to the disease but all sex and age classes contract conjunctivitis. During the breeding season, males in breeding condition are less likely to contract the disease than nonbreeders. The rapid increase in the prevalence of the disease in autumn may be caused by the recruitment of immunologically naive juveniles into the population. The disease may spread in autumn through contact at feeders and during migration in eastern populations. Eastern birds are

more vulnerable to conjunctivitis than western birds. The eastern population originated from a small number of birds and is inbred with lower genetic diversity, which may potentially make it more susceptible to disease. Conjunctivitis was first reported during the winter of 1993-94 around Washington, D.C. The disease spread rapidly in the east and was reported in Ontario as early as November 1994. Within 4 years of its initial detection, the disease spread throughout the eastern House Finch population, causing declines in abundance by as much as 60%. The peak of the disease occurred in 1995 and the rate of decline of the House Finch has been slowing since then. In Niagara Region, the presence of conjunctivitis was first confirmed in 1995 with its prevalence peaking in 1998 when 25-50% of birds were infected. An increasing proportion of the population is now resistant to conjunctivitis compared with several years ago. The disease is now at an endemic level in the House Finch. Conjunctivitis caused a significant decline in the Ontario population. Although the prevalence of the disease may have decreased, populations have not rebounded to their former numbers (Adelman et al. 2017; Altizer et al. 2004; Badyaev et al. 2020; Black and Roy 2010; Dhont et al. 1998; Fischer et al. 1997; Hartup et al. 2001; Hawley et al. 2007; Hochachka and Dhont 2000; Knight 2009; Yunick 1995b).

The House Finch is vulnerable to avian pox. This may cause damaged mandibles, blindness, and a reduced ability for males to have red plumage. Similar to conjunctivitis, this may lead to death either directly or indirectly due to impaired ability to see predators. The incidence of avian pox appeared to increase concurrently with the arrival of the West Nile virus (Campbell et al. 2001; Pellegrini et al. 2011).

West Nile virus was introduced into North America in New York City in 1999 and spread rapidly throughout the continent. The House Finch is a highly competent host for the virus and is fed upon frequently by the genus of mosquitoes (*Culex*) that is the vector. Similar to the House Finch, these mosquitoes are most abundant in urban areas and other areas associated with humans. In California, 19.6% of dead finches turned in by the public tested positive for the virus. In a laboratory experiment, 67% of experimentally infected birds died. Evidence indicated reduced survival in the wild and a decrease in population in California; laboratory tests indicated that mortality rates were higher than 60%. Those that survive have immunity to the virus so that the mortality rate within a population may decrease over time as acquired immunity increases (Kilpatrick et al. 2007; Pellegrini et al. 2011; Wheeler et al. 2009). The House Finch has been exposed to West Nile virus for approximately 2.5 decades so it is probable that most of the population is now immune to the virus.

Early nests have the potential to be destroyed by late snow storms. In St. Catharines, 4 of 5 nests were filled with snow during a storm on the last day of March; the other nest was under the eaves of a house (Kozlovic 1988).

In Alabama, all nests were infested by mites in the second half of the breeding season. This resulted in lower nestling mass and hemocrit values. Some nestling deaths were attributed to mites and there may have been increased mortality of fledglings. Stoehr et al. (2000) concluded that mites have the potential to reduce reproductive success.

The domestic cat is a significant nest predator. In a California study, almost the entire loss of nestlings was due to cats (Evenden 1957; Woods in Austin 1968).

In western North America, the House Finch is considered one of the most significant native pests because of depredation of fruit crops. In the late 1960s, more than 50,000 finches were destroyed by poison baits and trapping at a single orchard, and similar campaigns were widespread (Campbell et al. 2001; Woods in Austin 1968).

In many western populations, the House Sparrow is a significant nest competitor for the House Finch. The House Sparrow is dominant and excludes House Finches from potential nest sites; in addition, it destroys eggs and nestlings of finches. Finches are often so harried by sparrows that they abandon nests. In Colorado and California, most nest losses were due to a combination of House Sparrows and cats (Badyaev et al. 2020; Bergtold 1913; Evenden 1957). No evidence of competition with the House Sparrow has been observed in Ontario (Peck and James 1998b) or in Indiana (Hamilton 1993a) and there appear to be no such reports from the east.

Status

The House Finch is not native to Ontario or eastern North America, with native populations restricted to the west. In 1940, it was added to a list of migratory birds protected by agreement between the United States and Mexico. Until then, it was commonly sold as a cage bird in the east. Once the agreement was signed, selling caged birds became illegal. To avoid prosecution, it is thought that a single Long Island, New York dealer released his captive birds, which originated in California. The first nesting in New York occurred in 1943. By 1951 the entire eastern population was estimated at 280 birds. The first records off Long Island were in 1948 in New York, in New Jersey in 1949, in Connecticut in 1951, and in Ohio by 1964. Range expansion was by jump dispersal, with the sudden appearance of a few individuals, probably dispersing juveniles. In a few years, the leading edge of the core population would catch up with these pioneers and occupy the area. Colonization was rapid, with finches typically occurring in all major cities and most rural areas within 20 years of its first appearance in an area. Christmas Bird Count (CBC) data for the entire eastern population indicated that it increased at an exponential rate during 1962-71 (Aldrich and Weske 1978; Bock and Lepthien 1976c; Cecil and Dinsmore 1995; Elliott and Arbib 1953; Gill and Lanyon 1965).

The first Ontario sighting of the House Finch was in the Kingston area in 1970, but this record was not adequately documented. The first confirmed record was a female seen at Prince Edward Point on 27 August 1972. There were no further records until 1976 when it appeared at several scattered locations. The first nest in the province was found in St. Catharines on 20 June 1978. It spread widely in the 1980s from its original stronghold in the Niagara Peninsula. By 1983, it began a northward spread into the eastern lowlands between the St. Lawrence and Ottawa rivers. By then, it was fairly common along the shores of Lake Erie and Lake Ontario, but was still uncommon in the southern Georgian Bay area. It was most common in large urban centres along the southern Great Lakes and had begun to occupy the surrounding countryside. First nests reported from different areas include 1978 in Niagara Region, 1982 in Hamilton, 1985 in Guelph, and 1995 in Rainy River. Timing of the first atlas coincided with the initial colonization of the province by breeding birds, with its distribution confined to the area south of the Canadian Shield and greatest abundance from Long Point to Niagara and the Toronto area east along the north shore of Lake Ontario and the St. Lawrence River. It also occurred along Lake Erie and in scattered inland areas in larger population centres such as Ottawa, Kitchener-Waterloo, and Cambridge (Black and Roy 2010; Curry 2006;

Graham and Salvadori 1985; James 1978b; Kozlovic 1994; Kozlovic in Cadman et al. 1987; van Twest 2001). During the first atlas, it was observed in 1 square in 1981, 18 squares in 1982, 35 squares in 1983, 60 squares in 1984, and 108 squares in 1985. Results suggested that colonists were coming around both ends of Lake Ontario from New York. Thereafter, it appears to have spread east and west along the northern shores of Lake Erie and Lake Ontario and along the St. Lawrence and Ottawa rivers. Shorelines and rivers appeared to form major routes for dispersal (Dunn 1987). James (1991) considered the House Finch a common to locally abundant permanent resident near Lakes Erie and Ontario that rarely summered as far north as Georgian Bay and Renfrew County. It was a vagrant north to Marathon and Timiskaming District.

The second atlas revealed that the breeding range of the House Finch had expanded to include the entire area south of the Shield. There were scattered records on Manitoulin Island, in the Shield north to North Bay and Sudbury, on the north shore of Lake Superior including Thunder Bay, and in the Lake of the Woods area. Its probability of observation increased significantly province-wide and in all regions where it occurred. By the time that the second atlas was conducted, the House Finch population had already suffered a decline due to conjunctivitis. It was most abundant in areas of highest human population density: the Greater Toronto Area, the Niagara Peninsula, London, Ottawa, and Windsor. Moderate densities were present in the remainder of the Carolinian Forest Region, along the Lake Huron and southern Georgian Bay shores, and along Lake Ontario and the St. Lawrence River (Leckie in Cadman et al. 2007).

Cadman et al. (2016) reported that Breeding Bird Survey (BBS) data for Ontario indicated that the House Finch had increased at a rate of 13.8% per year from 1983 to 2016. This was the 6th largest increase for any Ontario species. This also includes the period when conjunctivitis was introduced, which caused a decline in numbers. BBS data for 1970-2021 indicate that the House Finch increased at annual rates of 1.94% in Canada and 21.4% in Ontario. During 2011-21, it decreased at annual rates of 0.273% in Canada and 6.05% in Ontario. All results were of low reliability except for the long-term Canadian trend, which was of medium reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Unless they fledge prematurely, young are capable of sustained flight when they leave the nest. They may fly as far as 60 m on their first flight to a tree or house. In California, the average distance of first flights was 15.0 m and the longest was 38.1 m. Others drop to the ground on their first flight attempt and crawl into corners, under shrubs, or amongst leaves. Fledglings sleep near the nest, typically remaining motionless for the first 1-2 days, then moving around in the vicinity of the nest. Once young leave the nest, they never return. They start actively following the adults 4-5 days after fledging. The brood flies with the male for about 2 weeks after fledging. Juveniles try to feed themselves as early as 7 days but typically 12-16 days after fledging; they are still fed by the male 18 days after fledging. Juveniles can completely feed themselves 2.5-3 weeks after fledging (Badyaev et al. 2020; Bergtold 1913; Evenden 1957; Gill and Lanyon 1965).

Juveniles form flocks beginning in mid-July with peak numbers occurring in late October. The first flocks consist of both sexes but later flocks become sex segregated. Recently fledged males strongly dominate and displace recently fledged females, resulting in sex-segregated flocks. The sex-segregated flocks remain in the general nesting vicinity until they are 90-110 days old; these

gather in areas with abundant food supplies. Older juveniles form large mixed-sex flocks and start autumn dispersal and, in some cases, large-scale movements. After the onset of juvenile dispersal, many individuals travel 500-700 km. Some travel as far as 900-1,200 km within 4 weeks. Birds that stay within an area for more than 2-3 weeks during this period are likely to breed there the following year. Pairing by juveniles may occur during the postfledging dispersal period. Pairs of juveniles have been observed prospecting for nests and making attempts at nest building in October and November (Badyaev et al. 2020; Bergtold 1913; Campbell et al. 2001).

Because the House Finch nests predominantly near buildings, fledglings are highly vulnerable to being preyed upon by domestic cats. Many die if they are soaked by rain or struck by hail (Badyaev et al. 2020; Bergtold 1913).

MIGRATION

Western populations of the House Finch are nonmigratory. In recently established northern populations in the west, there are pronounced seasonal movements along river valleys and from natural to urban habitats. Movements are particularly pronounced in areas with significant snow cover; movements may exceed 200 km. Strong altitudinal movements may occur in response to snow cover. Movements appear to be strictly diurnal (Badyaev et al. 2020). In British Columbia, it was completely migratory for the first decade of its occurrence and it was 10 years before any birds spent the winter. It is now nonmigratory with stable populations year-round (Campbell et al. 2001).

In the east, the House Finch is partially migratory, with some birds remaining all winter and others moving south. It is unknown if individuals switch wintering strategies between years. In Ontario, small loose flocks of 12-15 have been observed flying over Lakes Erie and Ontario in October and large numbers fly west along the Lake Erie shoreline in Elgin County. Birds banded in Ontario have been recaptured in winter in Michigan and Indiana and birds banded in Ohio have been recaptured in Ontario. Regular movements have been documented in many locations in the Midwest and east, including Quebec. In Ontario, more than 40 birds travelled further than 100 km between the banding and recovery locations. Of 35 recovered Ontario birds, 31 were recovered in Ontario and only 4 were encountered further south: 2 in New York and 1 each in Ohio and Tennessee (Badyaev et al. 2020; Brewer et al. 2018; Brush 1987; Curry 2006; Hamilton 1996; Hansrote and Hansrote 1992; Lancaster et al. 2004; Paquin in Gauthier and Aubry 1996; Stewart 1989a, 1989b). In the Midwest, which included Ontario, the mean distance travelled by birds banded in summer and recaptured in winter was 344.9 km, with 1 bird travelling further than 1,000 km. Birds banded in winter and recaptured in summer travelled an average of 416.4 km (Hamilton 1991). Further east in the United States, birds banded in summer and recaptured in winter travelled a mean distance of 176.7 km compared with 192.1 km for birds banded in winter and recaptured in summer. Birds travelled significantly shorter distances from the breeding grounds in a moderate (259.8 km) than a cold winter (492.8 km). Results indicated that it will extend its southward migration during exceptionally cold winters (Hamilton and Novis 1994). Belthoff and Gauthreaux (1991) determined that males were most abundant at latitudes north of 38°N; females outnumbered males south of latitude 38°N. The larger bodied males were better able to withstand the cold than the smaller females. Winter mortality has been reported as far south as Virginia and South Carolina and this may force females to migrate further south.

At Prince Edward Point, spring migrants move through from mid-March to mid-April (Weir 2008). Autumn movement occurs in October and early November (Curry 2006; Lancaster et al. 2004), but at Prince Edward Point, migrants occur from late August to late September (Weir 2008).

Migration habitat is similar to breeding habitat. In autumn, the House Finch may move to more protected habitat in river valleys and these may be used as migration corridors. It is attracted to weedy areas such as roadsides, dykes, utility corridors, fallow fields, and grassy backshore areas along beaches (Campbell et al. 2001; Dunn 1992; Woods in Austin 1968).

James (1991) considered the House Finch an uncommon to locally common migrant in Ontario.

WINTER

Winter habitat is similar to breeding habitat, but the winter distribution is closely linked to the distribution of feeders (Badyaev et al. 2020). In Vancouver, the House Finch switched from lightly wooded apartment and residential areas with 30% tree and shrub coverage in summer to more open residential areas with 7% tree and shrub coverage in winter. There was a prevalence of feeders in these areas (Campbell et al. 2001). In California, its abundance was positively correlated with structures and human activities and negatively associated with streams, shrubs, and trees (Kalinowski and Johnson 2010).

Roosts are important in winter. Birds may roost singly but more often communally. Roosts may be in ivy on building walls, in a nook in a building, in dense hedges, and in ornamental evergreens. One female roosted in ivy close to her nest site of the previous year. Some communal roosts were used by birds from a wide area distant from the nesting areas. In Vancouver and Victoria, small flocks regularly roost in dense hedges, evergreens, and ivy on building walls. Larger roosts of 200-1,000 birds occur in ivy covering buildings in downtown areas. The probability of an individual roosting in the same tree in consecutive nights was 62% in autumn and 81% in winter (Badyaev et al. 2020; Bergtold 1913; Campbell et al. 2001; Evenden 1957).

Winter site fidelity of the House Finch is low even in resident populations. Winter flocks wander between food sources and individuals may switch flocks. In Arizona, males had a higher propensity to switch flocks than females. Males with less colouration had the highest frequency of flock switching. In British Columbia, the entire population shifts northward in warm winters. At an Indiana feeder, there was a high rate of turnover in winter with few birds remaining in the same area for more than 4 weeks. At a Georgia feeder, 55.7% of banded birds were not seen or captured again. Another 24.7% were recorded as many as 5 times. Forty-four percent of birds that were resighted were present less than 50 days. Only 14% were encountered over a span longer than a year. Young birds were encountered more frequently than adults and females were encountered more frequently than males; young females were encountered most often. There was a high turnover of birds, with only a small fraction of those observed in suburban Atlanta remaining at individual sites year-round. Fidelity was characterized by high site fidelity of adults during the breeding season and low fidelity of juveniles captured early in the summer but becoming higher later in summer. Most birds captured in autumn were encountered for as long as 3 months, and these represented wintering birds. Fidelity declined in late winter and by February most birds that were captured were rarely seen again. In the Midwest, only 31.6% of birds recaptured in a subsequent winter were within

25 km of the original banding site. Others were recaptured at an average distance of 274.0 km. In eastern populations, the mean distance between captures in different winters was 118.3 km. In New York, 673 of 6,842 birds (9.8%) returned in another winter and 146 of 1,517 (9.6%) and 511 of 4,314 (10.4%) returned to 2 Pennsylvania banding stations (Badyaev et al. 2020; Belthoff and Gauthreaux 1991; Campbell et al. 2001; Davis 2008; Elliott and Arbib 1953; Hamilton 1991, 1992; Hamilton and Novis 1999; Yunick 1995b).

The House Finch has a strictly vegetarian diet in winter. In Ontario, it has eaten black alder and giant ragweed seeds (Dance 2008; Dance et al. 2012). In addition to the seeds and berries reported in the summer diet, it has fed on sumac berries and sweetgum seeds in winter (Elliott and Arbib 1953; Sprenkle and Blem 1984).

In winter, the House Finch congregates at bird feeders and its distribution is closely associated with feeder locations. Where sunflowers are offered at feeders, this is the preferred food (Campbell et al. 2001; Dunn 1992; Elliott and Arbib 1953). In Virginia, Sprenkle and Blem (1984) tested wild birds' preferences for 3 types of mash (chick mash, chick mash plus oil, and chick mash and soy), milo, white millet, and sunflower seeds. When fed oil-supplemented mash, birds were able to maintain their body weights at temperatures lower than 20°C.Their body weight was significantly higher at all temperatures than birds fed the other mashes. In the seed preference tests, sunflower seeds were selected almost exclusively at all temperatures. No milo was eaten at any temperature. Its cold tolerance is enhanced by foods high in lipids; these foods are preferred, particularly sunflower seeds. In Pennsylvania, it selected 62.9% cracked corn, 17.2% niger, 11.9% millet, 6.8% canary seed, and 1.2% whole corn. Striped sunflowers were offered but not consumed. Feeding heights included 36.6% at 6 m, 32.4% at 4 m, 25.8% at 2 m, and 5.2% on the ground. It preferred elevated platforms to foraging on the ground (Nastase and Linville 1995). Throughout the United States and Canada, 212,140 visits to feeders were recorded. The House Finch fed predominantly at tube feeders but also on platforms. The proportion of birds using the various seed types included 71% for black oil sunflowers, 58% for 0.5-cm sunflower chips, 56% for 0.3-cm sunflower chips, 52% for niger, 47% for safflower, 41% for striped sunflowers, 34% for peanuts, 25% for red milo, 23% for white proso millet, and 23% for cracked corn. Seeds with greater levels of fat, fibre, or protein were more likely to be selected. Seed use was greater with seeds with hulls (93%) and greater fat (65%) and protein (22%) content. Black oil sunflowers had the highest levels of fat which may have contributed to its high preference (Horn et al. 2014; Johansen et al. 2014). Project FeederWatch results indicated that flock sizes varied considerably, but averaged 10-15 birds in early January with a steady decrease thereafter. The most preferred foods were black oil and hulled sunflowers, but striped sunflowers, mixed seeds, safflower, niger, and water were also preferred foods. Infrequent choices included millet, canary seed, cracked corn, milo, wheat, hulled peanuts and hearts, oats, canola, suet, peanut butter mixes, bird puddings, fresh fruit, baked goods, sugar water, and popped corn (Dunn and Tessaglia-Hymes 1999). The House Finch eats hemp and field mustard seeds at feeders, but typically only if sunflowers are not available (Elliott and Arbib 1953).

Visiting feeders may bring the House Finch in contact with the House Sparrow. In interspecific conflicts, the House Sparrow won well over 90% of contests with the House Finch. A loss of a contest simply means that the subordinate bird is displaced. Competition with the House Sparrow is unlikely

to be a significant limiting factor for the House Finch except perhaps at locations where the House Sparrow population greatly exceeds that of the House Finch (Hamilton 1993b; Kalinowski 1995).

The House Finch is not well adapted to the cold, and eastern populations appear to be less tolerant of cold than western birds. In British Columbia, birds either migrate during winter storms or perish. In Virginia and South Carolina, considerable mortality has been reported during extremely cold mid-winter weather. Winter survival rates of the House Finch may be low, particularly in eastern populations. Winter mortality has not been documented in Ontario, but it is probably a significant limiting factor because this is at the northern extent of its range. Birds that have access to high-fat foods at feeders, such as black oil sunflower, are more likely to survive than those that must rely on natural foods (Campbell et al. 2001; Dunn 1992; Sprenkle and Blem 1984; Stewart 1989a).

The House Finch is highly vulnerable to suffering mortality from striking buildings. At 1-3 storey residences, it was 80.1 times more likely than average to collide with a building and was the fifth-most vulnerable species. It was not within the top 20 species for striking low-rises or high-rises (Loss et al. 2014). It is probable that most of this mortality occurs in winter at houses that have feeders.

Several studies used CBC results to chronicle the initial increase in the Ontario House Finch population and its subsequent decline due to conjunctivitis. Kozlovic (1994) summarized data from 50 southern Ontario CBCs for 1978-88. In 1977, the total number of birds observed on counts in the province was 2, increasing to 7,496 in 1987. Greatest abundance occurred in the Niagara Peninsula where more than 40% of all House Finches were recorded. Numbers in Niagara Falls and St. Catharines peaked in 1985 and subsequently declined, but continued to increase in other areas. Notable increases were documented at London, St. Thomas, Hamilton, Port Colborne, and in Simcoe County. It did not occur regularly at Ontario feeders until 1982. Tozer (1997b) analyzed results for the same 50 CBCs for 1988-96. The previous exponential increase continued from 1958 to 1994, but a dramatic downward trend occurred in 1995 and 1996. Numbers in the Niagara Peninsula peaked at 4,478 in 1994 but dropped to 3,148 in 1995 and 1,684 in 1996. The House Finch was uncommon in the southern Georgian Bay region and the Ottawa valley in 1987, but it had expanded significantly in these areas by 1996 with no decline. It also spread north to several communities in the Canadian Shield with no subsequent decline. Population declines occurred predominantly in areas of its greatest abundance and were probably linked to conjunctivitis. On the St. Catharines CBC, 0 were seen in 1979, 5 in 1980, 81 in 1981, and 196 in 1982 (Foley 1983). There was an exponential increase on Niagara Region CBCs until 1994 after which the population declined to half its peak (Black and Roy 2010). On Elgin County CBCs, numbers tallied were 10 in 1982, 1,260 in 1989, and 2,344 in 1991. It declined in the mid-1990s, with numbers dropping to 500-700 per year (Lancaster et al. 2004). In Hamilton, it was first recorded on the CBC in 1978. In 1982, there were 95 and numbers increased exponentially to a maximum of 1,669 in 1989. Since the advent of conjunctivitis, counts are now about 500 per year (Curry 2006). In the Kingston area, numbers on CBC counts increased steadily from 1988 to 2000 followed by a decline from 2000 to 2006 (Weir 2008). Wilcox (2007) summarized the percentage of Ontario feeders that were visited by House Finches during Project FeederWatch counts: 55% in 1988, 69% in 1993, 73% in 1995, 63% in 1998, and 58% in 2003 and 2007. It was concluded that populations had stabilized. The proportion of feeders that are visited does not account for the numbers of birds visiting feeders so is not a direct indicator of population trends.

Similar population trends have been documented on CBC counts in other eastern locations. For 1985-89 prior to the advent of conjunctivitis, the population growth rate was exponential at a rate of 15% per annum, taking 5 years to double during 1971-89 (S. Davis 1991). Yunick (1995b) summarized numbers at his feeder in New York. It first appeared in 1964 and numbers peaked at about 1,300 in 1985, with a sharp decline to the 1970s level 1985-94, with 0 seen in the last year. Ontario CBC population trends were an annual increase of 21.55% 1970-2021 and an annual decrease of 2.94% 2009-21 (National Audubon Society 2022).

Purple Finch

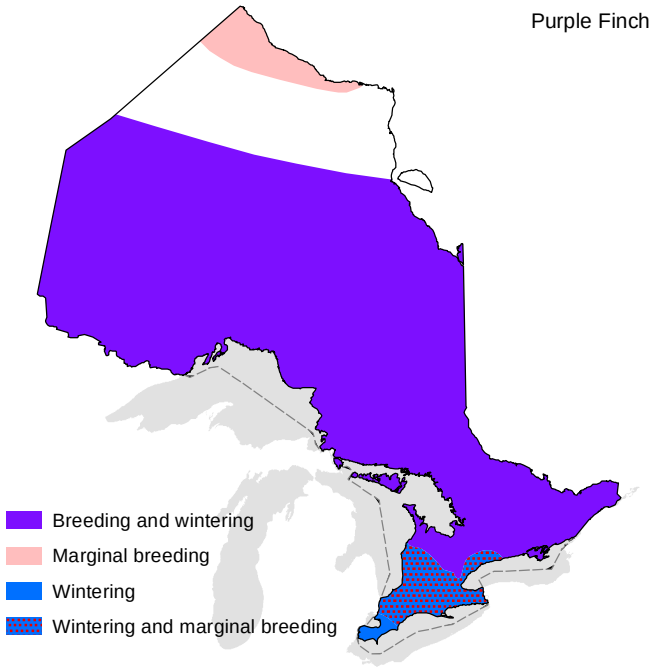
Haemorhous purpureus

BREEDING SEASON

Habitat Requirements

Ontario Purple Finch nests were in coniferous plantations that were predominantly Christmas tree farms (54.7% of nests), mixed forests (16.3%), coniferous forests (8.1%), unspecified woods (3.5%), sphagnum bogs and marshes (5.8%), residential and park areas (4.7%), shrubby pastures (4.7%), and islands and river shores (2.3%). Wooded habitat selected for nesting was usually open and occasionally wet (Peck and James 1987). Observer bias may have affected the results. Nests in Christmas tree plantations are easier to find than those in natural habitats. Most of these are south of the Canadian Shield but the Purple Finch is most abundant in the Canadian Shield where it occurs mostly in open coniferous and mixed woodlands.

In the Clay Belt in the Boreal Forest Region, the Purple Finch was most abundant in trembling aspen and balsam fir–white birch stands, followed by stands dominated by white spruce–white birch, tamarack–white cedar, white spruce, and black spruce; it was not observed in pure jack pine



stands. It occurred predominantly in moist to wet stands that were moderate to rich in nutrients (Welsh and Lougheed 1996). Near Pickle Lake, James (1980) observed it in low numbers in mixed forests. North of Lake Nipigon, it was twice as abundant in overmature trembling aspen than in immature spruce–balsam fir forest (Sanders 1970). Near White River, Venier and Pearce (2005) had only 4 observations of the Purple Finch in jack pine stands. Near Hearst, it nested in upland mixed clear-cuts 6-19 years old, in uncut mixed forests, and in lowland coniferous clear-cuts 11-24 years old (Welsh and Fillman 1980). It nested in coniferous and mixed forests and edge habitats in the Boreal Forest Region. It was characteristic of balsam fir but widespread in other types of coniferous forests where it was seldom regular or abundant. It is not found in pure spruce stands very often and tends to be absent or scarce in hemlock stands. It was characteristic of mature coniferous stands but scarce or lacking in young conifers. In Ontario, it occurred in stands dominated by balsam fir, spruce, hemlock, white and red pines, jack pine, tamarack, and poplar–white birch; it also occurred in bogs and fens with short conifers (Erskine 1977).

In white pine stands in the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region, the Purple Finch occurred in both old-growth and mature stands, but was more common in mature stands (Kirk et al. 2012). In Quetico Park, Apfelbaum and Haney (1999) reported relative abundances of 5 in 1-23-year-old stands, occasional visitor in 67-73-year-old stands, 0 in 112-176-year-old stands, and 14 in 367-370-year-old stands. In jack pine stands near Gogama, it was present in small numbers every year and in most ages and mixes of forests but never appeared to be a breeding species. James and Peck (1995a) concluded that it could potentially nest in any pine older than 10 years, but it appeared to be just foraging. In a mixed forest of sugar maple, yellow birch, balsam fir, and spruce near Sault Ste. Marie, it was associated with the number of hardwood saplings taller than 50 cm, but only slightly, and the percent coverage of hardwood saplings less than 50 cm tall (Holmes and Pitt 2007). In Parry Sound and Muskoka Districts, it bred in mixed forests, bogs, and along roadsides (Mills 1981). In open, young jack pine stands near Parry Sound, James (1979a) found it at moderate densities along 2 of 5 transects. In Algonquin Park, it was fairly common at edges of woods and in shrubby areas, particularly where raspberries occurred (MacLulich 1938). These areas may have been foraging rather than breeding areas. In white pine stands in Algonquin Park, Kingsley and Nol (1999) reported it in 20-28.6% of uncut stands, 40-54.5% of 10-16-year-old shelterwood cuts, and 16.7% of 2-9-year-old cuts. Also in Algonquin Park, Martin (1960) reported it in wet bogs; stands dominated by black spruce, black spruce–white cedar, white birch–poplar, balsam fir–spruce, white

birch–poplar–balsam fir–spruce, immature white pine, balsam fir–spruce-hardwood, and hemlock stands; and forest edge plots. He did not consider it characteristic of any habitat type.

In Durham Region, the Purple Finch occurred in a black spruce bog with a fringe of tamarack and white spruce, and a boggy stream bottom bordered by white cedar, balsam fir, and spruce. Speirs and Orenstein (1975) considered it a species of bog forests, although the latter habitat was a swamp. At Presqu'ile, it occasionally breeds in extensive coniferous plantations (LaForest 1993). In Halton Region, it nests in white cedar swamps mixed with white and black spruce, balsam fir, and tamarack (personal observation).

In the Carolinian Forest Region near Hamilton, the Purple Finch first began to nest in coniferous plantations in the mid-1950s and continues to do so (Curry 2006).

Throughout its range, the Purple Finch nests mostly in moist or cool coniferous or mixed forests, but also frequently at edges of bogs and in riparian corridors. Less frequently, it nests in deciduous forests with some conifers, orchards, plantations, pastures and lawns with scattered conifers and shrubs, hedgerows, suburban areas, city parks, forest edges, woodlands bordering waterways and roads, marshes, and edges of avalanche paths. It avoids forest interior and dense forest canopy and is associated with edges and small forest openings such as forest edges adjacent to clear-cuts and other clearings, lakes, rivers, creeks, ponds, and rock outcrops; and human-modified habitat along roads and power lines. In British Columbia, it breeds along riparian river corridors but is absent from dry river bottoms. In Quebec and Newfoundland, it was a forest generalist that was equally likely to occur in riparian areas, forest interior, and forest edges bordering on open habitat. It commonly nests in coniferous plantations in Quebec and the Maritime Provinces. In British Columbia, 63% of nests were in human-influenced habitats and 37% were in natural forests. Well-treed rural and suburban areas comprised 92% of the human-influenced habitat where nests were found. In the Yukon, the Purple Finch breeds in coniferous, mixed, and deciduous forests and is particularly common around well-treed residential yards (Austin 1968; Campbell et al. 2001; Crawford and Titterington 1979; Dawson 1979; Freedman and Johnson 1999; LaRue et al. 1995; Lent and Capen 1995; Morse 1979; Pauzé and Barrette in Gauthier and Aubry 1996; Sabo 1980; Sinclair et al. 2003; Taylor and Taylor 1979; Temple et al. 1979; Whitaker and Montevecchi 1997; Wootton 2020).

Several studies examined the Purple Finch´s preferences for forest age and the effects of natural succession. In New York, it decreased significantly in an agricultural field that succeeded to a second-growth forest over 35 years, increased significantly in a mixed forest that was undisturbed for 37 years, and increased significantly in a Christmas tree plantation over 25 years where the habitat was maintained but tree height increased (Brooks and Bonter 2010). In New York, it was never reported nesting in old-growth deciduous forest (Wootton 2020). In Pennsylvania, Haney (1999) reported it in 90.9% of old-growth mixed forests dominated by hemlock, white pine, and hardwoods. It was detected in 29.4% of forests statewide and in 48.5% of forests in the Appalachian Plateau. He considered it positively associated with old-growth forest. In northeastern northern hardwoods, Noon et al. (1979) detected it in 3% of plots in mature undisturbed habitat and 13% of plots in disturbed and early successional habitats. In northeastern poplar–white birch stands, including Ontario, it occurred in pole-sized and mature stands but not seedling- and sapling-sized stands (Back 1979). In northeastern stands dominated by white pine, red pine, or jack pine, it occurred in all age

classes and in stands of pine mixed with hardwoods (Capen 1979). In northeastern mixed forests, Temple et al. (1979) considered it a late seral species but not one of mature woods. In Newfoundland balsam fir stands, it was significantly more abundant in 40- and 60-year-old stands than in 80-year-old stands. It was associated with young stands on nutrient-rich soils. Younger stands had a high density of shrubs, pin cherry, and white birch and these were essentially absent in the older stands. Its decrease with increasing stand age was probably related to the accompanying decline in small deciduous trees, a probable food source, and decreasing deciduous litter (Thompson et al. 1999). In Wisconsin, it occurred in pole-sized and mature coniferous and mixed forests (Hoffman 1989a). The Purple Finch has nested in forest age classes from clear-cuts as young as 6 years to old-growth forests. Different studies have concluded that it is associated with young, mature, and old-growth forests. It is likely that forest structure is more important than age, with canopy gaps with deciduous trees and shrubs that bear fruit and large seeds being more important.

Some studies quantified microhabitat preferences of the Purple Finch. In a New York poplar–red maple stand, its abundance was positively correlated with the ratio of forest edge to area and the density of understorey vegetation (Wootton 2020). Also in New York, Keller et al. (2003) concluded that it was in a guild by itself. It was associated with conifers, foraging substrates more than 7 m from the ground, and edge. In subalpine areas of New Hampshire, Sabo (1980) described its habitat as midslope with wet depressions, 7.5 m canopy height, 64% canopy coverage, 64% conifer foliage volume, 30% conifer foliage volume 0-2 m from the ground, 45% deciduous foliage volume 0-5 m from the ground, and average of 10 cm diameter at breast height of live trees. In Wisconsin, it was most abundant in white birch–white cedar stands; equally abundant in red pine, poplar, and hemlock–yellow birch stands; and least abundant in sugar maple–yellow birch stands. It was not very common and not significantly associated with any vegetation parameters (Beal 1960).

Ontario nests were all in conifers: 51.2% in pines, 31.0% in spruces, 10.7% in balsam fir, 4.8% in white cedar, 1.2% in hemlock, and 1.2% in tamarack. Nests ranged from near the bottom to the top of trees but most were in the upper third, particularly in the preferred smaller trees. In small trees, most nests were at or near the trunk but nests have been found as far as 3 m from the trunk of larger trees. Nests were 0.8-18 m from the ground with most 1.5-7.5 m up (Peck and James 1987).

Although the Purple Finch nests predominantly in conifers, it occasionally nests in deciduous species. In the United States, 74 of 435 nests (17.0%) were in deciduous trees and 3 of 24 British Columbia nests (12.5%) were in deciduous trees (maples and a trembling aspen). Elsewhere, the preferred deciduous species for nesting include maples, oaks, and fruit trees, particularly apple. Other nesting substrates reported in the United States include 1.4% in coniferous shrubs, 0.7% in deciduous shrubs, 1.1% in vines, 0.5% in nesting platforms designed for Eastern Phoebes, 0.2% on a wreath of conifer branches, 0.2% on rock-crushing machinery, and 0.2% on an airplane. Southern populations nest significantly more frequently in deciduous species (25.0% south of Pennsylvania and 68.0% in southern California) than northern populations (5.8%). This is probably a direct effect of the relative abundance of conifers in the north and south. Most nests in larger trees are saddled on a horizontal branch with 78.6% of United States nests distant from the trunk. It also nests in the crown of trees, seldom in a main crotch of a branch, and rarely on the ground. Nests have been reported 0-18.3 m from the ground, with most 1.8-6.1 m up. In California, nests are preferentially

placed near water. There is no evidence to suggest that nests are used more than once (Austin 1968; Campbell et al. 2001; DeGarno and Strunk 1946; Grimm 1953; Wootton 2020).

It is uncertain whether the Purple Finch is territorial. Erskine (1977) considered all finches to be nonterritorial. North of Lake Nipigon, it ranged over a large area of undetermined size. Kendeigh (1947) surmised that the male´s song was related to mating behaviour rather than territorial defence. Many observations made by Martin (1960) in Algonquin Park were of birds flying and singing at great heights (45 m), also suggesting that this was a mating activity. James and Peck (1995a) observed it frequently during the breeding season in jack pine stands near Gogama but concluded that it was just wandering. Austin (1968) reported 6 active nests within a 0.2-ha hilly pasture with scattered red cedars. If the Purple Finch were territorial and the entire area was divided equally, the mean territory size would be only 0.03 ha, an exceptionally small area. In Maine, it wandered widely during the breeding season in spruce–balsam fir forests (Hensley and Cope 1951). Wootton (2020) stated that there was no evidence that males defend territories. There has been no documentation of territorial disputes or records of birds nesting close together or tolerating conspecifics near the nest. Some studies identified territory sizes for the Purple Finch. If it is not territorial, these would more appropriately be termed home ranges. In subalpine areas of New Hampshire, Sabo (1980) estimated the average home range size at 2.1 ha. In Quebec, most territories were 0.5-1.4 ha (average 0.9 ha); birds nesting in hemlock stands had an average territory size of 2.3 ha (Panzé and Barrette in Gauthier and Aubry 1996).

In New York, 184 of 1,855 juveniles (9.9%) returned in a subsequent year (Yunick 1983a). In the Adirondack Mountains in New York, 1,039 of 5,443 adults (19.1%) returned (Yunick 1983b); 13 of 823 (1.6%) and 418 of 1,770 (23.6%) returned at 2 New York sites (Yunick 1983a). In Michigan, 56.8% of adults returned to the same breeding area in a subsequent year (Wootton 2020). All 38 birds banded in Canada in summer were recovered in a later year at the same location or very nearby, suggesting breeding site fidelity (Brewer et al. 2018).

Limiting Factors

Eggs have been reported in Ontario nests from mid-May until the first week of August, but most are present in June (Peck and James 1998b). In Algonquin Park, nests are under construction from mid- to late May and dependent fledglings have been observed from mid-June to mid-August (Tozer 2012).

The nest takes 3-8 days to build and the female starts laying eggs 1-5 days after it is complete. Eggs are laid at the rate of 1 a day. It is unknown when incubation begins, but it is probably with the laying of the penultimate or last egg because eggs usually hatch within a 24-hour period. Incubation periods of 11-13 days have been reported in Ontario and 12-13 days elsewhere. The nestling period is 13-16 days (Austin 1968; Campbell et al. 2001; Peck and James 1987; Wootton 2020; Yunick 1983b).

Egg dates in Ontario and British Columbia suggest that 2 broods are raised but this has yet to be confirmed. Double broods have been confirmed elsewhere. It is probable that the Purple Finch raises 2 broods in much of its range. The interval between fledging the first brood and laying the first egg in the next nest is 1-2 days. Replacement clutches may be initiated if a nest is lost early in the season. New nests are constructed for second broods and replacement clutches. Clutches of 3-

6 eggs have been reported in Ontario, with most containing 3 or 4 eggs (mean 3.81 eggs). Elsewhere, clutches of 2-7 eggs have been reported. The mean clutch size of 258 nests from the United States was 3.94 eggs with 4 eggs most frequent. There is a tendency for clutch size to increase with latitude (Austin 1968; Campbell et al. 2001; Peck and James 1987, 1998b; Wootton 2020).

Both sexes can breed when they are 1 year old even if they have not attained adult plumage. Birds removed from a spruce–balsam fir forest in Maine were replaced suggesting that some birds were nonbreeders. During the replacement period, flocks of Purple Finches were observed so it is possible that the replacement birds were in their postfledging period. In New York, 15.7% of yearling males lacked a cloacal protruberance and therefore probably did not breed or breed successfully. Only 2 of 1,272 yearling females (0.16%) lacked brood patches and apparently did not breed (Hensley and Cope 1951; Wootton 2020; Yunick 1983b). The mating system appears to be strictly monogamous but limited study has been conducted. It is unknown how long the pair bond lasts. Mates are replaced if an original pair member disappears (Wootton 2020).

The Purple Finch usually feeds in the outer branches of trees at heights of 0.5-30 m, but occasionally feeds on the ground. It feeds predominantly on deciduous species rather than conifers. It feeds on flowers of domestic cherries in the west. None of the flower is eaten; it appears to feed on the small quantities of nectar in the flower. It may capture flying ants by sallying from a perch similar to a flycatcher. It occasionally drinks water, especially during hot weather in arid areas (Gullion 1950b; Wootton 2020). In subalpine areas of New Hampshire, foraging techniques included 0% aerial flycatching, 68.3% leaf gleaning, 11.5% leaf hawking, 7.2% leaf hovering, 1.0% twig pecking, 2.4% twig gleaning, 1.0% twig hawking and hovering, 2.4% branch pecking, 6.3% branch gleaning, and 0% litter pecking and gleaning, fallen log manoeuvres, and bole pecking and gleaning. Most (61.8%) foraging was distant from the trunk and 38.2% was near it. When feeding on foliage, 22.4% was on conifers, 77.6% was on deciduous species, and 0% was on herbaceous species. Foraging heights included 0% on the forest floor, 0% 0.1-2 m from the ground, 25.4% at 2-5 m, 54.8% at 5-8 m, and 19.7% above 5 m. It was a deciduous foliage specialist that preferred leaf gleaning in distal canopy locations (Sabo 1980).

The male feeds the female both on and off the nest while she is incubating. Both adults feed the nestlings by regurgitation with a diet consisting nearly entirely of seeds. Initially in spring, the Purple Finch eats buds and blossoms of predominantly deciduous species. In late spring and early summer, it feeds on insects and later switches to fruits in late summer and autumn, and finally to seeds and residual fruits in winter. Buds and blossoms of apple, cherry, peach, plum, poplar, fir, elm, tulip tree, maple, sweetgum, sycamore, ash, red cedar, common juniper, and mountain-ash are consumed. There is only 1 record of it feeding on spruce buds. In Algonquin Park, it feeds on trembling aspen catkins in spring. Insects that it eats include beetles, caterpillars, aphids, ants, grasshoppers, and spruce budworms. Fruit it consumes include those of strawberries, raspberries, blackberries, cherries, dogwoods, elderberries, viburnums, red cedar, winterberry holly, sumac, coralberry, hackberry, juneberry, cotoneaster, honeysuckle, grapes, and poison ivy. Ragweed seeds are a favourite but it also eats seeds of grasses, tulip tree, honeysuckle, white ash, elm, chickweed, hophornbeam, wild radish, dandelion, cocklebur, beech, birch, amaranths, and lamb's-quarters (Austin 1968; Tozer 2012; Wootton 2020).

The Purple Finch appears to be a spruce budworm specialist. In Maine in 1949, the diet of 4 birds consisted of 10% spruce budworms, 76% other invertebrates, and 14% plant material. The density of budworms was almost 2 times greater the following year. The diet of 49 birds consisted of 79% spruce budworms, 11% other invertebrates, and 10% plant material. It was one of the species that fed most heavily on spruce budworms (Mitchell 1952). In New Hampshire and Maine, stomachs contained an average of 11.9 budworms, the highest of all 25 species studied, including the Bay-breasted and Cape May warblers which are considered budworm specialists. It increased its consumption of budworms geometrically as densities of budworms increased, but the finch population did not increase with increasing budworm densities (Crawford and Jennings 1989). Near Manitouwadge, the number of Purple Finch territories increased in all ages of plots but especially in young and intermediate-aged stands as budworm populations increased (Venier et al. 2009). Morris et al. (1958) observed no finch population increase in New Brunswick as budworm populations increased.

The Purple Finch is an infrequent host of the Brown-headed Cowbird, except in Ontario where parasitism rates are higher. It accepts cowbird eggs if there are already finch eggs in the nest, but abandons the nest if no finch eggs are present when a cowbird egg appears. Mean clutch size is significantly lower in parasitized than unparasitized nests. The average number of fledglings produced was 1.88 in parasitized nests compared with 3.46 in unparasitized nests. One of 12 cowbird eggs (8.3%) produced a fledgling. The Purple Finch may be a poor host because it feeds its young predominantly vegetable matter and cowbird young require insects to grow adequately. In Ontario, 37 of 99 nests (37.4%) were parasitized. The high parasitism rate in the province is probably because most reported nests were south of the Shield where the Purple Finch is least abundant and the cowbird is most abundant. It is probable that the parasitism rate is much lower in the Shield where cowbirds are scarce and the finch reaches its maximum densities. In the United States, 22 of 372 nests (5.9%) were parasitized. Parasitism rates were significantly higher in the east (22 of 275 nests, 8.0%) than the west (0 of 97 nests, 0%). It is probable that western cowbirds have learned to avoid parasitizing Purple Finches because of the low likelihood of fledging young. In Quebec, 1 of 16 nests (6.2%) was parasitized. In British Columbia, 0 of 15 nests (0%) were parasitized but there are 3 reports of finches feeding cowbird fledglings (Campbell et al. 2001; Pauzé and Barrette in Gauthier and Aubry 1996; Peck and James 1998b; Wootton 2020).

In southern New England, the Purple Finch declined significantly after the House Sparrow was introduced. It was originally a common breeder there, often nesting in ornamental conifers planted in residential yards. It now occurs only as a migrant and a winter visitor (Austin 1968). It is uncertain whether the introduction of the House Sparrow resulted in a Purple Finch decline in Ontario. This finch did not appear to be common in residential and rural residential yards historically so it may not have been greatly affected by the House Sparrow.

Wootton (1987, 2020) concluded that there may be competitive interference between the House Finch and Purple Finch and that the introduction of the House Finch in the east resulted in a decline of the Purple Finch. He used Breeding Bird Survey (BBS) and Christmas Bird Count (CBC) data for 1966-79 and demonstrated that summer densities of the Purple Finch declined significantly with increasing House Finch populations. The conclusion that the increasing House Finch population

caused a decrease in the Purple Finch population appears to be incorrect. Much of the Purple Finch decline in the east occurred before the introduction of the House Finch and populations declined in vast areas where there are still no House Finches. With the exception of coniferous plantations, which are used sparingly by both species, there is very little overlap in their habitat use. The Purple Finch was eradicated by the House Sparrow from the nesting habitats that the House Finch prefers long before the House Finch was introduced. The most plausible reason for the more recent decline of the Purple Finch is the absence of major spruce budworm outbreaks that likely sustained larger populations in the past. Coincidentally, the major declines in areas affected by budworm outbreaks occurred during the period when House Finch populations were increasing. The House Finch appears to have little or no effect on Purple Finch populations. Spruce budworm abundance may be the most significant factor regulating its population (Bolgiano 2004; Dunn and Tessaglia-Hymes 1999; Leckie and Cadman in Cadman et al. 2007; Tozer 2012).

Selective thinning and other forest management prescriptions that retain some of the forest canopy are probably beneficial because the Purple Finch prefers open wooded habitat. Extensive clear-cutting has the potential to reduce populations by eliminating nesting habitats (Wootton 2020), but clear-cuts may provide important postfledging habitat and fruit. Vanderwel et al. (2009) predicted that it would increase in the Boreal Forest Region of Ontario if 30%, 50%, or 70% of the tree canopy was removed. In the Ontario Canadian Shield, it was equally abundant in early successional and mid-successional stands created by fire and clear-cutting. It was significantly less abundant in early and mid-successional stands than in mature stands (Zimmerling et al. 2017). In New York, Keller et al. (2003) could discern no clear trends in Purple Finch numbers over time since clear-cutting. Some canopy trees were retained in clear-cuts and these continued to provide habitat. In Wisconsin, it appeared to be unaffected by removal of trees in riparian buffers and the physical methods of harvesting had no effect (Hanowski et al. 2003, 2005). In Quebec, it was absent in clear-cuts, absent to very uncommon in strip-cuts, and present in low densities in final cuts (Falardeau et al. 1999).

Price (2004) predicted that the Purple Finch might disappear as a breeding species in southern Ontario if the average summer temperature increased by 2°C. In central Quebec and Labrador, it was associated with warmer temperatures and lower precipitation rates. In this area, climate change has the potential to be beneficial (DesGranges and LeBlanc 2012). In New York, Kirchman and Van Keuren (2017) studied the extent of occupation by the Purple Finch over an altitudinal gradient in the Adirondacks. Over a 40-year period, it shifted its range upwards by 475 m for the lower elevation and 150 m for the upper elevation. They concluded that the altitudinal shift was related to either climate change or natural succession.

Status

McIlwraith (1894) stated that the Purple Finch bred sparingly in southern Ontario. Fleming (1907) considered it uncommon in the Toronto area, although it was confirmed breeding in 1895. In Elgin County, it was a common summer resident in 1891, absent as a breeder in 1954, and a very rare breeder in 2000 (Lancaster et al. 2004). Baillie and Harrington (1937) considered it a fairly common breeder, particularly in the central and northern portions of the province, from the southern border to Lake of the Woods and James Bay. Baillie and Hope (1943) reported that it was common along

the northeast shore of Lake Superior where they saw as many as 20 a day. Smith (1957) considered it one of the most common species in the Clay Belt. In Algonquin Park, it was an abundant breeder in 1900, common in 1908-14 and 1922, fairly common in 1938, and occurred in all 70 squares during the first atlas (MacLulich 1938; Tozer 2012). Mills (1981) considered it a common breeder in Muskoka and Parry Sound districts. In the Hamilton area, it was absent as a breeding species in the 1930s and 1940s and first appeared as a breeder in the mid-1950s (Curry 2006). Breeding has not been confirmed in Niagara Region since 1972 (Black and Roy 2010). The first atlas indicated that its breeding range included most of the province except for Essex County. In the Hudson Bay Lowland, it was mostly absent except near Moosonee and near the Hudson Bay coast. It was scattered in distribution in the Carolinian Forest Region and areas south of a line from Goderich to north of Toronto. It was most abundant in the northern portion of its range with an area of high abundance in Nipissing and Parry Sound districts and Haliburton County (Middleton in Cadman et al. 1987).

The second atlas revealed that there had been no significant change in the range of the Purple Finch since the first atlas. It was documented in fewer locations in the northern Boreal Forest Region and in the Hudson Bay Lowland, but in more squares in the off-Shield portion of the Great Lakes–St. Lawrence Forest Region. Its probability of observation declined significantly province-wide, and in the Carolinian Forest Region, Shield portion of the Great Lakes–St. Lawrence Forest Region, Boreal Forest Region, and Hudson Bay Lowland. It increased significantly in the off-Shield portion of the Great Lakes–St. Lawrence Forest Region. The reason for the decline in the Shield and Hudson Bay Lowland is uncertain, but may be related to declines in spruce budworm populations. The increase in the off-Shield portion of the Great Lakes–St. Lawrence Forest Region may be due to natural succession and maturation of coniferous plantations. It was most abundant in the Shield portion of the Great Lakes–St. Lawrence Forest Region and in the Boreal Forest Region from Lake Nipigon and Wawa northeast to the Moosonee and Lake Abitibi regions. It was sparsely distributed in urban and intensive agricultural areas in the southwest, in the northwestern portion of the Boreal Forest Region, and in most of the Hudson Bay Lowland (Leckie and Cadman in Cadman et al. 2007).

BBS results for 1970-2021 indicate that the Purple Finch decreased at annual rates of 1.15% in Canada and 2.16% in Ontario. For 2011-21, it increased at an annual rate of 0124% in Canada and decreased at an annual rate of 4.73% in Ontario. The long-term trends were highly reliable; the short-term trends were of medium reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Young can fly weakly after they leave the nest. They remain near the nest for a week (Wootton 2020); their movements thereafter have not been documented. They appear to be dependent on the adults until 3 weeks after leaving the nest (Middleton in Cadman et al. 1987).

Both adults and juveniles have been documented inhabiting clear-cuts 2-10 years old in deciduous and mixed forests. In Pennsylvania, 16 adults and 7 juveniles were captured in clear-cuts and 0 in adjacent mature deciduous forests. Vegetation in the clear-cut was 1.5-2.5 m tall and 10-15% of the original trees were retained (Stoleson 2013). In Quebec, Major and Desrochers (2012) captured 14 in clear-cuts dominated by balsam fir and white birch in addition to planted black spruce. Fruit-bearing species present included red elderberry, pin cherry, mountain ash, juneberry,

red raspberry, and squashberry. In deciduous clear-cuts in Minnesota, Streby et al. (2011b) caught 9 adults and 4 juveniles in 4 postfledging periods and 1 adult during the breeding season.

In Michigan, Akresh et al. (2009) captured 5 adults and 3 juveniles in mature riparian forests and 0 in mature upland trembling aspen–large-toothed aspen forests. Riparian forests had an understorey of alder and honeysuckle that was lacking in upland forests. Shrubs are important to the Purple Finch during the postfledging period, particularly those that bear fruit.

Austin (1968) reported a male feeding a fledgling juneberries.

MIGRATION

Western populations of the Purple Finch may be resident or exhibit altitudinal migration, moving from high elevations in summer to lower areas in winter. High CBC counts in British Columbia in some years suggest that irruptions occasionally occur (Bock and Lepthien 1976b; Campbell et al. 2001; Wootton 2020). In the east, some birds migrate south every year but there is a tendency for large southward movements to occur every other year. These irruptions usually coincide with poor seed crops in the north. Southward invasions of all boreal and seed-eating birds tend to be synchronized, but high Purple Finch numbers may not coincide with those of other species or be as regular (Bock and Lepthien 1976b; Kennard 1977; Wootton 2020). Most other boreal species depend heavily on the seeds of conifers whereas the Purple Finch feeds predominantly on deciduous species. Irruptions of this finch are probably correlated with poor seed and fruit crops of species such as ash, elm, birch, alder, and mountain-ash.

Banding records indicated that over half of Ontario birds remained for the winter, but some moved to the lower Mississippi River area. Others overlapped in the northeastern United States with Prairie Province birds. Some birds banded in Ontario during the breeding season were recovered in winter in Vermont and North Carolina (Brewer et al. 2018). A bird banded in summer in Muskoka District was recovered in West Virginia the following winter and 1 captured in Muskoka District was banded in autumn in New York (Mills 1981). In Pennsylvania, 62.4% of 4,469 banded Purple Finches were captured in March and April; 0 were banded in September and only 3 in October over a 10-year period. This suggested that it did not pass through Philadelphia in autumn, but was a common spring migrant (Groskin 1950). Blake (1962) determined that the Purple Finch was more common during spring than autumn migration in North Carolina. It is probable that it migrates during the day; Curry (2006) reported that it was observed actively migrating during the day in Hamilton.

In New York, males arrived approximately a week before females and adult males were recorded 15 days earlier than yearling males (Yunick 1983b). In many areas of Ontario, the Purple Finch is an irregular migrant and it may be difficult to distinguish migrants from breeding or resident birds. Migrants mostly arrive in early to mid-April and continue moving through until mid-May. Birds may be observed as early as late March; those lingering into June may be yearlings (Black and Roy 2010; Curry 2006; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008). In Moosonee, Wilson and McRae (1993) saw as many as 30 3-5 June but no finches were seen later in the breeding season. It was uncertain if these were spring migrants or breeders. In New York, some adults departed in autumn 3-5 weeks before juveniles (Yunick 1983b). Wilson and McRae (1993) reported autumn migrants on 1 August at Ekwan, 10 September at Longridge, and 2 September at Moosonee. In the southern

Shield, most migration occurs in October (Mills 1981; Tozer 2012). In the south, autumn migration extends from mid-August to mid-November (Curry 2006; Lancaster et al. 2004; Weir 2008).

At Delta Marsh in Manitoba over 63 years from 1939 to 2001, the Purple Finch arrived significantly earlier with time at a rate of 2.21 days per 1°C increase in temperature. Climate change resulted in earlier spring arrival (Murphy-Klassen et al. 2005).

Migration habitat is similar to breeding habitat except that the Purple Finch is more likely to visit suburban and rural residential areas, particularly if feeders are present. In British Columbia, it prefers mixed open forests with a rich shrubby understorey and uses riparian and edge habitats more frequently during migration than in the breeding season. Migrants are often found around edges of beaver ponds, bogs and fens, lake shores, stream banks, woodlots, hedgerows bordering agricultural fields, and in trembling aspen stands. It also occurs in suburban and urban areas, edges of natural and human-made clearings, and in fields with scattered clumps of trees (Campbell et al. 2001). On 2 islands in the Gulf of Maine, it was significantly more abundant on the shrubby island than the treed island during both spring and autumn. Birds on the treed island gained more weight than those on the shrubby island. In autumn, at least 3 birds subsequently moved from the shrubby island to the treed island but none moved from the treed island to the shrubby island (Suomala et al. 2010, 2012). In Pennsylvania, an infestation of the viburnum leaf beetle resulted in a dramatic decline in southern arrowwood and an overall decline in shrub density and increase in snag density. The capture rate per 1,000 net-hours was 3.43 prior to the beetle infestation and 1.41 afterwards (Smith and Hatch 2017). Results suggested that shrub density was important to the Purple Finch. In Pennsylvania, the number of captures per 1,000 net-hours was 0.2 in forest habitat and 63 in shrub habitat; the difference was highly significant (Smith and Hatch 2008).

Site fidelity to migration stopover locations appears to be quite low. At a Tennessee site, there were no returns of birds banded in April and May; only 2 of 492 (0.41%) banded in March returned (Stedman 1989).

Feeders are used extensively during migration and the Purple Finch also takes sugar water from hummingbird feeders (Campbell et al. 2001).

James (1991) considered the Purple Finch an uncommon to common (rarely locally abundant) migrant.

WINTER

The Purple Finch is associated with snow in winter. It is less likely to be found where there are frequent changes between snow cover and bare ground (Keyser et al. 2023).

Winter habitat is the same as migration habitat. Choice of habitat is probably dictated by food availability rather than vegetation composition or structure (Wootton 2020). In Kansas, the Purple Finch occurred most frequently around margins of a pond, in weedy fields, and in a field of sunflowers (Fitch 1958). In South Carolina, it occurs in deciduous forests where it feeds on sweetgum and sycamore seeds. South of the extensively forested landscapes in the east, it is often seen in open country with flocks of Pine Siskins or American Goldfinches; it may also roost with these species. Roosts are usually in dense coniferous trees or thickets, but occasionally in open buildings or under

the shelter of a cupola roof (Austin 1968; Wootton 2020). In Tennessee, 200 roosted in cedars in a field densely overgrown with cedars interspersed with deciduous trees. Most roosted in this field but a few roosted in a cedar on an estate bordering a park. One afternoon, something disturbed about 20 birds in 1 tree and they flew across the road. A few days later, most birds moved to another cedar woods on the same road, so birds were then roosting at 3 locations (Laskey 1958b).

In Maine, the Purple Finch attempted to establish feeding territories at feeders. The first arrival at the feeder tried to keep all other birds off the feeder but invariably failed. Fighting intensified as the number of birds increased (Gobeil 1963). The Purple Finch is subordinate to the Pine Siskin in winter and dominant to the American Goldfinch (Wootton 2020). Shedd (1990) studied 1,585 displacement interactions between the Purple Finch and House Finch; 38.6% of interactions were between House Finches, 33.4% were between Purple Finches, and 28.0% were interspecific. Both species preferentially sought out members of their own species when making a displacement attempt. Female-plumaged Purple Finches won 95.6% of intraspecific displacements, significantly more than expected. In interspecific interactions, Purple Finches won only 9.0% of displacements, significantly less than expected. House Finches were competitively superior to Purple Finches at a feeder. Purple Finches could be effectively excluded from feeders where the House Finch is abundant.

The Purple Finch exhibits low winter site fidelity. Much of this is due to its irregular and irruptive movements. Individuals have been found wintering in widely disparate locations and birds often wander within winters. At Presqu'ile, it may be common in 1 year and absent in another with no real pattern (LaForest 1993). In Algonquin Park, it is absent most winters but present in years of bumper crops of both coniferous and deciduous seeds. Birds may appear there in February and March. These have likely wintered further north and moved south after exhausting seed supplies (Tozer 2012). In Indiana, its appearance is somewhat cyclic at 6-7-year intervals (Hamilton and Wise 1991). In Pennsylvania, invasions occurred in 1939, 1940, 1941, 1944, 1946, and 1947 (Groskin 1950). In New York, irruptions occurred in 1964, 1974, and 1976 (Yunick 1983a). In Tennessee, 19 of 1,166 birds (1.63%) returned in a subsequent year; 5 of 471 (1.06%) returned to a site 5 km distant. Another Tennessee study reported that 50 of 4,954 (1.01%) returned (Stedman 1989). In Philadelphia, 95 of 4,469 (2.1%) returned in a subsequent winter. Twenty-six birds were recaptured in a subsequent winter 16-1,208 km away (Groskin 1950). In New York, 0 of 1,999 birds returned. Birds banded there were recovered in winter in Tennessee, Georgia, Oklahoma, Louisiana, and Virginia (Yunick 1983a). Blake (1962, 1967) reported that 51 of 1,015 birds (5.0%) returned in a subsequent winter. Flocks wander widely within and between years and individuals do not remain in a particular flock (Wootton 2020).

In Tennessee, birds fed at residences where seeds had fallen on the ground and on the fruit of coralberries. In March, elm seeds were the favourite food, and the Purple Finch also ate hackberry seeds (Laskey 1958b). It is widely attracted to bird feeders. Some remain all winter at northern feeders but it is more abundant in the south. The number of feeders visited in the north increases as spring migration begins. During cold weather, birds may retreat to more sheltered areas and suddenly reappear in residential areas on warm sunny days giving the false impression that migration has occurred. It occurs at feeders in all habitat types but is less likely to be seen at urban

feeders, which also attract lower numbers. Black oil sunflowers are highly preferred over any other feeder offerings, but striped and hulled sunflowers are also preferred. Infrequently consumed foods include mixed seeds, millet, canary seed, safflower, cracked corn, niger, peanut butter mixes, peanut hearts, bird puddings, fresh fruit, water, meat scraps, and popped corn (Dunn and Tessaglia-Hymes 1999). Horn et al. (2014) reported that it was most common at hopper and tube feeders and preferred black oil sunflowers.

The Purple Finch is vulnerable to severe winter weather. Graber and Graber (1979) recorded its densities per km^2 in Illinois habitats before and after a prolonged severe storm: in bottomland forest, 1.0 and 0.5 (a 50% decrease); in upland forest, 21.2 and 0 (a 100% decrease); and in urban residential, 3.2 and 23.5 (a 630.8% increase). It exhibited a population shift to urban residential habitats, probably to visit bird feeders. They found 1 finch carcass, indicating that the storm caused some mortality.

The Purple Finch has been reported colliding with motor vehicles, windows, and other stationary objects (Wootton 2020). In the United States, it was not on the list of the top 20 vulnerable species for striking all types of buildings combined, or low-rises or high-rises. For 1-3-storey residences, it was the most vulnerable species, being 257.2 times more likely than average to strike a building (Loss et al. 2014).

James (1991) considered the Purple Finch a rare to common winter erratic in the south north to Manitoulin Island and occasional and rare to uncommon to Thunder Bay in the north. Freedman and Riley (1980) analyzed data from southern Ontario CBSs for 1929-77 and found that numbers were stable overall except for irruptions in 1950, 1953, and 1964. They concluded that populations had not changed overall in the last century.

Redpoll

Acanthis flammea

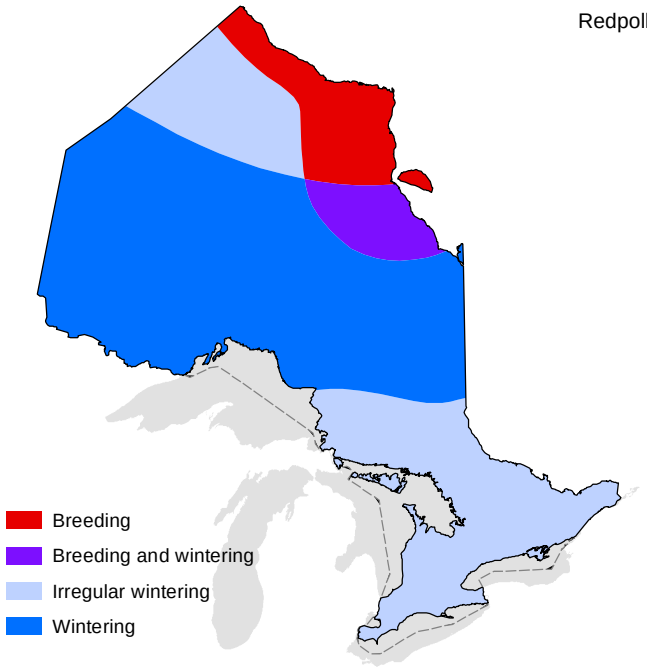
BREEDING SEASON

Habitat Requirements

Until 2024, the Redpoll was treated as 3 separate species and 2 of these (the Common Redpoll and Hoary Redpoll) nested in Ontario (Knox et al. 2024). Information on these 2 former species has been combined into this account, but an illustration is presented for both. This is because the Common Redpoll and Hoary Redpoll are easily distinguished in the field and there is still some debate about the taxonomy of the species.

In Ontario, the Redpoll nests on or near tundra or in riparian thickets. Nests have been found in spruce-willow swamps, willow thickets, and a semi-open alder-willow thicket. Almost all nests were near the shores of ponds and streams. Most nests were along the Hudson Bay and northern James Bay coasts (Peck and James 1987). One nest near the Little Shagamu River and Hudson Bay was in an open black spruce forest (Peck and James 1998b). Near Winisk, it was common in spruce-tamarack bogs (Schueler et al. 1974). Manning (1952) reported a nest on a ridge among dwarf birch along the James Bay or Hudson Bay coast. Breeding habitat in Ontario consists of wet tundra dominated by water, sedges, and bulrushes interspersed with low willow and swamp birch thickets;

numerous shallow lakes and ponds; and a parallel series of low gravel beach ridges extending inland. The beach ridges support a lichen-heath community dominated by cup lichen, mountain avens, crowberry, mountain cranberry, and Lapland rosebay. Approximately 7 km inland from the coast, widely scattered or small copses of white spruce become increasingly frequent on the ridges transitioning into lichen-spruce woodland about 10 km inland. The spruces are krummholz in character (stunted and twisted). Nests were on beach ridges with occasional or isolated krummholz white spruce; 2 were near willow or willow-birch thickets. Ridges supporting nests were bordered by wet sedge fens, small tundra lakes, and sedge flats overgrazed by Snow Geese (Burke et al. 2013).



Erskine (1977) considered the Redpoll characteristic of the ecotone between the Boreal Forest Region and tundra. In the west, it also occurs in subalpine areas in the transition zone between treed habitat and alpine meadows. In the arctic where trees are lacking, it nests on rocky slopes and gullies, south-facing slopes with shrubs, in sheltered shrubby gullies, and in and around settlements (Knox et al. 2024).

Hoary Redpoll

In Quebec, the Redpoll is one of the most abundant species in tundra and taiga habitats. On the northeast coast of James Bay, it nests in shrubs along the shoreline and around margins of islands, predominantly in alder and willow thickets. In the taiga area, it nests in patches of stunted spruce or scrub birch and in tamarack stands (Seutin et al. 1991; Seutin in Aubry and Gauthier 1996). In Manitoba, it is most common near the treeline but also nests in tundra. Near the treeline, it typically nests in scattered spruce but prefers dense willow scrub in other areas (Jehl 2004; Jehl and Hussell 1966; Jehl and Smith 1970). Near Churchill, it nested in white spruce–tamarack and black spruce–white spruce–

tamarack stands and in similar stands bordering on tundra; it also nested in riparian strips of willow (Gillespie and Kendeigh 1982). It was more common among thin lines or small clumps of dwarf black spruce near Churchill than among willows fringing ponds in open tundra (Grinnell 1943). In northeastern Manitoba, McLaren and McLaren (1981) reported low densities in the forest-tundra transition area and higher densities in tundra. Near Churchill, Sammler et al. (2008) considered the Redpoll to be in the willow-nesting guild. In the Mackenzie Delta, it is an abundant breeder in tundra and taiga habitats (Porsild 1943). In British Columbia, breeding habitat consists predominantly of subalpine willow thickets, mixed spruce and deciduous thickets at edges of openings, and edge habitat along streams and rivers. One nest was on a floodplain with scrubby thickets of alder, willow, and balsam poplar between channels. Nesting habitat is often associated with wetlands (Campbell et al. 2001). In the Yukon, most nesting occurs at higher elevations, often in willow or willow-birch thickets that are usually near water. It is most common along rivers, creeks, wet draws, and other wetland areas where shrubby habitats are most prevalent. Occasionally it nests at lower elevations, especially where birch trees are common (Sinclair et al. 2003). In Alaska, it nested in Fairbanks and in alder and willow habitats in tundra. In tundra, it nested in willows and alders along drainage channels, often over shallow water. It breeds in sheltered riparian shrubs; at the upper limit of subalpine low shrub habitats with scattered stunted conifers and dwarf birch, willow, and alder; and is frequent on floodplains (Baldwin in Austin 1968; Knox et al. 2024; Troy and Shields 1979; Walkinshaw 1948b). On Victoria Island in Nunavut, Parmelee et al. (1967) observed it only within or near the community of Cambridge Bay. Some nested in discarded spruce Christmas trees. Those outside the town nested in willow thickets. The Greenland subspecies breeds on the arctic archipelago of Canada and in Greenland. On Ellesmere Island, it was mostly confined to barren inland rocky areas where it nested in a deep gorge. It did not appear to require shrubs for nesting (Parmelee and MacDonald 1960). In Greenland, it is restricted to the interior where it frequents hillsides and mountain sides at higher altitudes. It requires willow or some other shrub of similar size for nesting. Along the coast, all plants trail along the ground and do not form erect shrubs so this habitat is unsuitable (Austin 1968).

At night, birds may roost communally in scrub birch. At Fairbanks, Alaska, the Redpoll roosted overnight in dense foliage of white spruce (Knox et al. 2024).

Most Ontario nests were in arctic willows. One was in a black spruce, 1 was on the ground in a clump of dead grasses at the base of a willow, and another was on the ground on a bank under willow branches. Three nests were in krummholz-form spruce trees 2-3 m tall, 0.6 m, 1.0 m, and 1.25 m from the ground. Nest distances from the tree trunk were 15 cm, 15 cm, and 43 cm. At 1 nest, the nest tree and several others nearby were isolated from any other trees by several kilometres (Burke et al. 2013). In willows, nests were placed centrally in crotches, usually below the midpoint of the shrub. Nest height was 0-4 m, but typically 0.3-1.2 m from the ground with most 0.4-0.6 m up (Peck and James 1987, 1998b).

Nests reported elsewhere in North America were 0-2.1 m from the ground, with most 0.5 m or less from the ground. North of the treeline, it may nest in human communities. In Alaska, 1 nest was in a picket-fence grave marker. Five Alaska nests averaged 71 cm above ground (range 30.5-99 cm). Of 25 nests in Alaska, 16 were in or under willows, 6 were in alders, 1 was in an unknown species of

shrub, and 2 were on artificial substrates; nest heights were 0-2.13 m. Another 8 nests in Alaska were in crotches of willows 45-91 cm from the ground. On Baffin Island, a nest was on the seat of a boat left beside a street in a town, and on Victoria Island one was built on a trailer. The trailer was moved several hundred metres before the nest was completed but the adults still completed the nest and raised a brood. In the Yukon, 1 nest was in a white birch in Whitehorse; 1 nest was on the end of a log protruding from a log cabin, near the roof. Four others were in open deciduous scrub or willows 0-20 cm from the ground. Most nests are in low shrubs or stunted trees, particularly willow, birch, and spruce but also alder, squashberry, and tamarack. Nests may either be saddled on a horizontal branch or in a crotch. Nests in spruce are well concealed under another branch. Nests in deciduous shrubs may be either conspicuous or hidden under clumps of dead leaves or among new foliage. Near Churchill, nests were in spruce, willow, tamarack, and birch at heights of 0.15-2.1 m. In Quebec, early nests are usually in conifers but July nests are built near the ground in small deciduous trees or shrubs such as alders, willows, or birch, or on the ground sheltered by a rock. On Ellesmere Island, 1 nest was in a niche in a vertical rock wall in a deep gorge. On Victoria Island, 1 nest was in an old Christmas tree with only the trunk and a few limbs and needles remaining. In Greenland, it nests in low willows or dwarf birches or in crevices in rocks covered by trailing twigs of willow. Where nest sites are limited, it has nested in cavities in driftwood and in an Inuit wooden grave. At Churchill, all nests built prior to 21 June were in conifers and later nests were in deciduous species. In open tundra lacking shrubs, tufts of grass or sedges, driftwood stranded by high tides, and human artifacts may be used for nest concealment. In the High Arctic, nests may be on the ground on rocky ledges. Further south, nests have been built on the ground on the banks of watercourses. A British Columbia nest was concealed under an overhanging lip of the bank of a river. In Manitoba, nests did not appear to be reused with nests for second or replacement clutches distant from the first nest. There is 1 case of a nest being reused on Baffin Island. A nest there had 4 distinct layers of lining suggesting that it had been used in 4 years. In Greenland, all nests appeared to have been used in previous years, enabling pairs to proceed rapidly to egg-laying in the shorter nesting season. Material from old nests is often used to construct new nests. The Redpoll has been reported adding lining to an old nest of an unspecified species (Austin 1968; Baldwin in Austin 1968; Campbell et al. 2001; Clement in Austin 1968; Grinnell 1943; Jehl 2004; Jehl and Hussell 1966; Jehl and Smith 1970; Knox et al. 2024; Lanoue and Seutin in Gauthier and Aubry 1996; Parmelee and MacDonald 1960; Parmelee et al. 1967; Seutin et al. 1991; Sinclair et al. 2003; Walkinshaw 1948b; Wynne-Edwards 1952).

The Redpoll appears to be nonterritorial. It nests either solitarily or in small groups but it is uncertain whether clustering of nests represents sociality or availability of preferred habitat. Birds move away from the nest on a daily basis and have been documented tens of kilometres distant in Asia. Birds are gregarious throughout the nesting season, occurring in loose flocks or all stopping together to feed in 1 location. Song appears to be solely for courtship and not for territoriality. Small foraging flocks occur throughout the breeding season and breeding birds, especially males, occur within these flocks (Baldwin in Austin 1968; Burke et al. 2013; Knox et al. 2024; Seutin et al. 1991).

No information is available on natal philopatry, but it is probably extremely low. In Alaska, 1 juvenile female returned to nest the year after it was banded; the number of juveniles that were banded was not stipulated (Troy and Shields 1979). The hatch-year female was banded in August. It

may not have been in its natal area when it was banded if it had already begun postfledging dispersal.

The return rate of adults in Alaska was among the lowest of all passerines at less than 1%. Large annual fluctuations in breeding densities have been documented in Manitoba, Quebec, Norway, and Finland. These fluctuations suggest that immigration and emigration of birds must occur at individual sites, providing additional evidence of low inter-annual site fidelity (Jehl 2004; Seutin in Gauthier and Aubry 1996; Troy 1983).

Limiting Factors

Eggs have been found in Ontario nests from mid-June until the end of July, with most present in the second week of June (Peck and James 1987). Burke et al. (2013) estimated that 17-19 June was the earliest that nests found in 2004 near West Pen Island could have been initiated, several weeks later than reported for Manitoba and Quebec. That year had the coldest April to June weather in the Hudson Bay Lowland for 1996-2007. Snow covered much of the area until mid-June. Nesting usually begins in late May in the Churchill area (Jehl and Smith 1970). At Churchill, nests took 4-7 days to build. Building may be interrupted for as long as 6 days during periods of poor weather. The first egg is laid 1-4 days after the nest is completed (mean 1.4 days at 33 nests). The interval may be longer during periods of inclement weather. At Churchill, eggs were laid at 1- or 2-day intervals, but mostly at 1-day intervals. Incubation usually begins with the laying of the penultimate egg. In Greenland, incubation may possibly begin with the laying of the first egg. The incubation period is 10-14 days. In Alaska 4-egg clutches, 3 eggs hatched on the first day and the fourth egg hatched the next day; in 5-egg clutches, 4 eggs hatched together and the fifth egg hatched the following day. In Alaska, the nestling period was 9-10 days; it was 11-12 days at Churchill. On Victoria Island, the nestling period was 11-12 days for some chicks but others in the same nest did not fledge until they were 15-16 days old (Grinnell 1943; Jehl 2004; Knox et al. 2024; Parmelee et al. 1967; Walkinshaw 1948b).

The Redpoll regularly raises 2 broods. Renesting is common if a clutch is lost. One Alaskan female renested twice before successfully fledging young. A maximum of 8 days elapsed between desertion of the second clutch and laying the fifth egg in the third nest. Ontario nests had clutches of 3-5 eggs, with most containing 4 eggs (mean 4.08 eggs). Elsewhere, clutches of 2-7 eggs have been reported, with most containing 4-6 eggs. On Victoria Island, all nests contained 5 eggs. In Greenland, clutches typically contained 5 or 6 eggs. Mean clutch size was 4.2 eggs in Alaska (Austin 1968; Clement in Austin 1968; Evans 1969; Jehl 2004; Jehl and Smith 1970; Knox et al. 2024; Peck and James 1987; Troy and Shields 1979).

The Redpoll is capable of breeding when it is 1 year old and breeds every year thereafter. The proportion of yearlings that do not breed is unknown. The mating system is assumed to be monogamous. Pairs have been documented remaining together for 2 or 3 nesting attempts within a season but there is no evidence of pair bonds persisting longer than a single season (Knox et al. 2024). In Manitoba, Seutin et al. (1991) documented a case of polyandry. A pair attended a nest containing nestlings 8-9 days old while another nest about 200 m distant was under construction. Two days later, the second nest contained a single egg and the same female and a yearling male attended this nest. Polyandry was advantageous and is probably more widespread than

documented. It has the capacity to raise 2 broods but the season is short so there is a great advantage to starting the second nest as early as possible. By selecting an experienced male for the first nest, success is more likely and older birds are likely to be on the breeding grounds earlier. Pairing with a young male for the second nest allows a male to breed that might not have had the opportunity otherwise. Polyandry is difficult to study in this species because subsequent nests may be considerable distances from each other. Extra-pair copulations are a part of the mating system. Little study has been devoted to this with the nestlings of only 6 nests having been tested genetically (Knox et al. 2024).

The Redpoll feeds in trees and shrubs, herbaceous plants, and on the ground. In trees and shrubs, it forages at or near the ends of small branches and may take several seeds from catkins at a time. Prior to leaf-out, it searches for insects on stems and in crotches and feeds in shrubs, herbaceous plants, and grasses and on the ground in the open. It also collects fallen seeds under trees. In low vegetation, it clings to thin stems to reach seeds. It uses its feet to hold food or stems and stores seeds in the diverticulum. It feeds predominantly in trees and shrubs in summer and more on the ground in early spring and winter except where birch and alder seeds are plentiful. In summer, it may forage for insects in conifers. In British Columbia it fed on spilled grain in open storage sheds. It feeds more on the ground in winter than in summer, usually on wind-swept and snow-free patches where seeds are exposed. It frequently drinks at puddles, ponds, or streams and eats snow in winter (Baldwin in Austin 1968; Campbell et al. 2001; Clement in Austin 1968; Grinnell 1943; Knox et al. 2024; Parmelee et al. 1967).

Most males feed the female (predominantly insects) during courtship and occasionally through to the nestling period. In Alaska, adults fed the young a white mash of seed kernels that consisted almost entirely of cottongrass seeds. Some mash contained insect parts and 1 female fed its young several insect larvae (Baldwin in Austin 1968; Knox et al. 2024). In Finland, the nestling diet by volume consisted of 61% insects and 39% seeds that were mostly birch. In Sweden, 1,203 animal food items collected from esophageal pouches of nestlings included 391 nematoceran flies, 241 fly pupae, 176 springtails, and other taxa; 4,770 seeds were consumed of which 4,585 were birch seeds. The diet consisted of 20.1% animal material, of which 51.7% were flies, and 79.9% seeds of which 96.1% were birch seeds (Grinnell 1943; Knox et al. 2024).

During summer, the Redpoll eats arthropods, particularly when feeding nestlings. It also eats plant material then and almost exclusively at other times of the year. Although it eats buds, leaves, flowering catkins, and algae, it subsists predominantly on very small seeds. Birch and alder seeds are the staples of its diet and it frequently eats willow seeds. In Alaska, adults ate mostly flies and caterpillars in June while they were feeding nestlings. From June to mid-August, the diet consisted of 20-25% insects and by mid-August, the diverticulae of many juveniles contained more than 50% willow catkins. In northern Alaska, the diet consisted entirely of seeds and buds of alder, birch, and willow. In early spring when snow is on the ground, grass seeds and lamb's-quarters seeds may be important in the diet. Six stomachs collected during summer at Fort Simpson, Northwest Territories, contained only the seeds of dwarf birch, white birch, and alders. On Baffin Island, it consumed spiders and seeds of willows, sedges, and grasses. In early June at Churchill before invertebrates became common, 10 stomachs contained 59% grit and 41% vegetation that was chiefly seeds of

buttercups, cottongrass, whitlow-grass, and mustards. Other seeds that may be important in the diet include those of shrubby cinquefoil, great willowherb, sedges, and tamarack. In Greenland, the summer diet is comprised mostly of arthropods, particularly spiders and leafhoppers, but it also eats wood-rushes and sedge seeds (Austin 1968; Baldwin in Austin 1968; Campbell et al. 2001; Evans 1969; Gabrielson 1924; Knox et al. 2024; Mills 1981; Porsild 1943; West et al. 1968b). Gabrielson (1924) analyzed the contents of 7 stomachs collected in Canada during the summer. The diet consisted of 25% animal material and 75% plant material. The animal food was predominantly spiders, ants, and flies. The vegetation consisted of seeds of the same plants that were consumed in winter.

The breeding ranges of the Redpoll and Brown-headed Cowbird barely overlap, so parasitism is rare. Only 2 cases of parasitism have been reported, both from Alberta (Knox et al. 2024).

Because of its northern breeding range, habitat loss is not an important limiting factor for the Redpoll. Localized habitat loss may occur due to activities associated with mining. In the Churchill area, Sammler et al. (2008) examined the effects of grazing by Snow and Ross's geese on the willow-nesting passerine guild, which included the Redpoll. In areas directly affected by grazing, density of passerines was significantly less by 2.4 times than in areas where grazing had not occurred. Goose grazing can have localized negative effects on Redpoll habitat.

Cold rainy weather has the potential to kill nestlings. All 5 nestlings died in a Churchill nest after 5 days of cold rainy weather in early July. Redpolls that began nesting in late May would have had time to fledge young before the storm (Jehl and Hussell 1966). Late springs may delay nesting (Burke et al. 2013). This may preclude second broods or replacement clutches and may result in smaller clutch sizes.

At Cambridge Bay on Victoria Island, breeding success in the settlement was low due to predation by children, cats, and natural predators such as weasels and lemmings (Parmelee et al. 1967).

The Redpoll may be highly vulnerable to climate change. It is intolerant of high temperatures and becomes less active, eats less, and drinks more in response to heat (Knox et al. 2024). In central Quebec and Labrador, it occurred mostly in stands with low summer temperatures and high rates of precipitation (DesGranges and LeBlanc 2012).

Status

Manning (1952) concluded that the Redpoll was a fairly well-distributed summer resident in certain locations along the Hudson Bay and western James Bay coasts. Baillie (1960) reported that it had been confirmed breeding at Fort Severn, east of Winisk, at Cape Henrietta Maria, and at Lake Attawaspiskat. Summer records suggested a much more extensive breeding range that included portions of Kenora, Thunder Bay, and Cochrane districts. Schueler et al. (1974) found that it was common in the Winisk area in spruce-tamarack bogs. The first atlas determined that it bred throughout the Hudson Bay Lowland. It was most abundant along the James Bay coast and at inland areas west of that coast (Middleton in Cadman et al. 1987).

The second atlas indicated that there had been no change in the range of the Redpoll or its probability of observation since the first atlas. Highest densities occurred along the Hudson Bay and

northern James Bay coasts and in the extensive tundra inland from Cape Henrietta Maria (Leckie and Pittaway in Cadman et al. 2007).

Breeding Bird Survey data indicate that the Redpoll decreased at annual rates of 2.99% in Canada and 1.15% in Ontario 1970-2021. Trends 2011-21 were annual decreases of 0.861% in Canada and 0.368% in Ontario. The long-term Canadian results were of medium reliability; the other trends were of low reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

In Manitoba, 4 broods were cared for only by the male, 1 by the female, and 2 by both adults. It is likely that the male cares for the first brood if the female attempts a second brood (Seutin et al. 1991).

Young are able to fly weakly and follow their parents when they are 12-13 days old. By age 15 days, fledglings can fly strongly and were as far as 180 m from the nest on Victoria Island. After leaving the nest, fledglings and 1 or 2 of the adults form a family group that moves into riparian alder-willow thickets. By mid-July, dwarf birch scrub may be preferred. In Quebec, family groups aggregate into loose flocks in August and begin moving south in September. In British Columbia, flocks of adults and juveniles begin to form after late June. Redpolls appeared to congregate in flocks shortly after breeding and roam around the breeding range until they flew south in autumn (Campbell et al. 2001; Clement in Austin 1968; Knox et al. 2024; Parmelee et al. 1967). No information is available on how far juveniles wander from the natal area before autumn migration.

On Ellesmere and Axel Heiberg islands, juveniles and adults moved about singly and in small groups feeding on seeds. All birds collected had eaten poppy seeds. A juvenile had consumed adult insects and buds of alpine smartweed. Families wandered about in groups as large as 20 until they initiated migration (Parmelee and MacDonald 1960). In Alaska, birds nested in riparian willows. As cottongrass seed heads began to mature in late July, they spent more time on the open tundra away from the willows, although they were still attracted to willow catkins. Both adults and juveniles were observed feeding on cottongrass. Throughout its range, Redpoll adults and juveniles wander considerably during the postfledging period with no apparent attachment to any site (Austin 1968; Baldwin in Austin 1968; Jehl 2004).

MIGRATION

The Redpoll is both a regular and irruptive migrant. In all years, it withdraws from the extreme northern extent of its breeding range with few overwintering north to the treeline and none occurring north of it in winter. In non-irruption years, a few birds may travel south of the normal breeding range but most remain within the breeding range. The northern extent of its winter range is not well defined. Wintering birds remain in Greenland and southern Baffin Island and may occur regularly throughout the Boreal Forest Region (Knox et al. 2024). It does not occur in the Churchill area in winter (Clement in Austin 1968; Jehl 2004; Jehl and Smith 1970).

During irruption years, Redpolls may be abundant in southern Ontario and occur south into the mid-latitudes of the United States. In these years, some birds remain in the northern extent of the wintering range. Based on Project FeederWatch data, birds may be more prevalent in the north in irruption years than in non-irruption years (Dunn and Tessaglia-Hymes 1999; Hochachka et al. 1999a). Bock and Lepthien (1976b) used Christmas Bird Count (CBC) data for a 10-year period to

determine the frequency of irruptions into the United States. They concluded that irruptions occurred approximately every other year and that they were a result of poor tree seed crops in the north; many tree species set seeds only in alternate years. Their own data do not support the 2-year cycle theory. The interval between irruptions ranged from 1 to 3 years. Instead of 5 2-year cycles within a decade, there were only 3. No actual analysis of tree seed abundance in the northern portion of the breeding grounds has ever been undertaken (Erskine and McManus 2003). Approximately 2-year cycles in irruptions have been reported in Saskatchewan and Manitoba (Houston and Smith 2001) and the northeastern states (Kennard 1976), but there were anomalies in the pattern in all areas. In Ontario, there appears to be no regular pattern to irruptions. Freedman and Riley (1980) analyzed southern Ontario CBCs for 1929-77. Irruptions were irregular with intervals of 2-10 years, averaging 4 years. Tozer (2012) stated that major irruptions in Algonquin Park are very irregular. In the Kingston area, Weir (2008) reported that it was present in 50 of 60 winters and that moderate to heavy flights occurred in 30 of those. The actual periodicity of the flights was not presented, although they averaged every 2 years. Project FeederWatch data from a feeder at Branchton for the winters of 1988-89 to 2022-23 indicated that the Redpoll occurred in 13 of 35 years, an average of once every 2.7 years. In 4 of these 13 years, only 1-3 redpolls were observed on all counts, with 9 years with total counts of 81-406. The actual interval between irruptions ranged from 1 to 7 years. Twice irruptions occurred in consecutive years and in only 3 times was the period between irruptions 2 years (personal observation). Larson and Bock (1986) analyzed CBC data for northeast and northcentral states for 1901-80. Irruptions from 1920-50 were much less dramatic and regular than those occurring before and after this period. In the Atlantic Provinces, the Redpoll occurs in winter most years but is irregular in its abundance. Erskine and McManus (2003) concluded that this better explained the observed patterns rather than attempting to find periodicity in irruptions. Undoubtedly, food abundance is a factor affecting migration in North America, but there must be other factors involved. In the east, both yellow and white birch set seeds every other year. This does not appear to be the case in Alaska, yet irruptions occur in the west as well (Campbell et al. 2001). Another possibility is that summers with high food abundance result in high postbreeding densities that in turn cause irruptive migrations (Hochachka et al. 1999a). Larson and Bock (1986) suggested that there must be some other factor that overrides the masting effect of northern trees, such as climate change. Another possibility is that heavy snows may make food difficult to access even if it is relatively abundant.

The Redpoll is mostly a diurnal migrant but it has been heard migrating at night and nocturnal migration has been documented in Greenland. It typically migrates in loose flocks of 100 or fewer birds, but occasionally flocks as large as 10,000 occur. Banding of spring migrants in Alaska suggests that the composition of flocks is constantly changing. Flocks may be conspecific, but commonly include Pine Siskins and American Goldfinches and occasionally crossbills and Pine Grosbeaks. In both spring and autumn, fat deposition is limited and normally sufficient only for short movements. During spring migration in Alaska, the number of birds recaptured was significantly less than expected indicating that birds were constantly moving in and out of the site with few remaining long enough to be recaptured. The average length of stay of birds that were recaptured was 6.2 days. This result was considered biased because only those birds that remain can be recaptured. It was concluded that the average length of stay was less than 6.2 days. Spring migrants were banded

in Massachusetts. Of the first 24 birds that were banded, 19 were recaptured and stayed at the site 3-22 days. Only 4 of the last 24 birds that were banded were recaptured and the maximum period they stayed was 4 days (Campbell et al. 2001; Dunn and Tessaglia-Hymes 1999; Knox et al. 2024; Nunnely 1964; West et al. 1968b).

Hochachka et al. (1999a) summarized Project FeederWatch data for North America for the irruption year of 1993-94. The pattern was a sparse distribution in most of the wintering range from the beginning of the FeederWatch period in mid-November with increasing prevalence in the east through the winter, most noticeably in the northeastern states. There was no evidence of continuous and systematic movements of the entire population throughout the irruption. Prevalence increased in all regions as the winter progressed with numbers starting to decline in most areas at the same time. The Redpoll differed from more conventional migrants mainly in the varying distances that they travelled in different years. Rather than moving to a specific location, birds stop when they encounter a sufficient food supply.

Most birds leave southern and central Ontario in March or early April with some remaining until early or mid-May. Late records tend to be of stragglers following major irruptions (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008). Wilson and McRae (1993) observed 3 at Shagamu on 31 May and these were considered migrants. Manning (1991) observed 7 on 21 May and 25 on 22 May on the Twin Islands in James Bay. Parmelee et al. (1967) reported that it was present on Victoria Island when they arrived on 31 May. On Ellesmere Island, the first spring birds were seen on 22 April. Autumn migrants were first seen on 8 September and all had left by 17 September (Parmelee and MacDonald 1960). The latest observation on Victoria Island was 12 September (Parmelee et al. 1967). At Ekwan, Wilson and McRae (1993) observed 22 on 1 August and these were likely either autumn migrants or a small group of postbreeding birds. At Longridge, they recorded 32 on 28 July and 75 on 12 September. Manning (1952) reported migrants at Moosonee on 25 September. The Redpoll usually arrives in Algonquin Park in late October or early November, but sightings occasionally occur from late September to mid-October. In some years, peak numbers do not occur until February or March in flight years, probably reflecting seed depletion further north (Tozer 2012). In the south, autumn arrival is in late October to mid-November, but peak numbers do not occur until February or March (Black and Roy 2010; Curry 2006; LaForest 1993; Weir 2008). Hochachka et al. (1999a) used Project FeederWatch data to chronicle the movements of Redpolls during the irruption year of 1993-94. During 15-28 November, low numbers of Ontario feeder watchers reported at least 1 Redpoll, including areas such as Moosonee, in the Lake of the Woods to Thunder Bay area, and scattered areas from Sault Ste. Marie southward. During 10-23 January, it was still present at Moosonee, at more feeders in the Lake of the Woods to Thunder Bay area, and occurred at almost all feeders south of Sault Ste. Marie. During 21 March to 3 April, it occurred from Lake of the Woods east through the Boreal Forest Region and in all of southern Ontario; it was not observed at Moosonee. In the Great Lakes Region (Ontario, Michigan, and Wisconsin), numbers grew from 15 November to a peak at the end of February with a drop-off thereafter into April. Its probability of observation at a feeder was 2% on 15 November, 55% at the end of February, and 50% at the end of March. Peak numbers at feeders occurred an average of

more than 7 weeks later than first sightings. This suggests that it takes some time before birds find feeders, or that they feed on natural seeds until they are locally depleted before visiting feeders.

Habitat used during migration consists of areas with an abundance of food. These may include open woodlands and scrub, particularly where birch, willow, or alder are common; weedy fields and roadsides; field edges; weed patches; and in towns and villages where the Redpoll may visit feeders (Knox et al. 2024; West et al. 1968b). During spring migration in Alaska, flocks concentrated in patches of lamb's-quarters exposed by melting snow. Birds dispersed once other areas became snow-free (West et al. 1968b). In the Saskatoon area, it occurs in weedy fields and ditches, grassy slough edges, shrubs, birch trees, mixed woods, and conifers. Flocks may be attracted to harvested fields of canola, flax, or sunflowers and remain in them for several weeks until the seed supply is depleted (Leighton et al. 2002). In British Columbia, it inhabits edges and deciduous vegetation along watercourses, alder and willow thickets, weedy grasslands and fields, roadsides, shrubby gullies, grain fields, birch and alder woodlands, orchards, abandoned landfills, hedgerows in agricultural areas, and suburban and urban gardens, particularly if bird feeders are present. Few occur in unbroken coniferous forests (Campbell et al. 2001). In the Yukon, it frequents shrubby areas in subalpine areas and at lower elevations. It is found along rivers, lakes, and wetlands and at forest edges, or in fairly open forests with an understorey of alders. Flocks often move along the tops of dense spruce forests, landing briefly to feed or rest (Sinclair et al. 2003).

During migration, the Redpoll feeds almost exclusively on vegetable matter, particularly seeds. It has been documented feeding on seeds of lamb's-quarters, grass seeds, grain in an open storage shed, and waste grain along railway tracks and near grain elevators. Birch seeds may be a staple during autumn migration (Campbell et al. 2001; Parmelee and MacDonald 1960; West et al. 1968b).

James (1991) considered the Redpoll a common to locally abundant migrant in the north and uncommon and erratic in the south. Largest flocks in the south often occur in February, but these may be spring migrants rather than birds that have spent the winter. Birds recorded on CBCs are more likely to be autumn migrants than winter residents.

WINTER

During winter irruptions, the Redpoll occurs mostly where the average minimum January temperature is below −12°C to −15°C (Root 1988). During extremely cold weather, it seeks areas that are sheltered from the wind, often in thickets of alder or willow in Alaska (Knox et al. 2024). It is a snow-associated species; important predictors of its presence are length of the snow season and absence of frozen ground without snow (Keyser et al. 2023). In the Yukon, it is most common at lower elevations in winter and most records are at bird feeders (Sinclair et al. 2003), suggesting that altitudinal migration may occur. Otherwise, winter habitat is similar to migration habitat. Where it remains north in winter, habitat used is similar to breeding habitat. The exceptions are that it withdraws from the High Arctic and areas above or close to the treeline and may be more prevalent in human settlements where there are feeding stations. In winter, it occurs within the Boreal Forest Region where it presumably seeks areas with plentiful birch and alder seeds. South of the normal wintering range during irruption years, it frequents similar areas as during migration. It may associate with other finches in winter such as the Pine Siskin and American Goldfinch (Austin 1968; Baldwin in Austin 1968; Knox et al. 2024).

Roosts are a very important habitat component in winter, particularly in more northern latitudes. In Germany, flocks of thousands have been observed roosting in spruce trees. The Redpoll also makes nocturnal roosting chambers in the snow. It excavates tunnels 27-40 cm long to a chamber 6-11 cm below the surface of the snow. When it leaves, it breaks through the roof of the chamber (Knox et al. 2024). In New York, Redpolls made temporary snow burrows during a cold (−15°C) and windy (32 km per hour) day. Birds excavated small burrows with their beaks and feet in a snow drift on a roof. Once the excavation was 5-7.5 cm deep, they turned around and roosted in them. Of the flock of 150-200, about half were engaged in this activity at any given time. As some left their burrows to go to feeders, others took up residence in the vacated burrows or displaced individuals already occupying burrows (Furness and Peterson 1987).

The Redpoll establishes a rigid social hierarchy in winter that remains constant until the development of sexual activities in late winter or early spring. Physical contact is rare and individuals simply avoid birds with higher status. This strategy results in no energy being consumed by aggressive encounters which is important to a species that experiences very cold winter weather. In winter, males are dominant to females. The hierarchy is linear from the most to least dominant male to the most dominant female down to the least dominant female (Dilger 1960).

Winter site fidelity of the Redpoll is very low, particularly south of the normal wintering area. Even where it consistently overwinters, site fidelity is low. Of 106 records of birds captured in 1 winter and recaptured in a subsequent winter, 5 were captured at the same location in the south and 56 in the northern wintering areas. At Fairbanks, Alaska, 16 of 5,200 birds (0.31%) returned; 0 of more than 1,800 returned in New Hampshire and 0 of 7,946 returned in New York. Many were recaptured further than 2,000 km from the original banding site and a Michigan bird was recovered in Russia. A few birds have been recovered in the south at the same location after having wintered somewhere else during the intervening year (Troy 1983; Yunick 1983a). In British Columbia, it is irregular and local in winter. Campbell et al. (2001) attributed this to its tendency to form large flocks so that most individuals from an area gather in relatively few locations. Its dependence on deciduous tree crops leads to concentrations in areas of high seed abundance. Once local seed crops are depleted, flocks move in search of another food source, thereby contributing to low site fidelity.

Conservation of energy is critical for a small bird wintering in harsh subarctic conditions. Many of the Redpoll's energy conservation measures are associated with its foraging behaviour and adaptations. It has a specialized diverticulum on the neck, a feature present in Redpolls and crossbills but absent in most other passerines. It fills the diverticulum with food just before nightfall and this provides the Redpoll with an additional source of energy over the night. When supplied with commercial food, the Redpoll's limits of temperature tolerance were −27°C to −38°C with both the lower and upper limits lower than for any other passerine studied. By substituting birch seeds, its natural food, its cold tolerance dropped to −51°C due to the high caloric value of the birch seeds. The amount of birch seeds that could be stored in the diverticulum and used at night would allow survival to −62°C compared with −30°C without it. The Redpoll is a common winter resident at Fairbanks, Alaska where temperatures occasionally drop to −60°C. Presence of the diverticulum is essential to its overnight survival. At a feeder, Redpolls hurriedly selected several seeds and stored them in the diverticulum. This reduced agonistic encounters at the feeder. Birds sought cover where

they shelled the seeds, thereby saving more energy while being concealed from predators. When feeding on birch seeds, it vigorously knocks seeds out of the catkins using its wings, legs, head, and tail. This burns more energy so this is completed as soon as possible. It then drops to the ground, quickly stores the seeds in the diverticulum and flies to shelter to shell and eat the seeds. Other adaptations it has for surviving cold weather include its abilities to increase digestive efficiency at very cold temperatures and to forage at very low light intensities (Brooks 1968, 1978). In Alaska, it fed on lamb's-quarters under the snow. Snow drifted over the plants but created tunnels and openings below the surface that allowed birds to access seeds. It digs small burrows in snow between foraging bouts during cold, windy periods (Furness and Peterson 1987). Feeding under snow allows it to access seeds and be sheltered from the elements (Cade 1953a). In the Mackenzie Delta, Redpolls disappeared during periods of stormy weather but reappeared on the first fine day even if the temperature was only -45°C (Porsild 1943).

In Algonquin Park, the Redpoll has fed on seeds of white birch, yellow birch, alder, white spruce, black spruce, and tamarack (Tozer 2012). Dance (2008) reported it feeding on black alder seeds in Oxford County. In Alaska, it feeds predominantly on seeds of alders and birches. In disturbed areas, it eats lamb's-quarters seeds and occasionally those of mustards and plants in the aster family (Cade 1953a). In Alaska, it consumed mostly birch seeds in winter but alder seeds comprised 25% of the diet (Knox et al. 2024). In winter in the Saskatoon area, redpolls eat seeds of a variety of weeds and grasses as well as those of shrubby cinquefoil, sunflowers, canola, flax, and birch (Leighton et al. 2002). Northern birds may feed on the seeds of willows (Clement in Austin 1968). Gabrielson (1924) analyzed 550 stomachs collected in winter in the United States. The diet consisted of 0.39% animal matter and 99.61% vegetable matter. The animal food included small cocoons that were probably those of clothes moths, fly larvae, bug eggs, and miscellaneous insect fragments. The vegetable matter was almost exclusively seeds, consisting of 34.62% alder seeds, 13.33% birch seeds, and 51.66% various weed seeds. Favourites included ragweed (24.7% of the diet), lamb's-quarters (11.81%), amaranths (4.79%), smartweeds, and catnip. Stomachs containing ragweed seeds were found throughout the northern United States indicating that it is actively selected. It also ate seeds of grasses and other species, fruits, and vegetable rubbish. Other seeds consumed included those of foxtails, timothy, panic grasses, sedges, willows, purslane, wintercress, blackberry, huckleberry, vervain, viburnums, knotweeds, love grass, amaranths, and beggar's-ticks.

The Redpoll is a common visitor at bird feeders. Different studies concluded that it prefers different seeds at feeders. In British Columbia, it is attracted predominantly to feeders with niger seed (Campbell et al. 2001). At a Massachusetts feeder, it selected millet over cracked corn, oats, barley, chick feed, buckwheat, hemp, and sunflowers. It stopped eating when the millet supply was exhausted and resumed when it was replenished (Knox et al. 2024). Results may have differed had niger seed been offered. In Canada and the United States, 7,945 observations of Redpolls feeding were made. The most abundant seeds eaten were 0.3-mm sunflower chips, 0.5-mm sunflower chips, and niger. It preferred hopper and tube feeders to platform feeders (Horn et al. 2014). In Saskatoon, it was attracted to feeders with niger, millet, black oil sunflowers, and flaxseed; it occasionally took suet (Leighton et al. 2002). Project FeederWatch data indicated that the favourite foods were hulled sunflowers and niger seed, but mixed seeds, black oil sunflowers, canola, water, and canary seed

were frequently eaten. Infrequently consumed foods included millet, cracked corn, suet, peanut butter mixes, bird puddings, baked goods, and milo. Once the Redpoll visits a feeder, it is likely to be faithful to it all winter, but the composition of flocks may change through the season. It tends to be most abundant and frequent at rural feeders (Dunn and Tessaglia-Hymes 1999). At a Yukon feeder, several gathered around a Pine Grosbeak that was eating sunflowers. Every time it opened a seed, the Redpolls quickly consumed the crumbs and occasionally snatched seed fragments from the grosbeak's bill (Sinclair et al. 2003). It also comes to sources of salt (Brooks 1978).

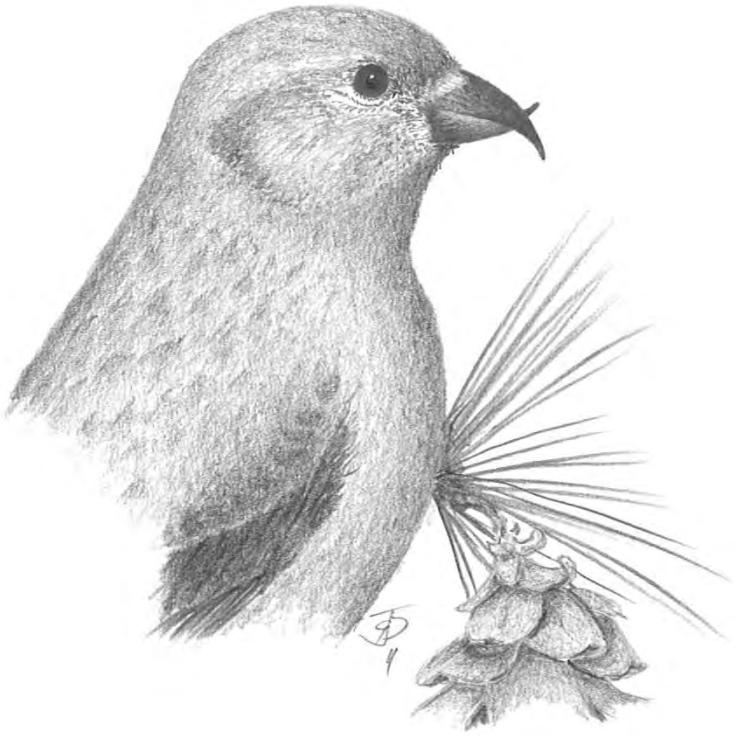
The Redpoll is attracted to roadsides by salt and sand in winter. Birds are frequently killed by vehicles as a result. It often strikes windows at houses in winter, particularly at residences with feeders (Campbell et al. 2001; Knox et al. 2024; Tozer 2012).

Salmonellosis killed large numbers of Redpolls in the eastern United States and Canada in early 1998 (Knox et al. 2024).

The Redpoll is a common winter resident in the north. In the south, it is erratic where it may range from absent to common or locally abundant. Numbers were highly irregular on southern Ontario CBCs 1929-77, with no apparent long-term trends to higher populations or more frequent occurrences (Freedman and Riley 1980). For 1970-21, CBC data indicated an annual increase of 0.50% in Ontario; from 2009-21, it decreased annually at a rate of 9.43% (National Audubon Society 2022).

Red Crossbill

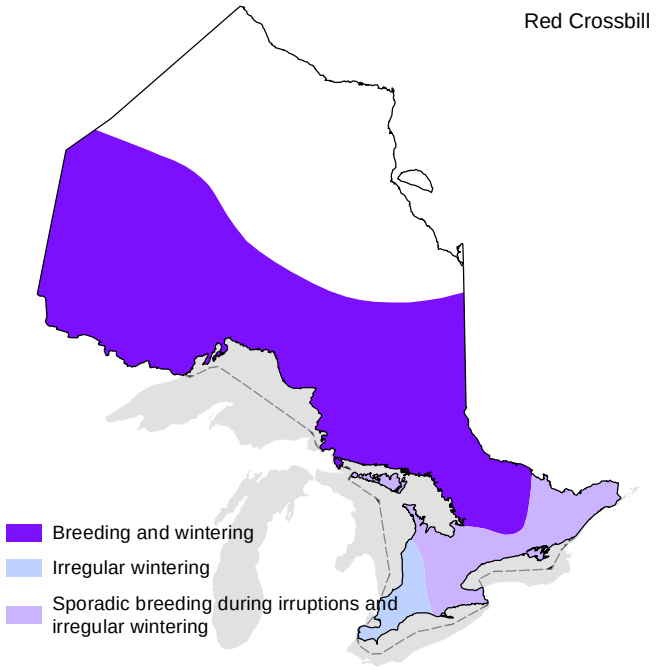
Loxia curvirostra



BREEDING SEASON

Habitat Requirements

Until 2011, the Red Crossbill consisted of a single species with 10 North American subspecies based on differing flight calls and bill morphology. The crossed mandibles are highly adapted to feeding on seeds that are extracted from conifer cones, with each bill type being highly efficient at extracting seeds from a particular species, or even subspecies, of conifer. Conifers and crossbills may co-evolve, with conifers developing cones that defend against seed extraction by crossbills and crossbills evolving their mandibles to become more efficient at removing seeds from cones. In Newfoundland, where the red squirrel was absent until the 1960s, crossbills and black spruce cones co-evolved over a period of 9,000 years. Black spruce cones in Newfoundland are longer, have more and heavier seeds, and thicker scales than those on the mainland where the red squirrel is the primary predator of seeds. The Newfoundland subspecies of the Red Crossbill has adapted a larger, deeper bill and is more efficient in feeding on black spruce cones in Newfoundland than on those from the mainland. The Red Crossbill is highly nomadic so 2 or more of the 10 different types may breed in a given location on occasion. When this occurs, birds selectively pair with birds of the same call type and very rarely with birds of another call type. Even where more than 1 call type regularly breeds in an area, bill types and flight calls remain constant with no evidence of birds with



intermediate characteristics. Many taxonomists are of the opinion that each call type represents an individual species (Benkman 1993a; Benkman and Young 2020; Edelaar and Benkman 2006; Groth 1988, 1993; Keenan and Benkman 2006; Parchman and Benkman 2002). Benkman et al. (2009) described what they considered a species distinct from the Red Crossbill in Idaho (the type 9 call of the Red Crossbill). It differed by feeding almost exclusively on the interior subspecies of the lodgepole pine. It has a deep bill that is highly adapted for foraging on these distinctive cones and is poorly adapted for foraging on cones of other conifers. All other types of Red Crossbills are highly nomadic whereas the Idaho species is very sedentary. Of more than 3,000 banded birds, none have been found outside of the 70 km^2 that supports this subspecies of lodgepole pine (Benkman 2011). In 2011, the American Ornithologists' Union concurred that these Idaho birds constituted a species distinct from the Red Crossbill and named it the Cassia Crossbill (Chesser et al. 2011). It is possible that the Red Crossbill will be further divided into additional species in future. Nonetheless, the habitat and behaviour of the 9 remaining types are similar except for their flight calls, bill structure, and the species of conifer seeds they are best adapted for foraging on.

Because of its specialized diet of conifer seeds, the Red Crossbill is restricted to breeding in areas that support conifers. In the Canadian Shield and Boreal Forest Region in Ontario, it is associated with coniferous and mixed forests. It typically nests in mature pine plantations south of the Shield. In the Boreal Forest Region, it is associated with spruces but it is more common in the Great Lakes–St. Lawrence Forest Region in the Shield where it frequents areas dominated by red and white pine. Ontario birds are predominantly larger-billed type 2 birds (the Ponderosa Pine Red Crossbill). Smaller-billed type 3 birds (the Western Hemlock Red Crossbill) may occur during irruptions; they are usually associated with hemlock or spruce. Type 1 (the Appalachian Red Crossbill) and type 7 (the Enigmatic Red Crossbill) also occur in Ontario during the breeding season, often following irruptions (Benkman and Young 2020; Lumsden and Smith in Cadman et al. 1987; Peck and James 1987; Simard in Cadman et al. 2007).

In the Clay Belt in the Boreal Forest Region, Welsh and Lougheed (1996) detected the Red Crossbill in only 2 of the forests they studied. Both were wet, nutrient-poor black spruce stands.

In the Shield portion of the Great Lakes–St. Lawrence Forest Region near Gogama, the Red Crossbill was numerous in jack pine stands, but only when jack pine budworms were abundant (James and Peck 1995a). At Pimisi Bay near North Bay, it nested in second-growth white pine and

red pine forests with lesser amounts of jack pine, balsam fir, white cedar, white spruce, and black spruce. Scattered deciduous trees among the conifers included white birch, yellow birch, trembling aspen, and large-toothed aspen; the understorey consisted of maples, willows, alders, and other shrubs (Lawrence 1949b). It was common in scattered locations within Algonquin Park, usually where there were tall pine trees (MacLulich 1938). Benkman (1987a) studied the Red Crossbill in 2 stands in the park. The conifer composition of the first stand was 58% white pine, 25% black spruce, 4% balsam fir, 6% white pine, 5% red pine, and 2% jack pine. The second stand was comprised of 1% white spruce, 84% white pine, 14% red pine, and 1% jack pine. In white pine stands in Algonquin Park, it occurred in 8.3% of 2-9-year-old shelterwood cuts, 9.1-10% of 10-16-year-old cuts, and 14.3-20.0% of stands with no recent history of cutting (Kingsley and Nol 1999). In Lanark County, it nested in an area of spruce and white pine where there was a heavy cone crop (Ross and Ross 1950). Nests have been found in large pine plantations in the Kingston area (Weir 2008).

In North America, the Red Crossbill breeds predominantly in mature coniferous and mixed forests, but only where there is an abundant supply of conifer seeds. The preferred species of conifer varies geographically and also with the type of crossbill. Spruce, pine, and hemlock species are the more important coniferous trees. Firs are important in the west but not in the east. Red and white pine stands are important in the east but it also nests in pitch pine stands. In the Yukon, it breeds mostly in lowland coniferous forests, white spruce forests, mixed conifers, and lodgepole pine stands; it occasionally breeds in black spruce forests. It prefers more open woodlands for nesting. During irruption years when it breeds south of its typical range, it may nest in anthropogenic habitats such as white or red pine plantations, linear strips of conifers on golf courses and similar habitats, and isolated trees in suburban areas and on university campuses. In British Columbia, 58% of nests were in mature coniferous forests and 38% were in treed suburban or rural areas (Austin 1968; Benkman and Young 2020; Bielefeldt and Rosenfield 1994: Campbell et al. 2001; Erskine 1977; Hagar 1960; Haggerty 1982; Johnson 1969; Leighton et al. 2002: Létourneau in Gauthier and Aubry 1996; Messineo 1985; Sinclair et al. 2003; Snyder 1951).

At night, the Red Crossbill roosts in dense foliage of conifers (Benkman and Young 2020). Birds of a captive nonbreeding flock preferred to roost in thick foliage of pine and cedar branches. In pine, they roosted in thick clumps of needles at the end of branches. No more than 1 or 2 birds roosted on the same twig (Tordoff 1954).

Lawrence (1949b) found 4 nests near Pimisi Bay: 2 in white spruce and 1 each in white pine and red pine. Nests were 7.0-10.7 m from the ground and 0.9-2.4 m from the tree trunks on a horizontal branch. Two nests were within 23 m of each other. One female was observed taking material from an old Red-eyed Vireo nest, but it was unknown if the material was used in nest construction. A nest near Pakenham was 6 m from the ground in a 9-m-tall white pine and 0.9 m from the trunk on a horizontal branch (Ross and Ross 1950). A nest in Algonquin Park was 18 m from the ground in a white pine and a Durham Region nest was 15 m from the ground in a red pine in a red pine plantation.

Almost all North American nests were in conifers. In British Columbia, 96% of nests were in conifers but it was not specified where the other nests were. A nest on a Minnesota university campus was in a white ash. In the east, the Red Crossbill commonly nests in pines (predominantly

red and white pines, but occasionally in pitch pine and possibly jack pine), white spruce, black spruce, and hemlock. There is a record of it nesting in a cedar tree in New York City and a Massachusetts nest was in a clump of ornamental Japanese black pines. Most nests are saddled on a horizontal branch but they are occasionally near the top of a conifer among thick tufts of needles and cones. Nests on branches are usually distant from the trunk and concealed from above by small boughs and clumps of needles. Often they are situated so that they receive sunlight the entire day. Nests have been reported 1.2-20 m from the ground; most British Columbia nests were 6-10.5 m from the ground. It occasionally nests in dead spruce trees, but only if there is abundant beard lichen for nest concealment. There is 1 report of a nest being reused in a subsequent year, but nests are typically used only once (Austin 1968; Benkman and Young 2020; Campbell et al. 2001; Haggerty 1982; Johnson 1969; Létourneau in Gauthier and Aubry 1996; Snyder 1951).

The Red Crossbill does not appear to be territorial. It occurs in flocks whether it is breeding or a vagrant and is social at all times. Breeding pairs may still remain part of a flock. Solitary nesting occurs, but typically a few to several pairs nest together with nests 20-100 m apart. At Pimisi Bay, strange crossbills often landed in nest trees. No battles ensued when this occurred. The territory consisted of nothing more than the nest tree and defence of it was low-key. There may be conflicts over cones, roosts, and perch sites, but these are more prevalent in the nonbreeding season. During courtship, disputes over mates may lead to chases and occasionally fighting, including aerial tumbling flights. It has a large home range, routinely travelling distances of more than 500 m to exploit food resources. At Pimisi Bay, birds travelled in excess of 800 m on each flight to obtain food and regularly flew at least 1.6 km to feed on road salt (Benkman and Young 2020; Jollie 1953; Lawrence 1949b).

There is no information on natal philopatry, but it is probably extremely low or nonexistent. Natal philopatry is highly unlikely to occur because conifers are usually unable to produce bumper crops of cones in successive years. Brewer et al. (2018) reported no recoveries of hatch-year birds in Canada.

Adults are nomadic and exhibit no breeding site fidelity. Birds typically breed in an area until the conifer seed crop is depleted then move to another area. Most conifers set seeds in alternate years with good crops at greater intervals. An exception is the interior subspecies of the lodgepole pine, which provides a consistent source of seeds. This has resulted in the evolution of the resident Cassia Crossbill that feeds exclusively on its seeds. No North American Red Crossbills have been recovered at the same location in a subsequent year. Some have been documented breeding more than 2,000 km from the breeding area where they were banded (Benkman 2011; Benkman and Young 2020; Brewer et al. 2018; Cornelius and Hahn 2012; Senar et al. 1993).

Limiting Factors

The timing of Red Crossbill breeding is linked to when conifer seeds are abundant and, to a lesser extent, photoperiod. In North America, it has nested from January through October and in December. Eggs may occur in Ontario nests from February to mid-August with most reported in April, but this is based upon a small sample size. Nesting is known to occur in the province in 2 periods: late summer to early autumn (late June to October) in response to maturing cones and in late winter (mid-January to May) where seed crops are maintained. In Algonquin Park and New York, timing of breeding was related to when there were sufficient conifer seed resources to raise

nestlings. When seed abundance was increasing, breeding was initiated before the crop was sufficient to support nestlings. In Algonquin Park, late summer breeding is associated with heavy crops of white spruce seeds. Once white spruce seeds decline in abundance, it switches to white pine seeds and finally to red pine seeds if the white pine seed crop becomes depleted. Cones of these pines begin opening in September and October. If there are insufficient pine seeds, it may emigrate as early as November. In Quebec, birds breed in jack pine stands in June and July, and this may be the case in Ontario. Photoperiod may play a minor role in the timing of breeding. In some areas, breeding may cease once there are 10.5 hours of daylight. In Ontario, the Red Crossbill could conceivably nest in spruce from August into October, in red and white pine in September and October and from mid-December to April, and in jack pine in June and July. Further study is required to determine the actual timing of Red Crossbill nesting in Ontario. When seeds are abundant, a population may breed in an area for approximately 9 months; it is unknown how long individual birds may continue nesting (Benkman 1987a, 1990; Benkman and Young 2020; Kemper 1959; Létourneau in Gauthier and Aubry 1996; McCabe and McCabe 1933; McNair 1985; Messineo 1985; Peck and James 1987; Tordoff and Dawson 1965; Tozer 2012). In Algonquin Park, nests have been found under construction from late December to early June; dependent fledglings have been observed from mid-August to late October (Tozer 2012).

In 1 case, a female dismantled an old nest and used it to construct a new one. The nest takes 3-5 days to build and 1-5 days may elapse between nest completion and laying of the first egg. One egg is typically laid per day but occasionally a day may be skipped. In cold weather, incubation starts with the laying of the first egg. It is not initiated until the last egg is laid in warmer weather. The male feeds the incubating female so that she does not have to leave the nest often or as long during cold weather. The incubation period at 1 Ontario nest was 13 days, 12 or 14 days at another depending upon when incubation was initiated, and 14 or 15 days at a third nest. Elsewhere, incubation periods of 12-16 days have been reported, with most eggs hatching in 14 days. Newly hatched young are covered with down which allows them to withstand temperatures below freezing for short periods. When it is very cold, young may become torpid and must be brooded to restore their metabolism before they can be fed. The nestling period at a Pimisi Bay nest was 17 days. Overall, young have been reported remaining in the nest for 15-25 days, occasionally as long as 35 days. The large variation in nestling periods is probably related to food abundance (Austin 1968; Benkman and Young 2020; Campbell et al. 2001; Haggerty 1982; Johnson 1969; Lawrence 1949b; Létourneau in Gauthier and Aubry 1996; McCabe and McCabe 1933; Peck and James 1987; Ross and Ross 1950; Snyder 1951).

The Red Crossbill is commonly double-brooded when conifer seeds are abundant. It is capable of raising 4 broods in succession in captivity, so it is possible that it does so in the wild. Although it has never been documented, it is possible that it may breed in 1 location then move hundreds of kilometres to breed in another location within the same year. Replacement clutches may be laid in a new nest if the first clutch is lost. Ontario clutches contained 2 or 3 eggs. Elsewhere, the clutch size is commonly 3 or 4 eggs, with clutches of 2 eggs uncommon and 5- and 6-egg clutches exceptional (Austin 1968; Benkman and Young 2020; Campbell et al. 2001; Johnson 1969; Lawrence 1949b; McNair 1988; Peck and James 1987; Ross and Ross 1950).

Both sexes are capable of breeding when they are less than 1 year old. Pairs in juvenile plumage have successfully fledged young in Ontario. Nonbreeding pairs are common during most of the year and some pairs apparently do not breed, probably due to inadequate seed supplies. Birds are apparently monogamous, with no records of polyandry, polygyny, or extra-pair fertilizations. Very little information is available on the mating strategies, however (Benkman and Young 2020; Lawrence 1949b; McCabe and McCabe 1933).

The crossed mandibles of the Red Crossbill are adapted specifically for removing seeds from conifer cones. Crossbills are the only species that can remove seeds from closed conifer cones. Each subspecies has a differently sized bill and palatine grooves and is best adapted for feeding on different species of conifers. The specialized bill results in it being inefficient at feeding on items other than conifer seeds. The entire ecology of the Red Crossbill depends on conifer seeds. It is adapted to extreme variations in conifer seed crops through nomadism, early onset of sexual maturity, rapid succession of broods, long potential breeding seasons that may include the shortest days of the year, tolerance of repeated cooling and extremely low temperatures, and slow development of young when food is scarce. The dependence upon conifer seeds can be costly. During major irruptions south into areas with predominantly deciduous cover, massive mortality may occur due to its low ability to exploit other food resources. These irruptions may result in the establishment of new populations. Extensive planting of red pine in the Great Lakes region resulted in colonization by a western subspecies. It has adapted by decreasing its bill size to extract seeds from the smaller cones of the red pine relative to the conifer species that it exploits in the west. There may be high mortality of young shortly after they reach independence because of their inexperience at extracting seeds (Benkman 1988a, 1993b; Benkman and Young 2020; Cornelius and Hahn 2012; Erskine 1977; Gabrielson 1924; Holoman et al. 1998).

The Red Crossbill often hangs upside down on attached cones or adjacent branches to probe for seeds. On hemlock, it tends to leave cones attached, turning and holding them upright with 1 foot. On pines, it sometimes detaches the cones by twisting or biting the stalk of the cone and holding it to extract the seeds. Cones that have fallen to the ground may be an important source of seeds in spring after snowmelt. The crossed mandibles are used to open the cone scales to expose the seeds. The palatine grooves in the bill are used to husk the seeds. It stores food temporarily in its crop when feeding nestlings or going to the night roost; the crop is capable of holding about 300 spruce seeds (Benkman 1987b; Benkman and Young 2020; Hess et al. 1998). At Pimisi Bay, it often hopped along the branches of pines much in the manner of a Red-breasted Nuthatch, searching for insects in bark crevices. A male captured a flying insect in flycatcher style (Lawrence 1949b). Hess et al. (1998) observed it gleaning on bark. It has fed on fallen almonds in an orchard, on woolly aphids in curled-up elm leaves by cutting open the cases with the bill, on woolly aphids within galls that it split with its bill, on caterpillars feeding in hemlock cones, on aphids on Manitoba maple, and on seed heads of common dandelion and other herbaceous species (Austin 1968).

The Red Crossbill selectively seeks tree species and individual trees and cones that provide the most profitable foraging. These include the conifer species that its bill is best adapted for removing seeds from the cones, trees with the heaviest crops of cones, and cones with the greatest number of seeds. As the seeds of its preferred conifer species become depleted, it may switch to another

species or move to another location. Trees with heavy cone crops are selected and may be exploited by a flock for several days until the number of seeds is diminished and the tree is no longer a profitable foraging site. Trees with sparser cone crops within a few metres of a tree laden with cones may be completely avoided. In Algonquin Park, birds forage initially on white spruce seeds but switch to white pine seeds when spruce seeds decline. If white pine seeds become depleted, it switches to red pine seeds. Birds foraging in Algonquin Park foraged on the most profitable conifer 53.8% of the time; 85% foraged on the most profitable conifer more than 60% of the time. Flocking enhances the profitability of foraging and provides maximum avoidance of predators. Flocks spend less time on unprofitable trees and find trees with good seed crops faster than individual birds. When husking seeds, birds raise their heads, allowing them to detect predators. The larger the flock size, the more likely a predator will be detected (Benkman 1987a, 1988b; Benkman and Young 2020; Smith et al. 1999).

Despite being highly social, the Red Crossbill may be aggressive while foraging. In a laboratory, the dominant bird often remained perched while others pried open the cone. The first bird to obtain seeds was invariably replaced by the dominant bird (Benkman 1988b; Hess et al. 1998). There is a pecking order in both males and females with a general dominance of all males over females. The pecking order is maintained predominantly by threat displays. Fighting may occur and this usually involves biting. Often threatening is not required and subordinate birds simply avoid dominant birds. Age and size are unimportant in determining dominance (Tordoff 1954).

Red and White-winged crossbills often forage together in the same flocks. White-winged Crossbills are dominant to Red Crossbills. After taking flight, mixed flocks often separate into Red Crossbill and White-winged Crossbill flocks. The 2 species of crossbills tend to forage on different species of seeds due to their differing bill sizes and efficiency rates of extracting seeds from different conifers. The Red Crossbill is more efficient at husking seeds of pines and hemlock than the White-winged Crossbill; the converse is true for the smaller seeds of spruce. Food overlap between the 2 species of crossbills is highest in summer when both forage on white spruce seeds. The rest of the year, the diet of the 2 species diverges. The large-billed type 2 Red Crossbill that is the most common subspecies in Ontario feeds predominantly on pine seeds; the White-winged Crossbill feeds mostly on white spruce, black spruce, and tamarack seeds. Red Crossbills are found mostly in stands dominated by pines and forage mostly on pines in mixed conifer stands. White-winged Crossbills inhabit mostly spruce stands and target spruce seeds in mixed conifer stands. Diet overlap between the 2 species may be 100% in late summer when both feed on white spruce seeds but this is a time when food abundance is high and increasing. Dietary overlap declines in late autumn and is nonexistent by late winter. There may be competition between the smaller subspecies of Red Crossbill and the White-winged Crossbill because hemlock seeds may be important to both their diets. In Alaska, where the small subspecies of Red Crossbill is present, the 2 species do not occur together (Benkman 1987a, 1988b; Benkman and Young 2020; Hess et al. 1988).

Other finches feed on conifer seeds and the Pine Siskin may join foraging flocks of Red Crossbills. Crossbills are the only finches that can remove seeds from closed cones. When seeds are readily available in open cones, the other finches have similar foraging rates as the crossbills, but crossbills require seed-encounter rates 2-3 times higher than the other finches. The other finches may

outcompete crossbills by lowering seed abundance below levels necessary for their survival (Benkman 1988a).

Both adults feed the nestlings by regurgitation. The male also feeds the female by regurgitation during incubation and the early nestling period. During courtship feeding, the male may offer the female salted grit and aspen buds. The material fed to young is a dark viscid paste that suggests that it may contain insect material, although this has not been substantiated. Nestling food that has been confirmed consisted of conifer and sunflower seeds that adults collected from feeders (Benkman and Young 2020; Haggerty 1982; Johnson 1969; Lawrence 1949b; McCabe and McCabe 1933).

In Algonquin Park, the most common subspecies of the Red Crossbill is type 2, which has a large bill, but type 3 is also present and it has a small bill. Type 2 birds feed on white spruce seeds in late summer and early autumn. These cones open in early September and intake rates of these seeds decline as they become depleted. Type 2 birds are fairly inefficient at feeding on white spruce and switch to white pine seeds as foraging profitability of spruce seeds declines and abundance of white pine seeds increases. When white pine seeds remain abundant, foraging on them may continue from mid-September to October, when cones contain an average of more than 10 seeds, to mid-June when only 0.19 seeds are present per cone. When the white pine crop becomes depleted, type 2 birds switch to red pine seeds. The smaller type 3 birds in Algonquin Park prefer white spruce and hemlock seeds. Throughout its range, this type appears to prefer to forage on hemlock, and foraged on it in Algonquin Park from December until the end of February (Benkman 1987a, 1988b; Tozer 2012). At Pimisi Bay, birds fed first on seeds of balsam fir and had emptied the cones by the end of December. Balsam fir seeds became an important food source again when the snow melted and uncovered seeds on the ground. It appeared to feed mostly on white pine seeds but also ate black spruce seeds. In addition to conifer seeds and dormant insects, it ate buds of aspens and birches and dried and frozen fruit of cranberries, wintergreen berries, and Canada mayflower berries (Lawrence 1949b). Conifer seeds are the most important food items in the diet. The preferred seeds vary geographically, by subspecies, and time of year. Outside Ontario, it has fed on white pine, Virginia pine, red pine, pitch pine, jack pine, white spruce, black spruce, Norway spruce, European larch, hemlock, mountain pine, and scotch pine. In addition, it eats staminate cones of conifers. It occasionally feeds on seeds, catkins, or buds of deciduous or herbaceous species such as yellow birch, tulip tree, sweet gum, cow parsnip, chokecherry, alders, willows, poplars, elms, and maples. It eats sunflower seeds which it may take directly from the plants or from bird feeders. It eats suet and hemp seeds at feeders. In Hamilton, it was observed digging seeds out of a squash that had been left out all winter (Austin 1968; Benkman 1987a; Benkman and Young 2020; Campbell et al. 2001; Haggerty 1982; Heck 1996; Hess et al. 1998; Létourneau in Gauthier and Aubry 1996; McIlwraith 1894; Messineo 1985; Sinclair et al. 2003; Snyder 1951; Tordoff 1954). In California from autumn to spring, the diet consisted of 1% insects by volume and the remainder was conifer seeds and other vegetative matter. It has eaten caterpillars, woolly and other aphids, and insects in galls of poplars and junipers (Benkman and Young 2020; Haggerty 1982). Budworms may be important in its diet. Near Gogama, it was abundant in jack pine forests when jack pine budworms were abundant, but absent once the budworms disappeared (James and Peck 1995a). On Anticosti Island, the crop of 1 bird was full of spruce budworms. Tremblay et al. (2018) concluded that budworm infestations may have influenced its foraging behaviour and that it may benefit from outbreaks by feeding on larvae.

Twenty percent of observations of Red Crossbills were in infested stands and 75% were within 1 km of an infested area. Gabrielson (1924) analyzed the contents of 243 stomachs: 202 were collected from November to April. The winter diet consisted of 96.47% conifer seeds and 96.0% of stomachs contained nothing else. Variation in its diet appeared to be geographical rather than seasonal. Pine seeds represented 78.29% of the winter diet (Virginia, ponderosa, white, and red pines), but it also consumed white spruce, black spruce, and hemlock seeds. In March, 1 stomach was filled with ragweed seeds and 2 contained 100% and 80% mast. Other vegetable matter included bits of wood, pine needles, and unidentified seeds. Animal food constituted only 1.07% of the winter diet and included spiders, caterpillars, and fly larvae, all of which may have been ingested incidentally. The summer food in 41 stomachs included 81.98% vegetable matter and 18.02% animal matter. Conifer seeds were found in 31 stomachs (75.6%) and constituted 68.34% of the diet. Other vegetable matter included seeds of a bulrush species and a plant in the aster family (1.69%), unidentified fruit pulp and skins (4.88%), and wood and debris (7.07%). The insect material consisted of 8.65% caterpillars plus 1 moth, 6.56% bugs (aphids and spittle bugs), 2.09% beetles (mostly weevils, but 1 click beetle larva), and less than 1% fragments of hymenopterans, an insect gall, and insect eggs. It has eaten ants, aphids, mourning cloak butterfly caterpillars, frozen apples, cottonwood buds, forest tent caterpillars, beechnuts, flowering crabapple fruits, and buds of apple, pear, and cherry trees. Results indicated that conifer seeds were the most important food items.

Minerals are important in the diet of the Red Crossbill. It routinely eats grit and other materials that contain calcium or sodium. It has been documented feeding where dishwater has been thrown on the ground, on snow discoloured by dog urine, on coal ashes and ashes of campfires, eating mortar from chimneys, and eating small bones. It is highly attracted to sources of salt. These may include roads that have been salted, beaches of saline water bodies, and shorelines of wetlands and water bodies where decomposing aquatic plants may provide a source of sodium and calcium. It also visits natural salt licks (Benkman and Young 2020; Campbell et al. 2001; Lawrence 1949b; Tozer 1994). Lawrence (1949b) concluded that salt consumption was not a daily necessity and that it might be restricted to the breeding season. No salt was eaten during snowstorms or rainy weather, but salty areas were visited by greater numbers of birds on days immediately following these events. In a laboratory experiment, it preferred 0.1 mole (M) sodium chloride and avoided 0.2 M sodium chloride. Dawson et al. (1965) concluded that it has no requirement for sodium chloride beyond what it eats in its diet. Its primary source of salt is roads and shoulders of roads. It is oblivious to traffic and large numbers are killed by vehicles every year (Benkman and Young 2020; Clark 1981; Lawrence 1949b; Messineo 1995; Tozer 2012).

Water is essential to the Red Crossbill; it drinks water or eats snow daily (Benkman and Young 2020; Lawrence 1949b).

Timber harvesting may be the most significant limiting factor for the Red Crossbill. Extensive deforestation occurred in the northeastern United States and Canada around the turn of the 20th century. Pines were particularly prized because they were excellent for ships' masts. The northeastern subspecies was almost extirpated as a result of this, but has somewhat recovered since, probably due to maturation of second-growth pine and hemlock (Dickerman 1987). Tozer (2012) estimated that white pine was 85% less abundant in Algonquin Park than in the 1880s. In

Newfoundland, this crossbill prefers old-growth black spruce forests. Both red and white pines may have previously provided important habitat, especially since this subspecies has a large bill better adapted to feeding on pine than spruce seeds. Both pine species were harvested extensively and continue to decline as a result of diseases. The minimum rotation age for harvesting on the island is 65 years and more frequently 80 years. Good cone-bearing usually begins at age 40 years for the conifers on the island and would therefore be available for 25-40 years prior to the next harvest. The potential effects of forest management on the Newfoundland Red Crossbill appeared to be understated in the recovery strategy (Sutton 2006). This subspecies is best adapted to foraging on pines which are now scarce and declining further. It currently forages mostly on black spruce cones. The red squirrel outcompetes the crossbill for seeds and squirrel densities are 2 times higher on Newfoundland than on the mainland (Benkman 1993b). In Washington and Oregon, only 10% of the original old-growth forest remains; only 2% remains in Alaska. The Red Crossbill is 30 times more abundant in old-growth (325 to more than 500 years old) forests on the western coast than in younger forests 65-140 years old. Older trees produce many more cones and are more consistent in producing cones than younger trees. In Alaska, birds foraged or perched only in mature stands. During extensive cone failures, only mature trees can support the Red Crossbill for extended periods. To protect it and prevent further declines, it has been recommended that large tracts of mature forests be protected and that rotation ages be increased (Benkman 1993b; Benkman and Young 2020; Holoman et al. 1998). It is highly vulnerable to changes in its habitat due to its reliance upon a single source of food. Loss of habitat generally results in a disproportionate decline in crossbills (Benkman 1993c).

Outbreaks of the larch cone maggot can severely decimate seed crops and cause the Red Crossbill to cease nesting and emigrate (Benkman 1990).

In Colorado, a massive die-off occurred as a result of salmonellosis. Several hundred dead birds were reported but the actual mortality toll could have been several thousand (Heck 1996).

Climate change is having an adverse effect on the Red Crossbill, at least in the west. Because of increasing temperatures, conifers are prematurely shedding seeds from their cones. According to the Breeding Bird Survey (BBS), numbers began to decline in 1980 when temperatures started to increase. Since then, it has increased 20-fold at feeders. Benkman (2011) predicted that it would continue to decline as a result of increasing temperatures, but that a higher proportion of birds would visit feeders in response to lower availability of conifer seeds.

Status

Type 2 birds, which are associated with pines, and type 3 birds, which are associated with spruce and hemlock, breed in the province. Type 4 (the Douglas Fir Red Crossbill) probably also breeds (Tozer 2012), mostly during irruptions and primarily in the area between Lake of the Woods and Thunder Bay, and type 7 breeds in central Ontario (Benkman and Young 2020). Baillie and Harrington (1937) noted that no nests had been reported, but breeding had been confirmed in Bruce, Nipissing, York, and Algoma. The Red Crossbill had been seen as far north as Hudson Bay leading them to conclude that its breeding range might include the entire province. The first atlas revealed that its breeding distribution was confined mostly to the Great Lakes–St. Lawrence Forest Region, predominantly in the Canadian Shield but also in more heavily forested areas south of the Shield.

There were scattered records in the southern Boreal Forest Region and in the northwest portion of this area. There were a few breeding records from the Carolinian Forest Region, mostly associated with mature conifer plantations in the Long Point area (Lumsden and Smith in Cadman et al. 1987). The breeding distribution of the Red Crossbill corresponds closely with the ranges of white pine and red pine (Kershaw 2001). During the initial 3 years of the first atlas, cone crops were poor and few breeding records were documented. Cone crops were excellent in 1984 and there were more breeding records in that year than in the 3 previous years combined. Additional breeding records were obtained in 1985 as a result of the carryover of the good pine and spruce seed crops (Lumsden and Smith 1987). James (1991) considered the Red Crossbill an uncommon permanent erratic resident across the province, north to Sandy Lake and Cochrane and south to Algonquin Park. It is occasional and rare in summer north to Fort Severn and Sutton Lake, and south to Norfolk and Haldimand counties. From autumn to spring, it is a rare to common erratic south to Lake Erie.

The second atlas revealed a similar distribution as in the first atlas, but there was no evidence of type 3 breeding due to a lack of a good crop of hemlock during the atlas. No breeding evidence was obtained for the Carolinian Forest Region. The probability of observation did not differ province-wide between the 2 atlases, but a significant decline occurred in the Great Lakes–St. Lawrence Forest Region south of the Shield and a significant increase occurred in the Boreal Forest Region (Simard in Cadman et al. 2007).

There are no reliable population estimates for the Red Crossbill anywhere within its range (Benkman and Young 2020). The BBS is conducted at a time when it is least likely to be breeding. Winter counts may include breeding birds as well as those that have irrupted from other areas. Its lack of site fidelity and extreme nomadism pose further constraints to estimating population numbers.

There are BBS results for the Red Crossbill, but they may not be very accurate. Data for 1970-2021 indicate that it decreased at an annual rate of 0.0415% in Canada and increased at an annual rate of 2.06% in Ontario. For 2011-21, it experienced annual decreases of 1.54% in Canada and 0.518% in Ontario. The Canadian results were of medium reliability; the Ontario results were of low reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Fledglings from a Pimisi Bay nest remained in the nest tree their first day out of the nest. The next day, they flew to the edge of a lake but were not capable of flying horizontally, losing altitude as they went. Fledging occurred in late April and flying juveniles were observed throughout May. Family groups were joined by nonbreeding birds and failed breeders. Flocks consisted of 4-6 adults and 1-2 juveniles. These groups amalgamated by the end of May, with flocks containing as many as 2 dozen birds (Lawrence 1949b). In Idaho, birds began to congregate and move about as soon as the young left the nest (Jollie 1953). Young may return to the nest to roost for some days after leaving the nest. They waited in trees for several days after fledging to be fed but families were fairly mobile within a week (Benkman and Young 2020).

Lawrence (1949b) observed no pairs with more than 2 fledglings, suggesting that about half the young did not survive. If a female lays a second clutch, the male cares for the first brood. Adults may

feed the young as long as 33 days after they fledge. Juveniles are capable of extracting and shelling seeds when they are 45 days old (Benkman and Young 2020).

MIGRATION

The Red Crossbill appears to undertake regular migrations. Birds have a peak of fat deposits in May and June suggesting that spring movement is true migration. Migration is nomadic in nature, being variable in distance and direction. This differs from nomadic wandering with no preparation or seasonal scheduling (Cornelius and Hahn 2012). It makes 1-3 movements annually with spring movements more regular than those in autumn. Large flocks often occur in May and June and in September and October. In British Columbia, there is evidence that it withdraws from northern areas in winter. Most flights occur during the regular migration periods, but they may occur at any time of the year. Migration appears to occur only during the day (Benkman and Young 2020; Campbell et al. 2001).

The Red Crossbill occasionally undertakes nomadic irruptions. These involve long-distance movements within the Boreal and Great Lakes–St. Lawrence forest regions. Birds often move much further south into areas dominated by deciduous trees, where they are at risk of starvation. Irruptions into Ontario typically include type 3 and 4 birds, and additional type 2 birds may invade the province. Type 10 (the Sitka Spruce Red Crossbill) may irrupt to the Great Lakes area and the northeast where it feeds on red and white pines as well as jack and pitch pines. Irruptions may occur at any time of the year, but especially from late summer through winter. Irruptions are in response to poor conifer seed crops. Seed crop failure tends to be synchronous over large areas at scales of hundreds to thousands of kilometres. Birds tend to undertake long movements during irruptions. Birds from the Pacific Northwest and Alaska may irrupt to the Great Lakes area. Breeding may occur in areas outside its normal breeding range following irruptions provided that there is still a good seed crop. There is unlikely to be any consistent direction of flight during irruptions and birds stop when they encounter a plentiful seed source rather than flying to regular destinations (Austin 1968; Benkman 1987a; Benkman and Young 2020; Bock and Lepthien 1976b; Cornelius and Hahn 2012; McNair 1988).

In Ontario, most conifer seeds form in summer and are shed in autumn. Seeds are usually available to crossbills between July and October. Black spruce cones may carry seeds for a number of years. For any given species of conifer, heavy seed crops rarely occur in the same location in successive years. Tamarack may produce a good crop every 3-6 years, white spruce every 2-8 years, and white pine every 3-10 years. Asynchronous seed production among different conifer species may provide food availability in successive years, but emigration is required when this does not occur (Lumsden and Smith 1987). Brewer et al. (2018) reported that irruptions into the eastern United States occurred about once every 10 years. Freedman and Riley (1980) analyzed Christmas Bird Counts (CBC) for southern Ontario for 1929-77. There was no pattern in occurrences of the Red Crossbill or trends in its numbers. In the Hamilton area, modest numbers occurred about every other winter for 15 years beginning in the winter of 1950-51; birds were observed every winter from 1965 to 1974. After 1988, only 19 individuals were seen within 5 winters (Curry 2006). In the Kingston area, it was documented in 40 of 60 years; many were migrants that passed through the area (Weir 2008).

In Elgin County, most records are in March and April. It has occurred from 26 December to 7 June (Lancaster et al. 2004). In the Hamilton area, average spring departure is 31 March and the latest record is 12 June. Average autumn arrival is 6-28 November and the earliest record is 25 September (Curry 2006). At Presqu'ile, the Red Crossbill occurs irregularly from early November to mid-May, and there are 3 summer records. Extreme dates of occurrence outside summer are 6 November to 12 May (LaForest 1993). In the Kingston area, average spring departure is 28 March and average autumn arrival is 6 November (Weir 2008).

NONBREEDING SEASON

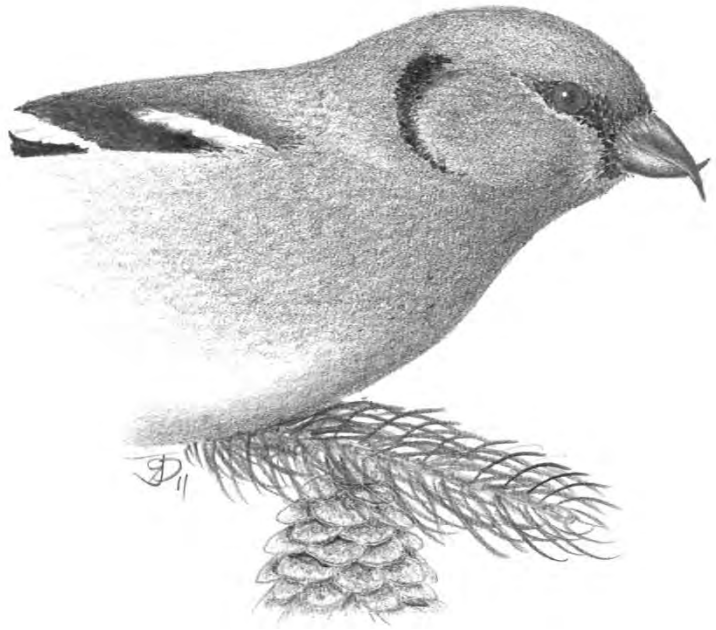
It is difficult to determine what constitutes the nonbreeding season for the Red Crossbill. It may potentially nest in most months of the year, but nonbreeding pairs may also be present all year. In Ontario, nonbreeding areas include the southern portion of the province where birds may overwinter during irruption years. Some of these birds may remain and subsequently breed.

During winter in the south, the Red Crossbill continues to be associated with conifers. It is found most frequently in mature coniferous plantations but may occur in solitary rows of conifers in windbreaks and on suburban and urban lots.

CBC data indicate that the Ontario Red Crossbill population increased at annual rates of 1.21% 1970-2021 and 13.12% 2009-21 (National Audubon Society 2022).

White-winged Crossbill

Loxia leucoptera



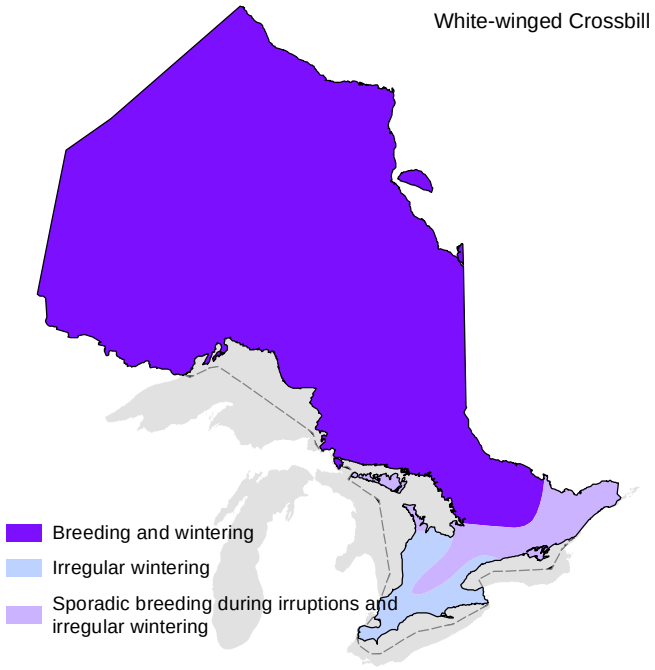
BREEDING SEASON

Habitat Requirements

White-winged Crossbill nests in Ontario were in coniferous forests (2 nests), coniferous plantations (1 nest), in mixed second-growth forests (3 nests), and in mixed Carolinian Forest Region woods (1 nest). These nests are not representative of its habitat in the province (Peck and James 1987, 1998b). It breeds in spruce and tamarack forests in the Boreal Forest Region and the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region. It may nest south of the Shield during or immediately after southward irruptions. In these areas, it nests mostly in older coniferous plantations, especially spruce plantations, but also in mature mixed woods. In Oxford County, it nested in a younger spruce plantation (Holdsworth and Graham 1990). The Carolinian mixed-wood forest where nesting was confirmed was at Old Cut at Long Point (Enright 1993a). A nest found in 2001 in Peel Region was in an area where there was a heavy crop of black spruce cones (Coady 2001).

In the Clay Belt in the Boreal Forest Region, the White-winged Crossbill was most common in black spruce stands, but also occurred in those dominated by trembling aspen, jack pine, tamarack, and white cedar (Welsh and Lougheed 1996). It is likely that the aspen stands contained some conifers because it relies almost exclusively on conifer seeds for food. It occurred in stands across the full spectrum of moisture regimes, but predominantly in wet stands. It is probable that the presence of conifer seeds is more important than habitat characteristics of the forest. In jack pine

stands near Gogama, it was common when jack pine budworms were abundant, but did not remain after the budworms were gone (James and Peck 1995a).



Throughout North America, the White-winged Crossbill is associated predominantly with the Boreal Forest Region because of its preference for spruce and tamarack seeds. It also occurs in mixed forests both within and south of this forest region, and occasionally nests in coniferous plantations and mixed forests south of its normal range. In mixed coniferous forests, it tends to select areas dominated by spruce and avoid those dominated by pines; the converse is true for the Red Crossbill (Benkman 2020). In Quebec, it breeds predominantly in the Boreal Forest Region but also further south in mixed forests and isolated coniferous forests. It occurs most frequently in stands dominated by spruce and tamarack and less frequently in stands of balsam fir. On Anticosti Island, it was associated mostly with white spruce and tamarack forests. Its frequency of occurrence was highest where forests were dominated by black spruce, white spruce, balsam fir, and tamarack. Its frequency of occurrence was much lower in the deciduous and mixed forests of the south (Létourneau in Gauthier and Aubry 1996). Near Quebec City, it was in a guild that was either restricted to or found in greater numbers in areas that had been logged. The higher abundance of these species in the sapling stage and young forests after logging indicated they were not restricted to mature stands (Imbeau et al. 1999). It is possible that it was not breeding at this time of the year. In Quebec in 6-year-old strip-cuts, it occurred in coniferous but not deciduous stands. In 10-year-old strip-cuts, it occurred in both types of stands but was more abundant in conifers. It was absent in strip-cuts 14-15 years old and in final cuts and occurred in coniferous but not deciduous clear-cuts (Falaradeau et al. 1999). In northeastern Manitoba, it was most abundant in coniferous forests without an understorey followed by mixed forests. It was present in trace numbers in coniferous forests with an understorey and in mixed scrub but was absent in deciduous forests, deciduous and coniferous scrub, heath, and tundra (McLaren and McLaren 1981). In northeastern lowland conifers, it was uncommon in young or low black spruce stands, most common in intermediate-aged to mature black spruce stands, and moderately common in white cedar stands (Dawson 1979). The White-winged Crossbill has nested in spruce plantations in Minnesota and Wisconsin (Bielefeldt and Rosenfield 1993, 1994; Little and Langeslag 1996). In the Prairie Provinces, it was in a guild associated with coniferous forests. It occurred only in forests 80 or more years old, predominantly in dry stands with a moderate nutrient status (Kirk et al. 1996). In British Columbia, it tends to be most abundant in mountainous areas or where spruce or tamarack occur. It is less abundant in drier areas where pine forests predominate. In the south, it

nests mostly in high-elevation subalpine forests. Further north, it breeds from valley bottoms up to the timberline (Campbell et al. 2001). In the Yukon, it inhabits lowland white spruce forests and also occurs in black spruce stands. It is common in mixed and riparian spruce forests. It has been reported occasionally in lodgepole pine forests. It is rarely encountered in deciduous forests (Sinclair et al. 2003). In Alaska, it is most abundant in spruce and mixed forests on floodplains followed by hills with black spruce forest on north-facing slopes, subalpine spruce forests, and lowland black spruce woodlands (Handel et al. 2009).

The White-winged Crossbill roosts nocturnally in dense foliage of conifers, with as many as 6 roosting together in the same tree. In Ontario, a male roosted in a white cedar in sight of the nest tree (Benkman 2020; Coady 2001).

Coady (2001) summarized the characteristics of 12 Ontario nests, including those described by Peck and James (1987, 1998b), Enright (1993a, 1993b), and Holdsworth and Graham (1990). All were in conifers 2.4-12.5 m from the ground, but most were 5-10 m up. Eight nests were in spruce (3 in white spruce, 3 in black spruce, 1 in Norway spruce, and 1 in an unidentified spruce). One nest each were in white cedar, jack pine, and balsam fir. Most were on horizontal branches either near the trunk or as far as 2 m from it. One was in a crotch between the trunk and 2 lateral branches. The nest was positioned so that it maximized the time that the nest was exposed to direct sunlight.

All nests reported in North America were in conifers, most frequently in spruce. Nests have been reported 0.8-21 m from the ground. Although most are on a horizontal branch at varying distances from the trunk, some are in the crown of trees, especially in shorter trees. In winter, nests tend to be on the southern and eastern sides of trees to gain better exposure to the sun. In Minnesota, 1 nest tree had no cones on it in an area with a heavy cone crop. This may have been an adaptation to discourage other crossbills from visiting the nest tree (Benkman 2020; Bielefeldt and Rosenfield 1993; Bond 1938; Little and Langeslag 1996; Taber in Austin 1968).

The White-winged Crossbill may nest singly but this occurs most frequently when it nests outside its normal range. Nests are usually clustered as a result of an abundance of food and favourable microclimates. Nest clustering may also enhance predator detection and defence. It may travel and forage in flocks year-round, even while it is nesting. Males often chase each other or females, especially prior to nesting. Males guard their females during the egg-laying stage, possibly in an attempt to prevent extra-pair copulations. Only a small area around the nest or nest tree is defended, and defence is very low key. It does not defend a feeding territory and routinely travels 1 km or more between nesting and foraging areas. Defence of food resources would probably decrease food intake rather than increase it. Nesting only occurs where seeds are abundant, so seed depletion as a result of other crossbills has little effect; energy would have to be expended to defend food resources. Defence of conifer cones would also inhibit flock formation. Birds in flocks have food intake rates 1.27 times greater than solitary birds (Benkman 1988c, 2020; Messineo 1985).

It is highly unlikely that the White-winged Crossbill exhibits any natal philopatry or adult site fidelity. It is extremely nomadic, searching for areas where conifer seeds are abundant and moving to another area as soon as the seed crop declines. Distances between successive breeding areas may be hundreds or even thousands of kilometres apart. Individual conifer species are incapable of

producing bumper crops of seeds 2 years in succession, so the likelihood of crossbills remaining in a given location for more than 1 breeding season is very low (Benkman 2020).

Limiting Factors

The White-winged Crossbill nests wherever conifer seed crops are sufficient to raise nestlings; this is the most demanding phase of breeding. When seed crops are increasing, it may initiate nesting as soon as the female can form eggs. Nests may be deserted if a warm dry spell causes cones to open and release most of their seeds (Benkman 1990). Breeding is opportunistic and may occur any time of the year provided that conifer seed crops are adequate. In the southern portion of its range, it infrequently nests in November and December. In Alaska, nesting occurs only between February and July (Benkman 2020). In Ontario, it has 3 nesting periods. The first coincides with the maturation of cones in early July when it feeds on developing cones of tamarack, white spruce, and to a lesser extent, red spruce. Nesting usually declines by November, but declines by early September when it feeds on tamarack seeds. Young may still be fledging in late December and early January during exceptional seed crops. The larger the cone crop, the longer it nests. During this nesting period in Algonquin Park, active nests have been observed in July, a nest was under construction in mid-August, and dependent fledglings have been observed from early August to mid-October. The second nesting period is in January and February when it requires large crops of white or red spruce cones that have held seeds through the winter. This is the least consistent nesting period and nests may be deserted if seeds fall out of the cones. During this period in Algonquin Park, nest construction has been observed from mid-December to late February, nestlings were present from early January to late February, and dependent fledglings have been observed in late March. The third nesting period begins in March or April when black spruce cones open, and nesting may continue into June. In Algonquin Park during this period, nest construction occurs in early to mid-March and dependent fledglings have been observed from early April to mid-June (Benkman 2020; Tozer 2012). As soon as nesting is complete, it searches for developing cone crops to begin nesting again. This may involve travelling great distances. Once an adequate food source is discovered, it begins nesting rapidly, nests several times in rapid succession, potentially nests much of the year, and begins nesting at a very early age (Benkman 2020).

No information is available on how long it takes to build a nest and if there is a delay between nest completion and the initiation of egg laying. Presumably 1 egg is laid per day. Incubation is almost continuous and may begin with the laying of the first egg, particularly in cold weather, but may be delayed until the last egg is laid when it is warmer. At the Long Point nest, incubation appeared to begin shortly after the nest was complete. The only information on the incubation period is from Ontario. The Long Point nest was abandoned after the female had incubated the eggs 14-15 days. The incubation period at the Peel Region nest was 14 or 16 days, depending upon whether incubation began with the laying of the first or third egg. No information is available on the nestling period. Nestlings may enter torpor during cold weather, and this may extend the nestling period (Benkman 2020; Coady 2001; Enright 1993a, 1993b; Little and Langeslag 1996).

In the southern part of the White-winged Crossbill's range, females may raise 2-4 broods in a year. Those in the north may raise 1 or 2 broods. During the July to September nesting period, birds that feed on tamarack seeds raise a single brood; those that feed on spruce seeds may raise multiple

broods. The actual number of broods raised has never been confirmed. It is possible, if not probable, that females may raise broods at widely disparate locations within a year. Adults appear to breed much more frequently than yearlings. There is circumstantial evidence that renesting may occur if a nest is depredated or abandoned. After the nest in Caledon Township was depredated, both adults returned to the nest several times. Each time, the female removed some material from the nest lining and flew off with it, suggesting that she was building a replacement nest. After a Minnesota nest was abandoned as a result of a snowstorm, a female was seen building a nest approximately 6 m from the original nest. It was assumed that the same female was involved, but there was no evidence to support this. Twenty days elapsed after the first nest was abandoned until construction started on the second nest. This was an unusually long interval between nest loss and initiation of a replacement nest. All Ontario nests contained either 3 eggs or 3 young. Clutches of 2-4 eggs are common; 5-egg clutches are rare (Benkman 2020; Bielefeldt and Rosenfield 1993; Bond 1938; Coady 2001; Little and Langeslag 1996; Peck and James 1998b; Taber in Austin 1968).

The White-winged Crossbill is capable of breeding when it is less than 5 months old. In Utah, all females and adult males were paired, but there was a population of unmated yearling males (Benkman 2020; Smith 1978). It appears to be monogamous, but it is unknown if females raising another brood retain their mate or mate with another male (serial polyandry). Polyandry is highly likely because the sex ratio is male biased. If females breed in different locations within a year, it is unlikely that the same mate would be retained. Some males and females associate with each other in the nonbreeding season as though they are paired. It is suspected that extra-pair copulations are part of the mating strategy. Males guard their females closely during the egg-laying stag. They also have relatively large testes, suggesting that extra-pair copulations may be common (Benkman 2020).

The mandibles of the White-winged Crossbill are designed specifically for feeding on conifer seeds, so it is inefficient at feeding on other plants. It has a smaller bill than all but 1 subspecies of the Red Crossbill. The White-winged Crossbill forages most efficiently and frequently on seeds of white spruce, black spruce, and tamarack, and also on red spruce to a lesser extent; the Red Crossbill forages most frequently on pines. The White-winged Crossbill husks the smaller spruce seeds more efficiently than the Red Crossbill. The converse is true for the larger seeds of pines and hemlock. Consequently, there is limited competition between the 2 crossbill species for food. Food overlap between them is greatest in summer when both feed on white spruce seeds. Seeds are most abundant and least limiting at this time. The White-winged Crossbill has evolved to harvest the more accessible but less abundant seeds in partially open black spruce cones (Benkman 1987a, 1987b). While foraging, certain trees may be used repeatedly but adjacent trees with seemingly equal numbers of cones may be ignored. Trees that are avoided typically have few seeds remaining in the cones, or seeds may be unavailable if the cones are closed (Benkman 2020; Little and Langeslag 1996). It usually forages on cones that are still attached to the tree, but it may feed on cones on the ground when they are exposed by spring snowmelt. Open cones are usually left attached to the tree, but closed cones are often removed by twisting them or biting the peduncle. Removal of cones distant from the foraging flock may also decrease agonistic interactions among flock members. It also forages on loose seeds among needles and on branches; they can be abundant after cones

open (Benkman 1997, 2020; Hess et al. 1998). At a feeder near Alliston, it fed on niger seeds in a tube feeder (Schmelefski 2002).

The White-winged Crossbill often eats ashes from fires, presumably for the minerals they contain. It may be attracted by smoke. In Algonquin Park, it ate dead wood from stumps and snags. The wood contained no evidence of mineral deposits, insects, fungi, or other organisms that may have provided a food source. The wood may be rich in ash and calcium and this may have been what the birds were seeking (Crins and McRae 1998; Crins and Strickland 1999; Lauzon and Nancekivell 1999; Taber in Austin 1968; Tozer 1999). Gallant (2008) reported it feeding on river otter feces and speculated that they were feeding on the fish bones in the scats, a potential source of calcium. The White-winged Crossbill is readily attracted to other sources of sodium and calcium, including natural mineral licks and roads that have had sodium chloride or calcium chloride applied to them. It is also attracted to dog urine in snow (Meade 1942; Taber in Austin 1968; Tozer 2012). In New York, flocks foraged regularly in a plowed field, but it was not determined what the birds were eating (Messineo 1985). It has been observed feeding on teasel twice in southern Ontario and has fed on wild parsnip seeds and on cow parsnip on treeless islands in British Columbia (Campbell et al. 2001; Curry 2006; Taber in Austin 1968). It occasionally gleans on bark at the base of trees and may peel off bark (Hess et al. 1998; Taber in Austin 1968). It has fed on snails or crustaceans among boulders on an Alaskan beach and on decayed garden fruits and seeds of lyme grass (Taber in Austin 1968). It drinks water or eats snow on a regular basis (Smith 1998; Taber in Austin 1968).

The White-winged Crossbill almost always forages in flocks. This increases foraging efficiency and its ability to detect predators. Solitary birds ingest significantly fewer seeds per unit time than birds in flocks. As flock size increases, the rate of aggression also increases. Adult males are consistently dominant to all females and to first-year males. Females fed at a progressively slower rate than males as the rate of agonistic interactions increased. In November and December, juvenile males avoid adult males and associate with adult females, which also avoid adult males. Aggression is highest in black spruce where all the cones are compactly located within 1 m of the narrow crown of the tree. Rates of agonistic interactions are lower on red spruce and even lower on white spruce where the branches are more continuous and cones are more uniformly dispersed. Agonistic rates are very low on tamarack and red pine where cones are widely dispersed throughout large crowns (Benkman 1997).

The Pine Siskin and Red Crossbill commonly join flocks of foraging White-winged Crossbills. When feeding flocks take flight, the siskins usually do not associate with the crossbills, and the crossbills typically divide into conspecific flocks. While foraging in conifers, both sexes of the White-winged Crossbill are dominant to the Red Crossbill (Benkman 2020; Hess et al. 1998). Crossbills are the only finches that can extract seeds from closed conifer cones. When cones open, other finches have similar feeding rates as the crossbills. Under these conditions, the other finches may outcompete the crossbills by lowering seed abundance below the threshold necessary for them to survive. Crossbills require seed encounter rates 2-3 times higher than other finches (Benkman 1988a). The Redpoll may irrupt southward in the same years as the White-winged Crossbill and this coincides with periods when seeds are most limiting. The Redpoll feeds on tamarack seeds at this time, so it may be a direct competitor of the White-winged Crossbill (Benkman 1987b).

Both adults feed the nestlings a regurgitated bolus that consists of seed kernels. The male feeds the female in a similar manner when she is incubating the eggs and brooding young nestlings (Coady 2001; Enright 1993a, 1993b; Taber in Austin 1968).

The White-winged Crossbill feeds almost exclusively on conifer seeds and may consume more than 3,000 seeds per day. Within its normal range, it feeds predominantly on seeds of tamarack and white, black, and red spruce. It feeds to a lesser extent on balsam fir seeds which may be less palatable because of their resin coating. Nonetheless, large balsam fir cone crops sustain populations in summer in southern Quebec, and it may also consume white cedar seeds. In the extreme southern portion of its range, hemlock seeds are often preferred. During irruptions south of its normal range, it may feed on seeds of nonnative conifers such as Norway spruce and European larch. Pine seeds are seldom consumed, but occasionally it eats red and white pine seeds (Benkman 2020; Hess et al. 1998; Lancaster et al. 2004; Létourneau in Gauthier and Aubry 1996; Little and Langeslag 1996; Messineo 1985; Sealy et al. 1980; Taber in Austin 1968; Tozer 2012). During an irruption into Manitoba when White-winged Crossbills were not breeding, it preferred tamarack seeds to spruce seeds. Of 117 feeding flocks, 83% fed on tamarack, 12% on black spruce, 3% on white spruce, and 1% on white cedar and forbs. Of 17 flocks flying over habitat dominated by black spruce, 16 (94.1%) settled in a tamarack and the other landed in a black spruce (Sealy et al. 1980).

Benkman (1987b) studied the foraging ecology of the White-winged Crossbill in Algonquin Park as well as in Quebec, Maine, and Vermont. It fed on seeds of white spruce, black spruce, and tamarack. The species selected was related to the abundance of seeds and how quickly seeds could be ingested. Intake rates on tamarack and white spruce increased from July through August and September as cones began opening, then declined as seeds were shed from the cones. The peak of foraging on tamarack occurred in August and September. The peak of feeding on white spruce and black spruce was in September and October. In 1 year in Algonquin Park, it foraged most effectively on white spruce from August to early January, with 80% of its time spent in white spruce and virtually ignoring black spruce. In late February, it foraged 61% of the time on black spruce even though white spruce was more profitable. In another year, it foraged nearly 100% of the time on white spruce, ignoring black spruce. There were 3 periods of change in its abundance that coincided with seed fall and conifer use. When seed profitability was high, it often remained in the area and influxes occurred into the park; it emigrated when profitability was low. The second period when it shifted habitats was in late February and March, coinciding with a decline in profitability of tamarack and white spruce and a switch to foraging on black spruce. It emigrated from the park in March 1983 when the average number of seeds per cone dropped from 9.4 on 1 February to 0.5 on 25 March. The third period of movement coincided with the switch from foraging on open black spruce cones to foraging on developing tamarack and white spruce cones in June and July. It often migrated at this time to areas of large crops of developing tamarack and white spruce cones and was first seen back at Algonquin Park on 17 July. The fewer species of conifers that are present in an area, the shorter the time period that it can support the White-winged Crossbill. When tamarack and white spruce seeds are abundant, it may switch to feeding on black spruce seeds later, but always does so by March. It often forages on hemlock seeds in winter because this tree holds its seeds during this period. The period between the falling of tamarack and white spruce seeds in late autumn and the opening of black spruce cones in late winter is when seed profitability relative to energy

requirements is lowest. It can meet its energy demands easier in late winter when black spruce seeds are available. In the northern Boreal Forest Region, black spruce is the most important species during seed crop failures because black spruce seed crops are the least variable and rarely fail (Benkman 2020; Messineo 1985; Taber in Austin 1968). It occasionally eats fruits and unusual food items. Some may be desperation foods when conifer seeds are scarce or absent. It has eaten juniper berries; sunflower seeds both from plants and feeders; seeds of crowberry, huckleberry, ragweeds, foxtails, lyme grass, teasel, and sweetgum; rotten garden fruits; berries from ornamental trees and shrubs; and suet at feeders (Benkman 2020; Campbell et al. 2001; Taber in Austin 1968).

Gabrielson (1924) examined the contents of 52 stomachs collected in the United States in February and September. The diet consisted of 93.12% vegetable matter and 6.88% animal matter. Conifer seeds comprised 76.21% of the diet, predominantly those of spruce and hemlock. No pine seeds were found in the stomachs, but 24% of the conifer seeds could not be identified to genus. Seventeen stomachs collected in February were 50% full of hemlock seeds and the remainder consisted of unidentified conifer seeds. One stomach taken in October was filled with balsam fir seeds and 1 collected in November contained juniper berries. Two birds had eaten nothing but buds and these constituted 3.84% of the entire sample. One stomach contained huckleberry and crowberry seeds. Weed seeds constituted 9.61% of the diet and included those of sunflowers, ragweeds, and foxtails. Various unidentified vegetable matter comprised 2.98% of the diet. Of the 6.88% animal food, 1.68% consisted of caterpillars and other larvae; the remainder was unidentified digested material. One large flock fed on larvae of pitch pine sawflies. It has been reported eating cankerworms and frozen apples. Sealy et al. (1980) examined stomachs of birds killed on roads during winter in southeastern Manitoba. Twenty-four diverticula and stomachs all contained tamarack seeds; 1 contained more white spruce than tamarack seeds; and 2 or 3 white spruce seeds were present in 2 other specimens. Arthropod remains and black spruce seeds were present in 3 and 2 stomachs respectively.

Timber harvesting reduces the quality and quantity of habitat for the White-winged Crossbill. In the Boreal Forest Region of Ontario, Vanderwel et al. (2009) determined that removal of 30% of the tree canopy had no effect on its abundance, but it declined when 50% or 70% of the canopy was removed. It appears to be less common in the Montreal area now due to removal of extensive stands of mature conifers as a result of logging and urbanization (Létourneau in Gauthier and Aubry 1996). Current forest management practices in the Boreal Forest Region are detrimental because construction of logging roads destroys habitat and shorter rotation periods result in forests being less productive for crossbills. Most conifers do not produce cones until they are more than 60 years old. Benkman (2020) recommended protecting more forested habitat, increasing rotation ages, and maintaining large tracts of mature forest throughout the Boreal Forest Region.

The White-winged Crossbill's habit of foraging on roads to obtain sodium or calcium chloride probably results in thousands being killed annually. Calcium chloride is poisonous to the birds, causing direct mortality or resulting in their being too sick to move out of the way of vehicles (Benkman 2020; Meade 1942; Messineo 1985; Tozer 2012).

Outbreaks of the larch cone maggot can decimate developing cone crops and cause the White-winged Crossbill to cease breeding or emigrate. It has been documented eating large quantities of

spruce budworms and pitch pine sawflies and disappeared from a forest in the Gogama area when the jack pine budworm was no longer present (Benkman 1990; James and Peck 1995a). It is possible that budworms and sawflies are an important supplement to the diet of birds breeding in the summer.

Birds that fledge in autumn may have reduced survivorship in their first winter because they are still inefficient at foraging and are subordinate to adults. Birds that fledged between August and October had significantly lower seed intake rates than adults in November and December. Juvenile females may suffer particularly high mortality because they are subordinate to all other sex-age classes and forage less rapidly when in flocks (Benkman 1990, 2020).

In Alberta, the White-winged Crossbill was significantly more abundant at seismic lines and pipelines than in adjacent forest interior (Bayne et al. 2016).

Benkman (2020) predicted that the Boreal Forest Region would shrink in response to global warming and that this would have a negative impact on the White-winged Crossbill.

Status

Baillie and Harrington (1937) reported that the White-winged Crossbill had been found more or less commonly from Middlesex County in the south to the northern limits of the province and west to the western end of Lake Superior. The first atlas demonstrated that its breeding range included the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region, the Boreal Forest Region, and the Hudson Bay Lowland, although its distribution within these areas was spotty. There were scattered breeding records south of the Shield. Few records were obtained in the first 3 years of the atlas, with more breeding evidence obtained in 1984 and 1985 during a period of excellent cone crops for most conifer species (Lumsden and Smith 1987; Smith and Lumsden in Cadman et al. 1987). James (1991) considered the White-winged Crossbill an uncommon to common permanent erratic resident across the province, south to the Algonquin Highlands. It is occasional further south to Oxford County and Lake Ontario in summer and a rare to locally abundant erratic south to Lake Erie from autumn to spring.

The second atlas confirmed that the distribution of the White-winged Crossbill had not changed since the first atlas. Many gaps in its previous distribution were filled because of more widespread and frequent irruptions into the province. In addition, atlassers were probably more aware of its breeding phenology than during the first atlas. Its probability of observation increased significantly from the first atlas province-wide and in all regions where it occurred except the Hudson Bay Lowland. It increased in that region as well, but not significantly. It was most abundant in areas dominated by spruce, including the Hudson Bay Lowland, the Boreal Forest Region, and limited areas in Algonquin Park. Because of its nomadic habits and unusual timing of breeding, these data should be treated with caution (Coady in Cadman et al. 2007).

The White-winged Crossbill is not adequately surveyed at any season of the year to determine trends in its population. The Breeding Bird Survey (BBS) is conducted when many crossbills may not be breeding, and most of its breeding range is not covered by this survey. There are few Christmas Bird Counts (CBCs) in the core of its range. The facts that it is nomadic, exhibits no site fidelity, and can range from being absent to abundant in a given area make determination of its population

trends extremely difficult. In addition, populations fluctuate widely, declining precipitously during periods of widespread cone crop failures and rebounding quickly when a plentiful food source is found. Specialized studies would be required to determine its population status. Nonetheless, BBS and CBC data are available for it. BBS data for 1970-2021 indicate annual increases of 3.47% in Canada and 3.95% in Ontario. During 2011-21, there were annual increases of 8.08% in Canada and 6.6% in Ontario. All results were of low reliability except for the long-term Ontario results, which were of medium reliability (A.C. Smith et al. 2023). CBC data for 1970-2021 indicate an annual increase of 1.15% in Ontario; it declined at an annual rate of 1.81% 2009-21 (National Audubon Society 2022).

POSTFLEDGING PERIOD

During the first few days after fledging, the young remain hidden in trees where they wait to be fed by the adults. Fledglings can fly well a week after they leave the nest and start to follow the adults closely. Family groups then coalesce into larger flocks. When food is abundant, some young may remain in the vicinity of the nesting area, but others appear to travel widely. If food is scarce, all adults and juveniles disperse from the breeding area, often for great distances. Dependent fledglings may drink water on their own without adults being present. In New York, juveniles remained in nearby trees while adults fed on road salt and grit (Benkman 2020: Messineo 1995; Smith 1978).

MIGRATION

The White-winged Crossbill makes 1-3 or even more migratory movements each year, travelling by day. These movements are best termed nomadic migration because movements are fairly regular but are not in a fixed direction, to a specific destination, or of a set distance. Movements are mostly in easterly and westerly directions within the Boreal Forest Region. Movements may be very long distance and could conceivably be from Alaska and the Yukon to Newfoundland. Movements are related to the availability of conifer seeds. One movement coincides with cone development in mid- to late May when birds begin searching for large developing cone crops of white spruce or tamarack. Large movements often occur in late October and November coincident with declines in seed availability. Emigration occurs when seed crops are low or when warm dry weather results in cones shedding most of their seeds. The threshold seed intake rate is approximately 0.4 mg of seeds per second. When intake levels decline below this, emigration typically occurs. Movement out of areas is most pronounced where black spruce is absent. It is the most reliable seed source in winter and its absence, despite large crops of spruce and tamarack seeds, may be an impetus for movement. In spring of 1983, the White-winged Crossbill emigrated from Quebec and Algonquin Park and was largely absent from eastern North America, except along the Maine coast and in Newfoundland. It was also absent from most of the western portion of the continent, but was abundant in Alaska and the Yukon. Large influxes were noted more than 3,600 km to the east and southeast, arriving in Algonquin Park by mid-July. It appeared as though birds moved from Alaska and the Yukon to Ontario and Quebec in about a month, travelling through the Boreal Forest Region (Benkman 1987b, 2020).

In non-irruption years, the nonbreeding and breeding ranges are the same. In addition to its wanderings within the Boreal Forest Region, the White-winged Crossbill makes occasional irruptive flights south of its normal range. Bumper cone crops occur at intervals of 2-10 years but cone crops

fail over large areas every 2-4 years. Southward irruptions are a response to failed cone crops, but may also occur if the population increases and the larger number of birds depletes the cone crop. Southward irruptions usually occur in late October and November when spruce and tamarack seeds are depleted. Birds tend to leave southern areas in March or early April with some stragglers persisting into early May; some birds may remain south of the normal range to breed (Benkman 1987b, 2020; Hess et al. 1998; Messineo 1985; Sealy et al. 1980).

Bock and Lepthien (1976b) analyzed United States CBC results from 1962 to 1972 and concluded that the White-winged Crossbill irrupted southward at regular intervals of 2-3 years, and that its irruptions coincided with those of several other boreal seed-eating birds. Their own data do not support this conclusion very well. There appears to be no pattern to this crossbill's irruptions. It may occasionally occur outside its normal range in consecutive years, but occurrences may be separated by decades with no apparent pattern. Freedman and Riley (1980) analyzed southern Ontario CBC data for 1929-77. They found no clear trend in its abundance or patterns of irruptions. Major irruptions into southern Ontario occurred in 1950-51, 1955-56, 1960-61, 1963-64, 1971-72 (Speirs 1985), 1984-85 (Smith and Lumsden in Cadman et al. 1987), and 2008-09. Often a decade or more elapses between irruptions in some areas, including Pennsylvania (Hess et al. 1998), southeastern Manitoba (Sealy et al. 1980), and southern Quebec (Létourneau in Gauthier and Aubry 1996). When irruptions occur, they are usually coincident with other boreal species, particularly the Redpoll and Pine Siskin. Red Crossbills often appear in the same years, but not always.

In the south, departure of spring migrants is irregular and is usually in March or April, but may be as early as January or as late as May (Black and Roy 2010; Curry 2006; LaForest 1993; Weir 2008). Manning (1952) reported that spring migrants arrived at the Severn River on the Hudson Bay coast in the last half of May but did not remain to breed. Autumn migrants may arrive in the south from mid-October to mid-November, but occasionally not until January (Curry 2006; LaForest 1993; Weir 2008)

Numbers seen during migration are highly variable. In the Hamilton area during 1950-90, either large or small irruptions occurred at least every other winter, but they are now less frequent and smaller (Curry 2006). At Presqu'ile, small numbers are seen each year but about 100 flocks of 25-100 birds flew by within a period of 90 minutes on 27 February 1985 (LaForest 1993). The number of birds seen on the Algonquin Park CBC has ranged from 1 to 8,728, with an average of 1,405 (Tozer 2012).

During extensive cone failures and irruptions, the White-winged Crossbill may experience massive mortality. It is ill adapted to foraging on anything but conifer seeds, but the southern areas that it irrupts to are dominated by deciduous species. It is often forced to adapt to unfamiliar food sources that it is inefficient at accessing. In addition to mortality due to starvation, it is much more likely to be struck by vehicles during irruptions. Its extraordinary ability to produce multiple broods in a short period usually allows the population to rebound following irruptions (Benkman 2020).

NONBREEDING SEASON

The White-winged Crossbill may breed in every month of the year, but nonbreeders may be present at any time. In non-irruption years, it remains in the same habitat year round and consumes the same food items whether it is breeding or not. In irruption years, it seeks conifers in areas that are

predominantly deciduous, agricultural, or urban in nature. It searches for natural coniferous and mixed stands and older plantations, especially those dominated by spruce. It also forages in conifers planted around residential lots, in shelterbelts in agricultural fields, and along roads.

Pine Siskin

Spinus pinus

BREEDING SEASON

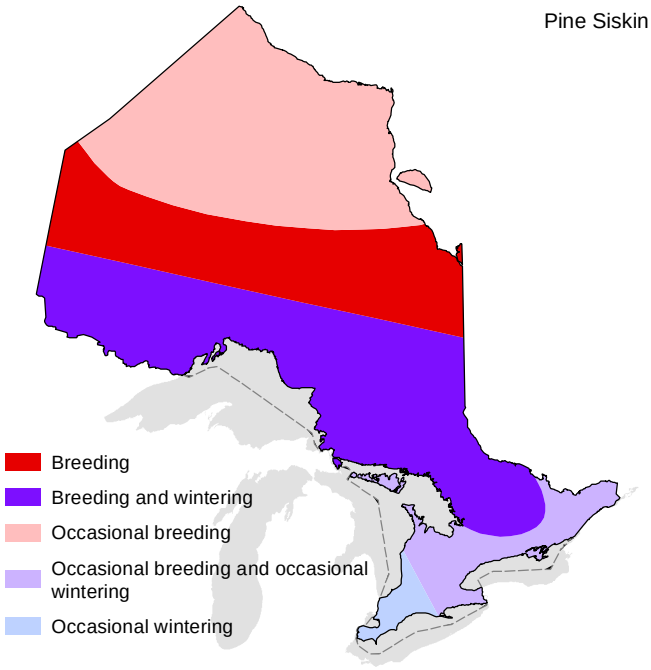
Habitat Requirements

In Ontario, the Pine Siskin has nested in coniferous and mixed forests and hedgerows. Four of 14 nests (28.6%) were on urban residential properties, 3 (21.4%) were in coniferous woods, 3 (21.4%) were on the University of Guelph campus, 2 (14.3%) were in mixed second-growth woods, and 1 each (7.1%) were in a tamarack bog and a hedgerow beside a road (Peck and James 1987). The nest records are not a representative sample, with many found south of its normal breeding range following irruptions.

In the Boreal Forest Region from Pickle Lake northwestward into northeastern Manitoba, the Pine Siskin was most abundant in coniferous forests without an understorey followed by mixed forests, coniferous forests with an understorey, and mixed scrub. It was not observed in deciduous forests, deciduous scrub, heath, or tundra (McLaren and McLaren 1981). Near White River, it was most abundant in jack pine stands 18-20 years after clear-cutting (Venier and Pearce 2005). It was most abundant in stands 60-223 years old at Manitouwadge (Venier et al. 2009). In the Clay Belt, it was most abundant in stands dominated by white spruce–balsam fir and black spruce, followed by trembling aspen stands mixed with balsam fir and black spruce. It occurred in stands that ranged

from nutrient-poor to nutrient-rich but was restricted to forests that were moist to wet (Welsh and Lougheed 1996).

In Algonquin Park, it was observed in 0% of 2-9-year-old white pine stands, 9.1-20% of 10-16-year-old stands, and 6.7-7.1% of stands with no recent history of harvesting (Kingsley and Nol 1999).



The normal breeding range of the Pine Siskin includes the Boreal Forest Region and the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region. Erskine (1977) considered it characteristic of the ecotone between boreal forest and alpine habitat. It is common and widespread in spruce forests but also nests in urban areas within the Boreal Forest Region. Breeding occurs mostly in open coniferous and mixed forests and occasionally in deciduous stands containing conifers (Dawson 2020). In Newfoundland, Whitaker and Montevecchi (1997, 1999) considered it a habitat generalist. In balsam fir forests, it was equally abundant along riparian edges, in forest interior, and at edges adjacent to roads and clear-cuts. There was no difference in its abundance in buffers adjacent to water bodies in intact forest and in areas where the adjacent forest had been clear-cut. In Newfoundland balsam fir stands, it was associated with nutrient-poor stands of young to moderate age (40-60 years). It was significantly less abundant in 80-year-old stands, which were somewhat more open, had larger numbers of dead standing trees, and lacked the deciduous small-tree layer that was present in younger stands (Thompson et al. 1999). In Quebec, the Pine Siskin's frequency of occurrence was highest in forest regions dominated by black spruce or balsam fir, but was still quite high in forests dominated by yellow birch. In the deciduous forest zone, it was associated with pockets of conifers scattered through agricultural, wooded, and urban landscapes. It often breeds nearby in the spring after frequenting a feeder in the winter (Rivard and Bombardier in Gauthier and Aubry 1996). Falardeau et al. (1999) reported it breeding in Quebec coniferous strip-cuts, including final cuts and those 6, 10, and 14-15 years old. It was rare in strip-cuts through deciduous forests. It occurred in both coniferous and deciduous clear-cuts. In Quebec black spruce stands, it was significantly more abundant in clear-cuts with 2-5-m tall saplings and 120-year-old forests than in 200-year-old forests and young clear-cuts with trees 5-11 m tall. Its abundance in burns with trees 5-11 m tall was not significantly different from that in any of the other stand types (Imbeau et al. 1999). In the Prairie Provinces, it was in a guild associated with conifers. It occurred mostly in old stands on dry soils that were moderate in nutrient richness (Kirk et al. 1996). In Saskatchewan, it was randomly distributed among landscapes but was slightly more common in large forest fragments with low forest cover within 5 km. It was significantly more common in white spruce stands than expected, moderate in abundance in mixed stands, and uncommon in

trembling aspen stands (Hobson and Bayne 2000). In Alberta, it was significantly more abundant in old trembling aspen–dominated stands than in mature and young stands. It was positively correlated with conifer density. Old trembling aspen stands are more likely to contain conifers than younger stands (Schieck et al. 1995). In British Columbia, conifers were an important component of Pine Siskin habitat in trembling aspen–dominated forests. In the taiga plains, it was most abundant in mature forests dominated by white birch, trembling aspen, and white spruce. Sixty-eight percent of nesting records were from low-elevation human-influenced or forest (28%) habitats. The human-influenced habitats included 30% suburban habitat, 21% cultivated farmland, and 16% rural areas. Results were not representative of the habitats that it used. It is a widespread breeder in subalpine forests (Campbell et al. 2001). In coniferous forests in southern British Columbia, it was negatively associated with deciduous riparian vegetation in spring, summer, and autumn, but significantly so only in summer (Wiebe and Martin 1998). In the Yukon, it inhabits open coniferous forests, especially those dominated by white spruce. It also nests in trembling aspen and mixed stands (Sinclair et al. 2003).

During or following irruptions south of its normal breeding range, the Pine Siskin may nest in a wider variety of habitats. These atypical nesting habitats tend to be over-reported in nest descriptions compared with their proportional use. In areas where high-elevation habitat is present, it may nest in more typical coniferous forest (McNair 1988) but also in hemlock stands (Messineo 1985). It may also breed in coniferous plantations (Bielefeldt and Rosenfield 1994; Messineo 1985) and wide-scale planting of conifers in the 20th century may have extended its breeding range southward (Dawson 2020). Other habitats that may be used for nesting south of the normal breeding range include planted conifers in urban and residential lots (McNair 1988; Messineo 1985; Pitelka 1942; Weaver and West 1943), road-side conifers (Knight 1994), university campuses and arboretums (Hull 1989; Perry 1965), ornamental conifers in parks and cemeteries (Dawson 2020), pine and oak barrens (Mossman et al. 1991), and small coniferous and mixed stands in urban and rural areas (Leighton et al. 2002).

All Ontario nests were in conifers: 57.9% in spruce, 21.2% in pine, and 5.3% in each of balsam fir, hemlock, tamarack, and white cedar. All were saddled on horizontal limbs. One was against the trunk and 8 were 1.1-2.5 m from the trunk and sometimes near the end of a branch. Nests were concealed and supported on the limbs by small branches, sometimes at forks. Nests were 1.8-10 m from the ground with most 3.5-6 m up (Peck and James 1987).

Within its normal range, the Pine Siskin nests predominantly in coniferous trees, but it occasionally nests in deciduous trees and shrubs south of its typical range. It commonly nests in spruces, pines, firs, hemlock, and white cedar. In more southern locations, red cedar, Norway spruce, and blue spruce are commonly used for nesting. It has nested in oaks, elms, Manitoba maple and other maples, cottonwood, lilac, juneberry, cypress, apple trees, and willows. Most nests are saddled on a horizontal branch, often distant from the trunk and occasionally near the tip of a branch. Less frequently nests are near the trunk or among small branches near the treetop. Nests on branches may be supported in part by twigs that also serve to conceal the nest. Others are not attached to the limb. These tend to be concealed by overhanging branches. Nest height is variable, and it may nest in shrub- or sapling-sized trees to large conifers. Nest heights of 0.6-30 m have been reported,

with most about 3-8 m up. It has been observed dismantling old nests of Pine Siskins, American Goldfinches, and orioles and using the material to build a new nest (Campbell et al. 2001; Dawson 2020; Hull 1989; Knight 1994; Leighton et al. 2002; Messineo 1985; Palmer in Austin 1968; Perry 1965; Rodgers 1937; Weaver and West 1943).

The Pine Siskin does not defend a feeding territory. A radius of 0.9-1.8 m is defended around the nest. The female will leave the nest to chase any birds that approach this close. The siskin is gregarious year round and breeding males may form small flocks as large as 6 birds. Males occasionally bring their flocks back to their nest tree, but both sexes chase them if they intrude into the defended territory. It may nest solitarily, but most often in loose colonies. Six nests were found in a single tree in Washington State. In British Columbia, 4 nests were found close together, but no 2 nests were in the same tree (Campbell et al. 2001; Palmer in Austin 1968; Weaver and West 1943).

No information is available on natal philopatry, but it is highly unlikely that any birds return to breed in the vicinity of their natal territory. The Pine Siskin is nomadic, breeding wherever there are abundant crops of conifer seeds. In Michigan, adults and young left the area as soon as the fledglings were proficient fliers (Hull 1989), but in other cases the family unit remained near the nest for several weeks.

There is no information on adult site fidelity. Banding returns indicate that birds may breed in widely disparate regions in different years. Some adults banded from May to June have been encountered in another state or province in the same months of a different year. There are 7 such encounters for Canada with an average distance of 1,375 km between the banding and recovery areas (Brewer et al. 2018). Cases of adult site fidelity are likely very rare to nonexistent.

Limiting Factors

Weaver and West (1943) stated that breeding could occur at any time of the year, but that is not the case. Nest building may occur from mid-February until August, mostly in April and May (Dawson 2020; Hull 1989; Messineo 1985; Palmer in Austin 1968). Eggs have been reported in Ontario nests from March until the third week of July, with most present from near the end of April until mid-May. The Pine Siskin is sporadic in its timing and distribution of nesting in the province (Peck and James 1998b). In Algonquin Park, nests are under construction in late March to mid-May, eggs are present mid-April to mid-June, and dependent fledglings are typically observed mid-May to mid-July with a few observations from late August to early October. Early breeding and highest densities are associated with large crops of conifer seeds, particularly those of spruce, white cedar, and hemlock (Tozer 2012). In Guelph, Salvadori et al. (2009) concluded that nest building occurred in late March or early April and that the final eggs were laid 8-15 April.

Nest construction takes 5-6 days and 2-3 days may elapse after nest completion until egg laying begins; eggs are laid on successive days. At 1 nest, incubation began with the laying of the first egg. At another nest, all eggs hatched on the same day suggesting that the onset of incubation was delayed until the penultimate or last egg was laid. It is possible that incubation may begin with the laying of the first egg when the weather is cold but be delayed in warmer weather. The incubation period is 13 days based upon a limited sample. The nestling period is normally 13-17 days but only 11-13 days in Nebraska. Young were weighed daily in the Nebraska nests, so they may have fledged

prematurely (Campbell et al. 2001; Dawson 2020; Hull 1989; Palmer in Austin 1968; Perry 1965; Weaver and West 1943).

It is likely that the Pine Siskin raises 2 broods, at least in some years, but this has yet to be confirmed. Peck and James (1987) concluded that second broods were a possibility in Ontario and Campbell et al. (2001) stated that egg dates suggested double broods in British Columbia. Palmer (in Austin 1968) stated that there was a strong probability of double broods in some years and that birds may change locations between nestings. It has been suggested that some birds may breed in the south early in the year and move north to raise a second brood. In a given population, there may be birds present in various stages of the nesting cycle, indicating that either some breed twice or different segments of the population breed at different times (Dawson 2020; Palmer in Austin 1968). If a nest is lost or abandoned, a replacement clutch may be laid (Dawson 2020). Clutches of 2-5 eggs have been reported in Ontario, with most containing 4 eggs (mean 3.40 eggs; Peck and James 1998b). Clutches of 2-6 eggs have been reported throughout its range, with most containing 3 or 4 eggs. Five- and 6-egg clutches are rare, and there appears to be no geographic variation in clutch size. It is unknown if there are seasonal differences in clutch sizes (Dawson 2020; Palmer in Bent 1968).

Both sexes are presumably capable of breeding when they are 1 year old, but this has yet to be confirmed. The mating system is apparently monogamous. It is possible that sequential polyandry occurs, but this requires documentation. The close association of the male to the female during nest building may represent mate guarding (Dawson 2020). If Pine Siskins raise 2 broods in different locations within a breeding season, it is possible that they switch mates.

Rodgers (1937) observed flocks landing in the top 1.8-2.4 m of alders and working down the trees on the cones. The regular procedure was to forage down to the lower limbs, never spreading over an area more than 3.7-4.6 m, then make a circular flight to the top of another tree and repeat the procedure. They also foraged in a nearly horizontal line through a group of trees without foraging throughout any of them completely. Direct flights among trees were either to distant trees or those within 3-4.6 m. Circular flights had a radius of about 23 m and probably functioned as reconnaissance flights to find potential suitable trees for foraging. In trees, siskins forage much in the manner of chickadees and crossbills, often hanging upside down under cones at the tips of branches. They are incapable of extracting conifer seeds from closed cones and are less dependent on conifer seeds in their diet than crossbills. Consequently, they forage on a wider variety of substrates and use more foraging techniques (Dawson 2020; Palmer in Austin 1968). In British Columbia, siskins foraged on winter moth caterpillars in an apple orchard. The number of birds and the amount of time an individual spent within a tree was correlated with larval density. Birds appeared to be responding to levels of leaf damage in their search of winter moth larvae (Roland et al. 1986). The Pine Siskin commonly forages on the ground. It may be attracted to lawns where it extracts seeds from dandelion heads. It visits weedy fields, clear-cuts, orchards, and sparsely forested areas where it feeds on seeds of various herbaceous species, soft stems and leaves of forbs, and tender buds and blossoms of deciduous trees. It may also drink from flowers that trap water. It commonly gleans arthropods from leaves and twig tips (Campbell et al. 2001; Dawson 2020; Rodgers 1937; Schaub 1951). It is ineffective in hulling seeds that have tough shells. At feeders, it

often eats fragments of thick-shelled sunflower seeds left by larger birds (Dawson 2020). Rodgers (1937) reported birds snatching insects out of the air. Batts (1953) reported a siskin feeding at a fresh Yellow-bellied Sapsucker boring in a sweetgum. It appeared to be taking sap because it hesitated between each feeding, presumably waiting for more sap to flow. Prescott (1985) observed siskins feeding nocturnally in Quebec on an area of bare grit where bird food had been placed. It was partially illuminated by a floodlight at a nearby cottage. The temperature was −30°C; nocturnal feeding may be a mechanism to survive cold nights. It regularly seeks minerals to supplement its diet. This may be accomplished by consuming road salt and grit, blue clay, fresh or decaying concrete, dish water, and plaster (Bennetts and Hutto 1985; Campbell et al. 2001; Dawson 2020; Lowther and Walker 1967; Messineo 1985; Palmer in Austin 1968).

The male feeds the female during the incubation and brooding periods. He regurgitates a semisolid yellowish or greenish paste, with the greenish paste being attributed to aphids. The male may also feed the female seeds and buds, one at a time (Knight 1994; Messineo 1985; Perry 1965; Rodgers 1937; Weaver and West 1943). The young are fed the same type of paste by regurgitation. Nestlings are fed predominantly aphids, but also alder, birch, and willow seeds (Dawson 2020; Palmer in Austin 1968; Perry 1965; Weaver and West 1943).

Adults eat predominantly seeds, particularly those of conifers, but also deciduous species such as alder, birch, and willow. The Pine Siskin also eats seeds of grasses and herbaceous species, especially those in the aster family (Dawson 2020). Gabrielson (1924) analyzed the contents of 266 stomachs collected in winter and 25 in summer, mostly from the mountainous western states. The winter diet consisted of 86.7% vegetable matter and 13.3% animal matter. Of the vegetable matter, 20.15% was finely divided unidentified material, 23.28% were seeds of conifers, 24.58% were weed seeds (mostly ragweed in the east and groundsel in the west) and 18.69% were birch or alder seeds. It frequently eats a single food item exclusively, with conifer seeds constituting 100% of the contents of nearly all 70 stomachs in which they occurred. The animal food consumed in winter consisted entirely of insects: 7.31% caterpillars, 1.38% aphids, 2.17% scale insects, and 2.44% fragments of beetles, grasshoppers, and other insects. The summer diet consisted of 71.92% vegetable matter and 28.08% animal matter. The vegetable matter consisted of 20% conifer seeds, 19.2% weed seeds, and 32.72% unidentified material. Seeds consumed included those of sweetgum, willow, juniper, and plantain, with lesser amounts of foxtails, elms, smartweeds, amaranths, chickweeds, catchflies, blackberries, clovers, catnip, lilac, and stork's-bill. It occasionally consumed buds of fruit trees. Animal food consumed during the summer included 8.48% aphids, 4.68% caterpillars, and 14.92% spiders, bugs, fly larvae, weevils, and other insects. In winter in California, it consumed book lice, scale insects, and small caterpillars (Rodgers 1937). In Kansas, it fed on sunflowers seeds from patches of this plant near a pond and in a fallow field (Fitch 1958). It ate black alder seeds in Ontario (Dance 2008). Other items it has eaten include seeds of dandelions, thistles, tamarack, hemlock, pines, elms, sweetgum, and maples; buds of elms and maples; berries of honeysuckles and red cedar; soft stems and leaves of a variety of forb species; blossoms of ornamental flowers; seedlings of garden vegetables such as beets, lettuce, radishes, and onions; and a variety of insects including chalcid wasp larvae, sawfly larvae living within leaf galls, spruce budworms (eggs, larvae, and pupae), and wood-boring insects that may be captured by breaking dead twigs off trees (Dawson 2020; Palmer in Austin 1968). During a spruce budworm outbreak in Maine, budworm larvae and pupae constituted 68% by volume of

the food that 1 bird had consumed (Mitchell 1952). Near Manitouwadge, abundance of the siskin was not related to spruce budworm abundance (Venier et al 2009).

The Pine Siskin is occasionally parasitized by the Brown-headed Cowbird, but the reported rates of parasitism are often inflated. Much of the siskin's breeding range does not overlap with that of the cowbird and this parasite avoids the coniferous forests that the siskin prefers. Nests initiated in March and early April are unlikely to be parasitized. Most nest records are from south of the siskin's normal breeding range following irruptions, and this brings the 2 species into contact. Nests that are parasitized have a poor success rate in fledging young of either species. In Kansas, only 3 siskins and 1 cowbird fledged from 16 parasitized nests; 7 unparasitized nests fledged 14 siskins. The siskin is a poor host for the cowbird because it often abandons the nestling cowbirds when they are 6-7 days old and the diet fed to young siskins is inadequate to raise cowbirds. In Ontario, 3 of 20 nests (15.0%) were parasitized. In British Columbia, 6 of 62 nests (9.7%) were parasitized but the results were considered biased due to the disproportionate number of nests from low-elevation areas in the sample. In 2 areas of Kentucky, 26 of 67 nests (38.8%) and 28 of 51 nests (54.9%) were parasitized (Campbell et al. 2001; Dawson 2020; Hull 1989; Peck and James 1998b; Perry 1965).

There appear to be no significant habitat losses or degradation for the Pine Siskin in Ontario. Maturing conifers in plantations and around dwellings and farmsteads may provide habitat during irruption years. No adverse effects of timber harvesting have been identified, but occasionally sample sizes are too small and its irregular breeding habits make it difficult to assess potential impacts. It is less dependent on conifer seeds than crossbills and some of the other finches, so it appears less vulnerable to removal of old-growth forests and shorter rotation ages. In the Ontario Canadian Shield, it was equally abundant in early successional and mid-successional clear-cuts and burns in the same seral stages. There was no difference in its abundance in early successional, mid-successional, and mature stands (Zimmerling et al. 2017). In response to partial harvesting in Alberta, the Pine Siskin colonized mixed forest when 50% of the canopy was removed and decreased when the entire canopy was removed. In coniferous forest, it became extirpated when any canopy was removed. None of the changes in population size were significant (Harrison et al. 2005). In British Columbia, there was no difference in its abundance in clear-cuts, remnant forest patches within clear-cuts, or old-growth forest. In Wyoming, it was significantly more abundant in old-growth subalpine forests that were altered by old strip-cut logging than it was in unfragmented forests (Campbell et al. 2001). In Idaho, Medin and Booth (1989) found no difference in its abundance before and after single-tree selection harvesting.

The Pine Siskin is well adapted to nesting in the cold when the ground is still snow-covered. The nest is thick-walled and insulated; the male feeds the female during incubation and brooding so that she can stay on the nest most of the time; it is not dependent upon long days for reproductive development, with testis size related more to food availability; it can store 1.1-1.5 g of seeds which produce enough energy to rest at night for 5.5 hours at −20°C; and it may forage opportunistically at night (Dawson 2020; Prescott 1985). Despite these adaptations, heavy snowstorms or sleet may result in nest losses and, in severe cases, starvation if the primary food sources become covered with snow. There are numerous reports of nests being blown out of trees by the wind, or tilting so much that the nestlings fell out (Campbell et al. 2001; Dawson 2020; Palmer in Austin 1968; Rodgers 1937).

In Alberta, there was no difference in the Pine Siskin's abundance at seismic lines and pipelines compared with forest interior adjacent to these facilities. It was significantly less abundant at well pads than in adjacent forest interior (Bayne et al. 2016).

Price (2004) predicted that the Pine Siskin might no longer breed in southern Ontario if the average summer temperature increased by 2°C. Although the extent of natural coniferous and mixed forests may decline as a result of climate change, it is likely that plantations and nonnative conifers will persist. In central Quebec and Labrador, it was closely associated with stands having a high summer temperature and high rates of summer precipitation. It could be adversely affected if climate change resulted in less precipitation during the growing season (DesGranges and LeBlanc 2012).

Status

Baillie and Harrington (1937) considered the Pine Siskin a nomad in Ontario, occurring irregularly but fairly commonly throughout the province, north at least to the transcontinental railway. They concluded that it probably bred throughout its range, but irregularly at any given location. In the summer of 1937, it was common in the Lake of the Woods area. During the first atlas, breeding evidence was obtained through much of the province, except in the extreme northeastern portion of the Hudson Bay Lowland and southwestern Ontario. In the southwest, it was widespread on the Bruce Peninsula but largely absent west of the Greater Toronto Area except for widely scattered records. Many records may have been obtained after breeding was complete. Breeding occurred predominantly in the Canadian Shield (Middleton in Cadman et al. 1987). James (1991) considered the Pine Siskin a common summer resident in the province north to Sandy Lake and Moosonee and south to Lake Simcoe and Ottawa, and rare north to Fort Severn and Attawapiskat and south to Lake Erie.

The second atlas indicated a similar breeding distribution as during the first atlas, with the exception that there were very few breeding records for the Hudson Bay Lowland. In the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region, there was a high turnover in the squares that were occupied during the 2 atlases. This may be related to its nomadic movements in response to conifer seed abundance. Its probability of observation declined province-wide, but not significantly. There was no change in its probability of observation in the Carolinian region, where it remained rare, and in the Boreal Forest Region. It declined significantly in the Great Lakes–St. Lawrence Forest Region and in the Hudson Bay Lowland. It was most abundant in the Boreal Forest Region, particularly in the northwest. This is in contrast to the first atlas when it was most abundant in the Shield portion of the Great Lakes–St. Lawrence Forest Region. This is probably a manifestation of its tendency to be most abundant wherever conifer seed crops are most plentiful. Abundance is likely to shift again in future atlases depending upon food availability (Pittaway in Cadman et al. 2007), but will probably be concentrated in the Canadian Shield and Hudson Bay Lowland where confers are most abundant.

It is difficult to measure population changes for the Pine Siskin. Its nomadic nature means that it may be abundant in 1 year and absent the next, and this may apply to broad regions in addition to specific locations. Birds that nest in Ontario in 1 year may nest hundreds or even thousands of kilometres distant the following year. The Breeding Bird Survey (BBS) is conducted in June and siskins

may have completed nesting by then. In addition, the BBS does not cover its entire breeding range. BBS data suggest that the Canadian Pine Siskin population peaked in the 1980s and has been declining significantly ever since. It is uncertain how reliable these data are. BBS data for 1970-2021 indicate that it decreased at annual rates of 1.2% in Canada and 1.85% in Ontario. For 2011-21, it decreased at annual rates of 0.909% in Canada and 1.66% in Ontario. All results were of medium reliability, except for the short-term Ontario results, which were of low reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Adults may feed fledglings for as long as 3 weeks after they leave the nest (Middleton in Cadman et al. 1987). Fledglings are fed undigested food items such aphids (Rodgers 1937).

In Michigan, all family groups left the natal territory 1-3 days after the young left the nest. In New Hampshire, fledglings remained near the nest tree for several weeks and visited nearby feeders and bird baths. Appearance of juveniles at feeders during winter irruptions suggested that some young may remain in the vicinity of the natal area for extended periods. In areas where breeding is erratic, fledglings may accompany adults and other family groups on lengthy flights, continuing to receive food from adults en route (Dawson 2020; Hull 1989; Salvadori et al. 2009; Weaver and West 1943).

MIGRATION

It was thought that the Pine Siskin migrated exclusively during the day, when large flocks may occur (Dawson 2020), until Watson et al. (2011) recorded numerous nocturnal flight calls in Maine. This was during an irruption so it is possible that nocturnal migration might occur only during extreme food shortages that induce long-distance movements.

Near the Pacific Coast, the Pine Siskin makes altitudinal movements, descending to lower elevations during winter. In the east, it moves short distances in a north-south direction and makes almost continent-wide movements in a south-southwest–north-northeast orientation. In the east, it may also make periodic irruptive movements far south of its normal wintering range. It is uncertain if the east-west movements occur on a regular basis and if they coincide with irruptions (Palmer in Austin 1968).

Brewer et al. (2018) reported that Ontario birds winter directly south and southeast of their breeding range, mainly in the Great Lakes states, but as far south as Texas and Louisiana in irruption years. Several birds banded or recaptured in Ontario exhibited strong east-west movements, providing no clue as to whether they were eastern or western breeders. This may result from some western birds travelling south in some winters and east to southeast in others. Birds captured in Ontario were banded in Edmonton (2,700 km distant) and Texas (2,055 km); a bird banded in Ontario was recovered in California (2,537 km). The maximum distance travelled by a bird banded or recovered in Canada was 3,983 km. Even in non-irruption years, siskins appear in southern Ontario. It occurs every year in Hamilton (Curry 2006) and a few birds migrate through Prince Edward Point in non-irruption years (Weir 2008). In New York, 9 of 4,045 Pine Siskins (0.22%) were recovered elsewhere at distances of 13-3,470 km. Seventy-seven percent of movements were in a north-south or northwest-southeast orientation that was limited to the eastern states and provinces. Distances travelled by these birds averaged 481 km (range 150-1,437 km). The other 23% of birds moved in an east-southeast–west-northwest orientation and travelled longer distances, averaging 2,099 km

(range 1,356-3,470 km; Yunick 1997). Longley (1992) reported a bird banded in Minnesota that flew approximately 2,100 km westward to Alberta. Two birds banded in Virginia flew northward to be recaptured near Montreal (990 km) and Quebec City, a distance of 1,239 km (Hansrote and Hansrote 1992). Banded birds that were recovered in British Columbia originated in states south of there, in Ontario, and in states along the Atlantic Coast south to South Carolina. The average distance between the banding and recovery locations was 2,800 km (range 360-4,300 km). A bird banded in December in Tennessee was recovered in British Columbia the following December, having travelled approximately 3,800 km (Campbell et al. 2001).

The cause of irruption appears to be widespread collapse of conifer seed crops in an area, resulting in birds moving to other areas where food supplies are more abundant (Dawson 2020). Strong et al. (2015) examined how climate affects conifer seed crops and consequently irruptions of boreal seed-eating birds. Seed production is favoured by a warm dry spring and summer in the year of cone initiation and a warm summer in the subsequent year. They analyzed climatic and Project FeederWatch data for the Pine Siskin across North America. Two irruption modes were detected, with the west-east irruption mode dominating the Boreal Forest Region and the north-south mode dominating the region south of the boreal forest. The north-south mode was positively correlated with spring precipitation in the previous year in the boreal forest and negatively in the Appalachian Region. This suggests a dipole pattern where unusually wet conditions throughout the Boreal Forest Region coincide with unusually dry conditions in the Appalachians. Wet years in the Boreal Forest Region coincide with a small cone crop whereas dry years in the Appalachians coincide with large crops. West-east irruptions tended to follow, at a 2-year lag, anomalously warm and dry summer conditions over western North America paired with anomalously cool and wet summers in the east. Large seed crops occur the year following 2 years of warm, dry conditions. This results in high recruitment and a large population in the west in the year of the irruption. The seed crop in this year will be low because trees must replenish their reserves after a strong cone crop. Conditions in the east are nearly the opposite of the west: wet conditions in the summer 2 years prior to irruption and cool conditions in spring and summer with a weak cone crop in the year before the irruption. This results in low recruitment and a low siskin population. This dynamic supports a migration pattern whereby Pine Siskins move back and forth in the coniferous forests from Alaska to Newfoundland searching for cone crops. Climate change may alter the strength, periodicity, synchrony, or orientation of irruptive patterns because of predicted changes in spring and summer temperatures.

Some studies investigated the periodicity of Pine Siskin irruptions and how synchronized they are with those of other boreal seed-eating birds. In New York, Yunick (1981) reported an almost biennial rhythm to its irruptions, but the pattern was broken in 4 of 18 years. Dawson (2020) reported that irruptions often occur in every second year, but they may also take place in consecutive years or at intervals of more than 2 years. Bock and Lepthien (1976b) reported irruptions into the southeastern states over a decade with intervals of 2 years twice and intervals of 1 and 3 years once. In the Kingston area, Weir (2008) reported major flights in 21 of 60 years or an average of approximately every 3 years. In Algonquin Park, high numbers occur every 5 or 6 years (Tozer 2012). Freedman and Riley (1980) analyzed results of Christmas Bird Counts (CBC) for 1929-77 for southern Ontario. Peak years for the Pine Siskin did not exhibit synchrony with other species, with the possible exceptions of 1955, 1969, and 1971. Bock and Lepthien (1976b) found that irruptions into the

southeastern states were highly synchronized with those of other northern seed-eating birds during 1962-72. Larson and Bock (1986) used CBC data to investigate the synchrony of irruptions of the Pine Siskin, Red-breasted Nuthatch, and Redpoll for 1901-80. The number of years of complete synchrony of the species was much higher than expected by chance from 1901 to 1920 and 1951-80; there was no evidence of synchrony from 1921 to 1950. Results indicated that the pattern and synchrony of irruptions of boreal seed-eating birds can decay and re-form over long periods.

Southward movements of the Pine Siskin occur from mid-August to November. Northward movement occurs from late February to May, but mostly in April and May. Its movements are erratic and can occur at other times as well (Dawson 2020). In irruption years, it arrives as early as September with major flights in October and November; in very heavy irruptions, it may arrive in mid-August. The northward migration is typically in March and April in New York, but may extend well into May in major flight years (Yunick 1981, 1996a, 1997).

In southern Ontario, spring migrants leave in mid- to late May (Black and Roy 2010; Curry 2006; Lancaster et al. 2004; Weir 2008). Wilson and McRae (1993) observed 1 bird at Brant on 21 August and 2 on 23 August, well north of the expected range. It was uncertain if these were autumn migrants or birds dispersing after breeding. Migrants arrive in the south predominantly in mid-October, but may occur in mid-September or even mid-August (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008).

In British Columbia during the nonbreeding season, the Pine Siskin occurs predominantly in coniferous and mixed forests, but also in deciduous woodlands where alder or white birch provide an abundant source of seeds. It inhabits weedy areas where seeds are abundant such as utility rights-of-way, roadsides, fields, recent clear-cuts, and other disturbed areas. It is attracted to orchards and backyards, especially those with bird feeders (Campbell et al. 2001).

The Pine Siskin is not known to exhibit any site fidelity to migratory stopover sites. In New York, Yunick (1983a) banded 2,007 migrants and 0 returned. In Virginia, Hansrote and Hansrote (1992) banded more than 1,500 siskins and had no returns.

Widespread failures of food supplies and subsequent irruptions probably decrease the survival rate of the siskin (Dawson 2020).

The abundance of the Pine Siskin within the Boreal Forest Region during migration is uncertain. Because of its nomadism, it probably varies from absent to abundant in different years at a given location. This is also the case in the portions of southern Ontario that are south of its normal wintering range.

WINTER

In non-irruption winters, the Pine Siskin mostly remains in coniferous and mixed forests in the Boreal Forest Region and the Shield portion of the Great Lakes–St. Lawrence Forest Region in Ontario. In irruption years, its winter habitat is similar to migration habitat. In winter, it commonly occurs in flocks with the American Goldfinch, Redpoll, and crossbills (Campbell et al. 2001; Dawson 2020; Palmer in Austin 1968).

The Pine Siskin defends food resources in winter, both from conspecifics and similarly sized finches. At a 0.9-m by 0.9-m platform feeder, the first arrival attempted to defend the entire feeder from other siskins. It may also defend a small area immediately around the head of a feeding Evening Grosbeak, where it feeds on crumbs of seeds that the grosbeak has broken up. The siskin is dominant to the American Goldfinch and Purple Finch, but subordinate to the larger Evening Grosbeak (Dawson 2020; Palmer in Austin 1968; Schaub 1951).

The Pine Siskin may exhibit site fidelity to an individual feeder or a general region within a winter, but rarely appears at the same location in a subsequent year. In Massachusetts, some birds remained at a feeder for approximately 2.5 months, 2 were seen at a feeder 2.4 km distant, and 1 was seen at a feeder 27 km away (Schaub 1951). In New York, 8 birds turned up at other local feeders in the same winter within 40 km of the banding site (Yunick 1981). At a Quebec site, 926 of 3,966 birds (23.3%) were recaptured in the same season and 715 of the 926 (77.2%) were recaptured where they were banded (Rivard and Bombardier in Gauthier and Aubry 1996). In Virginia, 0 of more than 1,500 birds returned in a subsequent year (Hansrote and Hansrote 1992) and 0 of 1,803 birds returned in New York (Yunick 1983a). In Oklahoma, 4 of 1,322 birds (0.3%) returned in a subsequent winter, after an interval of 4 years in 1 case (Dawson 2020).

The Pine Siskin is readily attracted to feeders in winter, especially those offering niger and sunflower seeds (Dawson 2020). Project FeederWatch data indicate that it prefers hulled sunflowers, niger seed, black oil sunflowers, and water. Infrequent choices include mixed seeds, millet, canary seed, striped sunflowers, safflower, cracked corn, milo, wheat, peanut hearts, suet, peanut butter mixes, bird puddings, and canola (Dunn and Tessaglia-Hymes 1999). In Canada and the United States, 30,574 siskin feeding bouts were documented. The most abundantly consumed seeds were 0.3-mm and 0.5-mm sunflower chips and niger seeds. It preferred tube and platform feeders over hopper feeders (Horn et al. 2014).

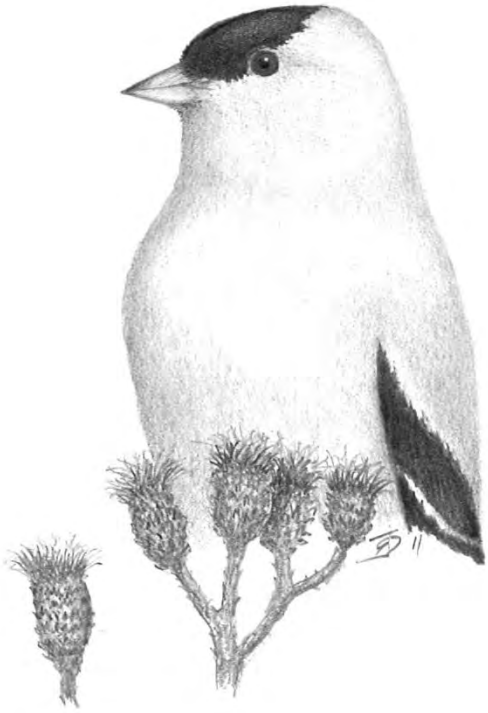
The Pine Siskin's feeding behaviour has the potential to result in extensive mortality, particularly during irruption years. It is highly susceptible to salmonellosis and may become infected at feeders. In Tennessee, several died of this disease during warm rainy days in mid-March (Rodgers 1991). During the winter of 1992-93, thousands died of salmonellosis in British Columbia, Washington, and Oregon (Campbell et al. 2001). Siskins are killed in large numbers on roads where they are attracted by salt. In British Columbia, a single passing car may kill hundreds (Campbell et al. 2001; Tozer 2012; Yunick 1997).

Severe winter weather may cause mortality. Wind, snow, and ice may curtail feeding opportunities and result in starvation (Dawson 2020).

James (1991) considered the Pine Siskin a common to locally abundant winter erratic in the south, becoming occasional north to Sioux Lookout and Cochrane. Numbers vary considerably due to its erratic nature. Freedman and Riley (1980) analyzed CBC data for southern Ontario from 1929 to 1977 and discerned no long-term trends in its overall numbers.

American Goldfinch

Spinus tristis



BREEDING SEASON

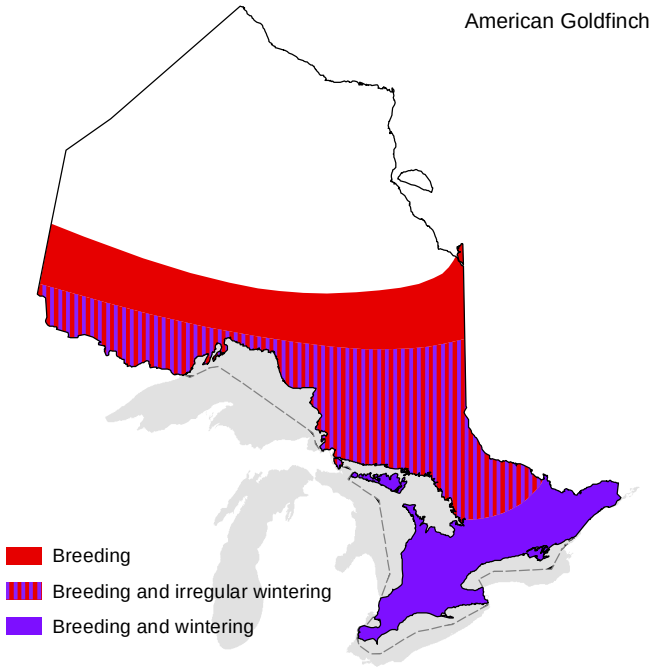
Habitat Requirements

Ontario American Goldfinch nests were in a variety of open and semiopen habitats. Most (54.1%) were in agricultural landscapes, including overgrown fields, pastures, hawthorn meadows, orchards, fencerows, and conifer plantations; 20.9% were at roadsides and shorelines of rivers, ponds, and marshes; 12.2% were in woodlands and swamps; 10.7% were along residential streets and in gardens, farmyards, and cemeteries; 1.5% were in willow swales and heath muskegs; and 0.5% were in sand-dune areas. Hawthorn meadows were the preferred habitat, with nests there very close and approximating coloniality. In woodlands, nests were either at edges or the canopy was open (Peck and James 1987).

In the Clay Belt, Welsh and Lougheed (1996) reported the American Goldfinch in a black spruce stand and a stand dominated by trembling aspen, balsam fir, and white spruce. Both stands were fairly wet and ranged from slightly below moderate to rich on the nutrient scale.

In Muskoka and Parry Sound districts, the American Goldfinch nested in bogs and open forests or clearings as well as along river edges, hydro transmission line corridors, and field edges (Mills 1981). In shelterwood cuts in white pine stands in Algonquin Park, it occurred in 14.3-20% of stands

with no recent history of harvesting, 10-18.2% of stands 10-16 years after cutting, and in 16.7% of stands 1-2 years after cutting (Kingsley and Nol 1999).



In the Great Lakes–St. Lawrence Forest Region south of the Shield, Speirs and Orenstein (1975) reported it in all 11 plots they surveyed in Durham Region. These included mature and very young pine plantations, with the latter still dominated by willow shrubs; an old orchard overgrown with hawthorns and apple trees; a bog; a coniferous swamp; and a variety of open deciduous woodlands. Highest densities occurred in shrub-dominated habitats: the very young plantation and the overgrown orchard. They considered it a species of early forest succession. In Guelph, Middleton (1979) studied it in 3 habitats. The natural habitat was 68 ha comprised of 25% old-field habitat, 50% willow scrub, and 25% maple-elm woodlot. It also nested in a 10-ha area that the university had developed as a nursery and in a 20-ha residential suburb that had been settled for approximately 20 years. The nursery appeared to be suboptimal habitat.

In Elgin County in the Carolinian Forest Region, the goldfinch nests in both rural and urban settings (Lancaster et al. 2004). In the Hamilton area, McIlwraith (1894) reported it in cultivated fields, orchards, and gardens. South of the Shield, its abundance was significantly negatively correlated with the amount of forest cover more than 100 m from edge and the amount of forest cover within 2 km. It was also negatively correlated with woodlot size and the amount of regional forest cover, but not significantly (Austen et al. 2001).

The American Goldfinch strongly favours weedy and grassy fields and floodplains with early successional growth for breeding. It may also use cultivated fields, roadsides, vineyards, orchards, and gardens. Its main food plants are in the aster family, with a preference for thistles, and it rarely nests far from them. The most common nest cover includes low shrubs, deciduous saplings, isolated mature trees, or forest edges. It avoids mature or extensive forests and prefers shrubs in early successional growth with a clear space on at least 1 side of the nest site (McGraw and Middleton 2020). Nests may be either in upland meadows or shrub thicket swamps and marshes with scattered trees and shrubs (Tyler in Austin 1968). In Quebec, it is found predominantly in southern urban and agricultural landscapes, although it also frequents regions of extensively forested habitat. It is less common in densely wooded landscapes where it is mostly restricted to clearings, burns, and clear-cuts, and along logging roads, hydro transmission line corridors, and shorelines of lakes and rivers. Near Montreal, it nests in abandoned fields and on edges of forests. It frequents mostly open areas with abundant food plants and preferably a few trees or shrubs for perching (Lepage and Limoges

in Gauthier and Aubry 1996). Falardeau et al. (1999) reported that it was absent in young, medium-aged, and old strip-cuts in Quebec, but occurred in low densities in final strip-cuts and clear-cuts. In the Prairie Provinces, it was in a guild concentrated in young aspen stands, but species in this guild also occurred in wet marshy areas and riverine mixed woods. The goldfinch occurred mostly in stands 20 years or younger on moist sites with moderate nutrient richness (Kirk et al. 1996). Flack (1976) concluded that aspen stands were not particularly suitable for it. In aspens, it preferred riparian woodlands, small groves, and edges. In northeastern poplar–white birch stands, it occurred in moderate densities in sapling- to pole-sized stands and was absent in seedling- to sapling-sized and mature stands (Back 1979). In Saskatchewan, Hartley (1994) reported the goldfinch in 6.3% of plots in planted grasslands 3-5 years old; it was absent in native grasslands and wheat fields. In British Columbia, it breeds in open riparian shrublands adjacent to weedy areas and agricultural areas that have shrubs for nesting and patches of thistles and dandelions for foraging. It prefers to breed there in weedy fields and early successional growth as well as cultivated fields, roadsides, orchards, and gardens. Thirty-one percent of nests were in natural areas and 69% were in human-influenced areas. Natural habitats included remnant stands of deciduous or coniferous trees (20% of nests), riparian habitats (6%), shrublands (3%), and grasslands (2%). Nests in human-influenced habitats were in orchards (30%), agricultural sites (25%), gardens (9% rural, 8% urban, 6% suburban), woodland edges (9%), riparian habitats (9%), and meadows (4%; Campbell et al. 2001). In the Boreal Forest Region, Erskine (1977) considered the goldfinch a species of open shrubby habitat. It also occurs in the earliest stages of succession in burns and clear-cuts. Overall, it is associated with artificial grasslands and shrublands, and often occurs at the boreal forest–prairie ecotone. In New York, it nested in purple loosestrife above water on intermittently saturated soils. Nests were in flooded freshwater marshes, patches of unmowed wet meadow, a wet meadow within a dry old field, extensive wet old fields, and a roadside wetland (Kiviat 1996). In Pennsylvania, it nested on hydro corridors through forests, but was absent in the adjacent forested habitat (Yahner et al. 2002). In Pennsylvania, it occurred in 9.1% of old-growth mixed forests compared with 94.4% of forests statewide and 92.4% in the Appalachian Plateau (Haney 1999). In Ohio, it inhabited 20 ha of wet prairie and deciduous scrub that had not been tilled for 10-20 years. The fields were grown up with thistles and other forbs and were separated by shrubby hedgerows (Holcomb 1969). In oak savannahs in Indiana, highest densities occurred where tree height was 8 m, the shortest category. Its abundance was 80% lower where tree heights were 12 m (Grundel and Pavlovic 2007a). Several studies examined goldfinch habitat use in Michigan. Stokes (1950) studied it in a mix of park and marshland 9.7 ha in area. The park consisted of lawn, shrubs, and shade trees; the remaining 6.5 ha was a peat marsh. Except for the occasional Manitoba maple and willow, the marsh was devoid of trees. Common elderberry was the most common shrub. Next in abundance were red-osier dogwood, buttonbush, and tartarian honeysuckle. Grasses and sedges covered most of the marsh, with common forbs including Joe-pye-weed, giant sunflower, goldenrods, asters, thistles, nettles, spotted jewelweed, wild cucumber, smartweeds, swamp milkweed, and dodder. Drum (1939) reported it in an open woodlot of maple and poplar with scattered pines, oaks, and white birch. The woodlot was fragmented by paths, firebreaks, and roads. Pin cherry, juneberry, and sumac were common and the ground flora was dominated by catchflies and blueberries. Nickell (1951) reported that highest concentrations of goldfinches occurred in open swamp habitats, but many nests were present in shrubs in uplands distant from wetlands. It also nested in fencerows, tree and shrub fringes along roads, abandoned

farm and pasture land, old orchards, house lots, and landscaped subdivisions. He had 3 study areas. The first was an unmowed area along a lake shore that supported thistles and other species in the aster family. The second consisted of second-growth oak-hickory forest, dense spruce-tamarack bogs, a leatherleaf bog with scattered black spruce, old pastures, old apple orchards, and open swamps of tamarack, steeplebush, buttonbush, and swamp birch. This site was marginal habitat due to the limited number of suitable nest sites and a scarcity of its preferred food plants. There were 3 habitat types at the final study area. The first included forest edges and adjacent open fields. The second consisted of shrubby fields, both close to and distant from lakes and swamps. They had scattered growths of hawthorns, gray dogwood, elms, staghorn sumac, wild plum, cherries, ninebark, tartarian honeysuckle, and blackberries. Herbaceous species present that were of most use for feeding and nesting included lesser burdock, bull thistle, Canada thistle, common dandelion, wild lettuces, common milkweed, and chicory. The third and most important habitat was a marshy area that could be either wet or dry during the breeding season. The dominant shrubs were gray dogwood, red-osier dogwood, silky dogwood, willow, elderberry, steeplebush, buttonbush, and poison sumac. Scattered trees occurred among the shrubs. Forbs present that were important for feeding and nesting included broad-leaved and narrow-leaved cattails, swamp thistle, swamp milkweed, and nodding beggarticks. Berger's (1957) Michigan study area consisted of a hawthorn meadow. Nests were also along roadsides, in shade trees in towns, and along edges of woods. On rehabilitated strip mines in Illinois, it was most abundant in early shrub habitat where the oldest trees were 10 years old, followed by late shrub habitat where the oldest trees were 37 years old. It was absent in bottomland and upland forests and in areas of bare soils (Karr 1968). Graber and Graber (1963) reported highest densities in Illinois in edge shrubs followed in order of declining abundance by orchards, ungrazed grasslands, shrub-grown areas, forests, pastures, oat fields, and marshes. It was 39 times more abundant in edge shrubs than in marshes. In Wisconsin, it was common in alder thickets (Hoffman 1989b); rare in northern mesic forests (Hoffman 1989a); present in upland forests where it preferred edges and small tracts and occasionally occurred in the canopy of stream gorges (Mossman and Hoffman 1989); was documented in 64% of floodplain forests, mostly in wet forests and shrubby edges (Mossman 1988); occurred in 18% of conifer plantations (Bielefeldt and Rosenfield 1994); and was abundant in pine and oak barrens (Mossman et al. 1991). In Arkansas, Shugart and James (1973) reported highest densities in a woody field, followed in order of declining abundance by clonal persimmon tree plots and a burned field. It was absent in a mowed hayfield, a broomsedge field, and 5 types of forest plots. It was the most abundant species in the 2 plots in the early tree stage of succession. In Missouri, it occurred in very low densities in prairie dominated by little bluestem, big bluestem, and Indian grass (Winter and Faaborg 1999). In Iowa, Benson et al. (2013) reported it in monotypic stands of reed canary grass. It was associated with densely vegetated fields that were grass-dominated with a well developed litter layer. In the same state, it nested in Conservation Reserve Program fields (Patterson and Best 1996). In Kansas, all goldfinch activities were concentrated in weedy fields (Fitch 1958). In South Dakota green ash woodlands that were narrow bands less than 30 m wide, it was significantly more abundant in late than early seral stages. Older woods had more chokecherry in the understorey than younger woods, resulting in a greater foliage density less than 2 m from the ground and less patchiness in this layer (Rumble and Gobeille 1998). In North Dakota, it occurred in moderate density in idle prairie plots that had not been grazed, burned, or mowed for 5-19 years and supported considerable shrub

cover. It was significantly more abundant in this habitat than in grazed grassland with no shrubs and homogeneous fields of alfalfa and wheat grass (Renken and Dinsmore 1987). In North Dakota, it occurred at moderate density in plots with 30-80% shrub coverage and was absent in plots with 5% shrub coverage (Arnold and Higgins 1986). In North Dakota, it was common, occurring in all forest types. Highest densities occurred in early seral stages of deciduous habitats, including juneberry thickets and willow shrub communities (Faanes and Andrew 1983). In Montana, Walcheck (1970) reported it in a 7.1-ha cottonwood forest, but it was absent in sagebrush shrublands, sagebrush grasslands, and a pine-juniper woodlot. In northeastern northern hardwoods, Noon et al. (1979) reported it in 8% of plots in mature undisturbed forests and in 13% of plots in disturbed and early successional habitat. In northeastern mixed forests, Temple et al. (1979) considered it associated with scattered stands of tall trees and shrubs. Taylor and Taylor (1979) considered it a bird of large and small openings and forest edges, but not of forests.

In North Dakota, the American Goldfinch was more abundant in landscapes with less than 30% tree cover at the 400-m scale. It responded positively to an increase in tree cover within 100 m in open landscapes, but negatively in forested landscapes (Cunningham and Johnson 2016, 2019).

In the mid-Atlantic states, the goldfinch's abundance was positively correlated with mean canopy height but negatively with the number of trees within a 0.04-ha circle, the amount of forest within 2 km, and the number of trees larger than 38 cm diameter at breast height (Robbins et al. 1989).

The American Goldfinch is not an area-sensitive species, but most study on this has been done in forests which are not preferred habitat. Johns (1993) surveyed trembling aspen groves in Saskatchewan that ranged in size from 0.04 to 36.7 ha. Its presence was unaffected by woodlot size or the degree of its isolation. Freemark and Collins (1992) and Robbins et al. (1989) concluded that it was not area sensitive in forested habitat. The goldfinch is also not area sensitive in its preferred shrubby habitats, where it may inhabit very small patches.

During the breeding season, individuals or pairs roost overnight close to the nest (McGraw and Middleton 2020). No information appears to be available on the roosting substrate.

Ontario nests were elevated, usually in living deciduous or coniferous trees and shrubs. Three nests were in herbaceous species: one each in burdock, goldenrod, and an unspecified species. Deciduous trees and shrubs (94.1% of nests, 25 species) were greatly preferred to conifers (5.9% of nests, 4 species). Nests were in hawthorns (40.8% of nests), maples (18.9%), willows (18.3%), apple (8.3%), birches (7.1%), and dogwoods (6.5%). Of 63 nests, 87.3% were in upright crotches or forks and 12.7% were on lateral branches. Nests were more often distant from the trunk than near it, at distances of 0.9-4.6 m from the trunk; most were 1.2-4 m from the trunk. More nests were reported from the tops of trees and shrubs than at the midpoint or lower. Several nests were in the same tree or shrub as in the previous year, and one was 30.5 cm above a previous year's nest. In all cases, it was unknown if the same birds were involved in the different years. Nests were 0.3-16.8 m from the ground, with most 1.2-2.4 m up (Peck and James 1987). In Guelph, Middleton (1979) described nests in 3 habitats. In the natural habitat, 37.5% of 200 nests were in shrub willows, 20.2% were in hawthorns, 13.4% were in maples, 13.0% were in juneberries, 4.3% were in trembling aspen, 2.4% were in white cedar and elderberry, 1.4% were in beech and alder, 1.0% were in yellow birch, red-

osier dogwood, and white elm, and 0.5% were in basswood and an unidentified shrub. Mean nest height was 1.8 m (range 0.6-6.1 m). In the nursery, 51.5% of 29 nests were in maples, 6.1% were in willows and beech, 3.0% were in alders, and 33.3% were in unidentified cultivars. Mean nest height was 2.5 m (range 1.7-3.7 m). In the suburban area of the city, 81.8% of 34 nests were in maples, 12.2% were in poplars, and 3.0% were in horse chestnut and ash. Mean nest height was 4.4 m (range 1.8-7.1 m). In the natural habitat, 74.1% of nests were in shrubs. A similar choice of shrubs was unavailable in the nursery and city where trees and saplings provided all nest sites. One Guelph nest was in a Japanese yew (Mariani et al. 1993). Dance (2008) reported a nest in a black alder in Oxford County.

Throughout its range, the American Goldfinch nests almost exclusively above ground. Most nests are in deciduous trees and shrubs, but it also nests in conifers and herbaceous species. It is opportunistic and nests in the most abundant tree or shrub species. Presence of suitable food plants within the home range, such as thistles and other members of the aster family, appears to be more important than nest sites. In different studies, the dominant nest species included common elderberry, red-osier dogwood, willows, wild roses, poplar saplings, hawthorn, gray dogwood, and orchard fruit trees (apple, pear, peach, plum, and cherries). Other woody species it has nested in include red oak, red pine, red cedar, tamarack, elm, swamp birch, lilac, ninebark, Manitoba maple, buttonbush, red maple, balsam poplar, bur oak, chokecherry, sugar maple, purple willow, honey locust, staghorn sumac, large-toothed aspen, white birch, silky dogwood, privet, trembling aspen, Osage orange, steeplebush, black locust, wild plum, black cherry, American bittersweet, swamp white oak, red mulberry, nannyberry, wild grape, white poplar, scotch pine, white pine, meadowsweet, sagebrush, Saskatoon, hazelnut, raspberry, white oak, crabapple, alder, cottonwood, black poplar, spruce, fir, walnut, and horse chestnut. It will apparently nest in any species of tree, shrub, or forb that provides good anchorage, proper support underneath the nest, a reasonable height, and concealment. Shrubs appear to be preferred to trees, with scattered trees in shrubby areas rarely, if ever, used. In contrast, most British Columbia nests were in trees rather than in shrubs. Nests are often in shrubs close to a tree that provides a singing perch (Berger 1948, 1968; Campbell et al. 2001; Holcomb 1969; Mousley 1930, 1932, 1935; Nickell 1951; Stokes 1950; Tyler in Austin 1968). Some nests are in herbaceous species. In Wisconsin, 5% of 230 nests were in thistles, 5% were in giant sunflowers, 2% were in asters, 1% were in Joe-pye-weed, 0.5% were in wild lettuce, and 0.5% were in goldenrods. In Ohio, 8.7% of 126 nests were in bull thistles and 1% were in goldenrods. It has nested in Canada thistle and purple loosestrife elsewhere. In Wisconsin, there was a marked increase in the use of forbs as the season progressed. Birds probably wait until forbs mature before nesting in them. Almost all nests in forbs were in rosettes where lateral buds had sprouted in response to insect damage near the top of the plant. In New York, purple loosestrife appeared to be selected as a nest substrate over apparently suitable nearby woody vegetation. Nesting in purple loosestrife allowed goldfinches to nest in marshes that would otherwise be unsuitable for nesting. An analysis of 5,991 nest-substrate records revealed that 87.5% of nests were in deciduous trees and shrubs and only 11.6% were in herbaceous species (mostly thistles). Thirty-two percent of the nest plants were wetland species, 22% were upland species, and the remainder were facultative species (Holcomb 1969; Kiviat 1996; Nice 1939a; Pierce 1922; Stokes 1950). In Michigan, Nickell (1951) described 6 types of nest placement for 147 nests that were mostly in shrubs. Type 1 nests were the

most important (81.6% of nests) and were in an upright fork with an average of 4 evenly spaced vertical branches that were used for attachment and formed a cradle-like support for the nest. Type 2 nests (6.8%) were also in an upright fork, but with all branches on 1 side, leaving the nest unsupported on the other side. Type 3 nests (3.2%) consisted of 2 parallel upright branches between which the nest was built with no support underneath. Type 4 nests (4.1%) consisted of tufts of small twigs growing in an upright position from horizontal branches; the nest was cradled within the twigs. Type 5 nests (4.1%) were saddled over and around horizontal branches and fastened to small horizontal twigs or leaves. Type 6 nests (1.4%) were wedged between horizontal forks and held in place by attaching the nesting materials to the 2 sides. The bottoms of these nests were unsupported and resembled the semipensile nests of vireos. In Wisconsin, 93% of nests in shrubs and forbs were within 60 cm of the top of the plant and 99% were within 90 cm of the top (Stokes 1950). Of British Columbia nests in trees and shrubs, 57% were in the fork of a branch and 31% were saddled on a larger branch. Seven percent were near the end of a branch and 5% were near the top of a shrub or tree (Campbell et al. 2001). Many nests in trees are distant from the trunk on limbs and the goldfinch has been documented nesting on limbs overhanging roads (Tyler in Austin 1968). A Michigan nest was on the ear of a standing corn plant. Another was in a tangle of bedstraw and a fence, with the nest attached to a vertical wire and resting on a horizontal wire. Vines such as bittersweet and grape were used as a nesting substrate only when they were climbing on more rigid plants to which the nest was attached (Nickell 1951). Nests have been reported 0-18 m above ground (Campbell et al. 2001; Tyler in Austin 1968), but these extremes are rare. Nests in herbaceous species are the lowest. Those in purple loosestrife in New York averaged 1.4 m from the ground (range 0.9-1.9 m; Kiviat 1996). In Wisconsin, Stokes (1950) reported that almost all nests in shrubs and forbs were 0.9-1.8 m from the ground; those in trees were usually 2.4-4.6 m up. In Ohio, mean nest height was 1.44 m in July (range 0.77-2.34 m), 1.37 m in August (range 0.60-2.92 m), 1.08 m in September (range 0.80-1.57 m), and 1.39 m overall (range 0.60-7.42 m). Most nests were in shrubs, but a few were in trees and forbs (Holcomb 1969). In Michigan, 71% of 583 nests were in hawthorns at an average height of 1.35 m (range 0.69-2.79 m; Berger 1968). In 3 different habitats in Michigan, nests averaged 5.7, 3.7, and 1.6 m from the ground. Highest nests were in trees along fencerows and at edges of forests. The overall average height of 211 nests was 1.86 m (Nickell 1951). In British Columbia, most nests were 1.8-4.0 m from the ground, with a range of from ground level to 12.0 m (Campbell et al. 2001). The goldfinch has been observed dismantling old Yellow Warbler and Baltimore Oriole nests and using the milkweed fibres in its own nest. Nests may rarely be used to raise a second brood but more commonly to lay a replacement clutch (McGraw and Middleton 2020).

It is most likely that the American Goldfinch defends only a small area around the nest, but there are conflicting reports in the literature. Food resources do not appear to be defended. Drum (1939) reported the most extensive territories in Michigan. Males circled the territory several times, roughly defining their boundaries. All areas defended by males contained at least a few trees and in 2 cases were more than 30 m long and 15 m wide (0.045 ha). The further the nesting area was from the feeding area and the more isolated the nesting area, the larger the territory was. One was at least 300 m long and 150 m wide (4.5 ha); the average territory size was about 0.2 ha. Males did not allow other males to land within their territories and females defended the territory from other females.

Although some of the large areas were defined as territories, it was unknown if these areas were actually defended because no other goldfinches were observed to alight in them. There was little or no defence around the nest site once the male began feeding the female at the nest. Despite the apparently large territories, nests were found as close together as 9 m. In Wisconsin, Stokes (1950) described the same circle flights by males. Males were intolerant of other males that approached their female. He used mounted goldfinches to determine the extent of territories. The greatest distance from the nest that a male defended was 27 m (0.23 ha). The territory consisted of the nest site and immediate area, but did not include sufficient food or water for the nesting pair. Some birds began defending their territory 2 weeks before nest building, but usually only 1 or 2 days earlier. Defence of the nest continued as late as the tenth day of incubation. In 4 cases, females built second nests in a new territory as far as 137 m from the first nests. These territories were vigorously fought for with the neighbouring males, suggesting that the female selects the territory. The goldfinch tends to nest in small aggregations or semicolonially, with each pair defending a small territory within the colony. At Guelph, groups of nesting goldfinches were randomly distributed in some habitats, and these same areas were used regularly from year to year. Coloniality may result from the distribution of some resource other than nest sites (McGraw and Middleton 2020; Middleton 1979). In Ohio, Nice (1939a) reported that 12 of 15 pairs nested in groups: 4 in 0.4 ha, 3 in 0.8 ha, and 5 in 0.8 ha. The grouping of nests was not dependent on nest-site availability because thistles, the nesting substrate, were abundant everywhere. Nickell (1951) saw no evidence of intraspecific aggression and found 3 nests within 0.5 ha. In Michigan, Berger (1957) reported that most nests in hawthorn meadows and swampy habitats were semicolonial, and only the immediate area around the nest appeared to be defended. The average distance between 7 nests in 1 group was 21 m and the minimum was 6.1 m. Isolated nests were more likely to occur along roadsides, in shade trees in towns, or at edges of woods. Feeding areas may be distant from the nest site, so the goldfinch may have a large breeding season home range. Nickell (1951) reported that most feeding areas were within 90 m of the nest site, but some were 180-225 m distant. Drum (1939) reported that the distance between some nest sites and feeding areas was greater than 1.6 km and Fitch (1958) reported separation distances of more than 800 m.

Natal philopatry is very low. Over a 24-year period at Guelph, only 2 nestlings returned to breed in their natal area (McGraw and Middleton 2020). In Michigan, 1 of 1,133 nestlings (0.09%) returned to nest. One nestling was recovered 2 years later in the breeding season in New York (Berger 1968).

Adult site fidelity appears to be fairly low. In Kansas, Verheijen et al. (2017) reported return rates of 6.1% for males and 7.2% for females. In Michigan, Berger (1968) banded 15 adults and the band of 1 female was found in an Eastern Screech-Owl pellet the following year. This was the only recovery, representing a 6.7% return rate. In Guelph, Middleton (1979) observed that returning females usually remained in the same habitat, particularly if they had nested successfully the previous years. A few unsuccessful females switched habitats the following year. Females were significantly more likely to remain in the same area in a subsequent year than males (81.1% compared with 25.0%). Attachment to a nesting area by a female appeared to increase with age and nesting experience. Two returning females in Wisconsin nested 45 and 13.5 m from their previous year's nest. Of 53 females that moved between nests within a breeding season, the longest move was 137 m and almost all remained in the same territory (Stokes 1950). In Michigan, 3 territories had

nearly identical boundaries in a subsequent year and nests were built in the same tree within 1 territory in 3 consecutive years. It was unknown if the same birds were involved each year (Drum 1939).

Limiting Factors

The American Goldfinch is a late breeder. Peck and James (1987) reported eggs in Ontario nests from the second week of June until the end of September, with most present from the last week of July until mid-August. Peck and James (1998b) reported that the earliest egg date in the province was 28 May, and that nests had been observed under construction on 21 and 26 May. In Algonquin Park, nests are under construction from early to late July and eggs are present from mid-July to mid-August (Tozer 2012). In Guelph, the first nests are typically found in late June or early July, with an early nest with an egg reported on 28 May. Over an 8-year period, the date of the first egg ranged from 2 to 10 July (average 6.5 July). The mean egg-laying date was 17.9 July (range 17.1-18.8 July). Old males came into breeding condition about 2 weeks before yearling males and lost their breeding condition slightly before yearlings. Females reached breeding condition in mid-July and it lasted until mid-August. Maximum ovarian development occurred in the latter half of July when all females were in breeding condition. Ovarian activity waned after that and no females had ovaries in breeding condition by September. Old birds built the earliest nests and typically laid the first eggs; yearlings built most of the late August nests. In all habitats at Guelph, most reproductive effort occurred in the last half of July with no difference in timing among habitats. The onset of egg laying was unrelated to temperature and rainfall and is probably regulated by photoperiod. Reproduction is timed to coincide with the flowering and fruiting of plants in the aster family, thereby ensuring maximum food availability (Gissing et al. 1998; Mariani et al. 1993; Middleton 1978, 1979). Similar timing of nesting has been reported in Michigan, Wisconsin, and Ohio. First nests may be 2 weeks later in New York and 2 weeks earlier in British Columbia. Because of the lateness of nesting, nestlings may be present until the end of September or very early October (Berger 1968; Campbell et al. 2001; Holcomb 1969; Nickell 1951; Stokes 1950).

The pair bond is established within prebreeding flocks during May and early June, and possibly sooner. Females select the male and therefore the territory. Brighter-coloured males are preferred because the yellow plumage and pink bill are a result of carotinoids in the diet, suggesting that they are superior at foraging. Most nests are completed in about 6 days, but extremes of 4-15 days have been reported. A longer period is taken to build the nest early in the season than later, and inexperienced birds may take longer than older birds. In Ohio, nests took an average of 8.6 days to complete in July compared with 4.1 days in August. In Wisconsin, it took an average of 13.0 days to build a nest in the first half of July, 10.8 days in the last half of July, 5.8 days in the first half of August, and 5.6 days in the last half of August. Usually some time elapses between nest completion and laying of the first egg. The interval is shorter later in the season, averaging 3.4 days in July and 1.3 days in August. In 1 case, the first egg was laid while down was still being added to the nest. Intervals as long as 27 days have been reported between nest completion and laying. Lengthy intervals were probably due to adverse weather or other unusual events. Eggs are laid at the rate of 1 a day. Incubation begins with the laying of the second or penultimate egg. Incubations periods of 8-14 days have been reported in Ontario, with most eggs hatching in 10-12 days. Elsewhere, incubation periods of 11-15 days have been reported, with most eggs hatching in 12-14 days. Eggs may hatch

either synchronously or asynchronously over a period as long as 4 days. Fledging success is higher in synchronous nests because all nestlings are fed equally. In asynchronous nests, larger nestlings receive a disproportionate amount of the food to the detriment of younger nestlings. Nestling periods of 11-17 days have been reported, with most chicks fledging when they are 13-15 days old. If undisturbed, nestlings rarely leave the nest before age 12 days (Berger 1953; Drum 1939; Holcomb 1969; McGraw and Middleton 2020; Mousley 1932, 1935; Nice 1939a; Peck and James 1987; Skagen 1987; Stokes 1950; Tyler in Austin 1968).

Due to the lateness of its breeding season and the limited time that it is physiologically capable of breeding, the American Goldfinch can raise a maximum of 2 broods a year. Most pairs raise a single brood. In Guelph, 34 of 508 nests (6.7%) were second broods. Most, if not all, were raised by older females who tended to initiate nesting earlier in the season. Their first broods usually fledged in early August, allowing sufficient time to raise a second brood before gonadal recession occurred. Guelph females must initiate their second brood by 16 August at the latest if the second brood is to be successful. Females invariably abandon their first nest before the young fledge, leaving the male to raise the first brood. Only experienced males are capable of this. Raising a second brood is highly advantageous, with those doing so raising a mean of 7.3 fledglings compared with 3.4 for older females raising a single brood and 2.8 for females of unknown age (Middleton 1979, 1988). In Wisconsin, most birds that raised their first brood before 20 August initiated a second clutch. Nine of 60 pairs (15.0%) were double brooded (Stokes 1950). If a nest is lost, a replacement clutch is laid, occasionally in the same nest. As many as 3 attempts may be made to raise a brood. At Guelph, the mean time between nest loss and laying the first egg in the replacement clutch was 6.9 days. Replacement nesting allowed 60% of birds that lost their first brood to raise a mean of 2.8 fledglings (McGraw and Middleton 2020; Middleton 1979). In Wisconsin, laying in replacement clutches started 4-21 days after nest loss, taking longer earlier in the season (Stokes 1950). In Michigan, a new nest was begun the day after the first one was damaged by a storm (Drum 1939). In Ontario, Peck and James (1987) reported clutch sizes of 2-7 eggs, but mostly 4-6 eggs with 5 eggs the most common clutch size (mean 4.89 eggs). At Guelph, clutch size was 2-7 eggs (mean 5.2 eggs); most clutches contained 5 eggs. Mean clutch size may have been somewhat inflated because parasitized nests were not included in the calculations. Mean clutch size of older females (5.3 eggs) was significantly greater than females of unknown age (5.0 eggs). The age classes of females cannot be distinguished, so the sample of unknown-age birds may have included some older females that nested in the area for the first time. Old females laid a higher proportion of 6- and 7-egg clutches than younger birds, who laid a higher proportion of 3- and 4-egg clutches. The mean clutch size of old females mated to old males was 5.6 eggs compared with 5.3 eggs for old females mated to young males. Older males may be more proficient at finding high-quality foods. Clutch size varied by habitat: 5.0 in the natural area, 5.6 in the nursery, and 5.2 in the city. Clutch size decreased significantly with the season in all habitats. The most common clutch size of 5 eggs was not the most productive, with no difference in the comparative success of 4-, 5-, and 6-egg clutches. Six eggs appeared to be the most productive clutch size, producing the greatest number of fledglings (McGraw and Middleton 2020; Middleton 1979). In Wisconsin, Stokes (1950) reported clutch sizes of 2-7 eggs (mean 5.3 eggs in July and 3.7 eggs in August). For 10 females that laid 2 clutches, mean clutch sizes were 4.8 eggs for the first clutch and 3.8 eggs for the second clutch. In Ohio, Holcomb (1969) reported clutch sizes of 3-6

eggs (mean 5.03 eggs). The clutch size of 4.0 eggs in September was significantly lower than in July (5.1 eggs) and August (5.0 eggs). Temperature did not appear to affect clutch size. In Michigan, clutch size was 2-7 eggs with a mean size of 4.89 eggs for 474 nests.

Both sexes are capable of breeding when they are 1 year old and they breed annually thereafter. Yearlings are physiologically incapable of breeding as early as older birds because their gonadal development is slower. The peak of nesting in the latter half of July is due to yearlings nesting. They may further delay nesting until large numbers of plants in the aster family are in bloom, ensuring an abundance of the most desirable nest-building materials and a later abundance of food. Yearlings raise a single brood only and produce few 6-egg clutches. This suggests that rearing young is a difficult task for them or they may be unable to find sufficient food to raise a large brood (McGraw and Middleton 2020; Middleton 1979).

The mating system is predominantly monogamous; all first nests of the season are monogamous. Some females are sequentially polyandrous when they raise a second brood. The female typically remains in the same territory for the second brood, but may switch mates. At Guelph, polyandry occurred at 25 of 508 nests (4.9%); 70.6% of females that attempted a second brood switched mates. In some cases, the polyandrous matings did not persist. The new male was displaced by the original male, who accompanied her at the second nest. Because the new male copulated with the female, some of the young in the nest were extra-pair. Polyandry is a successful strategy because it allows the female to abandon the first brood early and start a second brood. Polyandrous females produced an average of 7.4 fledglings per season, significantly more than for all other females (2.3) within the same time period. Polyandrous females select experienced males and build the first nests of the season (Middleton 1979, 1988). In Wisconsin, 1 of 3 double-brooded females appeared to be polyandrous (Stokes 1950). McGraw and Middleton (2020) concluded that as many as 15% of females were polyandrous, due in part to the male-biased sex ratio. At Guelph, 5 of 16 females (31.3%) and 1 of 8 males (12.5%) were faithful to their mate in a subsequent year (Middleton 1979). Extra-pair copulations are another mating strategy. At 15 Guelph replacement nests, the female was the genetic parent of the offspring in all cases. Ten of 70 nestlings (14.3%) in 4 of 15 broods (26.7%) had DNA profiles that were inconsistent with the attending male. Three of the 4 nests that contained extra-pair young were replacement nests; in the other nest, there was a protracted delay between nest completion and egg laying. Nest disruptions may be a factor in extra-pair paternity, which may result from nesting asynchrony and reduced mate-guarding efficiency (Gissing et al. 1998). Holcomb (1969) reported that 2 eggs were laid in an Ohio nest in 1 day. It is possible that this was a case of intraspecific parasitism.

The American Goldfinch feeds in flocks even during the breeding season, but birds may forage singly at this time. Flocks frequently feed in a rolling leap-frog fashion, especially in winter, thus exploiting food efficiently and maximizing protection from predators. It prefers to take seeds while perched on the flowering head of a plant to feeding on the ground. It hangs upside down from branches or thistle heads and strips bark from terminal shoots. It has a distensible esophagus or rudimentary crop so it can transport food to the nest or store food to meet overnight energy demands. It has been observed plucking winged elm fruits and extracting small larvae about 1 mm in length (McGraw and Middleton 2020; Tyler in Austin 1968). It needs to procure a seed on average

every 100 seconds to meets its daily energy requirements. It was most efficient at consuming the smallest seed sizes (less than 25 mg). It ate seeds ranging in size from 0.1 to 230 mg, but mostly those weighing 10-100 mg. Its low requirement for seed encounter rates and its ability to store food allow it to exploit concentrated food patches rapidly and use patchily distributed resources (Benkman and Pulliam 1988). The only apparent observation of a goldfinch eating fruit was reported by Chapman (1948). In early July in Ohio, birds commonly visited a large smooth juneberry tree heavily laden with ripe fruit. They pulled off the fruits and crushed them in their beaks, apparently eating both the seeds and pulp. Batts (1953) reported a goldfinch visiting a Yellow-bellied Sapsucker boring. It was evidently feeding on sap because it hesitated between pecks, probably waiting for more sap to flow. Prior to this, it had been feeding on the dried fruit capsules of a sweetgum. In spring, the goldfinch may pick caterpillars from their webs and it has been documented eating green algae. It regularly drinks from slow-moving streams, shallow pools, bird baths, and dew, and eats snow in winter (McGraw and Middleton 2020; Tyler in Austin 1968).

The male feeds the female while she is incubating and during the first few days of the nestling period. Older males are more proficient at this and contribute significantly to fledging success by allowing the female to maintain long unbroken periods of incubation. This is particularly important in the first few days after hatching when the male is providing all the food. The male feeds the female sticky semisolid masses of predominantly seeds by regurgitation (McGraw and Middleton 2020; Middleton 1979; Stokes 1950; Tyler in Austin 1968). The young are also fed by regurgitation and are fed the same food items that the adults eat. After the nestlings are a few days old, both adults feed them directly. If the female initiates a second brood, the male may be responsible for feeding the nestlings before they fledge and while they are dependent fledglings (Mousley 1930; Stokes 1950). In Wisconsin, only 1 of 12 nestlings' crops contained animal matter, a single caterpillar 1.9 cm long (Stokes 1950). Skagen (1987) observed adults feeding nestlings seeds of bull thistle, field thistle, Canada thistle, reed canary grass, timothy, moth mullein, and salsify as well as insect larvae and pieces of green vegetation; adults also consumed these food items. In Ohio, the nestling diet consisted of thistle seeds with a few small caterpillars and other insects (Holcomb 1969).

Adult American Goldfinches feed predominantly on seeds with a preference for species in the aster family, notably thistles and dandelions. It also eats seeds of grasses, certain trees and shrubs, buds of deciduous trees, and limited amounts of insects. It has eaten seeds of spotted Joe-pye-weed, giant sunflower, dandelions, several species of thistles (Canada, bull, nodding, and field), cutleaf coneflower (personal observation), blanketflower, sweet clover, black alder and other alders, birch, chickweed, wild lettuce, juneberry, white cedar, elm, pitch pine, catnip, burdock, sweetgum, sycamore, evening-primrose, ragweeds, asters, trumpet creeper, chicory, tulip tree, rough-stemmed goldenrod, cinquefoil, St. John's-wort, and apple. It also consumes seeds of cultivated coneflowers (personal observation). It eats buds of fruit trees, birches, and elms, and has eaten Japanese honeysuckle berries and young leaves of European mountain-ash. Insect foods include those found on oak galls growing on twigs, cankerworms, and aphids; 1 stomach contained 2,210 birch aphids. Illinois birds consumed Canada thistle bud weevils, imported long-horned weevils, and Japanese beetles. All fecal samples contained arthropod DNA (Dance 2008; Drum 1939; Fitch 1958; Garfinkle et al. 2022; Leighton et al. 2002; McGraw and Middleton 2020; Stokes 1950; Tyler in Austin 1968).

The American Goldfinch is usually an acceptor of Brown-headed Cowbird eggs, but it occasionally deserts the nest or builds another nest layer over the cowbird egg. Three-layered nests have been found, with a cowbird egg buried in each of the 2 bottom layers (Berger 1948; Rothstein 1975). At Guelph, parasitized nests had a significantly smaller clutch size (4.4 eggs) than unparasitized nests (5.2 eggs). The number of chicks that hatched and fledged was lower, but not significantly. Parasitism effectively reduced the clutch size by 1 egg, but had little influence on the subsequent success of the remaining eggs (Middleton 1977a). In the east, parasitism rates are low because there is a limited overlap in the nesting cycles of the 2 species. At Guelph, the mean laying date of the last cowbird egg was 14.1 July, approximately 8 days later than the mean laying date of the first goldfinch egg. Because of the short overlap in the breeding seasons of the 2 species, only those goldfinch nests that were initiated early were affected. Most early nests are by older females who produce the largest clutches and have higher nesting success rates, so parasitism may have a greater effect on reproductive success than previously anticipated. Yearlings, which nest later, are not affected by parasitism (Middleton 1977a, 1979). Peck and James (1998b) reported that 101 of 1,221 Ontario nests (8.3%) were parasitized. In Guelph, 47 of 802 nests (5.9%) were parasitized (Middleton 1991). Other eastern parasitism rates include 1 of 230 nests (0.4%) in Wisconsin (Stokes 1950), 1 of 102 nests (1.0%) in Ohio (Holcomb 1969), 0 of 25 nests in New York (Hahn and Hatfield 1995), 1 of 139 nests (0.7%) in Michigan (Nickell 1951), and 11 of 865 nests (1.3%) in Michigan (Berger 1968). In the east, the goldfinch has never been documented fledging a cowbird. Many cowbird eggs do not hatch. When eggs hatch, the cowbird nestling typically dies by the time it reaches 4-5 days of age, or sooner. The failure of cowbird eggs to hatch may be due to low fertility coincident with the end of its breeding season. The low fledging rate is probably due to the goldfinch's granivorous diet. Cowbird nestlings require protein to develop properly and this is mostly lacking in the food supplied by goldfinches (Mariani et al. 1993; Middleton 1977a, 1991). In British Columbia, the goldfinch begins nesting earlier than in the east, so there is much more overlap in the breeding seasons of the goldfinch and cowbird. Parasitism rates are higher there, with 32 of 140 nests (21.9%) parasitized. Two cases of goldfinches feeding cowbird fledglings were reported (Campbell et al. 2001).

It is probable that the amount of suitable breeding habitat for the American Goldfinch has declined, beginning around the 1950s. This is due to several factors including natural succession of old fields to treed habitats, establishment of plantations, fencerow removal, cleaner agricultural practices, roadside mowing, and urbanization. Older suburbs provide habitat, but many new subdivisions have high-density housing and very small lots. In Kansas, the quantity of sunflowers decreased due to natural succession and the goldfinch declined (Fitch 1958).

Some habitat loss may be offset by forest management, but only the heaviest cuts provide habitat, and this habitat is suitable for only a few years. Selective harvesting does not provide habitat for the goldfinch, but it responds positively to clear-cutting. In New York, its abundance increased 2-5 years after clear-cutting and began to decline in the sixth year (Keller et al 2003). In Pennsylvania, 1-ha squares were clear-cut in 4-ha blocks in deciduous forest. It was absent in uncut areas, uncommon when 50% of the squares were cut, and most abundant when 75% of the squares were cut; no 100% cuts were made (Yahner 1993). In Minnesota, it increased in response to timber harvesting (Hanowski et al. 2003).

The goldfinch responds positively to high-intensity burns in forested habitat. Only burns that significantly reduce canopy cover and remove most, if not all, the woody understorey are beneficial. In Georgia, it was most abundant 1-2 years after a severe burn but was still common 3-6 years postfire. In pine-oak forests in Tennessee and North Carolina, it occurred more frequently after a burn only if it was of high intensity. It declined again 25 years after fire (Klaus et al. 2010; Rose and Simons 2016).

Weather may affect nesting success. In Guelph, the year of lowest nesting and fledging success was the coldest and wettest of the study period (Middleton 1979). In Wisconsin, nestlings exposed to cold rainy weather for at least 2 days of their first week grew significantly slower than those not experiencing those conditions (Skagen 1987). In Wisconsin, most mortality was from storms, especially in nests in elderberries. Elderberry branches open up with the weight of the fruit, and this exposes nests to the wind. Fully completed nests are sometimes deserted if rainfall prohibits egg laying for several days (Holcomb 1969). The nest is so tightly woven that it holds water and nestlings sometimes drown after a heavy rainfall (Tyler in Austin 1968).

The goldfinch is susceptible to endocrine-disrupting herbicides and insecticides. Linuran, a broad-leaf herbicide, delays moult and lowers hemocrit levels. Dimethoate, an agricultural organophosphate, reduces daily activity levels (McGraw and Middleton 2020).

The goldfinch is highly tolerant of human disturbance (Middleton 1979; Tyler in Austin 1968). In North Carolina, abundance of the goldfinch within forested habitats was positively correlated with the number of buildings within 200 m (Lumpkin and Pearson 2013). In Illinois, Peak (2003) experimentally clipped all woody vegetation within 1 m of nests. The amount of concealment around nests did not appear to affect predation rates and no nests were abandoned due to disturbance. In Niagara Region, a pipeline was constructed through a shrubby field and 3 goldfinch nests were found on the right-of-way. A 5-m buffer was established around each nest and all other vegetation was removed using heavy equipment. All nests successfully fledged young despite the major disturbance (personal observation).

In Delaware, Tymkiw et al. (2013) reported no difference in goldfinch abundance in areas where white-tailed deer density was low, medium, or high.

In Minnesota, Hanowski et al. (1997) studied the effects of mosquito control in wetlands on the American Goldfinch. They applied Bti and methoprene and found that there were no significant differences in its abundance in control wetlands and wetlands treated with either method.

Status

Prior to European settlement, the range of the American Goldfinch was probably much more restricted than it is now, and it was probably considerably less common. It benefitted from forest clearing and the small agricultural fields surrounded by hedgerows that characterized early agriculture. Prior to settlement, it was probably confined to openings such as prairies, wetlands, and burns. Settlers introduced several nonnative species to the province, such as thistles and dandelions that are important sources of food and nesting material (McGraw and Middleton 2020; Nickell 1951; Stokes 1950). These species grow in the open, disturbed, early successional areas that the goldfinch prefers.

McIlwraith (1894) reported that the American Goldfinch nested throughout the south. In Elgin County, it was a fairly common resident in 1891 and was common in 1954 and 2000 (Lancaster et al. 2004). It was common in the Kingston area in 1864 (Weir 2008). Baillie and Harrington (1937) reported that it was a common summer resident in Ontario north to the transcontinental railway west to Thunder Bay, and that it probably nested throughout this area. The first atlas demonstrated that the goldfinch nested from the Red Lake area east to south of Moosonee, but was absent in the northwest portion of the Boreal Forest Region and the Hudson Bay Lowland. It was most abundant south of the Canadian Shield and less abundant in more northerly forested landscapes. It was absent from the northern portion of Algonquin Park and certain islands in Georgian Bay. These areas are characterized by dense forest cover, bedrock outcrops, and an absence of suitable food plants (Middleton in Cadman et al. 1987). James (1991) considered the goldfinch common north to Sioux Lookout and Cochrane, occasional and rare to James Bay, and a vagrant at Attawapiskat.

The second atlas revealed that there had been no substantial change in the goldfinch's range since the first atlas. It extended its range somewhat northward in the east to include Moosonee in the southern extreme of the Hudson Bay Lowland. Overall, there was a slight but nonsignificant increase in its probability of observation, but there was a significant increase in the Boreal Forest Region. This may have been a result of increased forestry activities. It was most abundant in the Great Lakes–St. Lawrence Forest Region south of the Shield, except in heavily forested areas such as the Bruce Peninsula. Areas of high density also occurred in the Carolinian Forest Region, notably along the south shore of Lake Huron and in Hamilton, Haldimand County, and most of Niagara Region. There is limited remaining shrubby habitat in the intensively farmed areas of the extreme southwest (Leckie and Cadman in Cadman et al. 2007).

Breeding Bird Survey (BBS) data for 1966-2017 indicated a nonsignificant decrease of 0.17% per annum rangewide and a decrease of 0.67% per year in Canada (McGraw and Middleton 2020). For 1970-2021, it decreased at annual rates of 0.771% in Canada and 1.06% in Ontario. For 2011-21, it decreased at annual rates of 1.47% in Canada and 2.8% in Ontario. All results were highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Older nestlings are capable of flying 30-45 m as soon as they leave the nest. Young birds fledge after a shorter time in the nest and may simply flutter to the ground below or near the nest. Once the fledglings are accomplished fliers, they follow their parents in a group and family groups range over a wide area. Fledglings begin to feed themselves once they have been out the nest for a week, but are dependent on the adults for about 3 weeks. Once juveniles are independent, they gather in flocks, often with adults. The flocks gradually increase in size and may number in the hundreds in late September and early October (Berger 1968; Drum 1939; McGraw and Middleton 2020; Mousley 1930; Tyler in Austin 1968).

During the postbreeding period, the goldfinch prefers the same types of weedy and shrubby habitats, and they must contain adequate food supplies in the form of seeds from plants in the aster family. Patches of thistles and other food plants attract flocks of goldfinches. Several studies netted goldfinches in young clear-cuts during the postfledging period. In Missouri clear-cuts in oak-hickory-pine forests, it was captured 2-4 years after harvest but not 5-15 years postharvest. In Michigan, it

was significantly more abundant in mature riparian than upland trembling aspen stands. Riparian stands also contained a shrubby layer of alder and honeysuckle that was absent in upland stands (Akresh et al. 2001; Marshall et al. 2003; Porneluzi et al. 2014; Streby et al. 2011b).

MIGRATION

Although the American Goldfinch occurs in Ontario year-round, it is a regular migrant. Banding at Guelph indicated that the breeding population leaves in winter and is replaced by a distinct wintering population. Birds may not migrate until their second winter, but some yearling males have been documented migrating to the southeastern United States. Females winter further south than males and young males winter further north than old males. Migration is presumed to be strictly diurnal. A high proportion of Ontario birds remain in the province for the winter. Others move to the states just south of the Great Lakes and east to the Atlantic coast. Birds banded in Ontario have wintered in most states east of Texas south to the Gulf of Mexico. Some travelled in excess of 1,600 km (Brewer et al. 2018; McGraw and Middleton 2020; Middleton 1978).

Males arrive earlier in spring than females. In Massachusetts, males arrived an average of 3.6 days earlier than females. This may be because males winter further north. Over a 33-year period, neither sex arrived earlier in response to climate change; the interval between the arrival of the sexes did not change (Bauböck et al. 2012). Spring migration may occur from mid-April to June throughout the goldfinch's range (McGraw and Middleton 2020). Birds start to return to the Guelph area in late May (Middleton 1979). At Prince Edward Point, migrants arrive during April and May (Weir 2008). Migrants arrive in Algonquin Park in early to mid-May (Tozer 2012). Autumn migration may extend from late October to mid-December rangewide (McGraw and Middleton 2020), and this is the case in Guelph (Middleton 1978). Most migration in Ontario is in September and October (Mills 1981; Tozer 2012; Weir 2008). There is a noticeable autumn migration along the Lake Erie shoreline in Elgin County when hundreds may be seen daily, especially in late September and early October (Lancaster et al. 2004).

During migration, the American Goldfinch occurs predominantly in open weedy areas that have ample food for large foraging flocks. It may also inhabit small isolated woodlots (McGraw and Middleton 2020; Tyler in Austin 1968). It is most common in farmlands and open fields where there are large patches of food plants. Hydro transmission line corridors, city parks, rural and suburban residential lots, orchards, and nurseries may be frequented (Campbell et al. 2001).

Shrubby areas are selected over treed areas during migration. In Pennsylvania, numbers of spring migrants declined when the viburnum leaf beetle killed most southern arrowwoods and decreased shrub coverage (Smith and Hatch 2017). During autumn migration in New York, mature shrublands were used more than early successional forests (Mudrzynski and Norment 2013). During spring migration in Pennsylvania, significantly more goldfinches were observed on transects and captured in mist nests in shrubs than in forests (Smith and Hatch 2008). During spring migration in Wisconsin and Minnesota, it was significantly more abundant in upland than floodplain forests. Upland forests were often small and dominated by oaks, sugar maple, beech, red cedar, and white pine plantings. Floodplain forests were dominated by silver maple, green ash, white elm, cottonwood, black willow, and Manitoba maple. Kirsch et al. (2013) considered the goldfinch an upland species during spring migration.

During migration, conifers are important for nocturnal roosting by the goldfinch (McGraw and Middleton 2020).

James (1991) considered the goldfinch a common to locally abundant migrant. It is more conspicuous as a migrant in autumn and juveniles are also present at this time, so counts tend to be higher in autumn.

WINTER

Root (1988) concluded that the winter distribution of the American Goldfinch was associated with climate. In the west, it is absent where the average January minimum temperature drops below −12°C. East of the Mississippi River, it appears to survive in areas where the average January temperature drops as low as −15°C. Vegetation and precipitation do not appear to strongly influence its range but may affect local abundance. In the west, all abundance peaks are associated with ecotones between forest and grassland or shrubsteppe. Where it winters in large numbers is strongly influenced by the distribution of feeders. McGraw and Middleton (2020) reported that there had been no major change in its range over time, but more birds overwintered in the north due to feeders.

Winter habitat is more variable than during the breeding season and migration, depending upon whether birds migrate. In the north, it remains in typical habitat until natural food supplies are depleted or covered with snow. Flocks then either move to sites with feeders or wander nomadically to access areas with less rigorous climate or snow cover. Flocks often mingle with Black-capped Chickadees, Pine Siskins, Redpolls, and American Tree Sparrows. Rural and suburban woodlots and riparian woodlands may be frequented, particularly if they have heavy seed crops of birch or alder. In Illinois in 1906-07, highest densities occurred in forests, followed by shrubs of all types, pasturelands, fallow fields, ungrazed grasslands, and cornstalk habitat (Campbell et al. 2001; Graber and Graber 1963; McGraw and Middleton 2020; Tyler in Austin 1968). Smith (2003) summarized the results of Winter Bird-Population Studies for 52 sites in southern Ontario. Densities per km^2 were 0 in row crops and treeless pastures, 9.1 in mixed rural areas, 23 in natural forests in urban settings, 27.3 in urban natural areas larger than 10 ha, 52.3 in urban natural areas smaller than 10 ha, 7.2 in urban areas with open water, and 2.5 in cities. In Arkansas, Kentucky, and Mississippi, it was significantly more abundant in row-crop fields that had a buffer of warm-season grasses and forbs than in fields without buffers. It was more abundant in fields with buffers wider than 23 m than those with narrower buffers, but not significantly (Evans et al. 2015).

Where winters are severe, the goldfinch usually roosts in conifers. In Guelph, it appeared to roost in dense stands of white cedar along river valleys. There is 1 record of a goldfinch roosting in a hole about 30 cm deep under the snow where there was access under a stump (McGraw and Middleton 2020; Prescott et al. 1989; Tyler in Austin 1968).

Some birds exhibit site fidelity between winters but others spend subsequent winters in disparate locations. Of 14 birds banded in Ontario in winter and encountered in another winter, 9 spent both winters in Ontario. The other 5 spent winters in Maryland, New York, Pennsylvania, Kentucky, and Alabama (Brewer et al. 2018). Within winters, the goldfinch may be nomadic, travelling regionally or locally among food sources. One banded in Guelph in January was retrapped in April of the same year 24 km distant in Cambridge. Another Guelph bird banded in December

was captured the following February 50 km distant in Toronto. Much daytime movement occurs between feeders with direct-distance movements of 7 km between feeders common (McGraw and Middleton 2020).

In winter, the goldfinch prefers to forage in sheltered areas or at feeders (McGraw and Middleton 2020; McIlwraith 1894). McIlwraith (1894) reported it feeding on hemlock seeds, the only apparent record of it feeding on this species. In Algonquin Park, it fed on seeds of white birch, grey alder, balsam fir, and a variety of herbaceous species (Tozer 2012). At a Guelph feeder, juvenile males and females arrived earlier in the morning. They may be less capable of overnight fasting than adult males. During snowy weather, the number of adults visiting the feeder was the same as on days when it was not snowing, but fewer juvenile males visited during snowstorms. This suggested that they were less likely to use suburban feeders at this time or that they are excluded from doing so by the dominant adult males (Prescott et al. 1989). In Pennsylvania, Nastase and Linville (1995) provided feeders at heights of 0, 2, 4, and 6 m. Striped sunflowers, niger seed, cracked corn, white millet, and canary seed were provided at each level. Foraging occurred 8.6% of the time on the ground, 52.6% at 2 m, 17.9% at 4 m, and 20.9% at 6 m. Seeds consumed included 17.7% niger, 0.3% canary seed, 1.4% millet, 1.7% corn, and 78.9% sunflowers. At a feeder in Wisconsin, goldfinches pecked at niger seeds and swallowed them, taking 0.1 second or less. It usually took more than 0.4 second to manipulate a sunflower seed, find the crack in the husk, and break it open (Popp 1988b).

In Canada and the United States, 187,892 American Goldfinch feeding observations were documented. It preferred niger seeds but commonly ate sunflower chips. Sixty-four percent of birds ate black oil sunflowers, 23% ate cracked corn, 71% ate 0.3-mm sunflower chips, 73% ate 0.5-mm sunflower chips, 85% ate niger seeds, 23% ate red milo, 26% ate safflower, 26% ate white proso millet, and 22% ate whole peanuts. It was more likely to select seeds with a greater bill to seed volume ratio, without hulls, and greater levels of protein. It was most abundant at tube feeders (Horn et al. 2014; Johansen et al. 2014). Project FeederWatch data indicate that the goldfinch visits feeders in all habitats, but flock sizes are almost 2 times as large at rural than urban feeders. Flock sizes increase in cold weather. Favourite foods include niger seed, canary seed, black oil and hulled sunflowers, and water. Less frequently, it eats mixed seeds, millet, striped sunflowers, safflower, cracked corn, milo, wheat, peanut hearts and peanuts in the shell, canola, peanut butter mixes, bird puddings, baked goods, sugar water, and popped corn (Dunn and Tessaglia-Hymes 1999). In Saskatchewan, niger and canola seeds were preferred at feeders (Leighton et al. 2002).

During a single-day severe winter storm in Guelph that included heavy rain, snow, and wind, goldfinches could not land on the feeder because of the strong winds and were restricted to gleaning seeds below it. They significantly increased their body weight before and during the storm. They may have been able to use the change in barometric pressure, wind speed, and wind chill as indicators of weather deterioration. They responded by rapidly increasing their body reserves. There was no evidence of mortality or a decrease in numbers (Middleton 1982). In Illinois, Graber and Graber (1979) monitored goldfinch populations after an extended period of heavy snow and extremely cold weather. It increased by 66% in bottomland forests after the storm and was found in low density (1 per km^2) in upland forests after the storm; it had been absent in them prior to the storm. It was not detected in urban residential areas before or after the storm. There was no

indication that mortality had occurred, and birds may have moved from habitats they did not survey to forested areas. Dunn and Tessaglia-Hymes (1999) concluded that the goldfinch was not particularly well adapted to extreme weather conditions. It relies more heavily on filling its crop each evening than it does on accumulated fat reserves. When severe snow or ice storms make food inaccessible, it can starve.

The goldfinch is vulnerable to contracting mycoplasmal conjunctivitis, especially from feeding at feeders (McGraw and Middleton 2020). This disease affects the eyes and eventually causes blindness. Birds typically succumb to the disease either from being unable to find food or to being preyed upon.

James (1991) considered the American Goldfinch a common winter resident in the south, north to Georgian Bay and Ottawa, and occasional north to Kenora and Cochrane. Mills (1981) reported that at least some remain in Parry Sound and Muskoka districts each year. It is absent some years in winter in Algonquin Park but is usually present in years when numbers of other finches are high due to plentiful conifer seeds (Tozer 2012).

Freedman and Riley (1980) analyzed Christmas Bird Count (CBC) data for southern Ontario for 1929-77. There was a large overall increase in the wintering population of the American Goldfinch over this period. At Guelph, it regularly overwinters in large numbers now, whereas wintering in the province was not common even by the mid-20th century. CBCs for southern Ontario indicated a significant increase in southern Ontario 1915-75 from 0.12 per party-hour to 1.76 per party-hour in 1966-78. There were significant negative correlations between populations and temperatures and snowfall. From 1969 to 1973, sales of bird seeds by 3 companies increased by 50% wholesale and 131% retail. Probably winter was formerly a period of large mortality in southern Ontario, but there is now no apparent increase in mortality due to snow or ice storms or low temperatures. In the early part of the period, it probably responded to reduced snowfall by greater numbers attempting to overwinter. Winter feeding is probably the reason for its increase and successful overwintering in the province (Middleton 1977b). Following the steady increase on Ontario CBCs from the 1920s to the mid-1970s, there was little change in the winter population 1968-91 (McGraw and Middleton 2020). CBC data for Ontario for 1970-2021 indicate that it increased at an annual rate of 4.9% but it decreased at an annual rate of 3.73% 2009-21 (National Audubon Society 2022).

Lapland Longspur

Calcarius lapponicus

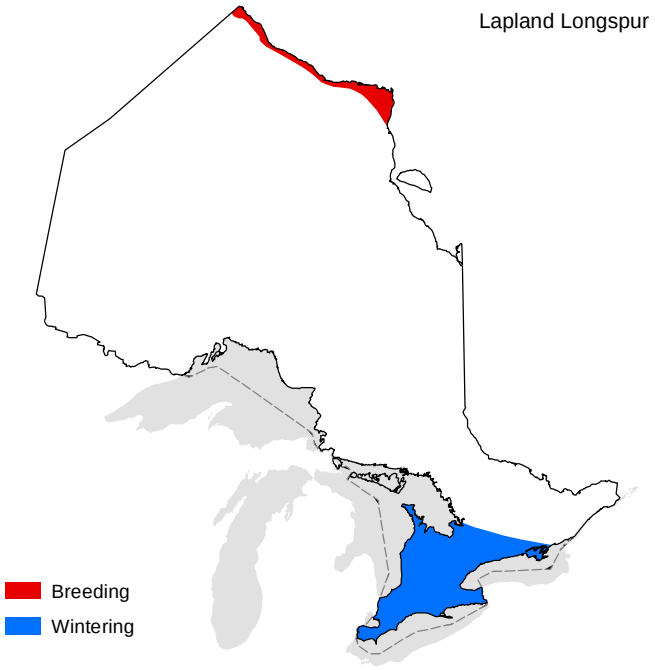
BREEDING SEASON

Habitat Requirements

In Ontario, the Lapland Longspur breeds on open, treeless tundra, usually in dry areas covered with a heath-lichen community, moss, grass, and the occasional arctic willow. One nest was in wet, graminoid tundra (Peck and James 1987).

Typical breeding habitat in Ontario, where it is confined to the strip of tundra along the Hudson Bay coast, is wet, hummocky graminoid tundra interspersed with low, sparsely vegetated gravel beach ridges. Hummocky meadows with good growth of mosses, grasses, sedges, and dwarf shrubs are favoured. It also nests on relict marine beaches with sparse vegetation and exposed gravel and cobblestones that intersect lower-lying, well-vegetated meadows (Hussell in Cadman et al. 2007).

Ontario represents the extreme southern extent of the Lapland Longspur's breeding range in North America. On the continent, it occurs in low-lying tundra and alpine meadows and is predominantly restricted to tundra and grass or sedge meadows in the High Arctic. It is a characteristic bird of tundra and in the far north it is often the most abundant species and only passerine present. Near Churchill, it commonly breeds in wet tundra, thickly vegetated uplands,



sedge margins along streams and ponds, and hummocks and sedges in marshes. Where it coexists with the Smith's Longspur, the Lapland Longspur prefers wetter, more hummocky habitats. Near Churchill, 38% of nests were in graminoid dwarf shrub tundra consisting of 75-100% cover by graminoids and moss, with herbaceous plants and dwarf shrubs on the occasional drier earthen hummocks; 28.6% were in mesic to hydric graminoid tundra with nearly contiguous graminoid cover and occasional dwarf shrubs that were mostly willows; 28.6% were in hummocky tundra that consisted of mounds and ridges supporting herbs, mosses, dwarf shrubs, and some graminoids in lower areas; and 4.8% were in dwarf shrub-lichen barrens that were windblown sites at higher elevations, such as beach ridges, with 25-50% vegetation coverage. No nests were found in wet sedge meadows with nearly continuous sedge cover and often shallow surface water, or in dwarf shrub tundra on moist but well-drained slopes with 50-75% coverage by dwarf shrubs (Boal and Anderson 2005; Jehl and Smith 1970). In Quebec, it nests in open tundra habitat where it uses rocks or shrubs for singing posts (Lanore and Doyon in Gauthier and Aubry 1996). In the Yukon, it nests in open, upland tussock tundra. These habitats range from dry tundra of mountain avens–horsetail terraces to complex wet tundra including both low-centred and high-centred polygons (Sinclair et al. 2003). In Alaska, it exhibited a modest selection for areas of dry and mesic habitat rather than wet habitat. Nesting density was highest on raised ridges or other areas of well-drained tundra. Wet meadows were not used unless they contained more elevated areas such as hummocks or ridges where nests could be placed. Very dry communities such as mountain avens and lichen-clad fell-fields of hills and mountains were avoided. In Alaska, it is most numerous in cottongrass tussocks, meadow-like tundra dominated by sedges, ankle-high areas of willows, and expanses of dwarf birch intermixed with various species of heaths. Areas that are moist support higher densities than areas with standing water. Highest densities are in low-lying flat meadows with dense stands of sedges mixed with herbaceous plants. Moderate densities occur in upland communities dominated by crowberry and lichens, with sedges, grasses, mosses, and shrubby species such as mountain cranberry. Mesic habitats are preferred in Alaska and throughout. Small territories contained significantly less dry and especially wet habitats, and a much larger proportion of mesic habitats. Large territories contained about equal amounts of wet, mesic, and dry habitats; the actual amount of mesic habitat was greater in small territories on average. The main mesic habitats used were gently sloping meadows of water sedge, arctic spear grass, and willows. Low, tidal salt marshes where Savannah Sparrows bred were avoided (Custer and Pitelka 1977; Hussell and Montgomerie 2020; Seastedt and MacLean 1979; Tryon and MacLean 1980; Williamson in Bent 1968). Alpine habitat used in Alaska included rounded

mountains covered with low and dwarf shrubs; wet sedge-graminoid meadows, often with tussocks on wetter substrates; and steep mountain peaks with patches of herbaceous plants or dwarf shrubs among considerable rock rubble and exposed bedrock (Handel et al. 2009). On Melville Peninsula, the northeastern tip of continental Nunavut, nests were mainly in dry mountain avens but occasionally on hummocks in wetter areas (Montgomerie et al. 1983).

Several studies were completed on the Lapland Longspur on Canada's arctic islands (Bylot, Baffin, Banks, Devon, Ellesmere, and Victoria islands). Tundra and graminoid meadows are mostly used for nesting in the High Arctic. It inhabits both extensive level meadows and sloping meadows. Sloping meadows may be only a few metres wide and often border tiny snow-fed streams. When slopes are used for nesting, it usually selects those facing south or east. Flat tundra areas that are inhabited are occasionally associated with shorelines of lakes. Areas that are too well drained, too gravelly, or too bare are not used. Prime habitat is wide, moist tundra intersected by ponds and streams and studded with grassy hummocks. On Banks Island, it was most abundant in hummocky tundra and graminoid–dwarf shrub tundra and least abundant on or adjacent to water bodies, in sparsely vegetated areas with less than 10% cover by vascular plants, and in dwarf shrub–lichen barrens (Drury 1961; Henry and Mico 2002; Hussell and Montgomerie 2020; Parmelee and MacDonald 1960; Parmelee et al. 1967; Soper 1946; Sutton and Parmelee 1955; Wynne-Edwards 1952). The Lapland Longspur also commonly nests in disturbed and settled areas close to roads and buildings (Höhn 1968; Parmelee et al. 1967).

During the nesting period, females roost at the nest. Males roost on their song perches or among hummocks. In the northern portion of the range, there may be almost continuous sunlight so birds may be active for as long as 20.5 hours per day. During cold weather, several pairs may roost together in grass tussocks (Hussell and Montgomerie 2020). On Victoria Island, birds often roosted in grassy, wet tundra areas during the postbreeding period rather than the barren tundra that was used earlier in the season (Parmelee et al. 1967).

Ontario nests were depressions in lichen, moss, and sedge hummocks, and one was near a clump of arctic willow (Peck and James 1987). The first nest found in Ontario, at Cape Henrietta Maria, was sunk in moss in a clump of arctic willow (Baillie 1962).

Nests are invariably in a depression in the ground. On Devon Island, nests were in fairly exposed sites on open ground. In other areas, most nests are well concealed and partially covered by sedges, grasses, small shrubs, or herbaceous material. Most nests are built into the sides of a bank or tussocks of sedges, often cottongrass, but they may also be in clumps of sedges, grasses, or Labrador tea. Almost all nests at Churchill were on the side or top of a pressure ridge (38.1%) or mound (57.1%). Nests averaged about midway (55.1%) up these features. The slope at nests was 30.1%, significantly greater than random (17.0%). Vegetation within of 400 cm^2 of the nest averaged 21.8% willow, 18.9% sedges (mostly water sedge), 10.3% moss, 12.8% litter, 10.6% Lapland rosebay, 7.6% dwarf birch, and 7.3% bog rosemary. Species occurring around nests in low frequency were 2.1% bearberry, 2.0% crowberry, 1.4% mountain cranberry, 2.4% Labrador tea, 0.3% mountain avens, and 0.2% cloudberry. Selected sites had comparatively greater amounts of willow, dwarf birch, and Lapland rosebay and lesser amounts of moss; graminoids were used in proportion to their availability. Nests were well concealed by vegetation, with average coverage of 67.0%. Nest concealment was negatively

associated with the amount of sedges at the nest. In the Northwest Territories, areas near nests had higher coverage of graminoids, shrubs, and forbs than random points, but lower coverage of lichens and mosses. Nests have a distinct entrance that faces away from the prevailing winds. At Churchill, nests had a predominantly southwestern orientation: 48% had a southwest orientation and 33% were oriented south. Further north, nests typically face south. Nesting in the side of hummocks or between hummocks provides shelter from wind that is often accompanied by near-freezing temperatures and rain and snow. On Banks Island, when the wind speed was 15 km per hour, the wind at the bottom of microdepressions was only 5% of what it was 1.5 m above ground and 10% of the wind speed at ground level. In depressions with overhanging vegetation, the wind velocity in the depression was 0.1% of what it was 1.5 m above ground. In Alaska, nests in burned and unburned tundra were placed similarly against or in edges of sedge tussocks. Monocots covered 45.0% of the area 15 cm around the nest in burned areas and 48.1% in unburned areas; these were mostly cottongrass and other sedges. Nests in burned areas were more exposed due to scarcity of shrubs (3% each of deciduous and evergreen shrubs within 15 cm of the nest). Nests in unburned areas had 28.1% coverage by deciduous shrubs (birch and blueberry) and 15.0% coverage by evergreen shrubs (blueberry and Labrador tea). In the arctic, nests may be in drier situations where they are typically more exposed. Near settlements, nests are often on roadsides. An unusual nest on Victoria Island was beneath a tilted, flat rock on a dry slope. Nests and nest depressions may be used in subsequent years, but the frequency of this is uncertain (Beyersbergen 1978; Boal and Anderson 2005; Drury 1961; Grinnell 1944; Henry and Mico 2002; Höhn 1968; Hussell 1972; Hussell and Holroyd 1974; Hussell and Montgomerie 2020; Jehl 2004; Male and Nol 2005; Parmelee et al. 1967; Sinclair et al. 2003; Soper 1946; Williamson in Austin 1968; Wright 1981).

Males establish territories shortly after arrival on the breeding grounds. In the event of a severe snowstorm early in the breeding season, territoriality may temporarily cease and birds may band together in flocks. Territorial defence may be intense and hostile, or almost nonexistent if territories are widely spaced. Some territories have undisputed boundaries along large snow patches that were present when territories were established. The Lapland Longspur does not use all available habitat and many territories do not have a contiguous territory. This is due, in part, because territories are established in snowfree areas so that areas that were initially snow covered are unoccupied. On Bylot Island, singing males appeared to attract other males so that territories were congregated in a small portion of the available habitat. Territoriality becomes much reduced when incubation commences and is essentially absent by the time there are young in the nest. The area that is defended varies greatly from area to area, probably due to differences in the quality of habitat and its abundance. On Bylot Island, there were 10 nests and territories in an area of 1.6 ha. Many territories were 0.2 ha or less; 1 territory was 0.08 ha. At Clyde Inlet on Bylot Island, territories were 2.0-6.1 ha. One Alaskan pair had a territory of 3.38 ha; territories of another 20 males in Alaska ranged from 1.09 to 2.83 ha. In some cases, the female built the nest outside the male's defended area, so the defended area was expanded to include the nest. Because of the variable territory sizes, distances between active nests are highly variable. On Bylot Island, nests in an area with small territory sizes were 91-155 m apart; they averaged 229 m apart at Clyde Inlet. Near Baker Lake, Nunavut, mean territory sizes were 0.40-0.54 ha. The closest distance between nests at Churchill was 183 m in 1 study but 2 nests in another study were only 39.5 m apart. The mean distance between 3 nests in

Alaska was 180 m. Territoriality spaces out birds and minimizes, but does not eliminate, direct competition for food in the first half of the breeding cycle. It also contributes to spacing of nests which provides exclusive use of resources immediately around the nest during the nestling period (Boal and Anderson 2005; Drury 1961; Grinnell 1944; Holmes et al. 2024; Hussell 1972; Seastedt and MacLean 1979; Tryon and MacLean 1980; Wynne-Edwards 1952).

The home range of the Lapland Longspur is larger than its territory. Both sexes forage outside the defended area. One Alaskan pair had a territory of 3.38 ha, a foraging area of 3.74 ha for the female and a foraging area of 8.21 ha for the male. Sixty-five percent of foraging by the male and 83% of foraging by the female occurred within the territory. The area used for foraging was smallest during the prenesting and nestling periods and increased in the fledgling period. During the early stages of nesting through incubation, the peak of adult activity occurred in the area between adjacent nests. Usage became concentrated around the nest in the nestling period but the total area used did not decrease. On Melville Peninsula, adults flew as far as 140 m to collect food for nestlings. Males continue to display after females begin incubation and often fly from their territories to pursue unattached females or females with incomplete clutches. Males have been seen as far as 6 km from their territory during this period (Hussell and Montgomerie 2020; McLaughlin and Montgomerie 1990; Seastedt and MacLean 1979).

Natal philopatry is very low and few, if any, birds return to their natal area to breed. Of banded young, 0 of 56 on Devon Island and 0 of 129 on Melville Peninsula returned. Ten of 382 (2.6%) nestlings returned in Alaska but none were confirmed as breeders. A nestling banded in Alaska was found breeding 6 years later 9.3 km from its natal site. Seven juveniles banded at McConnell River, Nunavut, were recaptured there the next year (Custer and Pitelka 1977; Hussell and Holroyd 1974; Hussell and Montgomerie 2020; McLaughlin and Montgomerie 1985).

When mortality rates are taken into account, adult site fidelity appears to be high. On Melville Peninsula, 47 of 86 adults (54.7%) returned. On Devon Island, only 3 of 22 (13.6%) returned. This may have been in response to high nest predation in marginal habitat near the northern extent of its range (Hussell and Holroyd 1974; Hussell and Montgomerie 2020). An adult banded in 1936 near Churchill was recaptured annually through 1939 (Jehl 2004). In Alaska, 11.6% of males and 23.5% of females returned to breed and 1 male and 1 female returned for all 6 years of the study (Custer and Pitelka 1977).

Limiting Factors

Eggs have been reported in Ontario nests from mid-June until the third week of July (Peck and James 1987). Within populations, nesting is highly synchronized and hatching of young usually coincides with peak emergence of insects. Timing of nest initiation varies annually depending upon snow cover. There is no evidence that timing varies by latitude. In Alaska, the nest-building period may span 17-18 days, but nests can be built within 3 days. Egg laying usually starts as soon as the lining in the nest is adequate, but 2-3 days may elapse before the first egg is laid. Eggs are laid at the rate of 1 a day but a day may rarely be missed. Incubation may begin with the laying of the first egg, but more often with laying of the third egg or later eggs. The incubation period at 1 Ontario nest was 11 days. The overall range of incubation periods for the last egg is 10.5-13 days. Hatching is asynchronous and may occur over 1-4 days. Mean hatching intervals were 27.0 hours at Churchill,

more than 38.8 hours on Devon Island, and 40.8 hours in Alaska. The overall hatching period ranges from 18.5 to 64.0 hours and is dependent upon clutch size but not latitude. Young leave the nest asynchronously over the same period that hatching takes. The nestling period ranges from 6-12 days, but is mostly 8-11 days with shorter periods due to disturbance (Custer and Pitelka 1977; Drury 1961; Grinnell 1944; Hussell 1972; Hussell and Montgomerie 2020; McLaughlin and Montgomerie 1985, 1989a, 1989b; Parmelee et al. 1967; Peck and James 1987; Soper 1946; Sutton and Parmelee 1955; Tryon and MacLean 1980; Williamson in Austin 1968; Wynne-Edwards 1952).

A single brood is raised in a nesting season. Some second clutches have been attempted after successfully rearing a first brood, progressing as far as hatching eggs in the second clutch. All attempts failed. Second nests are unlikely to be successful because the females need to moult, and cold weather and snow typically arrive before the second brood can be raised. Replacement clutches may be laid if the first clutch is lost early. In Alaska, all 4 females that lost nests during the egg-laying phase renested, 2 of 4 that lost nests during days 1-6 of incubation renested, and 0 of 18 that lost nests later in incubation renested. Clutches of 4-6 eggs have been reported in Ontario. In North America, clutches of 1-8 eggs have been reported, but the normal clutch size is 3-7 eggs. Clutch size declines with season; clutches smaller than 3 are typically late or replacement clutches. Overall, nearly all clutches are initiated between 20 June and 6 July and the mean clutch size declines from 6.0 to 4.0 during this period. Clutch size increases with latitude. The most frequent clutch size south of latitude 68°N is 5 eggs. Six-egg clutches are rare at the southern limits of the breeding range but are the most frequent clutch size in many areas north of latitude 68°N. Clutches of 7 eggs have been reported from north of latitude 66°N only. Larger clutch sizes in the north may be due in part to the long days that allow adults to feed the young for more than 20 hours a day. Clutch sizes at individual sites may vary annually depending upon when nesting is initiated and how many replacement clutches are laid. Individuals tend to lay the same number of eggs annually, with no change in performance with age. An exception is that yearling females may initiate nesting later and consequently have smaller clutches (Custer and Pitelka 1977; Drury 1961; Grinnell 1944; Hussell 1972; Hussell and Montgomerie 2020; Lyon and Montgomerie 1987; Parmelee et al. 1967; Peck and James 1987; Sinclair et al. 2003; Sutton and Parmelee 1955; Williamson in Austin 1968; Wynne-Edwards 1952).

Both sexes are capable of breeding when they are 1 year old and it is probable that most yearling females breed. Yearling males are usually unsuccessful in attracting a mate and few breed in their first year. Most populations have a surplus of males, so there are often floating, nonbreeding males present. In Alaska, only males that obtained a territory within an 9-day period (4-12 June) were successful in attracting mates although pair formation was observed as late as 16 June. Six of 28 males (21.4%) that established territories before 12 June and all 3 that established territories later failed to attract mates. The mating system is typically monogamous although bigamy and trigamy rarely occur. During a 13-year study, 96% of males were monogamous. One bigamous male had an unusual and large territory that included a 20-m cliff. One female nested at the bottom and the other at the top, both unaware of the other's existence. Females of polygynous males arrive on the breeding grounds first, nest first, and produce young that exhibit faster growth rates than females mated with monogamous males. There are unusual cases of 2 females laying eggs in the same nest and sharing incubation, even with both birds sitting on the nest at the same time; 2 females have

been observed feeding the same fledgling. Once females begin incubating, males often leave the territory to seek extra-pair copulations, occasionally traveling as far as 5-6 km. Because of intense mate guarding while the female is fertilizable, few attempts at extra-pair copulation are successful. Extra-pair fertilizations account for approximately 12% of nestlings (Beyersbergen 1978; Custer and Pitelka 1977; Hussell 1972; Hussell and Montgomerie 2020; Lyon and Montgomerie 1987; Montgomerie 1988; Seastedt and MacLean 1979; Sedinger 1986; Tryon and MacLean 1980; Wynne-Edwards 1952).

Adults creep, walk, and hop to pick food off the ground. When enough seeds cannot be found on the ground, they pull down plant stems or flutter upward and yank at the stalks with their bills. After a heavy snow, the Lapland Longspur takes seeds directly from emergent plants or shakes them so that the seeds fall on the snow where it picks them up. On Baffin Island, it caught large numbers of insects by snapping at them in the air, but also searched vegetation for insects when cold weather reduced the numbers of flying insects. Adults in 1 area were attracted to a tent where they fed on mosquitoes. Adults may obtain crane fly larvae and pupae by searching and picking through mosses, but are unable to probe wet areas to obtain larvae and pupae of a more aquatic crane fly species. Crane flies may be abundant in subarctic lowlands but unavailable to foraging Lapland Longspurs. Early in the breeding season, it spends a disproportionate amount of time is in areas of partial (0-49%) snow cover than in areas 50-100% snow covered. A large amount of time is spent feeding along retreating margins of snow fields, so foraging areas change day to day. There is a significant negative correlation between prey density and territory size. In Alaska, dry habitats produced more biomass of insects than wet meadows and longspurs selected drier areas for their territories. Territories appeared to be selected on the basis of habitat and not insect abundance. Over 90% of foraging by adults occurs in the territory early in the season when the territory is most actively defended. The percentage of foraging that occurs in the territory declines as the season progresses. The density of food within the territory is important because most food fed to the nestlings is obtained in or near the territory (Drury 1961; Hussell and Montgomerie 2020; Lyon and Montgomerie 1987; McLaughlin and Montgomerie 1985, 1989b; Seastedt 1980; Seastedt and MacLean 1979; Sutton and Parmelee 1955; Tryon and MacLean 1980; Williamson in Austin 1968).

Crane flies or midges are the dominant food provided to nestlings and fledglings, depending on the area. Egg laying is timed so that hatching is synchronous with the emergence of adult crane flies or midges. On Devon Island, food brought to nestlings from 12 to 18 July consisted of 80.9% adult insects, 15.6% other animal prey, and 3.5% plant material. From 20 to 30 July, the diet consisted of 97.1% adult insects, 2.5% other animal prey, and 0.5% plant material. Overall, the food delivered to nestlings was 92.7% adult insects, 6.0% other animal prey, and 1.3% plant material. In total, flies comprised 91.4% of nestlings' diet and 84.3% of these were midges. Other insects included 1.0% hymenopterans and 0.2% lepidopterans. Other animal prey included 1.0% larvae, 0.9% pupae (mostly lepidopterans), 0.1% eggs, 4.0% spiders, and other flies (crane, house, and dance flies). At 1 site in Alaska, over 90% of the biomass fed to nestlings older than 4 days and fledglings was crane flies. These were semiaquatic species associated with low, wetland habitats. At another site, the diet of young was dominated by another crane fly species found primarily in mesic and upland habitats. Sawflies that occurred on willows in mesic areas were secondary in importance (14.9% of diet) at the second site, but were nearly absent in the diet at the first site. Other prey items included a third

species of crane fly, midges (4.8% and 2.3% at the 2 sites), house flies (5.3% and 0.1%), and spiders (4.7% and 3.1%). The amount of dietary overlap as measured by the percent biomass shared in common at the 2 sites was only 12.4%. Both adult and larval crane flies (the species found in dry and mesic habitats) and sawflies occurred in the nestling diet more than their availability. On Baffin Island, crane fly adults were commonly fed to nestlings. Young have also been fed mosquitoes and beetles. In western Greenland, the diets of nestlings inhabiting lowlands and plateaus differed. Seventy-nine percent of the diet on plateaus consisted of adult flies; 76.5% of food items in lowlands were caterpillars. On Ellesmere Island, 1 immature female had eaten buttercup seeds. On Melville Peninsula, there was no difference in the diet of nestling Lapland Longspurs and Snow Buntings, with a 96.9% overlap in diet (Custer and Pitelka 1977; Drury 1961; Hussell and Montgomerie 2020; Lyon and Montgomerie 1987; Parmelee and MacDonald 1960; Seastedt 1980; Seastedt and MacLean 1979; Sutton and Parmelee 1955; Williamson in Austin 1968; Wynne-Edwards 1952).

During the breeding season, adults eat mostly seeds upon arrival and switch to insects in late June and July when they become plentiful. In early spring, the Lapland Longspur may forage on snow to capture springtails. An Alaskan study identified 8,849 food items from 174 stomachs and 61 esophagi. Seeds comprised 70% of the diet in late May, less than 6% in June and July, and 24-30% in mid- and late August. Seeds eaten were mostly those of sedges and grasses, although some herbaceous plant seeds were eaten, such as mountain avens and mouse-ear chickweed. It may consume moss capsules, leaf remains, and wood-rush seeds. Adults eat insect larvae early in the season, switch to adults in June and July then switch back to larvae. Arthropods eaten include crane flies, midges, other nematoceran flies, beetles (including weevils), bugs, spiders, springtails, butterflies, sawflies, and other hymenopterans. There is 1 record of an adult eating a snail and another of it feeding on blow flies on a carcass. Crane flies and midges dominate the diet; adults may feed almost exclusively on these when they are abundant. Sawfly larvae may be important in the diet in late July and August. At Churchill, adults fed on millet put out for them (Custer and Pitelka 1978; Drury 1961; Gabrielson 1924; Grinnell 1924; Hussell and Montgomerie 2020; Wynne-Edwards 1952).

Cold rain during the early nestling period may result in widespread mortality of young. A 5-day cold and rainy period occurred in early July near Churchill. Of 15 nests containing young, all nestlings died in 14 nests. In the other nest, 1 chick died; the other 3 survived. Death was caused by exposure. The nestlings were drenched and chilled while the adults gathered food; brooding failed to dry them. A single nest contained 4 eggs during this period and all hatched. Mortality from rain has been reported from other locations and this is probably a common event (Hussell 1972; Jehl and Hussell 1966; Seastedt and MacLean 1979; Austin in Bent 1968). Even if adverse weather does not result in direct death of nestlings, their growth rates may be inhibited in summers that are colder and wetter than normal. Adverse weather resulted in lower arthropod abundance. Rain appeared to be the primary environmental limitation to nestling growth, although growth was adversely affected by prolonged periods of low temperatures (Pérez et al. 2016).

Nests may experience high predation rates. On Melville Peninsula, the average rate of nest predation over 4 years was 51%. The decline of an Alaskan population was attributed to 3 consecutive years of high predation rates. High predation rates occurred when small rodent

populations were low, forcing jaegers, owls, weasels, and foxes to shift their prey bases (Custer and Pitelka 1977; Lyon and Montgomerie 1987). There was no difference in predation rates during the nestling and fledgling stages. Brood dispersal does not reduce predation risk and its main function appears to be to facilitate feeding of the young by adults (McLaughlin and Montgomerie 1989a; Wynne-Edwards 1952).

Wild fires can decrease habitat suitability and result in lower nesting densities. A fire in tundra habitat in Alaska consumed almost all above-ground vegetation, except for the cores of sedge tussocks and scattered small patches of moss. Density of longspurs in the burned area was one-third that of the unburned area. The fire may have deterred birds from settling into the area, and they may have required larger territories (Wright 1981). In habitats where there is dense shrub growth, fire could potentially improve habitat.

Overgrazing by geese may make sedge meadows less suitable for nesting by the Lapland Longspur. At Churchill and La Pérouse Bay, lower densities occur in grazed than ungrazed areas. Goose grazing is unlikely to be a major problem unless it is severe and occurs over a widespread area (Boal and Anderson 2005; Jehl 2004; Sammler et al. 2008).

Climate warming is likely to result in massive habitat loss in the Low Arctic and southern breeding areas. Gains are possible at higher elevations further north, but these are unlikely to compensate for losses in the south. The significant local contraction near Churchill may be due to climate change, but positive evidence for this is lacking (Hussell and Montgomerie 2020). Ontario represents the most southern area of the Lapland Longspur's breeding range, so the Ontario breeding population is at high risk of extirpation if global warming continues.

Oil, gas, mining, transportation, and urban development in the breeding range may result in small-scale, local loss of breeding habitat. The disappearance of this longspur near Churchill was a result of roads and drainage ditches. The current levels of disturbance are very low and will have little impact on population levels (Hussell and Montgomerie 2020; Jehl 2004).

Male and Nol (2005) investigated the impacts of roads associated with a diamond mine in the Northwest Territories. There was no evidence that Lapland Longspurs avoided placing their nests near roads and there was no difference in the success rates of nests near and distant from roads. Sites near roads supported significantly more invertebrates than those distant from roads. A maximum of 1,000 trucks per day created anthropogenic noise for 14% of the day. The truck noise overlapped with the lower range of longspur song. It may be tolerant of human disturbance but long-term changes in vegetation could occur that might affect nest-site selection.

Status

The first nest was found at Cape Henrietta Maria between 20 and 24 July 1947, and a juvenile not quite able to fly was collected; 41 were seen on this trip. A juvenile was taken at Little Cape west of Cape Henrietta Maria in 1947. In 1948, additional nests and young were observed at Cape Henrietta Maria and 100 were seen on 5 July 1948. It was considered likely that the Lapland Longspur bred all along the Hudson Bay coast (Baillie 1962; Manning 1952). Peck (1972) considered it an abundant breeder at Cape Henrietta Maria. Although earlier ornithologists speculated that it nested from Cape Henrietta Maria west to the Manitoba border, there was no positive evidence of this. During the first

atlas, breeding evidence was documented near the Manitoba border and from Winisk to Cape Henrietta Maria in the east. There was a distinct gap in its distribution that may have been partially due to lack of coverage, but there is considerably less suitable habitat in the intervening area. It was locally abundant in the Cape Henrietta Maria area (Hussell in Cadman et al. 1987). James (1991) considered the Lapland Longspur a common breeder in the Tundra Region. Wilson and McRae (1993) reported that it was a common breeder at Brant but apparently absent at Shagamu, supporting the evidence that there was a gap in its distribution.

The second atlas revealed a similar distribution with concentrations of breeding Lapland Longspurs at the Manitoba boundary and from Winisk to Cape Henrietta Maria. There were 2 breeding records from the intervening area, but only 7 squares were investigated in the central area of the Tundra Region. It was recorded in 23 squares during the second atlas and 18 squares in the first (Hussell in Cadman et al. 2007).

POSTFLEDGING PERIOD

As soon as the young leave the vicinity of the nest, brood division occurs with each adult taking 2 or 3 chicks. There is no difference in the number of chicks cared for by each adult or the age of chicks led by either sex in Alaska. On Baffin Island, males appeared to take charge of the oldest chicks. Adults forage around the chicks and feed each individual several times before making a long flight to feed the next chick. One of the main functions of early nest departure by young and brood division and dispersal appears to be to reduce distances that adults must travel to find food for young. Young are gradually led to prime foraging areas so that they are in good habitat once they begin feeding on their own (Hussell and Montgomerie 2020).

Young stay within their parents' territory for 3-5 days until they can fly at age 12-15 days, then drift through other territories to gather in damp areas. They begin to try and feed themselves at age 17-18 days, and are independent after age 23 days. Chicks are fairly immobile at this time and hide among hummocks, in crevices, or beside rocks. The distance between chicks in brood groups cared for by an individual parent increases from 0 m at nest departure to 200-325 m at independence. Young disperse from the nest with time. Just prior to independence, female-tended broods average 1 km from the nest compared with 250 m for those tended by males. During this dispersal process, adults lead the chicks closer to feeding areas. By age 18 days, chicks within a sub-brood averaged 132 m apart and 264 m from the closest chick in the other half of the same brood. At this time, the average distance of each chick to a feeding area was only 8.6 m. The strategy of young leaving the nest early before they can fly, brood division, and leading chicks toward parental feeding sites greatly reduces the amount of flying that adults have to undertake to raise young to independence. Young move to shrubby areas by ponds and streams once they become independent and strong fliers. Juveniles remain scattered until at least mid-August when they form flocks that presumably include adults. Flocks concentrate in wet, grassy tundra and less often on barren tundra. These flocks remain intact until autumn migration (Drury 1961; Hussell and Montgomerie 2020; McLaughlin and Montgomerie 1985, 1989a, 1989b; Sutton and Parmelee 1955; Tryon and MacLean 1980).

MIGRATION

The Lapland Longspur migrates both diurnally and nocturnally. Some birds observed during migration and winter in Ontario may breed in Greenland. During spring migration, birds migrate in

flocks. Individual birds remain in a given flock for as long as 3-5 days. Marked birds migrating to Alaska gradually disappeared from individual flocks but were replaced by other birds. Flocks remained at the same location and approximately the same size. Males migrate northward before females and arrive at the breeding grounds before they do. Early migrating flocks are dominated by males, later flocks have approximately equal numbers of the sexes, and late flocks are mostly females. Males arrive on the breeding grounds in flocks of 10-100 birds. In most areas, males arrive 3-6 days prior to females, but the differential in arrival times may range from 1 to 14 days. Males remain in small flocks initially and females may flock together upon arrival prior to pair formation. In 1 year on Victoria Island, males arrived in flocks 1 day, flocks containing equal numbers of males and females arrived the next day, and flight singing occurred the following day. Northward migration may be slowed by inclement weather and this may affect the timing of arrival of the sexes and how long they remain in discrete flocks before pairing (Brewer et al. 2018; Drury 1961; Freeman 1970; Hussell 1972; Hussell and Holroyd 1974; Hussell and Montgomerie 2020; Irving 1961; MacPherson and McLaren 1959; Manning et al. 1956; Parmelee et al. 1967; Soper 1946; West et al. 1968a; Williamson in Austin 1968; Wynne-Edwards 1952).

Northward movement may begin in the southern wintering range in late February or early March. The peak of migration in southern Canada is from late March until early May. The Lapland Longspur arrives at Churchill in mid-May with peak numbers in late May and early June. Arrival in the High Arctic is in late May or early June. In southern Ontario, numbers often increase in March as migrants move through from further south. Most leave in late March or early April, but stragglers may persist until mid-May. In Algonquin Park, average spring arrival is in late April, average departure is in late May, and some remain until early June. Late spring migrants occurred at Longridge on 6 and 8 June, on 14 June at Ekwan, and on 24 and 28 June at Shagamu, although the latter birds may have been failed breeders (Black and Roy 2010; Curry 2006; Jehl 2004; Jehl and Smith 1970; Hussell and Montgomerie 2020; Lancaster et al. 2004; Tozer 2012; Weir 2008; Williamson in Austin 1968; Wilson and McRae 1993).

In Alaska, Ward et al. (2016) compared spring arrival dates of migrants over a 50-year period. Warming during this period resulted in the transition from winter to summer occurring weeks earlier than it did previously. The Lapland Longspur arrived significantly earlier with time at a rate of 0.11 day per year or 0.8 day per 1°C increase in temperature.

Autumn flocking on the breeding grounds may begin in mid-July but is not prevalent until early August. Mixed flocks of Lapland Longspurs and Snow Buntings may be common at this time, and also during autumn migration and winter. Longspurs typically leave the northern portion of the breeding range from mid-August to early September, with some remaining into late September or early October. At Churchill, autumn migration begins in late August and peaks in September, with some remaining until mid-October. At Thunder Cape on the northern shore of Lake Superior, migrants pass through from mid-September to late October, peaking in the first half of October. Autumn migrants were observed at Ekwan 3-13 September and 4-13 September at Longridge. In the southern Shield, the Lapland Longspur may occur in late September but is more likely in October; some remain until late November. Some arrive in the south in mid-September, but most arrive in mid- to late October. Along the northern Lake Erie shoreline, numbers peak from late

October to mid-November (Black and Roy 2010; Curry 2006; Hussell and Montgomerie 2020; Jehl 2004; LaForest 1993; Lancaster et al. 2004; Lyon and Montgomerie 1987; MacPherson and McLaren 1959; Mills 1981; Parmelee and MacDonald 1960; Parmelee et al. 1967; Soper 1946; Sutton and Parmelee 1955; Tozer 2012; Weir 2008; Wilson and McRae 1993).

During migration, the Lapland Longspur occurs in flocks, occasionally only with conspecifics, but usually in the company of Snow Buntings or Horned Larks, and less frequently with American Pipits. This longspur avoids forested and treed habitats. In forested regions, it concentrates along coastlines; shorelines of lakes, rivers, and reservoirs; and on roadsides. In extensively forested landscapes, it makes greater use of human-created habitat including gravel pits, roadside clearings, sewage lagoon dykes, airstrips, utility corridors, recent clear-cuts, and settlement areas. In agricultural settings, where it is most common during migration, it prefers fields of grain stubble. It is attracted to fields with standing water, sloughs, small ponds, water-filled ditches, shorelines, sewage lagoons, and wetlands where flocks gather to drink. Autumn migrants in Davis Strait and the Labrador Sea were attracted to a ship 75 km off the Baffin Island coast. Birds circled and landed on the ship (Campbell et al. 2001; Crins 2004; Curry 2006; Hussell and Montgomerie 2020; LaForest 1993; Lanoue and Doyon in Gauthier and Aubry 1996; Leighton et al. 2002; Mills 1981; Orr et al. 1980; Sinclair et al. 2003).

West and Peyton (1980) collected 280 gizzards of Lapland Longspurs during spring migration in British Columbia, the Yukon, and Alaska. Twenty-seven types of seeds were eaten and they comprised 39.3% of the total dry weight of the gizzard contents. Fragmented material, estimated to be more than 90% plant material, comprised 60.3% of the gizzard contents. Squirrel-tail grass, bluejoint, bentgrass, and sedges comprised more than 77% of the identifiable food items. Unknown seeds of 2 types comprised 1.6% of the weight of food items. Larval, pupal, and adult insects constituted only 0.4% of the diet. Other foods included seeds of white spruce, fescues, smooth brome, wood-rushes, white birch, grey alder, lamb's-quarters, chickweeds, sandworts, buttercups, golden corydalis, geraniums, phlox, mints, and members of the aster family. Overall, the diet consisted of 59.7% grasses and 20.6% sedges. It preferred seeds of squirrel-tail grass and also selected seeds of chickweeds, sandworts, and bearberry more than their availability. Sedge seeds were taken in proportion to their availability. Bluejoint, bentgrass, and lamb's-quarters were taken slightly less than their availability. Brome grass, cinquefoils, and fescues were taken less than their availability. Some abundant plant species were not eaten at all including wheat grass and mustards. Crins (2004) observed one feeding on the seeds of ensheathed dropseed during autumn in Algonquin Park. The seeds of this grass are enclosed. The bird used its bill and tongue to separate the overlapping leaf sheaths to eat the grains. In agricultural areas, it feeds on waste grain seeds and a variety of other plant seeds. In New York in early October, Hoyt (1961) observed an adult feeding a young bird, apparently the only record of young being fed during autumn migration.

Seeding of agricultural crops and application of pesticides often coincide with spring migration, making the Lapland Longspur vulnerable to these chemicals. In 1984, at least 300 and probably more than 2,000 died in a Saskatchewan field that was recently planted to canola and treated with carbofuran. Although carbofuran has since been banned in Canada and the United States, the alternative pesticides currently in use are also toxic (Hussell and Montgomerie 2020).

Due to its habit of foraging along roadsides and flushing at close range, the Lapland Longspur is vulnerable to vehicle collisions (Campbell et al. 2001; Mills 1981).

The Lapland Longspur occasionally strikes tall structures during migration. One was killed at an unlit forestry tower during spring migration at Parry Sound (Mills 1981). Mass destruction of migrating flocks may occur at lighted structures, especially during periods of poor visibility due to snowstorms (Hussell and Montgomerie 2020).

On the prairies, the Lapland Longspur is an abundant migrant and often occurs in flocks larger than 5,000 (Hussell and Montgomerie 2020), but in Ontario it is an uncommon to locally abundant migrant (James 1991).

WINTER

The Lapland Longspur tends to avoid snow in winter. Snow cover variability is an important predictor of its presence, with it selecting areas where there are frequent changes between presence and absence of snow (Keyser et al. 2023).

In winter, the Lapland Longspur usually occurs in mixed flocks with Snow Buntings and Horned Larks. In southern Ontario, it is most frequent in large, windswept fields, particularly those where manure has been spread. Areas south of Hamilton, Wolfe Island, Amherst Island, Hay Bay, and Prince Edward County are favoured wintering areas. It is most frequent in agricultural fields, especially those with retained grain stubble, but also occurs in grazed pastures. In Oklahoma, it preferred sites with vegetation 0-10 cm tall with little to no litter cover. At an Oklahoma airport, it occurred in greatest numbers in grassy areas between the runways where it was associated with agalinis, panic grass, and ragweed. In another winter study, it preferred fields planted to winter wheat to grazed grasslands. In Massachusetts and Maine, it inhabits ocean sand dunes where the vegetation is sparse. In inland areas, it frequents fields where ragweed and other weed stalks protrude above the snow. In winter in British Columbia, it occurs mostly along the southern coast in open grassy or sparsely vegetated areas including cultivated fields, grazed pastures, roadsides, estuaries, rocky shorelines and islets, beaches, lagoons, jetties, causeways, sedge wetlands, golf courses, playing fields, and airports (Black and Roy 2010; Campbell et al. 2001; Curry 2006; Hussell and Montgomerie 2020; Weir 2008; Williamson in Austin 1968).

The Lapland Longspur does not maintain any particular home range in winter and is largely nomadic. Flocks forage in a given area for a few minutes to more than an hour and then fly to another location. Large-scale movements may occur in winter in response to food supplies and snow depths. When snowstorms cover plants, birds fly to areas with less snow cover. North of latitude 50°N, it may be abundant some years and absent in others (Hussell and Montgomerie 2020; Williamson in Bent 1968).

The degree of site fidelity that Lapland Longspurs exhibit for wintering areas is uncertain. One banded in October 1961 in North Dakota was recovered elsewhere in North Dakota in January 1963 indicating fidelity to the same general region. Another bird banded in North Dakota was recovered in California indicating a lack of winter fidelity (Hussell and Montgomerie 2020).

Gabrielson (1924) analyzed the contents of 600 stomachs of wintering birds. More than half were collected in January and February in Kansas under very similar conditions which may have

given undue prominence to millet and crabgrass in the diet (75% of the January food and 65% of the February food). Only 4.0% of the winter food was animal matter and almost half of this was taken by 4 birds in April that had fed exclusively on ground beetles. The remaining animal food consisted of leaf beetles, weevils, fly larvae, caterpillars, and spiders. Grass seeds dominated the diet and comprised 61.7% of the food: 30.6% foxtails, 10.0% cultivated millet, 8.7% hairy crabgrass, 2.3% panic grasses, and 10.5% other grasses such as smooth crabgrass and barnyard grass. Sedge seeds comprised 10.3% of the diet, taken mostly by birds in Montana, Ontario, and the Northwest Territories. Seventeen birds had eaten 64.4% sedge seeds in October but this food item was only 8% of the April and May diet. Seeds of purslane were common in the diet but were only 0.8% of the volume because they are so small. Amaranth seeds comprised 6.0% of the diet and miscellaneous seeds were 6.5%, of which lamb's-quarters and ragweed were most common. Wheat was eaten every month except October and represented 8.3% of the diet. It also ate timothy seeds and oats (1.4%). Most cultivated seeds were waste from crops, but it may also pick up newly sown grain or grass seeds. Judd (1901) summarized the contents of 113 stomachs collected in winter in the United States. The diet consisted of 94% plant material and 6% animal material. Waste oats, wheat, barley, and millet consumed in fields constituted 27% of the diet. The Lapland Longspur also ate large quantities of seeds of foxtails, crabgrasses, and panic grasses. Other seeds consumed included those of amaranths, lamb's-quarters, smartweeds, and ragweeds. Insects occurred only in stomachs of birds collected in Texas and included weevils, ground beetles, leaf beetles, and grasshoppers. Other winter foods commonly taken include seeds of bluegrasses, marram grass, and orache, and it may also eat snow (Hussell and Montgomerie 2020; Williamson in Austin 1968). The Lapland Longspur rarely visits bird feeders, usually when snow storms cover natural food supplies (Campbell et al. 2001; Curry 2006; Lancaster et al. 2004).

There has been no large-scale habitat degradation in the Lapland Longspur's winter range. Agriculture may have enhanced winter habitat and overwinter survival through increased availability of seeds (Hussell and Montgomerie 2020).

Until the 1960s, massive kills of the Lapland Longspur occurred almost every winter on the prairies. Most kills were associated with farmyards and other rural structures with less than 10 lights. Kills occurred during falling snow or foggy conditions around isolated groups of lights which disoriented birds. Many were killed by hitting human structures, but most flew into the ground or frozen lakes. On the night of 13-14 March 1904, 1-5 million were killed over an area of 3,800 km² in southwestern Minnesota, northwestern Iowa, and southeastern South Dakota. Approximately 10,000 were killed over an area of 9,000 km² in northwestern Iowa on 5-6 January 1939; 10,000 were killed in north-central Texas 19-23 February 1978 following snowfall; and on 22-23 January 1998, 5,000-10,000 were killed near 3 communication towers and a natural gas pumping station in Kansas. There have been no recent major kills associated with prairie towns, probably because of brighter and more general lighting than was present previously (Hussell and Montgomerie 2020; Williamson in Austin 1968). In Wyoming, Ramirez et al. (2015) reported a kill of 251 at an oil drilling rig. They attributed this to the birds entering the area illuminated by the drilling rig lights in fog and repeatedly circling until they fell to the ground in exhaustion, subsequently perishing.

The Lapland Longspur is the most abundant terrestrial bird wintering in northern North America. Flocks as large as 4 million occur in winter in the Great Plains from southern Canada to northern Texas. In eastern North America, it is uncommon in winter (Hussell and Montgomerie 2020). James (1991) considered it an uncommon to locally common wintering species in the south, north to Kingston.

Freedman and Riley (1980) examined Christmas Bird Count (CBC) results in southern Ontario. Numbers were extremely irregular dating back to 1929, with major peaks in 1939 and 1951 and minor peaks in 1936 and 1960. At the time of their publication, the Lapland Longspur was an irregular winter visitor. CBC data for Ontario indicate that the Lapland Longspur decreased at annual rates of 3.17% 1970-2021 and 14.67% 2009-21 (National Audubon Society 2022).

Smith's Longspur

Calcarius pictus

BREEDING SEASON

Habitat Requirements

In Ontario, the Smith's Longspur breeds on open, treeless tundra. It prefers grassy and somewhat wetter tussock tundra rather than the dry heath-lichen areas selected by the Lapland Longspur. The Smith's Longspur occasionally nests on raised, dry tundra areas and beach ridges (Peck and James 1987). Peck (1972) concluded that the Smith's Longspur preferred wetter habitat than the Lapland Longspur at Cape Henrietta Maria. Prime breeding habitat in Ontario consists of hummocky graminoid tundra with scattered stunted spruces interspersed with low gravel ridges. It may occur in suitable transition habitat 40-60 km inland from the Hudson Bay coast, but is absent from exposed treeless tundra near the coast (Hussell in Cadman et al. 2007).

Throughout its limited range, the Smith's Longspur is predominantly a bird of the more northern part of the transition zone between the Boreal Forest Region and the treeless tundra. In Alaska, southern Yukon, and northern British Columbia, it also breeds in alpine meadows and tundra. Suitable breeding habitat in tundra tends to be patchy in distribution, isolated from other suitable habitats by spruce forests or bedrock outcrops. Near Churchill, it nests most commonly in dry sedge meadows with scattered, isolated clumps of black spruce, but a few pairs breed well out into the tundra. It is found mostly where tongues of spruce forest extend out into the tundra. Nesting may occur on grassy eskers at Churchill. It nests most frequently where drier sedge meadows dominated

by tufted bulrush and dwarf birch are interrupted by low hillocks or small beach ridges bearing scattered, isolated clumps of black spruce or, less frequently, tamarack. These hillocks are dominated by heaths, predominantly Lapland rosebay, bog rosemary, bearberry, bog bilberry, and mountain cranberry. Other common species include mountain avens, crowberry, net-leaved willow, and reindeer lichen. In the Yukon, it inhabits open sedge tussock tundra, often in areas with scattered low willow or birch shrubs. In the north, it occurs in relatively bare tundra; it is restricted to high-elevation areas in the south. In British Columbia, it nests in subalpine tundra with shrub cover of willows, dwarf birches, and shrubby cinquefoil and a ground cover of sedges, mosses, lichens, and perennial forbs. In Alaska, it nested on hummocks in wet grassy areas; in tussock-heath tundra; in waterlogged sedge-grass marsh dominated by water sedge with scattered cottongrass; in a wet area with low willows, marsh horsetail, cottongrass, and water sedge; in a cottongrass tussock tundra by a small lake; in a sunken summit plateau bog with higher ground forming the rim; and in a well-drained site dominated by hummocks of mountain avens and Lapland rosebay. It selected wetter habitats than those used by the Lapland Longspur (Briskie 2020; Campbell et al. 2001; Jehl 1968, 2004; Jehl and Smith 1970; Martin et al. 1981; Sage 1976; Sinclair et al. 2003).

Wild et al. (2015) examined the distribution of the Smith's Longspur at landscape and microhabitat levels in Alaska. At the landscape level, it inhabited river valleys within the tundra-forest transition zone, large tundra valleys, areas along the front of a mountain range, and the edge of a river. It was positively associated with sedge and shrub ecotypes and negatively associated with barrens, water, and forest ecotypes. At the microhabitat scale, occupied and unoccupied habitats were composed of the same ground-cover species, but at varying levels of percent cover. It was most frequently associated with willow shrubs, dwarf willow, mountain avens, non-tussock sedges, and mosses. It was also associated with greater moss cover and, to a lesser degree, cover of lichens and heather. These habitats were closer to the northern coastline and at higher elevations. It was negatively associated with greater cover by birch, willow, and alder shrubs. At both scales, it was associated with a heterogeneous land cover of sedge and shrub habitats. Landscape heterogeneity may be an important habitat variable, but this was not tested. Large patches of closed shrub coverage appeared to be avoided, yet foraging occurred in some shrubby areas.

In Alaska, habitat at nests and random points was very similar, but shrubs tended to be taller at random sites than at nest sites. Mean shrub height at nests was 26.8 cm and nests were never found in tall shrubs. General nesting habitat consisted of open low-shrub tundra. Nest habitat selection

was weak with the shorter height of erect willows at nest sites being the best predictor (McFarland et al. 2017).

At night, the Smith's Longspur roosts on the ground, either singly or in pairs (Briskie 2020).

Ontario nests were on the ground in both tall and short sedges and grasses, sometimes with mosses and lichens near the nest. One was in a clump of rhodendrons; 1 was under a small dwarf birch; 1 was well hidden in tall, dead grass clumps; and another was on a hummock (Peck and James 1987). Most nests are in grass tufts on or beside hummocks or between frost boils (Hussell in Cadman et al. 2007).

Nests are invariably in a small depression in the ground or in the sides of tussocks of vegetation. In Alaska, 47.7% of nests were in the tops of hummocks, 24.4% were in the sides of hummocks, and 27.9% were on level ground. Of 86 nests, 44.2% were directly under clumps of graminoids, 33.7% were under shrubs less than 30 cm tall, and 22.1% had no overhead cover. Common shrubs associated with nests were willows, followed by bog bilberry, rhododendrons, and dwarf birches. Low shrubs (1.7-20.8 cm) were present at 88% of nests. Many nests are completely exposed from above; others are concealed at the base of a small shrub, in Labrador tea, or in graminoids (Briskie 2020; Campbell et al. 2001; Jehl 1968, 2004; Kemsies in Austin 1968; Martin et al. 1981; McFarland et al. 2017; Sage 1976; Sinclair et al. 2003).

The Smith's Longspur does not defend a territory but males compete for copulation. Males are aggressive with other males only when copulating with a female and may chase other males over several 100 m for several minutes. Males guard females by following them closely on the ground while they are foraging. Mate guarding by alpha males is most intense on the day before and the day of clutch initiation, when the first and second eggs are available for fertilization. Guarding by beta males is greatest after the third egg is laid, when the fourth egg could be fertilized. Mate guarding is most prevalent in the morning and evening, but nonexistent in the afternoon. Males sing from treetops, boulders, hummocks, or other conspicuous perches to attract females. Males are completely nonterritorial while advertising, with as many as 3 singing from the same tree at once without conflict. Male home ranges overlap extensively with 2-5 other males. Female home ranges overlap with 3-6 males and 2-5 other females. Populations tend to be distributed into discrete neighbourhoods delineated by the patchy nature of suitable habitat. At Churchill, each neighbourhood contained 4 to more than 20 birds, with larger areas supporting more birds. Neighbourhoods were separated by 100 m to several kilometres. The area used by 2 pairs during the incubation period at Churchill was 1.7 and 2.4 ha. Home ranges of 12 males at Churchill averaged 16.3 ha (range 9.4-30.9 ha). Home ranges of 8 females averaged 10.4 ha (range 5.4-19.5 ha; Briskie 1992; Jehl 1968).

Natal philopatry appears to be very low. Only 1 of 90 chicks (1.1%) returned to nest at Churchill, and it nested 3 km from its natal site (Briskie 1992, 2020). In Alaska, 4% of 431 juveniles were sighted in subsequent years. Nests were located for 3 returning males and 3 females. The mean distance between their natal and breeding nests was 1,674.4 m, significantly further than for returning adults. One of 6 returning birds nested within its natal neighbourhood (Craig et al. 2015).

Adult site fidelity is high. At Churchill, 13 of 15 adult males (86.7%) and 10 of 11 females (90.9%) returned to breed the following year. Birds that did not return were not seen in neighbouring populations and had likely died. In 1 case, a nest was placed in the same location in 2 consecutive years suggesting high fidelity, but it was unknown if the same birds were involved (Briskie 2020; Jehl 1968). In Alaska, return rates were 53% for males and 37% for females. Most returning adults nested within the same neighbourhood as in previous seasons. Four individuals (17%) returned to breed in a different neighbourhood; these were all females. The mean inter-annual nest distance was similar for the sexes: 325.2 m for females and 300.9 m for males. Dispersal rates of females were unrelated to reproductive success the previous year (Craig et al. 2015).

Limiting Factors

Eggs have been reported in Ontario nests from the last third of June until mid-July (Peck and James 1987). Nesting in populations is highly synchronized, with only 5, 6, and 8 days between the initiation of the first and last clutches at Churchill over 3 years. Timing varies annually depending upon weather conditions, with first clutch initiation ranging from 9 June in a warm spring to 21 June in a cold, late spring at Churchill. Fledging occurs over 6-14 days for entire populations. Pairing occurs as soon as males leave flocks and begin to sing from perches. Females begin to search for a nest site a few days to a week after this. In Alaska, nest building was initiated almost immediately upon arrival or as soon as temperature and snow conditions allowed. The length of the nest initiation period was 7-19 days, with longer periods occurring in years with warmer temperatures and fewer snow and rain events. The female begins to gather nest material as soon as the site is selected and completes building the nest in 3 or 4 days. Nests are not reused, with a new nest built for each clutch. Eggs are laid at the rate of 1 a day. Incubation begins with laying of the penultimate or final egg. The incubation period is 11-13.5 days (average 11.5 days). Nests may be temporarily abandoned during cold, wet weather, but eggs in these nests usually hatch once incubation is resumed. Hatching occurs over 11-36 hours (average 22 hours). Young begin to stray short distances from the nest by age 6 days and leave it completely when they are 7-9 days old. In Alaska, the mean nestling period was 7.0 days (Briskie 1992, 2020; Jehl 1968, 2004; Jehl and Smith 1970; McFarland et al. 2017).

A single brood is raised annually; renesting is rare if a clutch is lost. At Churchill, renesting occurred in only 2 of 6 years and in only 3 of 11 nest failures (27%). Clutches of 3-5 eggs have been found in Ontario, with most containing 4 or 5 eggs. Overall, clutches of 1-6 eggs have been reported, but those with 1 or 2 eggs may have suffered partial losses. Most clutches contain 4 or 5 eggs; 4 eggs is the most frequent clutch size. Mean clutch size in Alaska was 3.7 eggs (range 1-5 eggs); 1 nest contained 9 eggs. This nest was attended by a single female and hatched 6 young and fledged 4 (Briskie 1992, 2020; Campbell et al. 2001; Jehl 1968; Jehl and Hussell 1966; Martin et al. 1981; McFarland et al. 2017; Sinclair et al. 2003).

The age at first breeding is 1 year. Nonbreeding birds have not been detected in any populations, so it is likely that most, if not all, yearlings breed. The Smith's Longspur has an unusual mating system termed polygynandry and it is 1 of only 3 passerine species to exhibit this behaviour. Each female copulates with 1-3 males and each male copulates with 1-3 females. Females actively solicit copulations and copulate an average of 365 times per clutch (range 214-629 times). Of 13 females at Churchill, 77% were biandrous, 8% were triandrous, and 15% were monogamous. Of

males, 62.5% mated with at least 2 females, 12.5% with 3 females, and 25% with 1 female, but the level of polygyny may have been underestimated. The alpha male of 1 female might be the beta male of another female. Seventy-five percent of broods had mixed paternity. Alpha males fathered about 67% of the chicks and beta and gamma males fathered the rest. Alpha males fertilize most of the first-, second-, and third-laid eggs and beta and gamma males fertilize some of the third- and all of the last-laid eggs. All mating behaviour occurs in a 5-8-day period which centres on clutch initiation and usually ceases by the laying of the penultimate egg. Alpha, beta, and gamma males have all been observed feeding young, so polyandry may result in recruitment of males to assist in raising the young (Briskie 1992, 2020). Despite high site fidelity, only 1 pair reunited in a subsequent year in Alaska. There were 2 cases of males attending the same nest in 1 year and they were associated with each other again in subsequent years (Craig et al. 2015).

Birds walk rapidly over drier regions of tundra while foraging, peering and pecking for seeds and invertebrates. The Smith's Longspur does not scratch the substrate with its feet, but occasionally digs through moss clumps, lichen mats, and soil with its bill to capture ants or beetles. Later in the breeding season, it often hops or makes short flights to catch flying insects. Males and females forage solitarily except when mate guarding and copulating. After laying is complete, males and females do not associate closely until hatching, when most males return to assist the female in feeding. At 10 Churchill nests, chicks at 5 nests were fed by 1 male and 1 female, those at 4 nests were fed by 2 males and 1 female, and those at 1 nest were fed by 3 males and 1 female. All males that fed at nests had earlier copulated with the female, but not all males that copulated with a female later fed her brood (Briskie 2020; Jehl 1968).

The most conspicuous food items brought to nestlings are caterpillars, grasshoppers, and adult flies and lepidopterans, but many other items are provided to the young. Jehl (1968) examined the stomachs of 29 nestlings, but results may have been biased. They died of exposure during adverse weather, so adults may not have been able to secure some items that were normally fed to chicks. Spiders were found in 7 of 29 stomachs but otherwise there was no difference in the diet of nestlings and adults 1-20 July. Entire leaves of plants commonly occurring in the area were found in stomachs of 5 nestlings, but not in those of adults. Foods taken by adults and nestlings included spiders, damselflies, grasshoppers and locusts, earwigs, leafhoppers, geometer moth larvae, owlet moth larvae and pupae, crane flies, anthomyiid flies, soldier beetles, leaf beetles, ants, and spider wasps. Vegetable matter consumed included cinquefoil seeds; leaves of net-leaved willow, mountain avens, and bearberry; and reindeer lichen stem fragments. Jehl (1968) analyzed the stomach contents of 39 adults and 2 juveniles and found that they fed opportunistically on a wide variety of organisms through much of the summer. In the first 10 days of June, more than 90% of the volume of food was plant material, predominantly seeds. Invertebrates were taken when available, mostly ants, spiders, beetles, and caterpillars. In mid-June, when invertebrates are more abundant, the Smith's Longspur switches to a largely animal diet dominated by flying insects. After 20 June, the diet is comprised of more than 85% animal material, predominantly terrestrial species or immature stages of flying insects. Ants and spiders are taken frequently in early June but not in July; these are ignored once larger prey becomes available. Snails were found in 5 of 14 stomachs collected 11-20 July, reflective of the drying of small tundra pools. From late June through July, adults of flying insects comprised less than 25% of the diet.

The most significant limiting factors to the Smith's Longspur are predation and severe weather. During a cold and rainy period in early July, all young died in 18 nests near Churchill. Death was caused by exposure, with nestlings becoming drenched while adults searched for food. Subsequent brooding failed to dry them and all perished. One nest contained 4 eggs during this period, and 3 hatched (Briskie 2020; Jehl and Hussell 1966). Nest loss occurred in Alaska due to hail storms and unusually hot days (McFarland et al. 2017).

Human disturbance does not appear to be a significant factor. The Smith's Longspur is fairly tame and tolerant of humans and will nest in moderately disturbed habitat. Some declines occurred in the Churchill area due in part to habitat succession. Areas previously open along roads and airport runways have grown up with tamarack and are now unsuitable breeding habitat (Briskie 2020; Jehl 2004).

Drastic changes associated with climate change are predicted for Alaska, including advance of the treeline, increased shrub abundance and growth, decreased moss cover, and decreased soil moisture. Shrubs are already becoming larger and more abundant. Open tundra habitats may be lost which could affect the Smith's Longspur. How it responds will depend upon patterns of shrub growth and the persistence of mosses and sedges in the understorey. Increased shrub growth in sedge tundra could create the sedge-shrub tundra that it prefers; reductions in soil moisture and moss cover could drastically reduce habitat suitability. The extent to which Smith's Longspur will persist in increasingly shrubby sites or occupy new sites is uncertain (Wild et al. 2015). It had high nesting success in Alaska and the ability to delay nest initiation during inclement weather. This suggests that it may be resilient to predicted changes in weather, but the potential loss of low-shrub habitats is a significant threat (McFarland et al. 2017).

Status

Nesting was first confirmed in the province on 22 June 1940 when a nest was found at Fort Severn, and juveniles were collected at Little Cape and Cape Henrietta Maria in 1947 and 1948, respectively. More than 100 Smith's Longspurs were seen at Cape Henrietta Maria in 1948 and 2 nests were found that year (Baillie 1961; Manning 1952). Peck (1972) observed Smith's Longspurs daily near Radar Site 416, but they were less abundant than the Lapland Longspur and found in wetter areas of tundra. Schueler et al. (1974) considered the Smith's Longspur abundant at Winisk in 1965 and common in suitable habitat in 1971, with evidence of breeding obtained in both years. They saw it along the Sutton River in 1962, but no breeding evidence was obtained. During the first atlas, the Smith's Longspur was more abundant than the Lapland Longspur at Cape Henrietta Maria. Breeding evidence was found along the entire strip of tundra along the Hudson Bay coast, but it was absent from the more exposed outer coast at Cape Henrietta Maria and at West Pen Island (Hussell in Cadman et al. 1987). James (1991) considered it a common summer resident in the Tundra Region. Wilson and McRae (1993) found it nesting at Shagamu and Brant, seeing an average of 3-5 per day at Shagamu and 2-12 at Brant.

The second atlas demonstrated that the breeding distribution of the Smith's Longspur had not changed since the first atlas. The main areas of concentration were near the Manitoba border and inland from Cape Henrietta Maria (Hussell in Cadman et al. 2007).

POSTFLEDGING PERIOD

At fledging, young can run rapidly through the grass; by age 12 days, they can fly short distances but several more days are required before they can fly well. Brood division occurs as soon as the young leave the nest. Nest mates may be separated by 400 m a day after fledging. Some family groups disappear quickly from the vicinity of the nest; others remain nearby for as long as 3 weeks. The chicks are fed for about 3 weeks after they hatch (Briskie 2020; Jehl 1968).

MIGRATION

Most migration by the Smith's Longspur occurs through the Prairie Provinces and Great Plains states west of Ontario. It is regularly noted in small to moderate numbers in the Midwest in spring, mostly in central Illinois and Missouri, with smaller numbers from western Indiana. It may also occur in central and northern Ontario in April en route from Texas to Alaska. The autumn migration route may be further west although there are a number of autumn records from Thunder Bay and Duluth, Minnesota. It is uncertain if birds breeding in Ontario use the Thunder Bay area as a flyway to the plains or if these birds are strays (Briskie 2020; Dunn and Beadle 1998; Ryff 1987; Will et al. 2024). Wilson and McRae (1993) observed an autumn migrant on 12 September at Ekwan, south and a bit east of the breeding area.

The Smith's Longspur migrates by day and night, and may arrive at the breeding grounds at any hour. Birds usually travel in small flocks of 10-30 birds, but flocks as large as 250 have been seen. Flocks tend to be comprised solely of Smith's Longspurs. It is rarely seen in the company of the Lapland Longspur and Snow Bunting, typically only when forced to by crowding. Individuals at an Ohio airport remained for 6-19 days (Briskie 2020; Dunn and Beadle 1998; Jehl 1968; Sinclair et al. 2003).

Depending upon weather conditions, males usually arrive on the breeding grounds a few days before females. Most years, males remain in small flocks of 3-5 birds for several days after their arrival prior to establishing home ranges. If females arrive while the males are still in flocks, they may join the flocks but show no evidence of being attracted to the males. In years of colder weather when males arrive later, flocks disband almost immediately. Females that arrive after male flocks have disbanded immediately take up residency on males' home ranges. After spring arrival, only 10-12 days are available for pairing and mating before clutch initiation. At Churchill, birds arrive in the first days of June. In typical springs, most males have arrived by 6 June but in cold springs they may not appear until 18-20 June. Spring migration records from the north shore of Lake Superior range from 24 April to 19 May and there is an accepted spring migration record for southern Ontario on 20 April (Briskie 1992, 2020; Jehl 1968, 2004; Jehl and Smith 1970; Ryff 1987).

In the Churchill area, adults leave the young in late July and congregate in flocks. Migration there begins as early as mid-August some years and all are gone in the first week of September. Birds leave the Yukon in late July and August, occasionally into September. In British Columbia, birds start leaving in mid-August with 3 September the latest record from the northern breeding grounds. Late records for Ontario include 12 September at Ekwan, 29 September at Thunder Bay, and 31 October to 2 November at Long Point (Campbell et al. 2001; Jehl 1968; Jehl and Smith 1970; Ryff 1987; Sinclair et al. 2003; Wilson and McRae 1993).

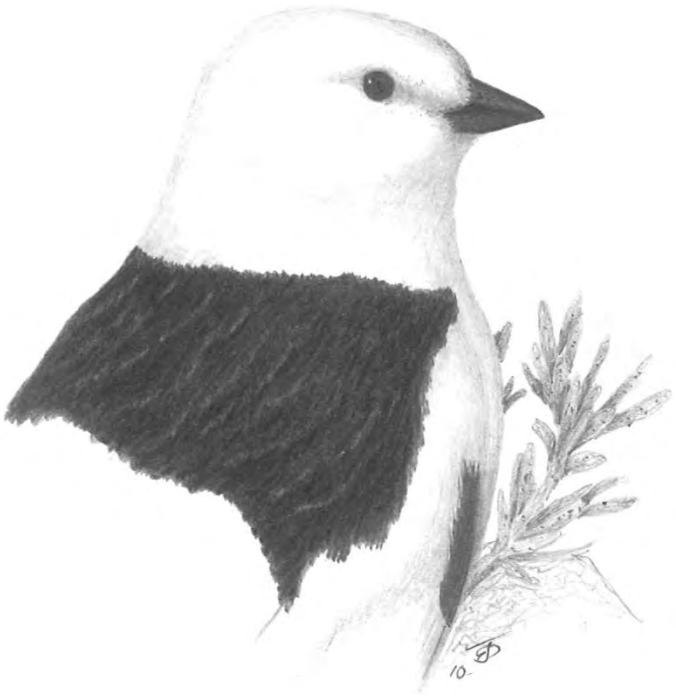
During spring migration in Alaska, the Smith's Longspur often occurred in wet, grassy areas and did not frequent dry areas. Near the breeding grounds in northern British Columbia, it fed in large flocks on open, grass-herb slopes or flats vegetated with dwarf birches, forbs, grasses, and sedges at subalpine sites. It also occurred in patches of dry grasses and weeds in logged areas, along gravel roads, in field verges, perched in shrubs in clear-cuts, and in grassy meadows bordering a lake. In agricultural landscapes, it is most often seen in stubble fields, pastures, and open, grassy fields and at airports (Briskie 2020; Campbell et al. 2001; Kemsies in Austin 1968).

Limited data are available on the diet of the Smith's Longspur during migration and winter. Ryff (1987) observed an autumn migrant at Thunder Bay capturing and eating a grasshopper. The stomachs of 9 birds collected in May at Fort Simpson, Northwest Territories contained insects almost exclusively. The diet of 21 birds collected in Illinois in April was composed of 37.1% animal matter and 62.9% vegetation. The predominant animal food consisted of beetles (mostly ground beetles with lesser numbers of click beetles and other beetles), comprising a total of 25.9% of the diet. Other animal foods included caterpillars (7.5%), other insects that were mostly grasshoppers and crickets (3.5%), and spiders (0.3%). Important grass seeds included those of tall dropseed (28.7%), foxtails (12.1%), witch grass (7.3%), wheat (4.7%), barley (0.7%), and small amounts of timothy, crabgrass, wiregrass, and millet. It also ate seeds of ragweeds, clover, and sedges. It eats cracked corn when it is available (Briskie 2020; Gabrielson 1924; Kemsies in Austin 1968). The diet of the Smith's Longspur is very similar to that of the Lapland Longspur (Gabrielson 1924).

The Smith's Longspur is an infrequent and rare migrant in the north. In the south, it is a rarely observed vagrant. There are only 4 accepted records for southern Ontario, including 3 migrants and 1 wintering bird (Curry et al. 2002).

Snow Bunting

Plectrophenax nivalis

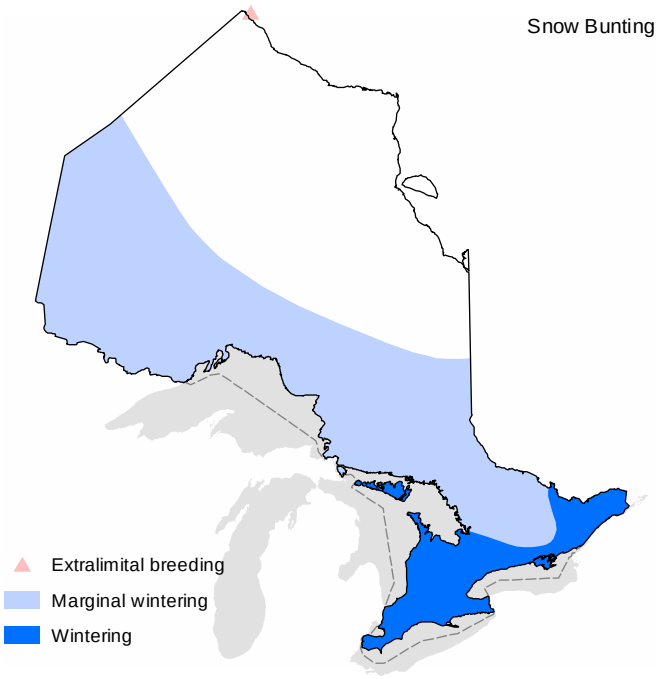


BREEDING SEASON

Habitat Requirements

In Ontario, breeding of the Snow Bunting has been confirmed only at West Pen Island on the Hudson Bay coast near the Manitoba border. The habitat there is not rocky, but piles of driftwood along the beach may have provided suitable nesting habitat (Hussell in Cadman et al. 1987).

The Snow Bunting nests in treeless areas, typically north of the treeline, but also in alpine areas in northern British Columbia, the Yukon, and Alaska. It prefers rocky terrain for nesting that is in or near vegetated areas that are used for feeding. Preferred habitats include stony beaches, cliffs along oceans, rocky outcrops in inland areas, rock piles, rock debris near remnant snowbeds, talus slopes at the base of cliffs, slumping benches along streams, and walls of steep ravines. It is attracted to outposts and villages where it may nest in a variety of artificial structures. Highest breeding densities may occur in disturbed areas. High densities often occur near seabird colonies because these birds transport nutrients into areas that would otherwise be nutrient-poor. Higher nutrient levels enhance conditions for aquatic insects that are critical to the diet of the Snow Bunting. In the Yukon, it nests on beaches strewn with driftwood. It is one of few species that inhabits nunataks, tundra islands on ice caps as far as 60 km from the edge of caps. In Greenland, it often nests in association with cliff-



nesting birds, particularly alcids. Lowest breeding densities occur in grassy tundra with little broken or rocky ground. It is mostly absent in marshes, grassy tundra devoid of rocks, higher areas of talus slopes and cliffs, and areas perpetually covered with snow (Bray 1943; Campbell et al. 2001; Drury 1961; Freedman and Svoboda 1982; Macdonald and Love 2012; Manning et al. 1956; Montgomerie and Lyon 2020; Montgomerie et al. 1983; Parmelee in Austin 1968; Parmelee et al. 1967; Sinclair et al. 2003; Smith and Marquiss 1994; Soper 1946; Vincent in Gauthier and Aubry 1996; Wynne-Edwards 1952).

Upon arrival on the breeding grounds, both sexes roost together in eroded snowbanks. Throughout the breeding season in the arctic, birds roost when the sun is low. Most roost in shadowy niches, but some sleep in direct sunlight. Some on Ellesmere Island roosted in a lumber pile. In natural areas, most roosted in shallow niches in sandstone outcrops and gullies. Even at −31.6°C, birds did not huddle together in roosts. After territories were established, few roosted in gullies; those that did used the same spots. Once territories are established, males roost alone in a crack or hole in their territory. In August, family groups roosted among rocks on steep banks, in nearly dry streambeds, or under huge snow banks undercut by running water. In September, large flocks roosted in open tundra where the ground was eroded or hummocky. In Greenland, birds roost in loose aggregations in cracks and holes in cliffs in spring (Montgomerie and Lyon 2020; Parmelee and MacDonald 1960).

In natural habitat, the Snow Bunting places its nest in a cavity under a boulder or rock, in a crevice in a rock, or in some similarly protected site. Nests, with rare exceptions, are not visible from above and are almost always in the shade, although some may be exposed to the sun for as long as an hour a day. Most nests are under rocks, but they may be in lemming burrows in banks, in holes on bare ridges, in piles of boulders, in vertical rock crevices, in cracks in cliffs, in earthen cavities created by slumping benches along streams, in shallow crevices in sandstone outcrops, and on or near the ground in piles of driftwood on beaches. Nests are usually well back from the cavity entrance and completely invisible. On Melville Peninsula, nests averaged 27 cm from the cavity entrance (range 10-60 cm); average distances of 30 cm have been reported elsewhere. Occasionally nests are hidden only under moss. Unusual nests include between 2 hummocks in open tundra, flat against a rock wall on a ledge 7.5 cm wide, and on a ledge of a sandstone outcrop. All these nests were completely exposed from above, but exposed nests are exceptional. Where rocks or artificial nest sites are lacking, it will nest in cracks or holes in soft ground, particularly where the earth is frost-heaved into piles of mud. Nests in soft mud are in depressions that are presumably scratched out by the birds. Nest cavities and old nests are frequently reused, occasionally for as many as 4 years,

because suitable nest sites are often limited. Of 56 nests found on Melville Peninsula, 9 were on top of an old nest, 2 were in the same cavity as an old nest, and 1 nest was used in 3 different years. On Ellesmere Island, all nests that were closely examined had been used in previous years. There is no clear orientation of nests. On Melville Peninsula, 59% of nests faced southward between 90° and 270°. The Snow Bunting readily uses artificial nest sites. It has nested in stone walls of buildings, old barrels, derelict buildings, tin cans, metal and wooden boxes, construction rubble, barrels filled with rocks, in the eaves of a building, on steel beams 3 m above the ground, under a piece of plywood, in skulls, in a coil of wire, under an oil drum, and in an old engine block (Bray 1943; Campbell and Van Der Raay 1985; Campbell et al. 2001; Drury 1961; Freedman and Svoboda 1982; Geale 1971; Höhn 1968; Hussell 1972, 1985; Hussell and Holroyd 1974; Kukal and Pattie 1988; Lyon and Montgomerie 1987; Montgomerie and Lyon 2020; Montgomerie et al. 1983; Parmelee in Austin 1968; Parmelee and MacDonald 1960; Parmelee et al. 1967; Sinclair et al. 2003; Soper 1946; Wynne-Edwards 1952).

Males may remain in flocks upon arrival on the breeding grounds. Once territories are established, they are vigorously defended by males. Females also challenge trespassing females. Territorial defence peaks in early June and gradually declines, ending in early July. During the period when the female may be fertilized, the male guards her from extra-pair copulations, rarely straying more than 3 m from her. Early on, males may leave their territory in midday to forage elsewhere, but remain and feed within the territory more as the season advances. After pairing, females occasionally leave the territory, but the male seldom does. In Canada, where males feed females on the nest during incubation, territorial defence wanes by the incubation period. In Greenland, where incubation-feeding does not occur, males continue to be territorial until hatching. Not all suitable habitat is used and males may forage together in undefended areas. By mid-July, some males abandon the territory and flock in common defence of the young. In Greenland, territory size shrinks with the season. Territories are initially 300-400 m in diameter (approximately 28-50 ha) but later shrink to 50-100 m (0.8-3 ha). A similar pattern was noticed on Melville Peninsula but the distances were not quantified. Adult home ranges are as large as 50 ha during the breeding season, depending upon the distribution of food. Nests are usually well dispersed, but 2 nests were found within 4.6 m of each other in a stone wall of a house on Bylot Island. On Devon Island, nearest-neighbour nests averaged 115 m apart with a range of 44-438 m (Drury 1961; Montgomerie and Lyon 2020; Nethersole-Thompson 1966; Parmelee in Austin 1968; Vincent in Gauthier and Aubry 1996).

The Snow Bunting exhibits very low natal philopatry. On Melville Peninsula, 1 of 53 nestlings (1.9%) returned to breed the following year; 0 of 135 returned to Devon Island. Adult site fidelity also appears to be low. On Melville Peninsula, 2 of 9 (22%) adult males and 0 of 10 adult females returned. On Devon Island, 2 females and 1 male of 32 adults (9.4%) returned. Although adult site fidelity is low, some adults return to the same general area, sometimes to the same home range, and rarely to the same nest site (Hussell and Holroyd 1974; Montgomerie and Lyon 2020).

Limiting Factors

The Snow Bunting is the earliest passerine to arrive in arctic breeding grounds, but it does not initiate nesting earlier than other species. Birds may remain in flocks for as long as a month before initiating

nesting. Nesting is highly asynchronous: by 6 July on Baffin Island, some nests were well incubated, other eggs were still fresh, and some birds were still building nests as late as 2 July. It is uncertain if the timing of nest initiation is related to snow melt or so that the peak of hatching coincides with insect emergence. Timing of nesting is independent of latitude but is related, at least in part, to disappearance of snow. Many crevices and cavities become filled with ice over winter and birds have to wait until it melts before nesting can be initiated. Nests are usually initiated 1 or 2 days after the appearance of large snow-free patches. The female may start several nests and abandon them before choosing the one that she finishes. Most nests take 3-4 days to build (range 1-8 days); 1 Alaskan nest was built in 14 hours. The first egg is usually laid on the day of nest completion or the following day. The first egg may be laid on bare substrate before nest building even starts; the nest is built around it while the clutch is completed. One egg is laid a day, although a day may rarely be skipped. Incubation usually starts before the clutch is complete. On Melville Peninsula, incubation began with the laying of the third or fourth egg; incubation started with laying of the first egg on Baffin Island; and incubation does not start in Greenland until the clutch is complete. The incubation period is usually about 12 days (range 10-15.5 days). Longer incubation periods (13-15.5 days) are often by females that are not being fed by males. These females are less attentive to their nests because they are forced to feed themselves. Nesting cavities have a harsh microclimate where eggs quickly become cool, thereby prolonging the incubation period and reducing hatching success when the female is absent. Because incubation begins before the clutch is complete, hatching is asynchronous and takes place over 3-5 days. The age of young within a brood may vary by as much as 3 days. On Devon Island, mean hatching intervals were 30.25 hours for 4-egg clutches (range 17-55 hours), 43.06 hours for 5-egg clutches (range 30-59 hours), 53.00 hours for 6-egg clutches (range 37-69 hours), and 55.00 hours for 7-egg clutches (range 24-80 hours). Young tend to remain in the nest cavity until they are about 13 days old, but are capable of leaving when they are as young as 9 days; some remain in the nest for 17 days. They may be almost ready to fly at age 10 days. Occasionally, the young leave the nest at the same time, but asynchronous departure is more common. On Melville Peninsula, 1 brood fledged over a 24-30 hour period. Fledging occurred over less than 15 hours in 2 other broods. Chicks may return to the nest cavity for 2 days after fledging. When the brood fledges asynchronously, the male feeds the first chicks to fledge while the female continues to attend to the nestlings. On Victoria Island, the interval from laying of the first egg to fledging of the last chick was 26 days for a 5-egg clutch and 28 days for a 7-egg clutch (Drury 1961; Hussell 1972, 1985; Lyon and Montgomerie 1985, 1987; MacDonald et al. 2014; Montgomerie and Lyon 2020; Montgomerie et al. 1983; Parmelee in Austin 1968; Parmelee and MacDonald 1960; Parmelee et al. 1967; Soper 1946; Wynne-Edwards 1952).

A single brood is raised in Canada and Alaska, although there is time to raise 2 broods. In 1 case, a female deserted half the first clutch as soon as some young left the nest and started raising a second brood. Therefore, she did not successfully rear 2 broods. The habits of Canadian Snow Buntings of incubation feeding and brood division make raising second broods difficult. Replacement clutches have not been confirmed in Canada or Alaska, but may occur in Greenland. Clutches contain 2-9 eggs, but mostly 4-6 eggs. Clutch size increases with latitude and is larger earlier in the season. There is little variation in the amount of day length at different latitudes and no difference in the amount of time that buntings are active. Other factors correlated with latitude may

influence clutch size. Clutches of 7 eggs were reported as far south as Iqaluit, where 5 eggs is the most frequent clutch size. On Victoria and Jenny Lind islands, 7 eggs was the most frequent clutch size. Clutches of 8 eggs have been found in the northern part of Ellesmere Island (latitude 80°N) and on Prince Patrick Island (latitude 76°N) where clutch size ranged from 5 to 8 eggs, but 6 eggs were most common. On Devon Island, average clutch size declined from 6.0 to 4.8 eggs between 20 June and 6 July. Similar declines in clutch size with season have been reported elsewhere. There are frequently significant differences in clutch sizes from year to year that may be related to timing of snow melt and when clutches can be initiated. On Devon Island, clutch-manipulation studies revealed that adults with broods of 7 could raise more young than those with any lower brood size, suggesting that 7 was the most productive brood size. Decline in food supply did not contribute to the decline in clutch size with season (Hussell 1972, 1985; Lyon and Montgomerie 1985, 1987; Montgomerie and Lyon 2020; Nethersole-Thompson 1966; Parmelee in Austin 1968; Parmelee and MacDonald 1960; Parmelee et al. 1967; Soper 1946).

Many first-year males breed, but some in Greenland are unable to obtain territories. Many or most yearling females breed if they can find a mate. In most populations, there is an excess of males resulting in unmated territorial males or small flocks of unmated males after the peak of nest initiation. On Melville Peninsula, the sex ratio was female biased. Unpaired females visited paired males but were chased off by resident females. Unpaired females formed small flocks once all males were paired. Once a bird has bred, it continues to do so annually. The Snow Bunting is typically monogamous, but polygyny occasionally occurs. On Melville Peninsula, 1 of 16 males (6.25%) was polygynous and polygyny was suspected in a second case. In Greenland, 1 male attracted a second female after his first female started incubating. In populations where incubation feeding occurs, widows were able to fledge only about 60% of the number of young raised by pairs and these were lighter and in poorer condition. Females benefit from monogamy because males feed the female during incubation, the nestlings, and half the brood (Lyon and Montgomerie 1987; Lyon et al. 1987; Montgomerie and Lyon 2020; Nethersole-Thompson 1966; Parmelee in Austin 1968).

Upon spring arrival, the Snow Bunting seeks snow-free patches for foraging, such as edges of barren beaches, wind-swept ridges, and steep slopes. At Resolute, flocks occurred at the town landfill. In early spring, it prefers to forage on newly exposed vegetation at the edge of melting snow and also forages on snow, gleaning insects that are immobilized by the cold. As more areas become ice-free, it prefers to feed in vegetated areas such as wet sedge meadows and well-vegetated dry tundra. On Bylot Island, where the Snow Bunting coexists with the Horned Lark, Lapland Longspur, and American Pipit, buntings and larks forage in drier areas and longspurs and pipits feed in thick, moist vegetation. The Snow Bunting forages on the ground by creeping through sparse vegetation, especially clumps of grasses, sedges, and rushes. It takes most food from the bare surface of the soil, but also picks at last year's grass heads to obtain seeds. On warm, sunny days, it captures basking spiders by darting around rocks. In July, it becomes a proficient flycatcher, rising every few seconds to snap at a passing insect. Large crane flies are frequently caught using this technique and butterflies are occasionally caught. Birds may fly as far as 500-700 m from the nest to obtain food for nestlings (Drury 1961; Freedman and Svoboda 1982; Freeman 1970; Geale 1971; Lyon and Montgomerie 1987; Montgomerie and Lyon 2020; Nethersole-Thompson 1966; Smith and Marquiss 1994; Wynne-Edwards 1952).

On Devon Island, more than 90% of food brought to nestlings was adult insects and more than 80% of food items were midges. Midges comprised only 56% of food items before 20 July, but constituted 87% in later samples. The percentage of all insects in the diet increased during this period from 93% to 98%. There was a close correspondence between the peak period of hatching and the initial emergence of adult insects. The nestling diet consisted of 97.0% adult insects, 2.1% other animal prey, and 0.9% vegetable matter. The adult insects were predominantly flies (95.9%), including 82.2% midges, 6.6% crane flies, 3.5% dance flies, 2.7% house flies, and 0.9% unidentified. Other animal foods included 0.4% lepidopteran adults, 0.5% sawflies, 0.2% ichneumonid wasps, 0.4% larvae (mostly lepidopterans), 0.4% pupae (mostly lepidopterans), and 1.5% spiders. Nestling diet in Greenland consisted of 57% spiders, 17% caterpillars, 2% adult lepidopterans, 9% larvae and pupae of crane flies, 7% adult crane flies, and 4% mosquitoes. On Melville Peninsula, the diet of nestling Snow Buntings and Lapland Longspurs overlapped by 96.9%. The food of adult Snow Buntings consists mainly of seeds, especially grass seeds. In summer and fall, they eat a mixture of insects (mainly beetles, lepidopterans, bugs, and flies), spiders, and buds. It eats marine crustaceans, especially sand fleas, and these may be locally important in the diet of birds nesting near coastlines; sand fleas may also be fed to nestlings. On Devon Island, the adult diet was restricted to seeds until mid-June followed by a rapid switch to 2 spider species, with another switch in late June to insects. Adults eat fruits of crowberry in mid-May on the Belcher Islands. On Ellesmere Island, adults ate toasted whole wheat cereal that was put out for them (Drury 1961; Freeman 1970; Hussell 1972; Lyon and Montgomerie 1987; Montgomerie and Lyon 2020; Parmelee in Austin 1968; Parmelee and MacDonald 1960; Sinclair et al. 2003). Gabrielson (1924) analyzed 43 stomachs collected in summer mainly from the Hudson Bay shoreline and the Pribilof Islands in Alaska. The diet consisted of 29.3% animal matter and 70.7% vegetable matter. The animal matter consisted of 3.8% beetles, 25.5% other insects (fly eggs, pupae, and adults, particularly those of crane flies), and 0.02% spider fragments. The vegetable matter consisted of 28.6% grass seeds, 7.0% sedge seeds, 0.2% smartweed seeds, 0.9% goosefoot seeds, 4.4% ragweed seeds, 1.2% grain seeds, and 28.4% of a variety of other seeds. Miscellaneous food items included bushy pondweed, crabgrass, barnyard grass, quack grass, switch grass, timothy, ensheathed dropseed, overlooked dropseed, marram grass, red fescue, campions, purslane, buttercups, cinquefoil, blackberry, clover, crowberry, Virginia creeper, Labrador tea, blueberry, vervain, lousewort, beggarticks, froghoppers, ground beetles, water-scavenger beetles, clown beetles, dung beetles, and leaf beetles.

Availability of suitable nest sites is a limiting factor for many populations. In many areas, there are few suitable nesting cavities close to good foraging areas. Consequently, many nest sites are used for multiple years. Although the Snow Bunting readily accepts artificial nest sites, these are usually present only near human settlements and reproductive success is lower in artificial than natural sites (Montgomerie and Lyon 2020). On Devon Island, Kukal and Pattie (1988) observed 2 cases where arctic bumble bees colonized active Snow Bunting nests and displaced nesting females. Both instances occurred within the same nest cavity so it is unknown how prevalent competition for nest sites by buntings and bumble bees is. Nest-seeking queen bees select well-insulated and isolated nest sites protected from predators, so Snow Bunting nests provide suitable sites for bees.

Spring snowstorms may cause widespread mortality due to starvation. Birds that do not starve may become weakened and become easy prey for predators. Food shortages are more likely during periods of inclement weather (Montgomerie and Lyon 2020; Parmelee in Austin 1968).

Smith and Marquiss (1994) identified a potential impact of climate change on the Snow Bunting. Reduced snow cover may result in decreased productivity, possibly due to effects on invertebrate food supply. This may be of broad conservation and biological significance.

Status

No Snow Bunting nests have been found in Ontario. The only confirmed breeding record in the province is an observation of a family of 2 adults and 2 or 3 fledglings on 20 July 1985 on West Pen Island. There is no other suitable nesting habitat for this species along the Hudson Bay coast except at Cape Henrietta Maria. It has been observed at Cape Henrietta Maria during the breeding season, but without any evidence of breeding (Hussell in Cadman et al. 1987). Wilson and McRae (1993) observed 25 on 21 August and 11 on 27 August at Brant, well before the usual start of migration. These may have been early migrants from an established breeding area, but it was possible that they were family groups raised nearby.

Ontario is at the extreme southern limit of the Snow Bunting's breeding range. The nearest regular breeding site is on the Belcher Islands in southern Hudson Bay (Freeman 1970), approximately 160 km northeast of Cape Henrietta Maria and 550 km east of West Pen Island (Hussell in Cadman et al. 1987). It also breeds on the Nastapoka Islands in Hudson Bay, northeast of the Belcher Islands near Quebec. On the west coast of Hudson Bay, the nearest regular breeding area is about 600 km from the Pen Islands (Godfrey 1986).

No evidence of breeding was obtained for the Snow Bunting during the second atlas, although there were some observations of nonbreeding birds. The 1985 observation remains the only record of breeding in Ontario (Sutherland in Cadman et al. 2007). The single record may represent an unusual extralimital nesting.

POSTFLEDGING PERIOD

The brood scatters soon after leaving the nest cavity, often beyond the male's territory, but some juveniles remain in the vicinity of the nest until they are 60 days old. Brood division occurs with each adult feeding a discrete portion of the brood. The adults continue to feed the young 8-12 days after they leave the nest, although the chicks are capable of catching flies 3-5 days after fledging. Shortly after becoming independent, most juveniles join together in flocks but a few remain with their parents. Fledglings may inhabit boulders in bare scree areas, stony creek beds, and slopes of fiords. A high proportion of juveniles are attracted by large bodies of water, especially oceans. They forage among large driftwood on beaches or on edges of ponds adjacent to the ocean. Premigratory flocking and wandering may occur as early as 30 June and most juveniles leave the parents in late July or early August to form flocks (Campbell and Van Der Raay 1985; Drury 1961; Montgomerie and Lyon 2020; Montgomerie et al. 1983; Parmelee in Austin 1968; Parmelee and MacDonald 1960; Parmelee et al. 1967; Sinclair et al. 2003).

MIGRATION

Birds that winter in Ontario may breed either in the Canadian arctic or in western and southeastern Greenland. Populations breeding in these areas of Greenland migrate across the Davis Strait in autumn, down the coast of eastern North America, and west along the St. Lawrence River. There are numerous spring sightings of birds crossing the Davis Strait from Canada to Greenland. Birds that breed in eastern Greenland winter in Europe. One bird banded in Canada presumably bred in Greenland and was recovered in Scotland. Some migratory populations appear to follow coastlines and concentrate along shorelines of oceans and rivers. Birds wintering in Ontario migrate along the St. Lawrence River to the Gulf of St. Lawrence and then along the Labrador coast to breeding areas in western Greenland. Birds breeding on East Bay Island adjacent to Southampton Island in Hudson Bay appear to winter in the prairies. These birds migrate along the western coast of Hudson Bay. Migration occurs during the day and at night with birds moving in small, loose flocks containing as many as 30 individuals. From 13 to 20 November 1987, approximately 500 per hour arrived at Niagara-on-the-Lake as if they had just crossed Lake Ontario, then crossed the Niagara River and flew west along the south shore of Lake Ontario. During migration, the Snow Bunting occasionally occurs in mixed flocks with Horned Larks, Lapland Longspurs, and Smith's Longspurs. The average staging period is about 10 days (Black and Roy 2010; Macdonald and Love 2012; Montgomerie and Lyon 2020; Orr et al. 1980; Parmelee in Austin 1968; Parmelee and MacDonald 1960; Vincent in Gauthier and Aubry 1996).

The Snow Bunting is the first landbird to arrive in the arctic in spring and the last to leave in autumn. Arrival dates of first spring migrants may vary by as much as a month, with birds arriving later in springs with late snowstorms or persisting snow cover. Adult males arrive on the breeding grounds 4-6 weeks in advance of females, the longest time lag recorded for any passerine species. The early arrival of adult males is probably related to competition for limited or high-quality nest sites. Juvenile males arrive later than adult males and may arrive with the females. Spring arrival even in northern locations may be prolonged over 30-46 days. In Canada, the first spring migrants arrive in the Low Arctic (latitude 60-65°N) in March and in April in the High Arctic (latitude 75-80°N). At this time, temperatures may drop to –30°C and food resources are largely covered with snow. Because of the extended spring migration and differential timing of migratory males and females, average departure dates in southern Ontario are not a good indicator of arrival times on the breeding grounds. In southern and central Ontario, most migrants move through in March with average departure in late March or early April, with some remaining until mid-May. At Shagamu, migrants were observed 28 May to 9 June but not afterwards. On the Belcher Islands, the first bird was observed on 31 March and flocks of about 2 dozen birds were seen occasionally from 29 April to 10 May; pair formation occurred by 12 May. On the Twin Islands in James Bay, spring migrants occurred from 8 May to 6 June. Arrival times in the arctic are the first week of April on Baffin Island with the peak in mid-May; mid-April on Victoria Island with peak numbers throughout May; early April on Banks Island, with most males appearing near the end of that month; on Ellesmere Island, as early as 13 April with the peak in late May; in mid-April on Cornwallis Island; and first migrants in the Yukon appear in late February and early March with the peak in the last half of April (Black and Roy 2010; Curry 2006; Freeman 1970; Geale 1971; LaForest 1993; Lancaster et al. 2004; Manning 1981; Manning et al. 1956; Mills 1981; Montgomerie and Lyon 2020; Parmelee in Austin 1968; Parmelee and

MacDonald 1960; Parmelee et al. 1967; Sinclair et al. 2003; Soper 1946; Tozer 2012; Vincent in Gauthier and Aubry 1996; Weir 2008; Wilson and McRae 1993).

In Alaska, Ward et al. (2016) compared spring arrival dates of migrants over a 50-year period. Warming during this period resulted in the transition from winter to summer occurring weeks earlier than it did previously. The Snow Bunting arrived significantly earlier with time at a rate of slightly over 0.15 day per year or 0.8 day per 1°C increase in temperature.

Flocks of adults and juveniles begin to congregate on the breeding grounds in August. Southward migration begins in August with peak departure from northern breeding grounds from mid- to late September, with stragglers remaining until early November. Females migrate earlier than males and move further south; juveniles leave the breeding grounds after adults. At Churchill, most autumn migrants pass through in early October and large flocks assembled on the coast of the Belcher Islands on 21 September. In southern and central Ontario, the first migrants usually appear in the last half of October with a peak in late October or early November. Migrants may occur from late September to late November (Black and Roy 2010; Curry 2006; Freeman 1970; Jehl and Smith 1970; LaForest 1993; Lancaster et al. 2004; Montgomerie and Lyon 2020; Mills 1981; Sinclair et al. 2003; Tozer 2012; Weir 2008).

The Snow Bunting uses a variety of open habitats during migration. In Muskoka and Parry Sound districts, it frequents beaches, rocky shorelines of lakes, gravel pits, and fields. In Algonquin Park, spring migrants occasionally occur on frozen lakes where they feed at the edge of melting ice. In the south, autumn migrants are initially found on beaches; rocky shorelines of large lakes, rivers, and islands; and occasionally in fields, gravel pits, and on roadsides. Once water freezes or the ground becomes snow-covered, it moves to open fields. During spring migration, it occurs along roads and in typical winter habitat such as old fields and agricultural lands, particularly where manure has been spread. During migration and winter in British Columbia, it occurs in almost any type of exposed habitat such as grasslands, windswept fields, sandspits, extensive lakeshores, and roadsides. It may also occur at airports, cattle feedlots, stockyards, areas of extensive mine tailings, golf courses, jetties, sewage ponds, and rock-strewn islets. Twenty-nine percent of nonbreeding records were from grasslands, 14% at airports, 14% along roads, and 10% at coastal jetties. It occasionally occurs on lawns and expanses of pavement. In the Yukon, some birds inhabit high altitude alpine areas during migration and in the far north it may be common in villages during spring migration (Campbell et al. 2001; Curry 2006; LaForest 1993; Mills 1981; Sinclair et al. 2003; Tozer 2012; Weir 2008).

At La Pérouse Bay in Manitoba, spring migrants fed on leaves of creeping alkali grass. This species and Hoppner's sedge are the dominant plant species in this area and along many subarctic coasts. The leaves of salt-marsh grass contain high concentrations of nitrogen suggesting that it may be an important source of nutrients for spring migrants. There are few records of the Snow Bunting eating vegetation other than seeds, and these include buttercup leaves, moss fragments, and leaves of bog bilberry and mountain avens (Bazely 1987). During autumn migration, Sutherland et al. (2016) reported it foraging in wild rice beds in Pigeon Lake, Peterborough County. The wild rice was approximately 500 m offshore in open water 1-3 m deep. A flock of 30 buntings landed in the tops of wild rice, bending them down to within a few centimetres of the water. Several times

the flock arose, shifted location, and repeated the process. They appeared to be gleaning rice grains or possibly invertebrates.

Montgomerie and Lyon (2020) suggested that the Snow Bunting could be exposed to agricultural pesticides during migration and winter but acknowledged that no studies had been done on this and that no data were available. In Quebec, overwintering birds sampled in March had no detectable amounts of atrazine, clothianidin, or imidacloprid in the blood and liver and there were no detectable amounts of glyphosate or aminomethyl phosponic acid in the liver. Wintering bunting may not be exposed to these chemicals during their presence in agricultural fields or be exposed to doses below detection levels (Ruhs et al. 2021).

James (1991) considered the Snow Bunting a common to locally abundant migrant in the province. Wilson and McRae (1993) noted that it was an abundant spring and autumn migrant along the Hudson and James bay coasts. Flocks of 1,000 birds may be seen with some regularity in most areas south of the Canadian Shield, but flocks on the Shield are much smaller and limited in distribution.

WINTER

In winter, the Snow Bunting typically occurs in flocks, often with Horned Larks and occasionally with Lapland Longspurs. It inhabits open weedy and grassy fields; grain stubble; shorelines, especially where the wind has piled up driftwood and debris or where there is little bluestem; tidal flats; manure-covered fields; and pastures. When snow is deep, it may occur along roadsides and railway lines and selects fields where herbaceous plants and grasses protrude through the snow. Females tend to winter further south than males. Near Ottawa, winter flocks are comprised of 90-95% males. Flocks in Windsor, Long Point, and Cayuga are dominated by females. Males exhibit higher cold tolerance than females because of their larger body size and can inhabit areas further north in winter. In alpine areas, adults winter at higher elevations than juveniles and adult males winter higher than adult females. When these areas are snow-free, they provide vast areas of open ground with seed-producing plants, a habitat that is largely unexploited by other bird species (Black and Roy 2010; Gabrielson 1924; Leighton et al. 2002; Macdonald and Love 2012; Macdonald et al. 2016; McIlwraith 1894; Montgomerie and Lyon 2020; Smith et al. 1993; Vincent in Gauthier and Aubry 1996; Vincent and Bédard 1976; Weir 2008).

In New York, the Snow Bunting occurred more frequently in fields with corn stubble than in pastures. Its probability of occurrence increased with increasing amounts of open habitat within 500 m (Rosenblatt and Bonter 2018).

The Snow Bunting is highly gregarious during the day, but just before sunset flocks break up into smaller groups of 7 or 8. These fly back and forth between feeding areas and recently preselected roosting sites. Roosts are in sites offering greater surface microrelief than normally found at foraging sites. Near Quebec City, birds made no attempt to select protected areas when night temperatures were above –7°C except under very windy or sleety conditions. Under colder conditions, birds settled individually on the leeside of snow drifts, but did not sleep in holes or under overhangs. The average distance between individual roosts was 2.5 m and seldom closer than 30 cm. Birds did not huddle together even under extreme conditions of –27°C with 45 km per hour winds. In Massachusetts, a flock of 150-200 buntings sought shelter from a temperature of –37°C

accompanied by winds by digging themselves into soft snow under the leeward edges of shallow snowdrifts in an open field. Temperatures remained below –29°C 1 day, and birds remained in these holes, leaving only occasionally to feed nearby. When the snow is frozen hard, flocks sleep in the open, protected from the wind only by some slight rise in the ground, by sand dunes, or by a stone wall. On windy days, birds attempt to find shelter on the leeside of irregularities in the snow and on exceptionally cold days, they withdraw 1 leg into the plumage and hop around. Although the Snow Bunting spends almost all its time on the ground, on warm days it may occasionally perch in trees or even on overhead wires (Bagg 1943; Leighton et al. 2002; Parmelee in Austin 1958; Vincent in Gauthier and Aubry 1996; Vincent and Bédard 1976).

Winter flocks near Quebec City followed a regular daily feeding pattern over an area of about 4 km². Flocks occasionally stayed in 1 location for 1-2 weeks where goldenrods and asters protruded through the snow. At less ideal sites, birds may remain for only a few hours, but flocks may remain for several weeks in fields where manure has been spread (Montgomerie and Lyon 2020; Vincent in Gauthier and Aubry 1996; Vincent and Bédard 1976).

The Snow Bunting may exhibit site fidelity to wintering areas. In Michigan, 51 of 596 birds (8.6%) returned in subsequent years; 1 bird was trapped in 9 different winters. Some birds wander during the winter. Birds banded in December or January have been recaptured the same winter 133-241 km further south (Brewer et al. 2018).

In winter, the Snow Bunting forages by walking on the snow and collecting seeds from stems of protruding tall plants. Occasionally, it reaches up or leaps to take seeds from taller stems, jumps against a stem to scatter seeds, or bends a stem over by stepping on it. It also feeds on seeds that are blown over the surface of the snow. As spring approaches, it may move to exposed ground in plowed fields or open terrain at margins of melting snow patches. Seeds and possibly insects accumulate in snow layers over winter and are transported by melt water and sought for in pools near snow patches. It is particularly attracted to fields where manure has been spread where it presumably feeds on undigested seeds in the manure. In maritime areas, it forages on open beaches, following waves in a manner similar to sandpipers. In open habitat, it occasionally visits winter bird feeders. It carries large fat stores even at its lowest winter weight and can survive 2-3 consecutive days of complete food deprivation (Black and Roy 2010; Lancaster et al. 2004; Montgomerie and Lyon 2020; Vincent in Gauthier and Aubry 1996; Vincent and Bédard 1976). McIlwraith (1894) reported that it fed on bare, sandy areas near Lake Ontario where it ate seeds of little bluestem. Near Quebec City, Vincent and Bédard (1976) observed it feeding on the seed heads of asters, goldenrods, and goosefoots. At feeders, it usually feeds on corn and millet and has been documented feeding on a pile of grain (Lancaster et al. 2004; Leighton et al. 2002). Parmelee (in Austin 1968) reported it feeding on seeds of ragweed, amaranth, goosefoot, locust, and oats. Gabrielson (1924) examined 418 stomachs collected from October until April. He reported on an earlier examination by Judd (1901) of 46 stomachs collected in New York, Michigan, Wisconsin, and Ontario that found that the dominant foods were seeds of ragweed, amaranth, and grain. In winter, 3.4% of the diet was comprised of animal matter and 96.6% was vegetable matter. Animal food was taken only in March, October, and November, possibly only during migration. Animal food included clover root weevils, other beetles, fragments of caterpillars and bugs, spiders, and isopods. The diet

of 2 Ontario birds consisted of 60% caterpillars. Of 24 birds collected in October, 7 had eaten animal matter, 13.5% of the total diet for that month. Of 27 November birds, 12 had eaten animals, including beetles (0.9%), other insects (mostly caterpillars, 6.3%), spiders (1.0%), and miscellaneous animals, for a total of 8.1%. The vegetable matter consumed during winter consisted of a variety of seeds. Wisconsin birds all fed extensively on seeds of foxtails, ragweed, goosefoots, and amaranth. Elsewhere, it also ate seeds of sedges, other grasses, and wheat that consisted of waste grain. Overall, grass seeds comprised 31.2% of the winter diet, including 11.8% yellow and green foxtail, plus 4.4% sand grass in New York. Other food items included 8.5% sedges, 3.7% smartweed (mostly pale smartweed and black bindweed), 5.5% goosefoot (mostly lamb's-quarters), 5.6% amaranth, 11.5% miscellaneous seeds, 9.4% ragweed, 13.1% wheat, and 4.7% other grain taken as waste (corn, oats, and barley). Miscellaneous seeds consumed included those of paspalum, meadow fescue, and yellow rocket. In April, 56.4% of the diet consisted of grain, predominantly wheat. This figure was inflated because 37 of the 64 birds were taken while feeding on stacks of grain.

James (1991) considered the Snow Bunting a common to abundant winter resident in the south and rare in the west in the Thunder Bay area. There are occasional winter records from Muskoka and Parry Sound districts, but most leave by the end of November as deep snow forces them further south (Mills 1981).

Freedman and Riley (1980) reported that numbers on southern Ontario Christmas Bird Counts (CBC) were variable, but they had increased since 1929. The Snow Bunting was abundant but exhibited an irregular cycle with periods between peaks ranging from 2 to 5 years. Montgomerie and Lyon (2020) noted that CBC results suggested that the Snow Bunting was in serious decline in North America. It is 1 of 20 species whose population has declined by more than 50% over the past 4 decades based upon CBC results. CBC data indicate a 64% decline in 40 years, with an annual decline of 2.5% per year. The CBC does not survey this species accurately because much of the population winters north of or outside local areas covered by this survey (National Audubon Society 2022).

Grasshopper Sparrow

Ammodramus savannarum

BREEDING SEASON

Habitat Requirements

Ontario Grasshopper Sparrow nests were in areas with short and tall grasses, hayfields, and pastures that were often overgrown with shrubs and small trees (51.5% of nests); in Christmas tree and other conifer plantations in grassy fields (33.8%); on road and railway rights-of-way (11.8%); a grass- and cedar-covered island near a gull colony (1.5%); and in a beach savannah (1.5%; Peck and James 1987).

There are a few breeding records from the southern Canadian Shield, but the Grasshopper Sparrow is predominantly limited to the area south of the Canadian Shield and the Rainy River area. In the Great Lakes–St. Lawrence Forest Region, it occurs mostly on droughty sand, till moraines, and alvars or areas of shallow soils over limestone. These areas are often pastures but others on moraines may consist of sparse grasslands where slopes are too steep to farm. In old-field habitats, it is often associated with common mullein stalks. These may be 0.9-1.5 m tall and are frequently used as

singing perches. Historically, the improved pastures and hayfields that it used were planted to a mix of clovers, alfalfa, and timothy. In the Great Lakes area, it prefers anthropogenic habitats such as pastures, hayfields, recently abandoned fields, grassy fields at airports, and young conifer plantations. Occupied sites are often dominated by plant species adapted to poor dry soils such as bluegrass, quack grass, poverty oat grass, wild strawberries, timothy, and silverweed. It also nests in alvars dominated by little bluestem and poverty oat grass. It rarely uses old fields with dense shrubs or tall vegetation, dense hayfields, or heavily grazed pastures with few perches. It prefers moderate vegetation height (25-50 cm), moderate amounts of bare soil (mean 17%), and a moderately thick litter layer (mean 4 cm; Earley in Cadman et al. 2007; Hope 1946; Savignac 2013; Speirs and Orenstein 1967).

In the Carolinian Forest Region, the Grasshopper Sparrow nests predominantly on moraines and drumlins, on alvars, and on sand plains and other areas where soils are poor with sparse grassy vegetation. In the Hamilton area, it may occur in grassy fields and meadows but prefers stony pastures where mullein stalks provide perches (Curry 2006). It nested in a Christmas tree plantation on the Flamborough Plain where the coverage of woody vegetation was higher than typically documented for this species (personal observation). It formerly nested in a weedy field in an industrial area in Cambridge, but the habitat was subsequently converted to a parking lot (personal observation). In Niagara Region, it is most abundant in fallow fields south of Welland created when the Welland Canal was diverted (Black and Roy 2010). Near Dain City in Niagara Region, it nested on a hill constructed of spoil from the excavation of the Welland Canal. The clay subsoil is nutrient-poor and results in sparse vegetation and patches of bare soil, preferred habitat (personal observation). On the Norfolk Sand Plain, it nests in fields planted to winter wheat and rye that produce grassland-like habitat early in the season. Even the mature crop is sparse because it is growing on sand and therefore provides suitable habitat (Earley in Cadman et al. 2007). In Elgin County, most nesting occurs in pastures and grassy meadows (Lancaster et al. 2004).

The Grasshopper Sparrow is a grassland species, occupying a wide range of grassy areas throughout its range. It is a fairly uncommon species, probably due to its microhabitat requirements. It requires a mix of clumped vegetation and bare soil and tends to avoid areas that do not have these characteristics. Bare soil facilitates movement by the birds and provides good foraging habitat. Denser vegetation provides concealment from predators and cover for the nest. Vegetation of intermediate height is preferred and it avoids areas with tall or dense grasses. Areas of uniform short

or sparse grass are also avoided. It avoids grasslands with a significant woody component. A small proportion of grasslands provide habitat that is suitable for the Grasshopper Sparrow.

In the northeast, the Grasshopper Sparrow nests predominantly in anthropogenic habitat such as pastures, old fields, and hayfields. It may nest on capped landfill sites and, further south, on reclaimed surface mines. It occasionally uses row crops for nesting, but at much lower densities. In Quebec, it shows a marked preference for fallow fields and old pastures where the soil is sandy and well drained. It is partial to areas with grasses such as timothy and quack grass along with other plants that thrive on poor acidic soils such as tufted vetch, viper's-bugloss, and common milkweed. It selects sites with few shrubs and is partial to fields with milkweeds, which it uses as song perches. In Maine, it nested in fields of lowbush blueberry that were commercially harvested; these areas were burned and mowed on a regular basis. Natural habitats used in the east include prairie remnants, oak savannahs, pine and oak barrens, and coastal sand dunes. In the Prairie Provinces and Great Plains, it nests in tallgrass and mixed-grass prairies and fields planted to nonnative grasses. Native grasses that are often in prairies that it inhabits include little and big bluestem, switch grass, broomsedge, Indian grass, native wheat grasses, grama grass, and wiregrass. Planted warm-season grasses that it may use include Kentucky bluegrass, smooth brome, timothy, quack grass, nonnative fescues, wild rye, Virginia wild rye, orchard grass, creeping bentgrass, and crested wheat grass. Conservation Reserve Program (CRP) and Dense Nesting Cover fields planted on marginal lands may be used. Lands that are maintained idle, grazed, or cut for hay may be used. Corn and small grain fields may be used for nesting, but it typically selects no-till fields where there is year-round crop residue. It rarely inhabits fields managed with conventional tillage. It occasionally nests in cottonwood forest. In the west and southwest, it nests in sparse grasslands and is less likely to nest in burned, cut, or grazed areas than in the lusher grasses of more mesic sites. The Florida subspecies of the Grasshopper Sparrow nests in dry prairie grasslands that are maintained by burning. Habitat for this subspecies is different from other locations within its range, although it still nests in sparse cover with a mix of clumped vegetation and bare ground. Other habitats it may occasionally nest in include grassed waterways in grain fields, airports, military bases, and road and railway rights-of-way (Ahlering et al. 2009; Askins et al. 2007; Campbell et al. 2001; Chapman et al. 2004; Dechant et al. 2002b; Delany et al. 1985, 1993; Dieni and Jones 2003; Giocomo et al. 2008; Graber and Graber 1963; Grant et al. 2004; Graves et al. 2010; Hainault in Gauthier and Aubry 1996; Herkert 1994a; Hill and Diefenbach 2013; Jones and Bock 2002; Mossman et al. 1991; Patterson and Best 1996; Renfrew and Ribic 2008; Rotenberry and Wiens 1980; Smith in Austin 1968; Smith and Smith 1992; Swanson 1996; Vickery 2020; Vickery et al. 1994; Walcheck 1970; Whitmore 1981; Wiens 1969, 1973; Wilson and Belcher 1989; Wray et al. 1982).

Several studies examined Grasshopper Sparrow habitat at the landscape scale, often with conflicting results. In Michigan, Minnesota, and Wisconsin, its abundance was positively correlated with coverage by grasslands within 800 m (Murray et al. 2008). Thogmartin et al. (2006) used Breeding Bird Survey (BBS) data and point counts to determine that its abundance was most influenced by climatic variables (wetness and temperature) rather than environmental variables. Models that included the proportion of the landscape that were in grassland or grassland patch area were not among the best models. It was negatively affected by the amount of forest cover within 800 m suggesting that it was more abundant in landscapes with greater herbaceous cover. In the

United States Great Plains at the 400-m scale, it selected drier sites with short or sparse vegetation. It increased significantly with the amount of grassland in the landscape. Probability of occurrence was low with less than 20% grassland within the sampling area and high at 80-100% grassland coverage (Niemuth et al. 2017). In South Dakota, it was unaffected by the amount of grassland in the landscape (Greer et al. 2016). In Quebec, occupied areas had more perennial crops (grasslands, pastures, and old fields) and less forest within 200 m than unoccupied areas. Around occupied areas, there was 59.1% coverage by perennial crops and 31.8% forest cover compared with 42.5% perennial crops and 16.0% forest around unoccupied sites. Male density was not affected by patch size but was positively correlated with the surrounding perennial crop coverage and negatively correlated with forest coverage (Jobin and Falardeau 2010). In Wisconsin, landscape composition was important at the 1,200-m scale, particularly the amount of grassland within this area. Percent grassland coverage was important at the 200-, 700-, and 1,200-m scales. Birds may respond, at least in part, to the landscape at a broader scale as they make settling decisions. Landscape composition may be more important than habitat fragmentation for grassland birds. In this area, grassland fragmentation is more related to a reduction in grassland quality by conversion of native grasslands to areas planted with nonnative grasses (Renfrew and Ribic 2008). In the same area, abundance of the Grasshopper Sparrow was associated with cover-type diversity within 200 and 400 m, the area of grassland within 400 m, and distance to hedgerows. Densities were higher when there was low cover-type diversity within 200 and 400 m; low cover-type diversity landscapes were dominated by hay and grassland. Densities were higher when there were more hedgerows in the landscape or when hedgerows were closer. Although effects as far away as 800 m were studied, it was associated only with landscape variables within 200 m, indicating a more local effect (Ribic and Sample 2001). In Pennsylvania, landscape characteristics did not affect occupancy in the largely forested landscape where grasslands constitute only 8% of the landscape. Hill and Diefenbach (2014) considered it landscape insensitive. Forests were not a barrier to its dispersal and colonization, even when more than 80% of the landscape was unsuitable habitat. In Nebraska and Iowa, the degree of urbanization within 1,600 m did not affect its occurrence, but density declined with the intensity of urbanization. Urbanization at the landscape scale may indirectly decrease the quality of grasslands for Grasshopper Sparrows even if vegetative characteristics do not change. Nonetheless, grasslands in suburban and urban areas may provide conservation value (McLaughlin et al. 2014). In Missouri, its abundance declined with increasing amounts of hayfields within 400 m, but only in hayfields; abundance increased with the amount of hayfields surrounding pastures (Davis et al. 2016). It preferred landscapes with 0-15% tree coverage in North Dakota (Cunningham and Johnson 2019).

The amount of woody vegetation within grasslands may affect suitability for the Grasshopper Sparrow. In the east, it tends to prefer areas with minimal shrub coverage; some shrub coverage may be essential in certain western habitats. Even within small geographic areas, the coverage of shrubs that it prefers or will tolerate may vary considerably. In New York, pastures it inhabited contained as much as 36% coverage by shrubs and trees, and hedgerows were frequent within the habitat (Smith and Smith 1992). In mixed-grass prairie in North Dakota, coverage by shrubs taller than 1 m and the amount of aspen within 100 and 500 m were significantly lower at sites where it was present compared with unoccupied areas. It reached its maximum occurrence of 80% in open treeless grassland. Its probability of occurrence dropped to 50% at 25% tree coverage. It also

declined with increasing abundance of tall shrubs. It was a woodland-sensitive species whose incidence dropped to 0% at about 65% woodland cover. It was negatively affected as woody plant height increased from shrubs shorter than 1 m to tall shrubs and trees (Grant et al. 2004). Arnold and Higgins (1986) surveyed transects with shrub coverage (30-80% coverage by snowberry and wolfberry) and transects with less than 10% coverage by these shrubs. Its density was approximately 3.2 times higher on the shrubless plots. Density of the Grasshopper Sparrow was strongly inversely related to the amount of woody cover in North Dakota and Saskatchewan (Ahlering et al. 2009). In mixed-grass prairie in Oklahoma, its abundance was strongly negatively correlated with coverage by red cedar and was consistently near 0% at 25% coverage by red cedar. Despite this, red cedars were frequently used as song perches. Chapman et al. (2004) suggested that its upper tolerance to woody vegetation was 25-35% coverage. In Georgia, densities were similar in 0% and 10% shrub coverage but it was absent when shrubs covered 35% of the field even though more than 50% of the total area had good grass coverage (Johnston and Odum 1956). In Florida, territories were devoid of trees and the Grasshopper Sparrow avoided areas of even widely spaced trees at densities of less than 1 tree per ha. Territories near trees were 75 m or more from edges of plantations. Singing perches were in shrubs 0.9 m or less in height (Delany et al. 1995). Shrub coverage was 19.9% in occupied territories and only 1.6% in territories abandoned in a declining population; this difference was significant. The range of shrub coverage in territories was 0-33.9% (Delany and Linda 1994; Delany et al. 1985). On reclaimed surface mines in West Virginia, shrub coverage was 0.7% in occupied territories, significantly less than in unoccupied areas (31.1%). It was 10 times more abundant on sites dominated by grasses than in areas with shrub coverage interspersed by small trees (Margenau et al. 2019; Whitmore 1981). On Ohio surface mines, woody vegetation negatively affected its abundance, nest placement, and nest success. Nest sites had 2.5 times less woody vegetation (1.5%) than random sites (4.0%) and daily nest survival rate was negatively affected by the amount of woody vegetation surrounding nests (Graves et al. 2010). In British Columbia, it avoided areas of dense sagebrush. Where shrubs are present, it appears to select patches of grasses among them (Campbell et al. 2001). In Maine, the Grasshopper Sparrow nested in meadows dominated by lowbush blueberry, a short shrub. The site supported lesser amounts of graminoids, forbs, and other shrub species (Vickery et al. 1994). In Nebraska and Iowa, its occurrence was positively correlated with shrub density per m^2. Probability of occurrence was approximately 55% at 0 shrub density, 75% at 0.25 shrub density, and 100% at 0.6-1.0 shrub density. Sparrow density per km^2 increased from 5 at 0 shrubs per m^2 to 10 at 4 shrubs per m^2 (McLaughlin et al. 2014) In Montana, it nested in a cottonwood forest with a subcanopy layer of green ash and Manitoba maple. The ground flora consisted of moderate to heavy thickets of snowberry and rose with a heavy litter accumulation, and limited amounts of forbs and grasses; wheat grass was the most common grass species (Walcheck 1970).

Several studies compared Grasshopper Sparrow usage of different grassland types. In Oklahoma, its density in nonnative bluestem grasslands was approximately 1.8 times higher than in native grasslands. Planted grasslands provided larger tracts of homogeneous habitat with little shrub coverage, less vertical cover, and shorter vegetation. These habitat characteristics were all favourable for it. The biomass of invertebrates that were suitable prey was lower in nonnative fields, suggesting that prey abundance was not a limiting factor (George et al. 2013). In Manitoba, its

abundance was significantly correlated with Kentucky bluegrass and negatively correlated with June grass (Wilson and Belcher 1989). In Missouri, it was more abundant in planted grasslands than in native grasslands (Davis et al. 2016). In North Carolina, there were no significant differences in its abundance in native and nonnative grasslands that were grazed or cut for hay, although it tended to be more common in nonnative grasses. It was absent in fields managed to maintain a mix of native grasses and forbs, possibly due to the lack of bare ground (Moorman et al. 2017). In Illinois, it prefers shorter, more open vegetation typical of grazed or hayed grasslands, or even croplands, to the dense cover of CRP fields. Highest density occurred in unplanted crop fields grown up with annual weeds. Fields of no-till soybeans with grassy residual vegetation supported good numbers, but the Grasshopper Sparrow was absent in conventionally tilled fields (Walk et al. 2010). In Iowa, nest success in CRP fields was twice that in alfalfa fields. It was an infrequent nester in grassed waterways and was not found in roadside habitats (Patterson and Best 1996). In Michigan, it preferred hayfields and avoided permanent pastures, but was more common in grazed than mowed fields (Dechant et al. 2002b). In Ohio, densities were higher in meadows than in corn and small grain fields. In Wisconsin, row crops were avoided during the breeding season. In the northeastern United States, densities in CRP fields are more than 40 times greater than in adjacent cropland (Swanson 1996). In Wisconsin, it occurred at higher densities in dry pastures and dry prairies than in alfalfa and nonnative cool-season grasses, where it was absent. Density in Kansas was higher in pastures than in CRP lands (Ribic and Sample 2001). In Pennsylvania, Smith (1963) attributed a sharp decline in population to a change in species cultivated for hay. Early crops consisted of timothy, alfalfa, and red clover. Later crops consisted of heavy growths of alfalfa and brome grass. Once dense hayfields were established, most of the population occurred in hay and abandoned fields that supported less vigorous growth. In Washington, it was more abundant in CRP fields than in native shrubsteppe vegetation; there was no difference in its abundance in old or newly established CRP lands. Its abundance was negatively correlated with shrub and perennial forb abundance (Vander Haegen et al. 2015).

Several studies compared vegetative structure at nest sites to the remainder of the territory or features within territories to those in unoccupied areas. The Grasshopper Sparrow tends to occupy habitat with moderate vegetation density and height with areas of bare ground. In Quebec, there were no significant differences in vegetation characteristics, structural heterogeneity, and perch-site density between occupied and unoccupied sites. Sites were all grasslands, ranging from young abandoned fields located on poor sandy soil to regularly mowed hayfields lacking prominent perch sites. The lack of difference between occupied and unoccupied areas may have been because they only studied sites that appeared to be suitable habitat (Jobin and Falardeau 2010). On reclaimed mine surfaces in West Virginia, nest sites had more bare ground, greater vegetation height-density, taller grass at the nest, and shorter grass 5 m from the nest than areas without nests. Vegetation height-density and maximum grass height increased with age after reclamation and the amount of bare ground decreased. The Grasshopper Sparrow used grasslands with a mix of native and nonnative grass and forb species interspersed with bare ground. Habitat suitability decreased with time after reclamation. Nest success was 30% higher in grasslands 3-10 years old than in those 11-20 or more than 20 years old (Wood and Ammer 2015). In North Dakota, coverage by live vegetation, shrubs taller than 1 m, aspen within 100 and 500 m, and Kentucky bluegrass and smooth brome

was significantly less where it was present than where it was absent. Occurrence was greatest on plots dominated by Kentucky bluegrass intermingled with native grasses and forbs (Grant et al. 2004). In Kentucky, nest sites had fewer shrubs (48.85 compared with 52.96 in a 0.04-ha circle), more tree coverage (3.96% compared with 0.78%), less vertical cover 0.5-2 m from the ground, and greater foliage coverage 0.5-1 m from the ground (0.70 compared with 0.33 stems within 10 cm) than random sites in territories (Sutter and Ritchison 2005). In Florida, most vegetation characteristics did not differ significantly between nest sites and non-nest sites within territories. Vegetation density at non-nest sites was significantly lower than within 1 cm of the nest and significantly higher than at 1 and 2 m from the nest. Vegetation density was the most important nesting parameter. The availability of small clumps of dense vegetation slightly larger than the nest diameter within more open patches 4 m or less in diameter was an important factor influencing nest selection. Features of occupied territories compared with those of territories abandoned by a declining population were strikingly different. Values for occupied and abandoned territories respectively included: grass cover, 36.7% and 83.1%; shrub cover, 19.9% and 1.6%; forb cover, 7.7% and 2.0%; litter cover, 10.2% and 12.7%; bare ground cover, 25.6% and 0.2%; and vegetation height, 21.4 cm and 11.0 cm. All parameters except for forb and litter coverage were significantly different. Sparrows selected areas with taller vegetation but less vegetative cover and more bare ground (Delany and Linda 1994, 1998a). On West Virginia reclaimed mines, Whitmore (1981) also reported differences between territories and unoccupied areas, with differences significant for all variables except vertical density and percent forb cover. Values for territories and unoccupied areas respectively included: grass cover, 25.7% and 84.1%; shrub cover, 0.7% and 31.1%; litter depth, 2.4 cm and 6.6 cm; horizontal diversity, 1.2 and 1.5; vertical density in hits by live vegetation per 10 cm, 4.2 and 3.8; bare ground cover, 21.9% and 3.6%; vertical diversity, 0.8 and 1.2; total vegetation density in hits per transect, 339.4 and 504.8; effective vegetation height, 43.8 cm and 56.5 cm; forb cover, 24.7% and 28.7%; and litter cover, 72.5% and 93.3%. Territories were more sparsely vegetated, with higher values for bare ground and lower values for all variables related to vegetation height and grass, forb, and shrub coverage. It typically inhabited open areas dominated by grasses that grow in clumps rather than those that form continuous sod. Sod-forming grasses create a mat of dense vegetation that inhibits foraging; clump-forming grasses leave openings. In Montana, nest sites differed significantly from random sites for four parameters. Values for these parameters for nest and random sites respectively included: bare ground, 0.4% and 1.5%; visual obstruction, 1.3 and 0.9; plant height, 32.5 cm and 24.1 cm; and vertical density, 5.5 and 3.5. In addition, 31.0% of nests were associated with grama grass compared with 12.0% of random sites and 4.8% of nests were associated with western wheat grass compared with 29.2% of random sites. It selected for vertical vegetative characteristics at the immediate nest site rather than at the nest-patch scale. Unlike many other areas, nest patches were devoid of any significant amounts of bare ground. For nesting substrate, western wheat grass was avoided and grama grass was selected (Dieni and Jones 2003). On reclaimed surface mines in Indiana, height of the dominant vegetation within 1 m of the nest was positively correlated with nest success (Galligan et al. 2006). In Wyoming, Montana, and South Dakota, the Grasshopper Sparrow greatly preferred sites where black-tailed prairie dogs were absent and vegetation had not been altered. Sites without prairie dogs had a higher percentage of grass cover, higher visual obstruction, and less bare ground (Augustine and Baker 2013). In Wisconsin, coverage by forbs and grasses was similar in territories and unoccupied areas. Forb density was lower in unoccupied areas;

these forbs were significantly taller than in territories. Vegetation density was significantly less in territories: total vertical vegetation density and mean effective height were significantly less, light penetration to the ground was increased, and coverage by lawn-like vegetation was greater. Vegetation density in the 0-10-cm height interval was significantly greater in territories. Litter was slightly less compact and significantly shallower than in unoccupied areas. Vertical vegetation density about nests did not differ significantly from the entire territory, but the mean effective height of vegetation was significantly higher at the nest. Forbs at nests were significantly taller than those in the entire territory (Wiens 1969). In desert grasslands in Arizona, it selected territories in areas of sparser vegetation structure with more shrubs taller than 2 m than in random plots. Some taller shrubs were preferred for song posts. Even in these sparse grasslands, grass structure can be too high and dense. Males selected territories with a maximum of 10 cm of visual obstruction and 7 vegetation hits in 40 cm for vertical vegetation density. The proportion of area covered by nonnative grasses did not influence territory selection. There was limited evidence for territory selection based on litter depth or amount of bare ground. Females selected nest sites in areas with low densities of shrubs 1-2 m tall and preferentially selected areas with native grasses to build nests under. Suitable habitat for territories and nests consisted of visual obstruction readings of 4-14 cm for territories and 5-12 cm for nest sites, vertical vegetation density of 4.8-7.8 hits on a 40-cm pole for territories and 5.0-7.6 for nest sites, more than 40% native grasses at the nest site, 0.2-0.5 shrubs 1-2 m tall per ha (slightly lower for nests), and 0.2-0.3 shrubs taller than 2 m per ha (Ruth and Skagen 2017).

Microhabitat preferences of the Grasshopper Sparrow were identified in several studies. In Quebec, mean coverage of live vegetation was 47%, coverage by dead vegetation was 33%, and bare soil coverage was 19%. The mean vegetation height was 23 cm and the litter depth was less than 4 cm. Plant species present at more than 50% of occupied sites included bluegrass, quack grass, silver cinquefoil, creeping cinquefoil, poverty oat grass, wild strawberry, and timothy (Jobin and Falardeau 2010). In Wisconsin, it occurred at highest densities in the driest habitats with relatively short vegetation (Ribic and Sample 2001). It is typically associated with dry soils and often with nutrient-poor or shallow soils that inhibit dense growths of vegetation. Mean habitat characteristics in Florida included 25.5% grass cover, 19.2% shrub cover, 4.5% forb cover, 14.4% litter cover, 36.2% bare ground, 30.7 stems per m^2, 0.7 cm litter depth, and 27.8 cm vegetation height (Delany et al. 1985). At 2 other Florida sites, mean grass height was 56 and 58 cm. Nest sites had more grass cover and less bare ground (Larned et al. 2020). In North Dakota on both shrubby and non-shrubby transects, highest density occurred in areas with the highest vegetation-height densities. These areas were subjected to light grazing. Grazing intensity was more important than shrub coverage in defining habitat quality. In West Virginia on 3 reclaimed mines, optimal conditions included 73.1% litter cover, 24.1% bare ground, and 27.8% grass cover. Habitat selected at all sites did not vary significantly from the optimum values. Choice of territories was dictated by the overall density of ground cover. There must be enough open or bare ground (a minimum of 24% in this case) to allow free movement but provide adequate cover for nest sites. Density at each site was related to the proportion of habitat that provided conditions similar to the optimal variables (Whitmore 1979). In Pennsylvania, ground cover at nests averaged 6% bare ground, 30% forbs, and 64% grass. Height of vegetation at nests was 28 cm for forbs, 54 cm for grasses, and 6 cm for thatch (Hill and Diefenbach 2013). In North Dakota grazed mixed-grass prairie, abundance of the Grasshopper Sparrow was

positively correlated with grass cover, litter depth, visual obstruction, density of low-growing shrubs, vegetation density, and communities dominated by shrubs with smooth brome, Kentucky bluegrass, and quack grass; and those dominated by Kentucky bluegrass, wiregrass, grama grass, and Indian grass. It was negatively correlated with clubmoss. The strongest predictors were decreasing clubmoss cover, decreasing bare ground, and increasing litter cover. In Missouri tallgrass prairies, it decreased with increasing vegetation height and amount of woody cover (Dechant et al. 2002b). In shrubsteppe vegetation, it was positively correlated with grass cover, litter cover, total hits by live vegetation, maximum interval containing hits, effective height, and litter depth. It was negatively correlated with bare ground, litter depth, and litter height. The abundance of tallgrass species (Grasshopper Sparrow, Dickcissel, and Eastern Meadowlark) was associated with dense grass and deep litter, but these species had a strong negative association with bare ground and other variables associated with increasing horizontal heterogeneity (Rotenberry and Wiens 1980). In Kentucky and Tennessee, its abundance was positively correlated with a 30-70% grass mixture of native warm-season grasses, cool-season grasses, and herbaceous cover. Its abundance was not affected by distance from low-traffic roads (Lituma and Buehler 2016). In Missouri, it was associated with planted grasslands with higher cover by bare ground (Davis et al. 2016). Swanson (1996) reported that it was negatively correlated with legume cover. Mean habitat characteristics in Wisconsin were 3% woody cover, 76% herbaceous cover, 16% litter cover, 8% bare ground, 57 cm maximum vegetation height, and 14 cm vegetation-height density. Mean characteristics in Arizona included 5% woody cover, 72% grass cover, 4% forb cover, 23% bare ground, and 30 cm mean grass height. In Iowa, its abundance was negatively correlated with the vertical cover of vegetation. It was most abundant in fields with grass height less than 0.5 m and moderate vertical cover of 0.3 m. Thick stands of brome grass did not appeal to it even when the grass was optimum height. Mean vegetation characteristics included: 24 cm vertical cover, 45 cm height of living vegetation, 95% grass cover, and 7% forb cover. All parameters were significantly different from those for the Ring-necked Pheasant, Dickcissel, and Red-winged Blackbird, but similar to those for the Western Meadowlark except that grass coverage was significantly greater for the Grasshopper Sparrow than the meadowlark (Patterson and Best 1996). In summary, excluding data for the Florida Grasshopper Sparrow, territories have 3-5% woody cover, 28-95% grass cover, 8-24% bare ground, and 4-76% herbaceous cover with vegetation height of 28-54 cm.

Singing perches are an important habitat component for the Grasshopper Sparrow. In Wisconsin, 60% of territories contained posts, 53% a fence line, 20% a wire bale or tangle, and 10% trees. Nonetheless, the supply of singing perches appeared to be limited. There was considerable overlap in their usage, with some used by as many as 4 species. This did not lead to excessive competition and was usually resolved quickly through the hierarchy of species (Wiens 1969). In Pennsylvania, grass clumps, alfalfa stalks, tall forbs, small shrubs, fence posts, utility wires, trees, hay bales, grain shocks, and farm equipment left in fields were used as song perches. Perches were 50-125 m from the nest. It appeared to select the tallest available perches. When a stake 60 cm taller than the grass was provided, it was claimed within minutes. The next day a taller perch was provided and the first artificial perch was immediately abandoned for it. Singing was confined to grassy areas even if the territory contained row crops. Consequently, singing areas may be separate from nesting areas (Smith 1963; Smith in Austin 1968). Harrison (1977) provided artificial perches 1.5 and 2.0 m

tall in Michigan alfalfa fields. Grasshopper Sparrows preferred the shorter perches. If birds selected perches randomly, 13 of each height class would be used. Twenty-three of the 1.5-m perches were used compared with 3 of the 2.0-m perches. In Ontario and Quebec, common mullein and common milkweed are frequently used as perches.

Some studies compared the habitats of sympatrically nesting grassland birds. In Pennsylvania, the Grasshopper Sparrow preferred shorter vegetation and was more tolerant of woody vegetation than the Henslow's Sparrow (Hill and Diefenbach 2013). In Wisconsin, areas initially settled by the Grasshopper Sparrow were characterized by significantly lower grass cover, somewhat less litter depth, and greater forb height than areas initially selected by the Savannah Sparrow. These differences disappeared as the season progressed and territories of the 2 species were quite similar by mid-June. The earliest Savannah Sparrows settled on areas that later developed deeper and more variable litter, greater grass cover and density, and shorter forbs than early Grasshopper Sparrow territories. The Grasshopper Sparrow foraged more frequently in open unvegetated areas. Savannah Sparrows concentrated their foraging around the perimeter of grass clumps. The Grasshopper Sparrow nested in somewhat more open situations and had considerably less litter associated with its nests. Both species used forbs for singing perches; the Grasshopper Sparrow showed a distinct tendency to sing from higher perches than the Savannah Sparrow. Habitat usage by the Grasshopper and Savannah sparrows was very similar. The average height of forbs in Grasshopper Sparrow territories was less than in those of the Bobolink and Henslow's Sparrows, but exceeded those in Vesper Sparrow and Western Meadowlark territories. The general vegetation density and coverage by bare ground and low vegetation was similar for Grasshopper and Savannah sparrows and the Eastern Meadowlark. Vertical vegetation density and density in the 0-10-cm height interval in Grasshopper Sparrow territories differed significantly only from those of the Henslow's Sparrow. Mean effective vegetation height in Grasshopper Sparrow territories was similar to the Savannah Sparrow, greater than for the Vesper Sparrow and Western Meadowlark, and less than for the Bobolink, Eastern Meadowlark, and Henslow's Sparrow. Litter depth, coverage, and composition in Grasshopper Sparrow territories were intermediate; litter depth varied significantly only from the Henslow's Sparrow. Grasshopper Sparrows used grass slightly less than the Savannah Sparrow. Vegetation density at Grasshopper Sparrow nest sites was somewhat less than at nests of other species. Litter was shallower and forbs were somewhat taller near Grasshopper Sparrow nests than at nests of other species. The species could be arranged in order of increasing habitat richness (vegetation density and height, litter coverage and depth): Western Meadowlark, Vesper Sparrow, Savannah Sparrow, Grasshopper Sparrow, Eastern Meadowlark, Bobolink, and Henslow's Sparrow. The difference in rankings was small, especially between the Grasshopper Sparrow, Savannah Sparrow, and Eastern Meadowlark. Each species avoided competition by performing their activities in slightly different manners by differentially using the various substrate types or by using different strata in the same substrate (Wiens 1969).

In some areas, the Grasshopper Sparrow appears to avoid edges of grassland patches or be affected by patch shape; in other areas, these features have no effect on it. In South Dakota, it was negatively associated with increasing amounts of wooded edge surrounding a grassland patch. Its probability of occurrence was greater than 75% when no wooded edge was present but fell to less than 15% when wooded edge surrounded more than 75% of the patch. Patch shape had no effect

on occupancy (Greer et al. 2016). In North Dakota, fewer nests were within 45 m of aspen woodland than further away (Grant et al. 2004). In Wisconsin, mean distances of territory boundaries from edges were: 82.8 m for cultivated fields (range 10-240 m), 24.5 m from fence lines (range 0-130 m), and 207.8 m from woods (range 10-340 m; Wiens 1969). Also in Wisconsin, there was a significantly lower density of nests within 50 m of edge than more centrally in fields. The type of edge (wooded or open) was not a significant predictor of nest density within 50 m of edge (Renfrew et al. 2005). In Nebraska, only 1 of 31 territories (3.2%) had more than 50% of its area within 50 m of edge but 17 territories (54.8%) had more than 50% of their area within 100 m of edge. The average distance from edge of 10 nests was 119 m; no nests were found within 50 m of edge (Dechant et al. 2002b). In Pennsylvania, Hill and Diefenbach (2014) detected the Grasshopper Sparrow in grasslands with perimeter-to-area ratios as high as 0.25 km to 1 ha. They concluded that it was more likely to occupy grasslands with a small perimeter-to-area ratio. Density was not consistently related to the perimeter-to-area ratio, suggesting that habitat selection is less influenced by edge effects than for certain other species. The probabilities of occupancy related to the perimeter-to-area ratio in km per ha were 95% at 0.05, 80% at 0.15, and 20% at 0.25. In Saskatchewan, its probability of occurrence was not affected by patch shape (Davis 2004). In Nebraska and Iowa, McLaughlin et al. (2014) used an edge-to-interior ratio in their models to explain its abundance and density and concluded that the ratio was not important.

Some studies concluded that the Grasshopper Sparrow is area sensitive. Other studies found no relationship between occupancy and patch size. Vickery et al. (1994) considered it area sensitive in Maine. This study was done where the population is declining and in meadows dominated by blueberries, an atypical habitat. It was detected on only 14 of 235 point counts (6.0%). Its incidence rose sharply with patch area and reached 50% at approximately 100 ha. Herkert (1994a) considered it area sensitive in Illinois. Its probability of occurrence was 10% at 1 ha, 20% at 10 ha, and 60% at 100 ha with 50% occupancy attained at approximately 30 ha. It occupied 82% of transects in suitable habitat in grasslands larger than 100 ha compared with 36% in grasslands smaller than 100 ha. In Ohio, 8 fields that were used averaged 16 ha and inhabited CRP lands averaged 11 ha (range 1-21 ha). It was considered area sensitive in the CRP lands because density increased with patch size (Swanson 1996) but a correlation between density and area is not a true measure of area sensitivity. In Saskatchewan, Davis (2004) concluded that it was area sensitive because its density increased with patch size. The minimum size of field it occurred on was 15 ha, suggesting some degree of area sensitivity. The increase associated with patch size may have interacted with other variables such as shrub density. Its occurrence appeared to be influenced predominantly by vegetation parameters. It was concluded that area sensitivity in this study may be a local phenomenon that may not be evident in other areas with different landscape compositions or regional abundances of this sparrow. It was suggested that it was area sensitive but its actual size requirements were unknown. In Pennsylvania, Hill and Diefenbach (2014) found that grassland area itself was insufficient to explain occupancy patterns and concluded that shape complexity needed to be considered. It was less likely to occupy small grasslands, particularly those with complex shapes. The smallest field it was detected in was 4.6 ha. This study also found that shrub density affected occupancy and this may have been a confounding influence. In Nebraska, the smallest patches it occurred in were 8-12 ha (Dechant et al. 2002b). Johnson and Igl (2001) studied its area sensitivity in Montana, South Dakota,

and North Dakota. At 2 sites, it was positively correlated with grassland size; it was negatively correlated with size at the other 7 sites. Results indicated that there were regional variations in area sensitivity. Walk and Warner (1999) studied area sensitivity in 9 grasslands 7-120 ha in area in Illinois. It occurred regularly on all sites except for the 7-ha site where it occurred in only 1 of 4 years. There was no significant relationship between its occurrence and patch size. Fifty percent occurrence was attained at 12 ha, the least of all species studied. In New York, the smallest pasture that supported the Grasshopper Sparrow was 10.9 ha, but this was the smallest available pasture (Smith and Smith 1992). In Quebec, it nested in fields as small as 6.4 ha but fields with sparrows averaged 15.9 ha compared with 7.6 ha for unoccupied fields (Jobin and Falardeau 2010). In New York, it nested in fields 1.8-13.2 ha. Populations in large grasslands persisted better than those in small fragments and adult return rates, proportion of successful nests, and number of fledglings produced per female tended to be higher in larger fields. Balent and Norment (2003) concluded that small fields were unlikely to support persistent populations. In Missouri, its density was not influenced by patch size but was affected by vegetation characteristics. The smallest grassland they studied was 31.2 ha, however (Winter and Faaborg 1999). Field size has been determined to have no effect on the Grasshopper Sparrow in Wisconsin, Missouri, South Dakota, Nebraska, and Iowa; 1-10 ha was considered sufficient to maintain a viable population in Missouri (Dechant et al. 2002b; Greer et al. 2016; McLaughlin et al. 2014; Ribic and Sample 2001; Swanson 1996). In Quebec, where the Grasshopper Sparrow is uncommon and local, it nests on sites as small as 6 ha (Savignac 2013) suggesting that it is not particularly area sensitive there. Prior to European settlement, the eastern subspecies of the Grasshopper Sparrow probably nested in small natural openings in the extensive forest cover. As late as the 1940s, it nested in forest openings only a few hectares in size in Michigan (Smith in Austin 1968). This subspecies may be adapted to nesting in smaller habitat patches than the western subspecies. Coleman et al. (2000) considered the Grasshopper Sparrow area sensitive in Ontario and concluded that it required grasslands larger than 10 ha. No actual studies on area sensitivity of the Grasshopper Sparrow have been conducted in Ontario so it is uncertain if this conclusion is correct. The evidence for area sensitivity by the Grasshopper Sparrow is weak and it is not universally area sensitive. It has nested in grasslands as small as 1 ha.

All but 1 Ontario nests were in a depression in the ground, in or under dead or occasionally living clumps of grasses or other plants. The exception was a nest 7.6 cm above ground in the crotch of the lowest branch of a 0.6-m red pine. This appears to be the only elevated nest that has been reported. Some nests were near trees or logs and 8 (minimum of 10.5%) were under small trees or dead branches. Most nests were partially domed by nearby grasses and other vegetation (Peck and James 1987).

All nests reported elsewhere were on the ground in a shallow depression that the female may excavate. The rim of the nest is either flush with the ground or as much as 1.3 cm above it. Most nests are domed with nesting material that is woven into overhead grasses and they are typically very well concealed; some nests may be open above. In Kentucky, the mean concealment at nests was 88.9% and there was no difference in the concealment of successful and unsuccessful nests. The Grasshopper Sparrow prefers to build its nest at the base of grass species that form clumps. In Iowa, nests were found exclusively in smooth brome or orchard grass litter even though it avoided dense stands of brome. Nests may have 1 or 2 trails leading to them under the vegetation. In Florida,

orientation of nest entrances was random, probably because they were positioned toward areas of low vegetation density and bare ground. Most Wisconsin nests faced north or northeast; nests in Kansas and Oklahoma faced northwest. In these areas, the directions of prevailing winds and nest openings both shifted seasonally. Mean nest orientation was not directly downwind and shifts in orientation were not completely in concert with changes in wind direction. Although avoidance of wind was important, it was not the only factor in determining nest orientation. Shading from the sun may also be important. In 1 area of Kansas, nests were normally oriented east to northeast. During a drought year, nests were oriented southward. This diminished morning solar radiation and increased cooling due to the prevailing southerly winds. Nests are not reused (Corimanya et al. 2024; Delany and Linda 1998a, 1998b; Long et al. 2009; Patterson and Best 1996; Smith in Austin 1968; Vickery 2020; Whitmore 1981; Wiens 1969).

Males establish territories immediately upon arrival on the breeding grounds. Almost all activities are conducted within the territories, but females occasionally fly considerable distances outside the territory to obtain food for nestlings. Both mated and unmated males defend territories. Boundaries are rigidly maintained during territory establishment, nest building, and incubation. Once the young hatch, territorial defence wanes and considerable movement occurs among territories. Movement is often initiated by young birds that are just able to fly. Territorial defence increases sharply for 2-3 days prior to second nestings. In some areas, territory sizes and boundaries are stable throughout the season but these may change considerably in other areas. Near Ottawa, Grasshopper Sparrows nested in an alvar grassland and a lightly grazed pasture. The 95% kernel territory estimates were 0.5-2.21 ha (average 1.05 ha). Home range sizes were 0.86-5.79 ha (average 2.24 ha), significantly larger than territories. Territories overlapped home ranges an average of 54.7% (range 25.0-95.9%). Home ranges were significantly larger on the alvar (4.96 ha) than the pasture (1.32 ha). The average amount of territory overlap was 3.3% at the alvar and 29.9% at the pasture. The home ranges overlapped by 8.1% at the alvar and 50.1% at the pasture. In Florida, territories were stable throughout the season but densities were low and territories were not contiguous, often separated by 30 m or more. In Pennsylvania, territorial boundaries often shifted considerably in response to habitat changes or disturbances related to mowing. In Montana, territory sizes remained constant throughout the year but varied annually, probably in response to density. In Wisconsin, where territories were contiguous, their size and shape fluctuated throughout the breeding season. Territories were significantly smaller when first established than later in the season during the peak of the breeding season. Birds continued to arrive into early June and forced themselves in among the existing territories until all habitat was occupied. As a result, territory sizes shrank again and considerable modifications were made to boundaries. There was no difference in the size of territories at the periphery of the field than in its centre, with territories averaging 0.81 ha in both locations (range 0.53-1.34 ha). In 1 Wisconsin study, early territories averaged 0.36 ha but expanded and contracted as described above. In another Wisconsin study, territory sizes increased throughout the season with the latest established territories significantly larger than the earliest. Territories averaged 0.73 ha 1-10 May, 0.77 ha 15-25 May, and 0.93 ha after 25 May. In Georgia, territories were 0.4-0.8 ha. In Florida, 30 territories averaged 1.8 ha (range 0.6-4.8 ha). Mean territory size of mated males was 1.55 ha compared with 1.01 ha for unmated males. Twenty-two Pennsylvania territories averaged 0.82 ha (range 0.49-1.34 ha). Twenty-six Montana territories

averaged 0.43 ha (range 0.16-1.87 ha). Seventy-three Wisconsin territories averaged 0.85 ha (range 0.32-1.74 ha). Territory sizes averaged 0.37 ha in California, 1.38 ha in Iowa prairies, 0.81 ha on a West Virginia farm (range 0.49-1.34 ha), 0.19 ha in Pennsylvania, and 0.66 ha and 0.78 ha in Connecticut in 2 years (Delany et al. 1995; Hannah et al. 2024b; Johnston and Odum 1956; Jones 2011; Smith 1963; Vickery 2020; Wiens 1969, 1973).

Limited information is available on natal philopatry. Return rates vary from 0% to 12%. In Montana, 0 of 138 nestlings returned. In New York, 1 of 43 nestlings (2.3%) returned; it established a territory that overlapped with its natal territory. In Florida, where the Grasshopper Sparrow is resident year-round, only 1 of 50 nestlings and 6 fledglings (1.8%) were resighted in a subsequent year. One Florida male moved 2 km from his natal site. In Maine, 2 of 19 juveniles (10.5%) returned (Balent and Norment 2003; Delany et al. 1992, 1995; S.L. Jones et al. 2007; Perkins and Vickery 2001; Savignac 2013; Vickery 2020).

Adult site fidelity rates vary and are considerably higher in the east than the Midwest. In Montana, 4 of 45 adults (8.9%) returned and 3 returned to the same location where they were banded; the fourth bird could not be individually identified. In Kentucky, 6 of 39 adults (15.4%) returned, including 5 males and 1 female, and all returned to territories near those occupied the previous year. Other return rates include 22 of 111 (19.8%) in Kansas, 5 of 10 (50.0%) in Connecticut, 15 of 42 (35.7%) in California, 0 of 85 in Nebraska, 20% in another California location, 33% in New York (29% for males and 27% for females), 15 of 42 (35.7%) in Maine, and 57% in Maryland. In New York, 3 fields that were only 20 m apart appeared to function as separate local subpopulations, with no evidence of movement among them and no defence of territories that included more than 1 field. There were no significant differences in return rates of birds from small and large fields and for birds that bred successfully or unsuccessfully the previous year. In resident populations in Florida, annual return rates of males were 52.1-66.7% but 0 of 15 females returned. Eighty-four percent of returning males occupied the same territory as in the previous year. Three moved 183, 366, and 570 m from the previous year's territory. In Maine, 70% of returning males occupied the same territory (Delany et al. 1992, 1995; S.L. Jones et al. 2007; Kaspari and O'Leary 1988; Savignac 2013; Vickery 2020). Higher fidelity rates in the east may be due to the limited areas of suitable habitat.

In Kansas, Williams and Boyle (2018) determined that male Grasshopper Sparrows dispersed between breeding sites within individual breeding seasons. They based this on 3 factors: seasonal changes in density, turnover of males within plots, and direct observations of individuals defending 2 or more territories in succession within seasons. The mean turnover rate of males among years was 52%, indicating that over half of territory holders changed every month. Seventy-five percent of males changed territories some time during the breeding season. Birds dispersed out of plots that had very low and especially very high territory densities and dispersed into plots with intermediate densities. Nine of 19 males (47.4%) established new territories 120-1,229 m from their initial territories; 7 (36.8%) remained in their original territory. Of 647 males, 33% were observed defending territories more than 100 m from their initial territory; 42% remained on the original territory. Dispersal distances ranged from 101 m to 8,940 m (median 197 m). Over half of dispersal distances were less than 400 m; 4% moved more than 5 km. Seven females dispersed 144-1,321 m. Four

females were detected at subsequent nests, 2 of which divorced their mates and dispersed following nest failure. One pair dispersed together to a new territory.

Limiting Factors

Eggs have been reported in Ontario Grasshopper Sparrow nests from the beginning of May until mid-August, with most present in the first 3 weeks of June (Peck and James 1987). Pairs are formed as soon as the females arrive and nest building begins almost immediately. The nest is usually built within 2-3 days. It is unknown when egg laying begins in relation to nest completion; presumably 1 egg is laid per day. The timing of the onset of incubation is uncertain, but may be with the laying of the penultimate egg. The incubation period at 4 Ontario nests was 11 days. Incubation periods of 7-13 days have been reported elsewhere but most eggs hatch in 11-13 days in the eastern subspecies. In Montana, the incubation period for 86 nests averaged 10.9 days (range 7-13 days). The nestling period for the eastern subspecies is typically 8 or 9 days. Nestlings may fledge when they are as young as 7 days if they are disturbed. In Montana, the average nestling period was 9.7 days (range 7-12 days). In Nebraska, nestlings fledged at age 6-8 days (S.L. Jones et al. 2010; Kaspari and O'Leary 1988; Peck and James 1987; Smith 1963; Smith in Austin 1968; Vickery 2020).

Ontario egg dates suggest that 2 broods may be raised, but this has yet to be confirmed. In most of its range, the Grasshopper Sparrow raises 1 or 2 broods. It appears to be single-brooded in Wisconsin and Montana and double-brooded in Florida, West Virginia, and Nebraska. In Oklahoma and Maryland, 2 and sometimes 3 broods are raised. Under favourable conditions, it is likely that it can raise 2 broods even in the northern portions of its range. Yearlings typically raise only a single brood. It readily renests if a nest is lost and 3 or 4 attempts may be made to raise a brood. Clutches of 3-5 eggs have been reported in Ontario (average 4.39 eggs); 5-egg clutches are most frequent. Throughout its range, clutches of 2-6 eggs have been documented and there is a single case of a 7-egg clutch. The normal clutch size range is 3-5 eggs, with 2- and 6-egg clutches rare; most clutches contain 4 or 5 eggs. Mean clutch sizes reported elsewhere are 4.1-4.5 eggs. Clutch size declines with season. The decline with season was not significant in Montana and West Virginia but significant in Kentucky and Tennessee at a rate of 0.5 egg every 62 days. At this rate, the second clutch would be reduced by about 0.5 egg; later clutches often have only 3 eggs. In another Kentucky study, mean clutch sizes were 4.79 eggs in May, 4.06 eggs in June, and 3.71 eggs in July. Clutch sizes were significantly larger in ungrazed (4.48 eggs) than grazed (3.91 eggs) areas (Danner et al. 2018; Delany et al. 1993; Giocomo et al. 2008; Jones 2011; S.L. Jones et al. 2010; Kaspari and O'Leary 1988; Peck and James 1987, 1998b; Smith 1963; Smith in Austin 1968; Sutter and Ritchison 2005; Vickery 2020; Wiens 1969; Wray et al. 1982).

Both sexes are capable of breeding as yearlings and presumably breed every year thereafter. In Florida, some territories were defended by unmated males that were probably yearlings (Delany et al. 1995; Vickery 2020). The Grasshopper Sparrow is typically monogamous but Small et al. (2009) reported 4 cases of polygyny in Maryland. These represented only 1.2% of the 337 males that were studied. Three cases involved 1 male and 2 females; another male may have had 3 females breeding simultaneously, but this could not be confirmed. The average distance between polygynous nests was 60.6 m. In 2 cases, both nests were within 20 m of each other and in the other 2 cases they were more than 90 m apart. In 2 cases, one of the nests was outside the male's territory; in 1 case, both

nests were in the territory; and in another case, both nests were outside the territory. Polyterritoriality was not documented.

In Maryland, 77 of 124 broods (62.1%) contained at least 1 extra-pair young; 165 of 448 nestlings (36.8%) were the result of extra-pair mating. There was substantial annual variation in the extent of extra-pair paternity. Over 6 years, 43-76% of broods contained at least 1 extra-pair young and 26-60% of nestlings were a result of extra-pair mating. The probability of extra-pair paternity increased with the number of neighbours. Eighty-one percent of extra-pair copulations were with neighbours. Males that were not cuckolded had the highest number of genetic offspring, both within- and extra-pair. These males were better at mate guarding or were perhaps of greater quality. Cuckolded males failed to sire many offspring, including extra-pair young. Males of lower quality can pair with a female and be social fathers but not necessarily genetic fathers. This suggests that females paired with low-quality males actively seek extra-pair copulations whereas those paired with high-quality males have little need to seek matings outside the pair bond (Danner et al. 2018).

The Grasshopper Sparrow forages exclusively on the ground and presence of bare ground is critical for effective foraging. In Wisconsin, most foraging was done in grass 0-5 cm tall, but it used grasses 6-10 cm and 11-15 cm tall more than the Savannah Sparrow. All 7 grassland species there foraged in grass, but there were differences in their patterns of foraging that may have been sufficient to bring them into contact with different foods. In agricultural lands in North Carolina, soybeans and other monoculture crops were important foraging areas (Swanson 1996; Vickery 2020; Wiens 1969).

Adults remove chitinous material from prey before it is fed to nestlings, particularly from grasshoppers. This increases room in the gut for more prey, and increases the proportion of nutrients in the food. Small prey often has a higher proportion of chitin by weight than large prey. A diet of small prey would fill the gut more quickly with less nutritious food. Birds reduce the amount of chitin ingested by avoiding small prey and removing chitin from large prey (Adler and Ritchison 2011; Kaspari and Joern 1993). In Nebraska, the diet of nestlings differed from that of adults. Nestlings consumed significantly larger (15-31 mm) prey than adults (12-15 mm). The diet of adults contained 3-61% seeds, but nestlings were fed arthropods exclusively. Nestlings received more grasshoppers and caterpillars and fewer beetles and bugs than adults ate (Kaspari and Joern 1993). Grasshoppers were the most important food items in the stomachs of 2 Florida nestlings. They constituted 63% of food items and 71% of arthropod prey. They also consumed click beetles, ground beetles, spittle bugs, deer flies, braconid wasps, spiders, and flatsedge seeds (Delany et al. 2000). In Kentucky, grasshoppers constituted 68.1% of food items fed to nestlings. They were also fed 22.6% orthopteran larvae, 5.6% crickets, and 1.9% moths; overall, the diet consisted of 96.3% orthopterans. The mean length of grasshoppers fed to nestlings was 24.4 mm and the mean length of crickets was 21.8 mm. Other nestling prey items included bees, beetles, and spiders (Adler and Ritchison 2011). In Wisconsin, prey items brought to nestlings consisted of 22 unidentified caterpillars, 7 geometer moth caterpillars, 4 damselflies, 2 adult lepidopterans, and 1 each of orthopteran, bug, beetle larva, fly larva, spider, and oligochaete. In this small sample, lepidopterans constituted 75.6% of the diet and orthopterans represented only 2.4% of the diet (Wiens 1969). Judd (1901) reported that nestlings were fed mostly grasshoppers.

Judd (1901) analyzed the contents of 170 stomachs. They contained 63% animal matter and 37% vegetable matter. Fifty-seven percent of the diet consisted of insects and the remaining 6% of the invertebrates consisted mostly of spiders with occasional myriapods, snails, and earthworms. The insects consisted of 23% grasshoppers, 14% caterpillars, 11% ants, 8% beetles (click, leaf, and dung beetles and weevils) and 1% bugs (leafhoppers, assassin bugs, and soldier bugs). In June, 60% of the diet consisted of grasshoppers. Caterpillars were more dominant in the diet in May when they constituted 33% of the diet. More than half the caterpillars were owlet moths (cutworms). The vegetable matter in the diet consisted of seeds, including 17% foxtails, panic grasses, and a few other miscellaneous grasses; 11% other plants, including smartweeds, purslane, plantain, and sedges; 5% wood-sorrel; and 2% waste grain. No fruit was consumed other than a few blueberries in 1 stomach. The Grasshopper Sparrow fed on vegetable matter much less than other sparrows, including the Savannah Sparrow. Insects were the staple of the diet and grasshoppers, caterpillars, and beetles were most important. In Florida, Smith (in Austin 1968) reported that 10 birds had eaten 69% insects and spiders and 31% seeds. The most frequently consumed insects were grasshoppers and crickets, beetles and weevils, and moths and moth larvae, along with a few flies and bugs. The vegetation consisted predominantly of sedge seeds with some seeds of grasses and yellow stargrass. Vickery (2020) stated that the summer diet consisted of 61% invertebrates and 39% seeds compared with 29% invertebrates and 71% seeds in autumn. The summer diet consists predominantly of insects, mostly grasshoppers. Major taxa in the diet in Oklahoma and South Dakota mixed prairies were, respectively: orthopterans, 36% and 30%; caterpillars, 20% and 16%; beetles, 18% and 10%; true bugs, 9% and 1%; spiders, 4% and 3%; soft-winged bugs, 0% and 6%; hymenopterans, 0% and 2%; and seeds, 14% and 31%. Seeds in order of abundance included foxtails, sheep sorrel, oats, and smartweeds. The western and Californian subspecies eat seeds of foxtails, ragweed, panic grass, wood-sorrel, sunflowers, sedges, knotweeds, campions, oats, and amaranths. In Oklahoma, South Dakota, and Texas, seeds constituted less than 20% of the diet and frequently less than 10%. Orthopterans dominated the diet at 1 location but were less important at another site. Beetles never comprised more than 8% of the diet; weevils were the most consistently ingested beetles. Caterpillars comprised more than 25% of the diet biomass except at 1 site in 1 year. In several cases, more than 50% of the diet consisted of caterpillars. Other animal prey (hymenopterans, bugs, flies, neuropterans, spiders, and snails) made minor contributions to the diet, although cicadas and other soft-winged bugs constituted more than 10% of the diet at 1 location. The seeds consumed were mostly those of grasses with very small amounts of goosefoots, wood-sorrel, smartweeds, and borages. Variation in the diet was the least for the Grasshopper Sparrow of the studied species. Its dietary stability was also most stable among the species studied, with 87% stability over the years. The diet had limited variety; at 1 site, only 11 prey items were selected by the entire population and individual specimens contained 57% of those taxa on average. There was no significant difference in the diet of the sexes and the diet varied little among locations. It consumed prey 1-32 mm in length, mostly in the 1-4 mm range except at 1 site where it ate many items in the 4-8 mm range. Mean prey sizes in different locations ranged from 3.39 to 9.86 mm (Wiens and Rotenberry 1979). Kaspari and Joern (1993) determined that 67% of the diet of Nebraska Grasshopper Sparrows consisted of arthropods and that grasshoppers were the preferred prey. Bugs were numerically dominant in the environment, but were not preferred. The percentage of seeds in the diet over 2 years was 36% and 18% in June, 22% and 41% in July, and 24% and 40% in August. The diet consisted

of 40% short-horned grasshoppers, 16% beetles, and 14% bugs. The dominant trend was an increase in the proportion of grasshoppers in the diet over the breeding season. It was the only species studied that consumed beetle larvae smaller than 5 mm or 15-25 mm in length. Preferred prey was 15-35 mm in length and it avoided prey outside this range.

Some studies evaluated whether there is competition among grassland birds for food. In Oklahoma, South Dakota, and Texas, the Grasshopper Sparrow had a high niche overlap with the Western Meadowlark at 1 site in all years. Relations to the Eastern Meadowlark at another site were close some years and distant in others, and at 1 site it consistently overlapped highly with the Dickcissel. Larger species (Upland Sandpiper and the 2 meadowlarks) consumed larger prey than the Grasshopper Sparrow and Dickcissel. Wiens and Rotenberry (1979) concluded that food was not normally limiting and that populations were exploiting food resources in an opportunistic fashion. This led to considerable individual, between-year, and between-location variation in diet compositions and interspecific overlaps. Kaspari and Joern (1993) reached a different conclusion in Nebraska. Diets of the Grasshopper Sparrow, Lark Sparrow, and Western Meadowlark strongly varied over time and they preferred most of the same prey. Competition for prey between the Grasshopper Sparrow and Western Meadowlark was partially avoided through prey-size selection, with some large prey avoided by the sparrow and preferred by the meadowlark. This suggested that there was some competition for food and that these species were not dietary opportunists. In Wisconsin, Wiens (1969) concluded that the food supply for grassland birds was abundant and not a limiting factor that would lead to competition.

The Grasshopper Sparrow is an infrequent host of the Brown-headed Cowbird and is capable of fledging some of its own from parasitized nests. In Kansas, parasitism resulted in an average loss of 2 eggs per nest and fledging success was only 7%. In another Kansas area, unparasitized nests had clutches of 4.5 eggs compared with 3.1 eggs in parasitized nests. In Minnesota, parasitism rates decreased with distance from woody edges. There were no differences in predation rates within 100 m of a forest or agricultural edge or more distant from edge. In Illinois, real and artificial cowbird eggs used to artificially parasitize nests were all accepted, as were all eggs that were laid naturally by cowbirds. Many undersized artificial eggs were ejected. Cowbird eggs may be too large for the Grasshopper Sparrow to eject and the eggs of the 2 species are similar, so the sparrow is at risk of ejecting its own eggs. In Ontario, 7 of 83 nests (8.4%) were parasitized. Other parasitism rates include 29% in Manitoba, 2% in Montana, 0 of 51 nests in West Virginia, 0 of 34 nests in Wisconsin, 2 of 21 nests (9.5%) in North Dakota, 0 of 131 nests in Kentucky and Tennessee, 1 of 41 nests (2.4%) in Indiana, 13 of 318 nests (4.1%) in Illinois, 22 of 46 nests (47.8%) in Kansas, 0 of 153 nests in Pennsylvania, 8% of 119 nests at 2 sites in North Dakota and 1 in Saskatchewan combined, 2% in Ohio, 4 of 18 nests (22.2%) in Kansas, 9 of 121 nests (7.4%) in Oklahoma, 7 of 14 nests (50.0%) in Kansas, and 1 of 6 nests (16.7%) in British Columbia. Kansas, where the highest parasitism rates have been reported, has a very high density of cowbirds (Ahlering et al. 2009; Campbell et al. 2001; Dechant et al. 2002b; Galligan et al. 2006; Giocomo et al. 2008; Gransfors et al. 2001; Hill and Diefenbach 2013; S.L. Jones et al. 2010; Peck and James 1998b; Peer et al. 2000; Renfrew et al. 2005; Rivers et al. 2010; Sroor et al. 2025; Verheijen et al. 2022; Vickery 2020; Wray et al. 1982).

Habitat loss is the most significant limiting factor for the Grasshopper Sparrow in Ontario and throughout its range. Habitat loss occurred as a result of converting pastures and grasslands to row crops or urban development, converting grassy hayfields to alfalfa crops, planting marginal farmlands to coniferous plantations, and natural succession. A high proportion of Ontario's pastures have been converted to cropland dominated by row crops. Except in the Norfolk Sand Plain, row crops are rarely, if ever, used for breeding. Traditional hay crops in Ontario consisted of red and white clover, timothy, and limited amounts of alfalfa. This provided heterogeneous and fairly sparse cover that was somewhat suitable for breeding. Most hayfields are now monotypic stands of alfalfa that grow taller and denser and are very uniform. These hayfields have no bare ground and are rarely, if ever, used for breeding. In a Pennsylvania field dominated by poor growth of timothy, alfalfa, and clovers, the Grasshopper Sparrow abandoned it after it was fertilized and planted to a lusher growth of alfalfa. Beginning in the 1930s and still continuing to some extent, marginal farmland has been planted to coniferous plantations. Areas that were particularly targeted for this management were areas of steep slopes, especially on the Oak Ridges Moraine, but also on other moraines, drumlins, and eskers in the southern portion of the province. Many of these areas were probably prime habitat for the Grasshopper Sparrow because they had dry sandy or gravelly soil with low sparse grass cover and areas of bare soil. Introduction of grasses, such as smooth brome and reed canary grass that form tall, dense monotypic stands has been detrimental. These grasses do not provide any suitable habitat for the Grasshopper Sparrow and may eliminate other grass species that are more beneficial. Unmanaged meadows may be invaded by shrubs, reducing habitat suitability; once shrubs become too dense, it disappears. The Grasshopper Sparrow responds well and quickly to appropriate habitat management. Planting of CRP lands in the west slowed its rate of decline and it may become quite common in managed grasslands at airports. Changing agricultural practices in Pennsylvania with an emphasis on grasslands appears to be resulting in an increase. Reclaimed surface mines provide excellent habitat and it may be locally abundant on them. Habitat at most of these areas is temporary due to rapid succession of woody vegetation; some areas may only be occupied for about 3 years. Significant management for the Grasshopper Sparrow is unlikely to occur in southern Ontario due to the intensity of current land uses and the high price of land (Askins et al. 2007; Galligan et al. 2006; Herkert 1988; Savignac 2013; Smith 1963; Smith in Austin 1968; Swanson 1996; Vickery 2020; Whitmore 1979; Wray et al. 1982).

The effects of grazing on the Grasshopper Sparrow vary depending upon the type of grassland and the intensity and timing of grazing. Grazing in arid grasslands is detrimental because these areas tend to be sparsely vegetated even without grazing. Further reductions in vegetation height and density in these grasslands may convert them to unsuitable habitat. Grazing in lusher grasslands may be beneficial because it reduces vegetation height and density and may create areas of bare soil, all of which are beneficial. Light grazing that results in 20-40% vegetative cover 25 cm in height or taller is beneficial but more intensive grazing may be detrimental. In tallgrass prairies and eastern hayfields, light grazing tends to be beneficial. In Ontario, some of the highest densities occur on lightly grazed moraines and limestone plains such as the Mulmer Hills west of Lake Simcoe, the Dummer Moraine east of Peterborough, the Oak Ridges Moraine, the Carden Plain, the Napanee Plain, and Dufferin County. In most other areas south of the Canadian Shield, grazing tends to be intense so that habitat is unsuitable. In Kentucky, clutch size was smaller in grazed areas, and nest

success was significantly higher in ungrazed (70%) than grazed (25%) fields. Invertebrate biomass was significantly greater in ungrazed fields and this may have been the cause of smaller clutch sizes in grazed areas. Grazed areas had less litter, more shrubs, and shorter, less dense vegetation. Late-season grazing after birds had completed nesting resulted in an increase in density of the Grasshopper Sparrow in Illinois. Except for arid grasslands, light grazing has the potential to improve habitat but moderate to heavy grazing is typically detrimental. Not grazing homogeneous stands of mid-height grasses for an entire growing season during wet years could increase its abundance. One adverse effect of grazing is that cattle often trample nests or lay on them. In Wisconsin, trampling by cattle was the second-most common cause of nest failure after predation (Askins et al. 2007; Campbell et al. 2001; Davis et al. 2021; Delany and Linda 1998a; Powell 2008; Renfrew et al. 2005; Rolek et al. 2016; Savignac 2013; Smith and Smith 1992; Sutter and Ritchison 2005; Swanson 1996; Vickery 2020).

Mowing may be beneficial or detrimental to the Grasshopper Sparrow, depending upon the initial characteristics of the grassland and the timing of cutting. Mowing of hayfields during the breeding season may have a variety of effects. Existing nests may be destroyed by farm equipment and undamaged nests are left exposed to predators. After mowing in alfalfa fields, birds that were present tended to remain and renest. Densities of sparrows may increase for 2-3 weeks after alfalfa fields are cut and fields that previously supported no sparrows may be colonized. In Iowa, cut alfalfa fields were attractive to Grasshopper Sparrows until vegetation reached about 30 cm tall then densities began to decline. Hayfields are now cut earlier and more frequently than previously. In many areas, early hay cutting is considered a major contributor to its decline. Mowing prior to or after the breeding season may be beneficial where the grass cover is dense. In Illinois, densities were twice as high in areas cut 1-4 months prior to 1 May than in uncut areas. In Iowa row crops, it nested only on grassed waterways that had been mowed the previous year. When sections of fields were mowed for weed control, it quickly colonized areas with shorter grass cover. Densities were 5 times greater along Illinois roads that were not mowed until after 1 August than those mowed repeatedly during the summer. At a military base in Massachusetts, populations more than doubled as a result of deferred mowing. At a Massachusetts airport, populations declined when grass was mowed in the spring. In grass hayfields in New Jersey, 0.25-ha refugia were left unmowed. Grasshopper Sparrow use of refugia increased following hay harvest and may have reduced field abandonment. It decreased sharply following harvest in fields without refugia but less steeply or not at all in fields with refugia. In grasslands that are already good habitat, mowing may decrease habitat suitability (Allen et al. 2019; Askins et al. 2007; Dechant et al. 2002b; Frawley and Best 1991; Johnston and Odum 1956; Patterson and Best 1996; Smith 1963; Smith in Austin 1968; Swanson 1996; Vickery 2020). In Iowa, disking monocultures of reed canary grass resulted in a change in the vegetation and an increase in insect biomass, but there was no noticeable response by the Grasshopper Sparrow. Overall densities in these habitats were quite low (Benson et al. 2013). Wolcott et al. (2023) recommended that grassland management be delayed until August to protect both nests and fledglings.

The effects of fire on the Grasshopper Sparrow are variable. In Ontario, prescribed burns in arid grasslands often stimulate mass germination of white sweet clover, making the habitat unsuitable. In Washington shrubsteppe habitat, an intense wildfire increased its abundance because most of

the shrub cover was killed. In western areas of the tallgrass prairie, it tends to be more abundant in areas that have not been burned. Fire removes accumulated litter and standing vegetation. This is beneficial in grasslands that are initially too dense for this sparrow but may be detrimental if current conditions are suitable. Spring burning makes habitat unsuitable for that breeding season, so it is preferable to conduct burns in autumn or winter. In Arizona, where shrubs are an important habitat component, densities were similar in native and exotic grasslands prior to fire and 3-4 years after fire. It was absent on burned plots in both types of grasslands for 2 years following fire. In Florida, there was no difference in its abundance before or after fire, but reproductive success was higher 0.5 years postburn than 1.5-2.5 years postburn. Another Florida study determined that its probability of persistence was greatest when areas were burned in early April within 1 year and least when areas had not been burned for 35 years in dry prairie habitat. In Kansas, abundance was higher 1-3 years postfire than during the year of the fire. Numbers were higher in areas that were on annual or 2-year frequencies of burns than areas burned every 4 years, which tended to become invaded with shrubs. In Texas, there was no significant difference in its abundance in burned and unburned areas. It was concluded that fire was important in preventing grasslands from becoming too homogenous. In Maine, density declined for 1 year immediately following fire but was quite high for the subsequent 5-7 years. In Illinois, it preferred recently burned tracts less than 1 year after burning. In North Dakota, it responded positively to fire and was most abundant 2-7 years postfire and absent in grasslands that had not been burned for more than 80 years. In South Dakota, it decreased immediately after fire due to loss of litter but increased 2-3 years postburn. The same was true in Wisconsin, but density decreased when the area was burned a second time. In Kansas, fire had no effect in moist years but resulted in a decline during drought years. In 1 Kansas study, both grazing and fire were beneficial (Askins et al. 2007; Bock and Bock 1992; Dechant et al. 2002b; Delany et al. 2002; Earnst et al. 2009; Larned et al. 2003; Madden et al. 1999; Powell 2008; Roberts et al. 2012; Savignac 2013; Swanson 1996; Verheijen et al. 2022; Vickery 2020; Williams and Boyle 2018; Zimmerman 1989).

The Grasshopper Sparrow may be adversely affected by drought. In Maryland, production of fledglings was particularly low in 2 summers of record-breaking drought. Grassland vegetation was brown and wilted by mid-July, insect density was low, and mortality of fledglings was presumably high (Anthony et al. 2013). In western North Dakota and Saskatchewan, densities were higher during wet springs preceded by warmer winters. Spring precipitation increased primary productivity and invertebrate density. Weather conditions such as precipitation and temperature may be important factors that influence settlement decisions (Ahlering et al. 2009). In eastern North Dakota, it was negatively correlated with the number of ponds present in May and was therefore negatively affected by moisture. Its abundance was correlated to a drought severity index. Niemuth et al. (2008) concluded that it might respond differently to moisture in different locations. In areas where it is sensitive to drought, climate change has the potential to affect population densities and reproductive success. In the northern Great Plains, Gorzo et al. (2016) used BBS data to demonstrate that it was more abundant in wet years, particularly in wet years that followed another wet year. In desert grasslands in Arizona, nest survival decreased with a wetter previous season and with large rain events on previous days. The increased frequency of extreme weather events predicted for the area as a result of climate change may result in reduced nest survival, but lower seasonal precipitation prior to nesting may positively influence nest survival (Ruth and Skagen 2018).

Zuckerberg et al. (2018) summarized data from the United States regarding the effects of temperature and precipitation on the Grasshopper Sparrow. Nesting success was higher following a year with higher precipitation and lower when May temperatures were below or above average in the previous year. Nesting success was lower with increased rain in May and June to August of the year in which nesting occurred.

Cold and wet summers may be detrimental in some areas. In Maryland, many nests were flooded in such a summer and fledgling production was poor (Anthony et al. 2013). In Nebraska, Grasshopper Sparrow abundance was lower in springs with more precipitation, but productivity was not affected. Increased temperatures had no effect on abundance. It is vulnerable to climate change in this area because more frequent droughts and extreme precipitation events are predicted (Glass et al. 2020).

Shaffer and Buhl (2015) studied the effects of wind farms in North and South Dakota. At 1 of 3 sites, there was immediate displacement of the Grasshopper Sparrow, with lower density at the wind farm than at reference sites. At all 3 sites, there was displacement within 200 m of turbines and at 1 site, displacement extended out to 300 m. Wind farms were detrimental. Sparrows did not completely abandon them, but relocated away from them, establishing territories 200-300 m distant from them.

Robertson et al. (2012) examined the potential effects of cultivating grasses for biofuels on the Grasshopper Sparrow. Planting of switch grass for biofuel production has the potential to be beneficial. Production that maximizes biomass and homogenizes vegetation structure is unlikely to support it. If occupied habitat is converted to biofuel production areas in Ontario, it is most likely to be detrimental.

Declines of the Grasshopper Sparrow have been linked to large-scale applications of granular pesticides on agricultural land. These are designed to eliminate insect pests, including grasshoppers that make up a large portion of its diet (Savignac 2013).

In Illinois, Andrews et al. (2015) broadcast vocalizations at some newly created grasslands but not at others to determine if social cues were used as part of the settling decision process. The Grasshopper Sparrow was not more likely to settle at treatment sites than control sites. Densities on treatment sites were twice that of controls. Densities at treatment sites increased sharply at the beginning of the season and remained high. Densities increased slowly at control sites, reaching a peak at the end of July. Social cues are not used upon arrival but are used to select breeding locations within the breeding season. It appeared to disperse in mid-season and use social cues to locate new breeding sites; song may be an indication that successful breeding has taken place.

In Wisconsin, abandonment rates were significantly higher at nests equipped with video cameras than at nests without cameras (Renfrew and Ribic 2003).

Dechant et al. (2002b) recommended management strategies for the Grasshopper Sparrow: create habitat patches a minimum size of 10-15 ha with minimal perimeter-to-area ratio; treat portions of large areas on a rotational schedule to provide a mosaic of successional stages; discourage woody vegetation in eastern and Great Plains grasslands; maintain open grassland by burning every 2-4 years; and lightly graze areas of tall dense vegetation except in arid western areas.

Price (2004) predicted that the population of the Grasshopper Sparrow might increase in southern Ontario if the average summer temperature increased by 2°C. Nixon et al. (2016) predicted the effects of climate change on the Grasshopper Sparrow in Alberta. They concluded that it would benefit from climate change due to a northward expansion of suitable climate with no or limited change in the southern portion of the province.

Status

McIlwraith (1894) was aware of only 2 records of the Grasshopper Sparrow for Ontario, from London and Hamilton. The southern border of the province appeared to be the extreme northern limit of its distribution at that time. He concluded that it might be a rare summer resident but that it was mostly a casual visitor. By 1891, it had not been reported in Elgin County; by 1954, it was a regular breeder in moderate numbers; it was a local and declining breeder in 2000 (Lancaster et al. 2004). Peak populations in Hamilton and Ontario occurred in the 1930s and 1940s, but it has been declining for about the past 50 years (Curry 2006). Between 1900 and the 1950s, it was estimated that it had extended its range northward by about 300 km. The first Kingston record was a spring migrant in 1949, but it has been recorded there every year since except for one (Weir 2008). Baillie and Harrington (1937) reported that it nested north to Grey, Simcoe, and Victoria counties and east to Ottawa. At that time, it was fairly common along Lake Erie. The first atlas demonstrated that the Grasshopper Sparrow bred locally south of the Canadian Shield. There were scattered records in the southern portion of the Shield, near Sudbury, and in the Lake of the Woods area. There were concentrations of records along the Niagara Escarpment, in the Guelph area, and north of Lake Ontario, particularly near Kingston and on the Oak Ridges Moraine (Rising in Cadman et al. 1987). James (1991) considered the Grasshopper Sparrow an uncommon local breeder south of the Shield and rare north to Sudbury and in western Rainy River District.

The second atlas demonstrated that there had been no significant change in the distribution of the Grasshopper Sparrow since the first atlas. There was no significant change in its probability of observation throughout the province, but it declined significantly in the Carolinian Forest Region. These declines were likely due to agricultural intensification. It was fairly common along the Lake Erie shoreline in the 1930s, but there were only scattered breeding records from Rondeau and Long Point, a few records in Niagara, and a larger concentration of records in the Norfolk Sand Plain. The highest concentrations of records were on the Oak Ridges Moraine, Frontenac Axis, Niagara Escarpment, and northern Bruce County. Highest densities occurred in a band from the southern Bruce Peninsula to the Kingston area. This included the Mono and Mulmur Hills in Dufferin County, the Carden Plain, the Oak Ridges Moraine, the Napanee Limestone Plain, and Prince Edward County (Earley in Cadman et al. 2007).

Prior to European settlement, the Grasshopper Sparrow was probably confined to prairies, limestone plains, arid tops of moraines and drumlins, and forest openings created by fire and First Nations. It is uncertain if it even inhabited Ontario during this period because there were few records prior to the beginning of the 20th century. It responded favourably to the creation of abundant suitable habitat by increasing in numbers and extending its range further northward to include Ontario. Numbers in Ontario appear to have peaked in the 1930s and 1940s, and this is true in many other locations. Even where it is common, it tends to be local in occurrence, with many areas of

apparently suitable habitat unoccupied. Populations at a given location may fluctuate considerably annually. Although this may be a response to annual differences in moisture as suggested by some studies, the reasons for this are not clear (Badzinski 2001; Curry 2006; Herkert 1994a; McCracken 2005; Savignac 2013; Smith 1963; Smith in Austin 1968; Vickery 2020; Wiens 1969).

The BBS has limitations for surveying for the Grasshopper Sparrow because it sings infrequently and mostly early in the morning, its density is low, and it is detected on few routes. BBS results for 1970-2021 indicate annual decreases of 2.38% in Canada and 2.99% in Ontario. Results for 2011-21 were annual decreases of 6.58% in Canada and 5.92% in Ontario. The long-term trends were highly reliable. The Canadian short-term trend was of low reliability; the Ontario short-term trend was of medium reliability (A.C. Smith et al. 2023).

The Grasshopper Sparrow is designated special concern in Canada and Ontario.

POSTFLEDGING PERIOD

Usually only 1 or 2 fledglings are seen with an adult, but it is uncertain if brood division occurs. On average, fledglings are capable of flying 4 days after they leave the nest (range 1-7 days). Initial flights average 7 m; fledglings are capable of flights longer than 10 m at an average of 9 days (range 4-12 days). They run mouse-like under the grass and rarely appear at the tops of grasses (Hovick et al. 2011; Smith in Austin 1968; Vickery 2020).

In Maryland, Small et al. (2015) compared the habitat preferences of dependent and independent fledglings and compared these to random sites. Dependent birds selected sites averaging 16% less bare ground, 11% more coverage by warm-season grasses, 17% more total vegetation cover, and 7% more forb cover than independent birds; all differences were significant. Because dependent birds do not forage on their own and are less able to escape predators than older birds, they benefit from remaining in areas with greater vegetation cover. Habitat selected by independent juveniles was similar to that used by adults. Juveniles transitioning to independence must successfully forage on their own, possibly explaining increased use of more open areas where foraging may be easier. Vegetation parameters that were significantly different for dependent fledglings compared with random sites respectively, included 11.5% and 7.6% bare ground, 27.0% and 23.5% litter cover, 31.8% and 38.9% warm-season grass coverage, 61.6% and 68.7% total vegetation coverage, and vertical density 32.5 cm and 37.2 cm. Vegetation parameters that were significantly different for independent fledglings compared with random sites respectively, included 27.5% and 9.5% bare ground, 17.3% and 34.3% warm-season grass coverage, 43.8% and 60.0% total vegetation coverage, and vertical density 30.7 cm and 41.3 cm. Microhabitats where dependent birds were found had significantly more bare ground, litter, and plant species richness than random plots. Random plots had greater cover by warm-season grasses, total vegetation cover, and vertical density. Plots where independent fledglings occurred had significantly more bare ground than random plots. Random plots had greater cover by warm-season grasses, total vegetation cover, and vertical density. Results demonstrated the importance of diverse grassland ecosystems and that homogenous monotypic stands may not provide all the required habitat features.

In Iowa, daily movements from the nest by fledglings increased the first 4 days after fledging and then became stable for the remainder of the 14-day study period. Extreme distances moved by fledglings over the entire study period ranged from less than 1 m to 135 m. Average daily movement

from the nest site was 37.5 m (Hovick et al. 2011). At 1 Maryland site, the distance fledglings dispersed from the nest increased with time. The mean distance travelled from the nest was 346 m. The youngest bird was recaptured 5 days after fledging and had travelled 510 m. The longest distance travelled was 1,615 m and this was accomplished in no more than 20 days. The shortest net distance travelled was 9 m after 18 days. The fledgling that stayed the longest remained at least 97 days and travelled 753 m from the nest. Young travelled a mean of 90 m in 10 days and 1,000 m in 100 days. Most fledglings were encountered within 200 m of their nest throughout the summer (Anthony et al. 2013). Small et al. (2015) compared movement patterns of dependent and independent fledglings in Maryland. Daily movement of recently fledged young increased with age with an average daily distance from the nest of 88.8 m (range 3.4-1,042 m). The average distance travelled from the previous day's location by dependent fledglings was 46.3 m (range 6.1-401.5 m) and was fairly consistent with an overall increase in distance moved daily as the birds aged. The average distance travelled from the previous day's location for independent fledglings was 146.1 m (range 5.2-966 m) and it varied daily. Daily movements by independent birds were greater than for dependent birds. Mean daily distance from the nest for dependent juveniles was 25-50 m at ages 9-24 days, increasing to 350 m by day 31. Mean daily distance moved was 25 m or less at age 9-26 days with a maximum of about 120 m on day 30. Dependent fledglings remained within their natal territories for the first 2.5-3.5 weeks after fledging. Mean distance from the nest for independent juveniles was 0-50 m at age 34-44 days, then varied from 50 to 325 m at age 45-60 days with no apparent pattern. Independent juveniles travelled greater distances than dependent juveniles and crossed neighbouring territories on a daily basis. Territorial males are tolerant of unrelated juveniles. Young of the first brood have usually dispersed from the natal territory by the time adults are feeding young of the second brood. Independent fledglings congregate in loose flocks 3-4 weeks postfledging and both adults and juveniles remain in breeding habitat until they commence autumn migration (Perkins and Vickery 2001; Smith 1963; Vickery 2020).

Hovick et al. (2011) examined survival rates of fledglings in Iowa. The average survival period was 6.8 days (range 0-27 days) and the overall survival rate was 21%. Seventy-four percent of fledgling deaths occurred in the first 3 days. As fledglings aged, their survival rates increased. Survival rates increased rapidly over the first 4 days after fledging, became stable at 5-11 days, then increased for the remainder of the first 2 weeks. Young were most vulnerable shortly after leaving the nest because they were unable to make long flights, relied on their parents for food, and had high energy demands that could result in high thermal stress. Forb abundance and vegetation height had a negative but nonsignificant effect on daily survival rates, possibly because the Grasshopper Sparrow forages preferentially on bare ground and avoids tall dense vegetation. Survival rates were similar in burned and grazed grasslands. Predation accounted for 49% of deaths and an additional 31% died of exposure, usually within 3 days of fledging. In Montana and North Dakota, fledgling survival declined with increasing cover by dead vegetation which may have impeded movement or provided fewer food resources (Bernath-Plaisted et al. 2021).

MIGRATION

The subspecies of Grasshopper Sparrow that breeds in Ontario migrates to Florida and Jamaica in winter. It migrates at night but sometimes continues movement in the morning. It appears to migrate individually or possibly in small numbers. It does not form large conspecific flocks, but

during autumn migration it may join mixed-species flocks of other sparrows (Smith in Austin 1968; Vickery 2020).

In Maine and Massachusetts, males arrive 5-10 days before females and this is likely the case throughout its range. In Pennsylvania, males usually do not arrive in spring until the grass is tall enough to conceal them (Smith in Austin 1968; Vickery 2020). In southern Ontario, the Grasshopper Sparrow arrives in late April and early May, with the earliest records in mid-April (Black and Roy 2010; Curry 2006; Lancaster et al. 2004; Tozer 2012; Weir 2008). Autumn migration is more protracted but the Grasshopper Sparrow is seldom common during this period (Vickery 2020). Because it does not form flocks, does not sing at this time, and prefers grassy habitats, many move through undetected and there are few autumn records. In southern Ontario, it has been observed from early August until early November, but most migrants leave by late September (LaForest 1993; Lancaster et al. 2004; Weir 2008). There is a record for 1 January from Port Credit and 2 isolated records of vagrants overwintering at Port Credit and Brantford (Curry 2006).

Migration habitat is essentially identical to breeding habitat. The Grasshopper Sparrow is seldom seen outside of grasslands. In Ontario, it has also been observed at a sewage lagoon. In British Columbia, all nonbreeding-season records were from the breeding range, but it may occur in grass-dominated habitats near wetlands. Occasionally it may occur in shrubby fencerows and one was caught in a trap set in an elderberry thicket (Black and Roy 2010; Campbell et al. 2001; Smith in Austin 1968; Vickery 2020).

The Grasshopper Sparrow uncommonly strikes television towers during migration. At a Florida tower, 382 were killed during autumn migration compared with 19 in spring (Vickery 2020). It probably strikes other tall structures during migration.

James (1991) considered the Grasshopper Sparrow a rare migrant in Ontario.

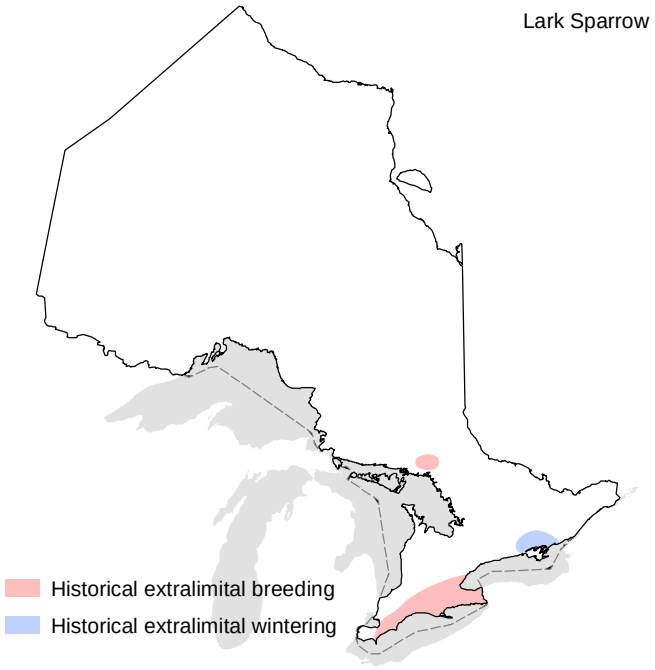
Lark Sparrow

Chondestes grammacus

BREEDING SEASON

Habitat Requirements

In Ontario, the Lark Sparrow has nested in coniferous plantations with scattered trees, in open deciduous woods in a city park, on a roadside bank, and in a garden hedge. At least half of nests were in areas with sandy soils (Peck and James 1987). Curry (2006) was of the opinion that it probably nested on the beach at Hamilton in 1885. At that time, the beach was ideal habitat consisting of mixed shrubs with open sand patches. Austen et al. (1994) concluded that suitable habitats probably included dry savannahs and prairies prior to extensive deforestation, assuming that it was actually present at that time. Later, roadsides, overgrazed pastures, and abandoned and cultivated fields provided suitable habitat. Most records for Norfolk County were from the St. Williams Forest where the Norfolk Sand Plain provided the dry sandy open scrubby grasslands that it prefers.



The Lark Sparrow is an open-country bird, with habitat requirements similar to those of the Vesper Sparrow. The Lark Sparrow is considerably less likely to nest in active agricultural land than the Vesper Sparrow. The Lark Sparrow is more of a shrub or woodland edge species than a true grassland species. In the core of its range, it commonly nests in grazed pastures and grasslands, particularly those with scattered shrubs or trees; shortgrass and mixed-grass prairies and, to a lesser extent, tallgrass prairies; shrubsteppe habitat; savannahs; open or park-like woodlands; brushy edges of woodlands, roads, and cultivated fields; desert scrub; grasslands with juniper or sagebrush cover; sand hills, dunes, and barrens; shelterbelts; and cultivated fields. It occasionally nests in gardens and near farm homesteads (especially those that are abandoned), in cemeteries, in orchards, in wet meadows, in abandoned pits and quarries; in city parks, on edges of towns; and in bare spots in lawns (Baepler in Austin 1968; Campbell et al. 2001; Crowell et al. 1982; Dechant et al. 2002f; Fitch 1958; Gier 1949; Graber and Graber 1963; Houston and Houston 2001; Jacobson et al. 2011; Leighton et al. 2002; Lusk et al. 2003; Martin and Parrish 2020; Mossman et al. 1991; Newman 1970; Rivers et al. 2010; Swanson 1996; Walcheck 1970; Wood et al. 2013).

At the macro level, the Lark Sparrow prefers areas with sandy or other nutrient-poor soils. These result in its preferred conditions of sparse low vegetation with scattered woody plants and patches of bare soil. In Illinois, it demonstrated no habitat preferences and its distribution appeared to be governed by the distribution of sandy and other poor soils. It exhibits a preference for ecotones between grasslands and forested habitat or between shrubby areas and forested habitat. These are often disturbed sites with exposed soils due to grazing, erosion, or recent fires; fallow fields may provide suitable habitat. It has an affinity for shrubsteppe with shrubs 1-2 m tall adjoining woodlands or grasslands. Upland grasslands are significantly preferred over lowland grasslands. Within areas of contiguous suitable habitat, it prefers sites that are slightly elevated. In Saskatchewan, it preferred drier northern valley slopes. In Colorado, it was typical of disturbed areas with more heterogeneous vegetation structure than areas inhabited by the Vesper Sparrow. In this area, it appears to avoid urban edges; it nests close to urban areas in other regions (Baepler in Austin 1968; Dechant et al. 2002f; Fitch 1958; Graber and Graber 1963; Houston and Houston 2001; Jones and Bock 2002; Lowther 1997; Martin and Parrish 2020; Swanson 1996).

In North Dakota, the Lark Sparrow decreased with increasing tree cover within 100 m in 400-m landscapes with both more and less than 30% tree cover. In open landscapes, its probability of observation initially increased, from 3% at 20% tree cover to 9% at 40% tree cover, but decreased to

7% at 70% tree cover. In wooded landscapes, its probability of occurrence was 10% at 10% tree cover, 14% at 40% tree cover, 1% at 70% tree cover, and 0% at 80-100% tree cover. It preferred landscapes that were 25-52% forested (Cunningham and Johnson 2016, 2019).

Some grassy cover is almost essential in territories, with grass coverage greatly preferred to herbaceous cover. Occasionally the Lark Sparrow nests in row-crop agricultural fields. Crop species such as peanuts provide the required nesting cover. Short sparse grasses with no or minimal litter cover are preferred to dense or tall grasses and areas with deep litter. Grazed grasslands are highly preferred over ungrazed areas. Grazing reduces grass height and density and provides more suitable habitat structure than undisturbed areas. Grazing also reduces litter coverage and may create areas of bare soils. Conservation Reserve Program (CRP) lands, where dense grass cover is provided for waterfowl and grassland species, seldom support the Lark Sparrow. In Arizona, it exhibited a significant preference for grazed areas. It was observed 50% of its time in grass shorter than 15 cm, 30-50% of its time in bare ground, and less than 3% of time in shrub canopy, although it usually occurred near shrubs. In Colorado, it preferred shortgrass and mixed-grass prairies to tallgrass prairies and hayfields (Dechant et al. 2002f; Lusk et al. 2003; Martin and Parrish 2020).

Scattered shrubs and trees are an important habitat feature. They provide singing perches for males and are occasionally used to conceal and shelter nests. Where woody vegetation is lacking in territories, boulders, elevated rock outcrops, or fence posts may be used as singing perches. In Montana, density on rock outcrops was 19 times higher than in sagebrush-grassland habitat. Outcrops supported patchy shrub communities and had large sumacs and other shrubs associated with them. These were used for perching, singing, and nesting. It exhibited a positive association with sumac and rock outcrops taller than 0.5 m. It was probably responding to the sumac which was closely associated with the average height of outcrops (Rumble 1987). Also in Montana, presence of creosote bush and sagebrush appeared to be essential in territories, but there were more specific habitat requirements associated with sagebrush. The Lark Sparrow forms a depression in the ground for nesting. The soil under sagebrush was more granular; soil under greasewood was more hardpan because its leaves fail to intercept rainfall. It preferred to nest under sagebrush. Total canopy coverage by shrubs was 64% (Walcheck 1970). Dechant et al. (2002f) reported that it avoided an area of shrubsteppe that was devoid of woody vegetation. In Nevada, it preferred areas of crested wheat grass that were invaded by sagebrush over areas dominated solely by wheat grass. Nonetheless, its abundance was negatively correlated with sagebrush density because it avoids pure stands of shrubs. In Oklahoma, it was correlated with the presence of red cedar and tolerated intermediate levels of canopy cover by this species. There were no relationships between its abundance and visual obstruction or percent grass cover (Chapman et al. 2004). In Washington, it preferred savannahs where shrubs were present but scarce and grasses dominated, particularly downy brome.

Some studies examined microhabitat preferences of the Lark Sparrow. Vegetation in the immediate vicinity of 1 Ohio nest was very sparse and consisted of very short crabgrass and scattered horseweed (Gier 1949). In Oklahoma, percent structural cover (any plant that provided nesting cover similar to woody plants), amount of bare ground, and percent litter cover were important parameters in determining nest location. When the distance to structural elements

exceeded 270 cm, locations became unsuitable for nests. Points with more than 87% bare ground, with more than 74% litter cover, or with less than 9% structural cover were unsuitable. Average nest-site variables included 5.0 m to a visual obstruction (6.0 m overall including nest and random sites), 2.8 mm litter depth (2.8 mm overall), 37.4 cm height of the tallest plant (34.2 cm overall), 3.0 screening cover class (2.9 overall), 8.0 cm to nearest structural element (31.7 cm overall), 16.0% bare ground (30.6% overall), 9.6% grass cover (10.0% overall), 9.1% forb cover (10.3% overall), and 41.6% structural cover (22.5% overall). Nests were shaded from sunlight 60% of the day and 40% at midday. Nesting near structural elements may reduce predation risk and lower temperature at the nest, with thermoregulation probably being the most important function (Lusk et al. 2003). Along the Platte River in Colorado, it spent the early part of the breeding season outside the floodplain in overgrazed weedy annual grasses and forbs with widely spaced cottonwoods. During the peak of the breeding season, it occurred at the fringe of the floodplain in sedges, rushes, willows, and cottonwoods in addition to overgrazed prairie habitat. In the western portion of its range, it may inhabit a variety of seral stages such as woodlands with less than 24% canopy closure, preferring deciduous trees to conifers, and grasslands with moderate to dense coverage of 40-100% (Martin and Parrish 2020). In North and South Dakota, it nests in wooded draws and small wooded areas dominated by green ash. It is an edge species in these woodlots where it is more common in early seral stages, but not significantly. Younger wooded areas had less canopy cover, a patchier canopy, less chokecherry in the understorey, lower basal area, and smaller trees than older stands (Faanes 1987; Rumble and Gobeille 1998). In California, it used oak savannahs significantly more than oak woodlands and montane hardwoods. Occupancy rates were 93% in savannahs with a grass understorey, 94% in savannahs with a shrub understorey, 46% in montane hardwoods, and 35% in oak woodlands. Its abundance was negatively correlated with hardwood and shrub coverage and positively correlated with herbaceous cover and large trees. Coverage by hardwoods was the habitat characteristic that most strongly influenced its occupancy. Wood et al. (2013) considered it an oak affiliate. Augustine and Baker (2013) compared Lark Sparrow usage of sites with and without black-tailed prairie dogs in South Dakota, Montana, and Wyoming. In eastern plots, there was no difference in its abundance off and on prairie dog colonies but in western plots it was significantly more abundant in areas without prairie dogs. Off-colony sites had significantly greater visual obstruction, more grass cover, more shrub cover, a higher percentage of bare ground, and more grass cover than on-colony sites. In Arizona, inhabited areas averaged 38% bare ground, 54% grass cover, and 7% forb cover with less than 2% canopy cover, an average grass height of 13 cm, and 0.068 shrubs per m^2. In Missouri, it was found on only 1 of 53 sites which was characterized by sparse litter and few (24-50 stems per ha) woody stems 2.5 cm diameter at breast height or less (Dechant et al. 2002f).

In Colorado, the Lark Sparrow occurred more frequently on plots 200 m from suburban edge than in plots closer to suburban areas (Dechant et al. 2002f). Suburban edges may support higher densities of predators than areas distant from edge.

It is unknown if the Lark Sparrow is area sensitive. It has been estimated that 10-100 ha of contiguous grassland is required to maintain a viable population (Swanson 1996), but there appears to be no documentation to verify these estimates.

Seven Ontario nests (87.5%) were on the ground and the other was elevated at a height of 1.1 m in a honeysuckle vine in a garden hedge. One nest each was below an overhanging bank, under a small pine, and under a fallen oak branch (Dale 1931; Peck and James 1987).

The Lark Sparrow may nest either on the ground or a short distance above it in a shrub or sapling. In California, Texas, and Oklahoma, more than 50% of nests were on the ground; ground-nesting is more frequent in the east. Ground nests are prepared by scraping a depression in the ground. Several scrapes may be made before one is chosen for the nest site. Ground nests are often in a bare or eroded site but under or very close to a shrub or tall herbaceous plant that provides some shade to the nest and aids in concealing it from predators. Some ground nests are completely exposed. In North Carolina, nests were orientated southeastward on areas with 3° or less slope. Mean heights of elevated nests in 2 areas were 1.46 and 1.39 m with maximum heights of 2-7.6 m; most nests are within 2.1 m of the ground. Favoured nest trees and shrubs include red cedar, pine, juniper, prairie rose, white cedar, black willow, hawthorn, oak, elm, raspberries, osage orange, and other species not found in Ontario. In Oklahoma, some nests were in green milkweed, red clover, greenbrier, and little bluestem. In California, 28 nests were in crevices in caves 1.5-3 m from the ground. In Oklahoma, nests were often in ornamental conifers near buildings, often only about 20 m apart. One nest was in a cavity in a dead black willow and another was under a cow chip that had been raised by grass. The chip completely surrounded the nest except for an opening to the southeast. It may reuse its own nest or another Lark Sparrow nest, with nest reuse most prevalent in Oklahoma and Texas. It may also use old nests of Scissor-tailed Flycatcher, Western Kingbird, Curve-billed Thrasher, Pyrrhuloxia, and Northern Mockingbird. Nests of the mockingbird and thrasher are used more often than those of other species (Baepler in Austin 1968; Campbell et al. 2001; Crowell et al. 1982; Dechant et al. 2002f; Gier 1949; Leighton et al. 2002; Martin and Parrish 2020; McNair 1984; Newman 1970; Swanson 1996; Walcheck 1970).

The Lark Sparrow is territorial, but typically only in the vicinity of the nest early in the breeding season. Most authors state that only the immediate area of the nest is defended but 1 Kansas pair had a territory that was 200 m wide. The male defended both boundaries against his neighbours. Even at the height of the breeding season, it may be gregarious, feeding in flocks distant from the nest site. It appears as though foraging areas are not defended. A Kansas pair had a home range larger than 6 ha but foraging was concentrated in small parts of it, usually within 30 m of a woodland edge or isolated trees. Individuals sometimes range over 10-100 ha to meet all their habitat requirements. During nest building and early incubation, both sexes drive away other Lark Sparrows. Once incubation is well underway, there is no response to other birds (Baepler in Austin 1968; Fitch 1958; Martin and Parrish 2020).

No information is available on natal philopatry and almost nothing is known about adult site fidelity. Five adults banded during the breeding season were recaptured in subsequent years in the same 10-minute block, indicating some degree of site fidelity. One bird was recaptured 8 years later where it was banded (Dechant et al. 2002f; Martin and Parrish 2020).

Limiting Factors

Nests with eggs have been found in Ontario from mid-May to early July, with most present from the last week of May until mid-June (Peck and James 1987). First nests take 3-4 days to build but later or

reused nests may take only 2 days. Usually a full day elapses between nest completion and laying of the first egg. At 1 nest, egg laying began after only 2 days of construction when the nest was still incomplete; the lining was added later. It is probable that 1 egg is laid per day. In first nests, incubation does not begin until the clutch is complete but it may start with the first or second egg in replacement clutches; incubation seldom starts before the penultimate egg is laid. The incubation period at 1 Ontario nest was no more than 11 days. Elsewhere, incubation periods of 11-12 days have been reported. The nestling period is 9-12 days but young may leave the nest as early as age 6 days if disturbed (Baepler in Austin 1968; Martin and Parrish 2020; Peck and James 1987).

It is probable that only a single brood is raised in Ontario. Double broods have been suspected or confirmed in other areas, but the Lark Sparrow typically raises a single brood. Many birds that successfully fledge young early in the season do not attempt to raise a second brood. Renesting is common if the first nest fails. In Ontario, clutches of 4 and 5 eggs have been reported (mean 4.50 eggs). Throughout its range, clutches of 3-6 eggs have been reported. Nests typically contain 4 or 5 eggs, with 3-egg clutches occurring occasionally and 6-egg clutches rare. In Oklahoma, the average size of unparasitized clutches was 3.63 eggs. Mean overall clutch size has been reported as 4.09 eggs (mode 4 eggs; Baepler in Austin 1968; Campbell et al. 2001; Martin and Parrish 2020; Newman 1970; Peck and James 1987).

The age at first breeding has not been confirmed but is probably 1 year. The mating system is typically monogamous. One instance of polygyny was reported in Saskatchewan where the females of a single male nested approximately 100 m apart (Baepler in Austin 1968; Martin and Parrish 2020).

The Lark Sparrow forages mostly on the ground for insects and seeds, but also gleans arthropods from low annuals and the lower stems and leaves of shrubs. It searches the litter for seeds, and insects on bare ground or among grasses, forbs, and shrubs. It tends to walk from 1 foraging location to another. Even during the breeding season, birds gather together in small flocks when foraging. Members of a pair tend to keep within a few metres of each other when foraging. At 1 Oklahoma site, the adults gathered food for their young from an unmowed lawn where the grass was 38 cm tall (Baepler in Austin 1968; Fitch 1958; Martin and Parrish 2020).

Prey fed to nestlings averaged 25 mm (range 24-26 mm) compared with an average of 13-14 mm for adults (range 5-23 mm). Caterpillars, short-horned grasshoppers, and crickets dominate nestlings' diets, with lesser numbers of adult beetles and brome grass seeds. Caterpillars may be the most important nestling food item; grasshoppers may be the most important food item for fledglings (Baepler in Austin 1968; Martin and Parrish 2020; Swanson 1996). Judd (1901) analyzed the contents of 167 stomachs. The food consisted of 73% vegetable matter, which was all seeds, and 27% animal matter, which consisted entirely of insects. Over half the vegetable food was seeds of grain and grasses, especially foxtails and panic grasses; it also ate Johnson grass. Grass seeds comprised 21% of the annual diet. It eats more grain than most other sparrows, with corn, wheat, and oats constituting 13% of the total diet; most was consumed in winter and was waste grain. Eight percent of the diet consisted of legumes such as clover and alfalfa. Fifteen percent of the food consisted of seeds of ragweeds and smartweeds that were about equal in abundance in the diet. The remainder of the plant food was made up of a variety of seeds, with wild sunflowers and purslane most prevalent; wood-sorrel, lamb's-quarters, and amaranths were a minor component of

the diet. More than half the animal food consisted of grasshoppers and they comprised 43% of the June diet. In the prairies and plains, it helped check invasions by the Rocky Mountain locust, which is now extinct. It ate fair quantities of weevils, but the amounts of other beetles and caterpillars consumed were far less than average for sparrows. Throughout its range during the breeding season, the Lark Sparrow eats more insects than seeds by biomass. Seeds are the predominant food when the weather is colder and insects are less available. It opportunistically exploits temporary or seasonally abundant prey such as irruptions of locusts or beetles. During outbreaks by the Rocky Mountain locust, this insect formerly constituted 91% of the diet; large quantities of alfalfa weevils are also consumed. An adult female in Kansas had eaten terrestrial snails in addition to insects and seeds. In shortgrass prairie in Nebraska where froghoppers and leafhoppers were numerically dominant, the diet consisted of 61% seeds and 39% insects. The insects were comprised of 60% short-horned grasshoppers, 13% adult beetles, 12% caterpillars, 5% locusts, 5% hymenopterans, and a few bugs, flies, and froghoppers. There was an increase in consumption of short-horned grasshoppers as the season progressed from June to August. Prey less than 15 mm in length was avoided and intermediate-sized prey (15-35 mm) was selected (Baepler in Austin 1968; Kaspari and Joern 1993; Martin and Parrish 2020).

The Lark Sparrow is commonly parasitized by the Brown-headed Cowbird. When a parasitic egg is added to an incomplete clutch, the nest may be abandoned. Once incubation has started, eggs are more likely to be accepted. Cowbird eggs may be too large for sparrows to eject them. The effects of parasitism on the Lark Sparrow are unknown. It is capable of fledging both its own young and cowbirds, but it is likely that reproductive success is reduced as a result of cowbirds ejecting sparrow eggs. Parasitism rates are variable, even within the same general area. In Ontario, 1 of 8 nests (12.5%) was parasitized. In Oklahoma, 7 of 11 ground nests (63.6%) were parasitized compared with 8 of 22 elevated nests (36.4%). Ground nests were in pastures where they were probably more accessible to cowbirds, and cowbirds were more abundant in this habitat. In 2 Oklahoma studies, 15 of 33 nests (45.5%) and 4 of 21 nests (19.0%) were parasitized. Other parasitism rates include 12 of 17 nests (70.6%) in Kansas, 7 of 30 nests (23.3%) in Illinois grasslands, 1 of 17 nests (5.9%) and 9 of 11 nests (81.8%) in unspecified areas, and 1 of 25 nests (4.0%) in British Columbia. Second broods or replacement clutches are seldom parasitized (Baepler in Austin 1968; Campbell et al. 2001; Dechant et al. 2002f; Martin and Parrish 2020; Newman 1970; Peck and James 1987; Peer et al. 2000; Rivers et al. 2010).

In South Dakota, habitat loss due to increasing agricultural use over a 6-year period was considered the major factor in the Lark Sparrow becoming rare or absent in parts of the state (Swanson 1996). Agricultural intensification, urbanization, and succession to forest are probably largely responsible for its withdrawal from much of eastern North America (Martin and Parrish 2020).

Nest success can be affected by a number of factors. In Oklahoma, nests above ground were significantly more successful (44.5%) than those on the ground (23.7%). Above-ground nests were better protected from the elements and less likely to be depredated. Snakes were the main predators and they may be more likely to find ground nests. Successful nests were associated with less bare ground and had one third of the coverage by bare soil of unsuccessful nests. Successful nests had 2 times the litter coverage as unsuccessful nests. There was more variation in structural

coverage at successful nests (18.1-57.1%) than at unsuccessful nests (35.1-55.2%; Lusk et al. 2003; Newman 1970). A high rate of nest failure occurs when reusing nests built by other species due mostly to aggressive behaviour of the other species (Martin and Parrish 2020).

Grazing is usually beneficial to the Lark Sparrow because it reduces grass height and density and may create areas of bare soils. In Oklahoma, Lusk et al. (2003) studied plots on a pasture where no grazing had occurred for more than 50 years, on pastures moderately grazed with 0.2 animals per ha, and on heavily grazed pastures with 0.4 animals per ha. Of 40 nests, 2 (5%) were in the control pastures, 22 (55%) were in moderately grazed pasture, and 16 (40%) were in heavily grazed pasture. Among successful nests, 0% were in the control pasture, 60% were in moderately grazed pasture, and 40% were in heavily grazed pasture. In Kansas, Fitch (1958) reported that it was formerly more abundant when livestock grazing kept the herbaceous vegetation cropped short. In Arizona, higher nesting densities occurred on grazed than ungrazed semi-desert grasslands (Swanson 1996).

Fire may be either beneficial or detrimental depending upon the intensity of the fire and whether it occurs in native or nonnative grasslands. Long-term fire suppression allows communities to develop dense stands of grasses and shrubs, reducing the amount of edge habitat and bare soils that the Lark Sparrow prefers. In stands of nonnative grasses and weeds, fires are more intense and frequent, further promoting growth of nonnative species. A Utah fire removed dense living and dead annuals, exposed bare soils, and left standing snags. Numbers of adults and juveniles remained high in the 2 years following fire. In the third year, annual weeds had increased enough that the Lark Sparrow abandoned nesting attempts except in areas that were burned again. In Texas, burns that completely eliminated woody vegetation negatively affected it and its nesting success. In Montana, only minor reductions occurred where shrubs were partially killed but areas where all sagebrush was killed were avoided. In Texas, nest survival rate was negatively correlated with the frequency of burning. In Utah, it increased at an artillery training area where contiguous juniper and shrubsteppe vegetation was fragmented by fires and roads. On Kansas CRP lands, abundance was significantly higher on lands that were burned in the spring than in unburned fields. In Arizona desert grasslands, it increased 2 years postburn and its abundance was positively correlated with herbaceous cover. In a Washington fire in shrubsteppe habitat, it increased shortly after fire but the increase was short-lived. The increase immediately after fire may have been a result of an increase in the amount of bare ground. In summary, fire that retards natural succession and lowers the amount of litter and dead and alive vegetation and creates patches of bare ground is beneficial; intense fires that kill all woody cover are detrimental (Dechant et al. 2002f; Earnst et al. 2009; Jacobson et al. 2011; Martin and Parrish 2020; Roberts et al. 2012).

A number of miscellaneous factors may affect the Lark Sparrow. Precipitation may adversely affect it; some Oklahoma nests were washed away by heavy rains and in Washington fewer individuals were recorded in wetter years (Earnst et al. 2009; Newman 1970). There are large annual variations in its breeding density. These are likely related to overwintering survival. Grasshoppers are a major food item and it has declined in response to intensive grasshopper control measures using pesticides (Martin and Parrish 2020). In British Columbia, it may be adversely affected by recreational vehicles (Campbell et al. 2001).

In Alberta, Nixon et al. (2016) predicted the effects of climate change on the Lark Sparrow. They projected that the area of suitable habitat would increase by 250% by the 2050s and 400% by the 2080s. Suitable climate was expected to expand to the north with little change in the south, resulting in an expansion in occupied range.

Several management recommendations have been proposed for the Lark Sparrow. For Oklahoma, Lusk et al. (2003) recommended that management should attempt to provide moderate levels of litter accumulation and bare ground. Maintaining bare-ground coverage below 12% should increase nest success. Increased structural cover should also increase the attractiveness of habitat and decrease the distance between nests. Dechant et al. (2002f) concluded that the keys to management included providing open grassland with sparse to moderate herbaceous and litter cover and allowing moderate grazing or occasional burning. They recommended conducting burns before it arrives in spring at intervals of 5-8 years and retaining approximately 10% shrub coverage.

Status

During a brief eastward expansion of its range, the Lark Sparrow was a rare and irregular breeder in Ontario. The first report of it in Ontario occurred near Hamilton in 1862. In June 1885 a male and 2 females were seen on the Hamilton beach and these may have nested. Some birds were observed as far north as Sault Ste. Marie in 1880 and as far east as Toronto in 1891. It was a rare and very local summer resident in Toronto by 1907 where nesting was confirmed in the oak plains in High Park in 1898 and 1899. From 1878-89, 1 or 2 pairs nested regularly near London. It was rare at Point Pelee in the 1900s although it was believed to have been common there previously; nests were found there in 1884, 1905, and 1913. A pair was seen near Komoka in 1900. There were no further breeding season records until a nest was found near Walsingham in 1930. Prior to the first atlas, breeding had been confirmed only from Toronto, Sudbury District, Chatham-Kent, and Essex, Middlesex, and Norfolk counties. At that time, the last confirmed breeding record was a nest on the Norfolk Sand Plain in 1976. The nest found at Sudbury in 1973 is the northernmost confirmed record. During the first atlas, the only record was of a pair east of Thunder Bay seen in 1982. No other records were obtained during the subsequent Ontario Rare Breeding Bird Program (Austen et al. 1994; Baillie 1967; Baillie and Harrington 1937; Curry 2006; Dale 1931; Fleming 1907; Hussell in Cadman et al. 1987; McIlwraith 1894). James (1991) considered the Lark Sparrow an occasional rare summer resident in the south north to Bruce County and Durham Region and in Sudbury. There are summer records from Atikokan, Thunder Bay, and Moosonee.

During the second atlas, no breeding records for the Lark Sparrow were obtained. Documentation was received for 7 records, all involving apparent vagrants (Sutherland in Cadman et al. 2007).

Prior to European settlement, the Lark Sparrow nested eastward only to the prairies and Great Plains. With deforestation, it spread its breeding range as far east as the northern and central states. This range expansion was short-lived, with it withdrawing from the east to its original range as a result of more intensive agriculture, urbanization, and natural succession of marginal farmlands to forest. Its status in Ohio was very similar to what occurred in Ontario. It expanded into Ohio in the late 1880s and was common in several areas by 1900. It began declining there during the 1930s and disappeared from much of its former range by 1965. The Breeding Bird Survey indicates that the Lark

Sparrow decreased significantly at a rate of 2.5% per year from 1966 to 2004. This was attributed to the withdrawal from the east with populations in the western United States remaining stable or increasing slightly (Graber and Graber 1963; Houston and Houston 2001; Leighton et al. 2002; Lusk et al. 2003; Martin and Parrish 2020; McCracken 2005; Swanson 1996).

The greatest limiting factor to the Ontario breeding population of Lark Sparrows is the general contraction of its range from the east. Even when it was more widespread, Ontario was on the extreme outer limits of its range. Due to its current almost complete absence in the states south of Ontario (New York, Pennsylvania, Ohio, and Indiana), it is unlikely that it will re-establish itself as a breeding species in southern Ontario. If breeding occurs in future in Ontario, it will most likely be in the northwest. There are currently populations in southern Manitoba and northern Wisconsin that are potential sources of breeding birds.

POSTFLEDGING PERIOD

If undisturbed, young are capable of flight when they leave the nest. They are led to more shrubby areas by adults after fledging. In Ohio where a pair nested in a garden, the adults and young remained in or near the garden for at least 3 days. Almost immediately after fledging, some adults leave the breeding grounds; this may occur as early as mid-July or August. Mixing of migratory adults with adults that are still breeding is common in late summer. In Oklahoma after fledging, most pairs joined other families in flocks in nearby fields. Flock sizes increase as the summer wanes and flocks may be joined by other species such as the Field Sparrow. In British Columbia and probably elsewhere, similar open habitats were used during the postfledging period and migration. These included beaches, trails, brushy edges of fields and hedgerows, urban lawns, weedy fields, and feeders (Baepler in Austin 1968; Campbell et al. 2001; Gier 1949; Leighton et al. 2002; Martin and Parrish 2020).

MIGRATION

During migration, and particularly in autumn, the Lark Sparrow occurs in conspecific or mixed-species flocks that may contain 40-50 individuals in September and October (Griscom 1948; Martin and Parrish 2020).

In the southern portion of the Lark Sparrow's range, males arrive 30 or more days before females. Timing of arrival of the sexes has not been documented in Ontario but it is unlikely that males would arrive here much more than a week before females. There are few spring records, so the timing of spring migration is somewhat unclear. Throughout the province, spring records span the period 3 April to 29 May (Black and Roy 2010; Fleming 1907; LaForest 1993; Lancaster et al. 2004; Martin and Parrish 2020; Speirs 1985; Tozer 2012; Weir 2008). In Algonquin Park, autumn migrants have been observed from 3 September to 13 October (Tozer 2012). In the Kingston area, average departure is 6 October and the extreme dates are 2 September to 22 December, excluding an overwintering bird (Weir 2008). The only recent autumn record in Hamilton was on 15 August (Curry 2006). In Elgin County, autumn migrants have been reported from 19 September to 1 November (Lancaster et al. 2004).

Migration habitat is very similar to breeding and postfledging habitat. A spring migrant at Presqu'ile foraged on mowed grass along the park road and perched on roadside wires (LaForest 1993). In Algonquin Park, a spring migrant fed on seeds below a feeder. Autumn migrants were seen

on the grassy tile bed of the museum, along a roadway on the abandoned airfield, and along the weedy edge of a large field (Tozer 2012). In British Columbia, migrants inhabit beaches, trails, shrubby edges of fields and fencerows, urban lawns, weedy fields, and feeders. Habitat similar to that inhabited during the breeding season may also be used including shrubsteppe grasslands and grazed pastures (Campbell et al. 2001). In Kansas, spring migrants foraged where bluestem prairie had been burned the previous month and new growth of grass was beginning to appear (Fitch 1958). In the heart of its range, autumn migrants may be found in open cottonwood stands, floodplains with dense vegetation comprised predominantly of small cottonwoods and weedy annuals, and overgrazed prairies. At this time, migrants and residents mix together (Martin and Parrish 2020).

Baillie (1967) stated that the Lark Sparrow was still rarely observed during migration, mostly along the Lake Erie shoreline. James (1991) considered it a rare migrant. Because it no longer occurs anywhere within the province regularly during migration and may be completely absent for many successive years, it might better be described as a vagrant during migration.

WINTER

James (1991) considered the Lark Sparrow a vagrant in Ontario during winter. One remained in the Kingston area from 30 November to 22 March (Weir 2008), the only known overwintering attempt.

Chipping Sparrow

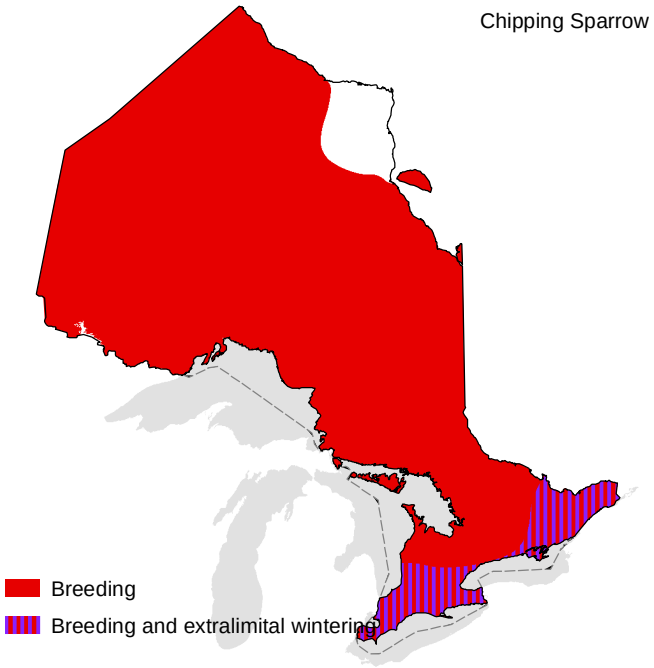
Spizella passerina

BREEDING SEASON

Habitat Requirements

Ontario Chipping Sparrow nests were in residential gardens and farmyards (55.6% of nests); in wooded areas, including natural coniferous stands and plantations (12.8%), mixed stands (4.3%), and deciduous stands (2.1%); in overgrown fields and pastures, orchards, vineyards, and nurseries (10.4%); in parks, campgrounds, and cottage lots (7.2%); in other rural and urban habitats including schoolyards, cemeteries, golf courses, tennis courts, parking lots, and gravel yards (2.9%); on road and railway rights-of-way (2.7%); in treed sand dunes (1.6%); and in treed bogs (0.5%). Most nesting habitats were dry and almost invariably contained trees and shrubs. Nests in wooded areas were usually in areas of open canopy or at edges (Peck and James 1987).

In the Hudson Bay Lowland, the Chipping Sparrow was a common breeder in the Moosonee area, particularly around the town site (Wilson and McRae 1993).



In the Boreal Forest Region from Pickle Lake north to the Manitoba border, the Chipping Sparrow was most abundant in deciduous and coniferous scrub followed by mixed scrub and coniferous forest with a deciduous understorey, coniferous forest without an understorey, and heath. It was absent in deciduous forest and tundra (McLaren and McLaren 1981). It occurred in disturbed or open mixed woods and about towns in the Pickle Lake area (James 1980). Near Hearst, it occurred in low density in a 9-year-old clear-cut in coniferous lowland forest (Welsh and Fillman 1980). Near White River, it was much more abundant in stands cut 8-10 years previously than in stands 3-5, 13-15, 18-20, 23-25, and 4-10 years old. It was an indicator species of 8-10-year-old stands (Venier and Pearce 2005). Near Manitouwadge, highest densities occurred in stands 1-21 years old; it was uncommon in stands 24-36 years old and absent in stands 60-223 years old (Venier et al. 2009). It occurred both in forests and around settlements in the Clay Belt (Smith 1957). In the same physiographic region, it was most abundant in stands dominated by jack pine followed by those dominated by white spruce, trembling aspen–white birch (often mixed with spruce), black spruce, and balsam poplar. It occurred in both nutrient-poor and nutrient-rich sites, mostly in wetter areas (Welsh 1993; Welsh and Lougheed 1996).

In the Canadian Shield in the Great Lakes–St. Lawrence Forest Region, the Chipping Sparrow occurred in both old-growth and mature white pine stands (Kirk et al. 2012). In Quetico Park, it was equally abundant in 1-23-year-old jack pine stands with scattered black spruce and trembling aspen regeneration and 67-73-year-old jack pine–poplar stands; half as abundant in 112-176-year-old stands of jack pine, poplar, spruce, and balsam fir, and absent in 367-370-year-old stands of white pine, red pine, spruce, balsam fir, and white cedar (Apfelbaum and Haney 1985). Near Gogama, it was characteristic of jack pine stands where it preferred openings and edges and avoided closed-canopy areas. It first appeared when trees attained an age of about 10 years. Although it occurred in all older stands, it reached its maximum abundance when trees were about 20 years old when there were still numerous openings in the canopy that allowed shrub growth (James and Peck 1995a). In jack pine stands near Parry Sound, it was one of the most abundant species. These were very open stands mixed with deciduous tree species and contained numerous bedrock outcrops (James 1979a). The Chipping Sparrow was one of the most common breeding birds in Parry Sound and Muskoka districts where it nested in residential and rural areas, along road sides, and at forest edges (Mills 1981). In largely forested areas near Restoule Park, it appears to prefer to nest in areas of open bedrock outcrops with scattered white spruce (personal observation). Middleton (2020) reported that it nested in habitats dominated by white spruce, white pine, and balsam fir in

Algonquin Park. MacLulich (1935) observed that it was common in more open areas in the park but absent in unbroken forest. It frequented trees in clearings, edges of woods, and burns. Tozer (2012) noted that it was less abundant in the western portion of the park that is dominated by hardwoods than in the conifer-dominated east side. Nesting habitat included clearings, forest edges, road margins, gravel pits, clear-cuts, logging landings, open coniferous forests, open areas around buildings, campgrounds, and open shorelines of rivers, lakes, and ponds. Kingsley and Nol (1999) determined that it was associated with coniferous non-white pine habitat in the park. There was no difference in its abundance in stands with no recent history of cutting and those that had been cut 2-9 or 10-16 years previously. Martin (1960) documented the Chipping Sparrow breeding in hemlock stands in the park. Also in Algonquin Park, the dominant plants and trees within 1 m of nests were typically early successional species that occurred in well-drained areas. The frequency of tree species nearest nests was 45% white spruce, 11% trembling aspen, 8% balsam fir, 8% white pine, 8% black cherry, 5% red pine, 2% red maple, and 2% sugar maple. The frequency of plant species within 1 m of nests was 91% white spruce, 82% grasses (mostly poverty oat grass), 45% haircup moss, 45% lowbush blueberry, 14% balsam fir, and 6% red pine (Reynolds and Knapton 1984).

At Presqu'ile in the off-Shield portion of the Great Lakes–St. Lawrence Forest Region, the Chipping Sparrow favoured coniferous plantations for nesting and commonly nested around residences. It also nests in open woodlands, open areas near forests, or open areas with scattered trees (LaForest 1993). In Durham Region, highest densities were in a mature pine plantation dominated by red pine but that contained some white pine. It also occurred in a black spruce bog fringed with white spruce and tamarack; low densities occurred in mature beech–sugar maple forest. Speirs and Orenstein (1975) considered it associated with conifers, particularly pines. On the University of Guelph campus, it nested in open grassy areas surrounded by extensive plantings of species such as maples, crabapples, cherries, plum, junipers, pines, spruces, yews, and white cedar (Middleton and Prescott 1989).

In the Carolinian Forest Region, it was common on the University of Western Ontario campus at London (Scott and Lemon 1996). In Hamilton, it was the most common bird around buildings until the arrival of the House Sparrow. Although it declined with increased populations of House Sparrows, it continued to nest in gardens, shade trees in cities, and weedy corners and thorn bushes in pastures (McIlwraith 1894). In Elgin County, it frequently occurs around rural and urban homes (Lancaster et al. 2004).

The tree species it uses vary geographically but the Chipping Sparrow nests in similar habitat throughout its range. It is more abundant in suburban areas and around rural residences, orchards, and farms than in undisturbed areas. Park-like streetscapes and landscaped urban and rural residential areas often provide ideal habitat. In the north, it may be more common around isolated human habitation than in natural habitat, and may occur around cottages, hunting and trapping camps, and along roads through boreal forests. In more natural habitats, it prefers open woodlands, edges of natural forest openings, margins of rivers and lakes, and shrubby weedy fields. It prefers groves and open glades of coniferous forests for nesting and shrubby open areas for foraging and is well adapted to human-altered habitats. It may be the most abundant species in areas with ornamental plantings and in coniferous plantations, including Christmas tree plantations. In the

southern portion of its range, it inhabits a variety of deciduous forest types but retains its affinity for nesting in shrubby habitats with conifers. Mixed pine and oak stands provide suitable habitat in the south (Middleton 2020).

In Quebec, the Chipping Sparrow is most common where urbanization and agriculture have created open habitat. It breeds in urban residential areas, city parks, cemeteries, golf courses, farm fields, coniferous and Christmas tree plantations, and road and hydro rights-of-way. It occurs mostly in openings, woodland edges, and clumps of trees bordering open grassy areas. A few conifers appear to be required because it frequently nests in them. It needs a certain minimum amount of open space in its territory. The small yards typical of new subdivisions may not be large enough to support it (Perreault and Barrette in Gauthier and Aubry 1996). Mousley (1916a) reported that it could be found nesting around every farm home in Quebec as well as throughout the agricultural south. It is one of the typical species in the Boreal Forest Region. It is frequent in jack pine stands and among the species most commonly detected in tamarack stands and bogs. It is characteristic of human-altered habitat including settlements, alpine ecotones with boreal forest, prairie-forest ecotones, and open bogs with scattered trees. In poplar-birch stands, it is associated with openings or young growths of deciduous species. In addition to open pine stands, it also occurs in those dominated by spruce and balsam fir and occasionally is present in hemlock stands (Erskine 1977). In the Prairie Provinces, the Chipping Sparrow was most abundant in black spruce or jack pine stands. It occupied sites that tended to be drier and nutrient-poor. Kirk et al. (1996) considered it an early successional species, being most abundant in stands 15-20 years old. In trembling aspen forests in Alberta, it was equally abundant in young and mature stands. It was more abundant in old stands, but not significantly. Old stands had more conifers in the understorey, possibly making them slightly more attractive (Schieck et al. 1995). In British Columbia, it breeds in a variety of shrubby habitats where it usually occurs in open spaces and is often associated with edges of both coniferous and deciduous forests, wetlands, clear-cuts, and agricultural areas. Seventy-two percent of nests along the coast were in areas modified by humans, including 27% in suburban areas and 15% on farms. Other breeding habitats include open fir and oak stands, open coniferous forests, deciduous woodlands dominated by birch, subalpine grasslands and meadows, rangeland, grass or sedge meadows, trembling aspen stands, and wetlands surrounded by patches of willow, alder, and birch (Campbell et al. 2001). In the Yukon, it inhabits open forests that are mostly in lowland areas. These include mixed forests with some spruce, shrubby woodlands with openings, areas above the treeline, and mature trembling aspen forests where it is the most abundant songbird (Sinclair et al. 2003). In the United States, the Chipping Sparrow is abundant in urban and suburban areas. In Illinois, almost every yard that has a blue spruce supports a pair. In that state and others in the Midwest, it is common in savannah-like habitats and may also occur in a variety of woody and old-field habitats. It may be one of the most abundant species in coniferous plantations and in Scotch pine plantations managed for Christmas tree production. These short but dense trees within open habitat provide ideal conditions. Other habitats used for breeding include open pine stands, shrubby fields with scattered trees (particularly if red cedar or other conifers are present), clear-cuts, open deciduous and mixed stands including riparian vegetation, small woodland openings, mixed tallgrass prairie, savannahs with either grass or shrub understorey, montane meadows, aspen stands in the west, hydro rights-of-way, black spruce bogs, and pine and pine-oak barrens (Allaire and Fisher

1975; Beals 1960; Bielefeldt and Rosenfield 1994; Brush 1987; Buech 1982; Capen 1979; Dawson 1979; Flack 1976; Graber and Graber 1963; Hebrard 1978; Hoffman 1989a; Hughes and Hudson 1997; Mossman et al. 1991; Niemi and Hanowski 1984a; Noon et al. 1979; Ortega and Ortega 2001; Rotenberry and Wiens 1980; Rumble and Gobeille 1998; Samson 1979; Simmons and Sloan 1974; Stull in Austin 1968; Swanson et al. 2004; Taylor and Taylor 1979; Temple et al. 1979; Walk et al. 2011; Walkinshaw 1944; Wood et al. 2013; Yahner et al. 2002).

At the landscape level, abundance of the Chipping Sparrow in southern Ontario was positively correlated with the amount of forest cover within 2 km and the amount of regional forest cover, but not significantly (Austen et al. 2001). In Saskatchewan, it occurred both in fragmented and forested landscapes. It was more common in large forest fragments where there were low amounts of forest cover within 5 km (Hobson and Bayne 2000). It preferred landscapes that were 33-59% forested in North Dakota and 44-58% forested in New York (Cunningham and Johnson 2019).

Several studies examined microhabitats of the Chipping Sparrow. In the northeast, it was in a guild that was common in mature coniferous upland forests, uncommon in mature coniferous lowland forests, and rare in alder thickets, mature deciduous upland forests, disturbed shrub habitat, young plantations, aspen regeneration, and recent clear-cuts (Niemi and Pfannmuller 1979). In North Carolina, its abundance was negatively correlated with canopy closure (Lumpkin and Pearson 2013). In Saskatchewan, it was significantly more abundant in spruce and mixed forests than in trembling aspen forests (Hobson and Bayne 2000). In Pennsylvania, it occurred in 90.9% of old-growth mixed forests, 97.1% of forests statewide, and 93.1% of forests in the Appalachian Plateau. Haney (1999) considered it to have neutral affinities with old-growth forest. In Massachusetts suburban habitat, coniferous shrub volume 3.4-4.6 m from the ground was the most important variable in determining its abundance. It was associated with conifers as tall as 4.6 m with little overstorey, and open grassland or lawn (Thomas et al. 1977). In British Columbia, it strongly selected for nest patches with more vegetation, particularly deciduous shrubs. It nested in habitats with open canopies, choosing patches with greater percent coverage by shrubs, high numbers of stems of deciduous trees that preferred dry sites, and areas with high numbers of pine and fir stems. It consistently selected nest patches with more deciduous vegetation than was available. It chose patches with conifers for nesting but also areas with deciduous vegetation that provided sources of seeds and ground-dwelling invertebrates (Easton and Martin 2002).

Freemark and Collins (1992) classified the Chipping Sparrow as a forest edge species. In Arizona, Battin and Sisk (2011) restored thinned pine forest and conducted prescribed burns, reducing the basal area by 45% and the density of pines by 80%. It was significantly more abundant in the treated area, with detectability 91% greater in the treated area. In the treated area, it occurred throughout the habitat and demonstrated no preference for edge. In the untreated forest plot, it was significantly more abundant near edge.

The Chipping Sparrow is not an area-sensitive species. In southern Ontario, its abundance was negatively correlated with woodlot size and the amount of forest habitat 100 m or more from edge, but not significantly (Austen et al. 2001). In Saskatchewan, its abundance was not correlated with forest size, although it was more common than expected in mature white spruce stands that were large but isolated (Hobson and Bayne 2000). In Maryland and Delaware, it was equally abundant in

riparian forests 50, 100, 200, 300, and 800 m wide (Keller et al. 1993). In Minnesota, Howe (1979) found it nesting on islands as small as 0.4, 0.9, and 1.1 ha.

In Michigan suburban habitat, 1 female roosted overnight in a dense white cedar 1.2 m from the nest and another roosted in a dense clump of lilacs 13.7 m from the nest. Males often roosted in white cedars (Walkinshaw 1944).

Most Ontario nests (98.2%) were elevated in living trees, shrubs, and vines. Eight species of coniferous trees and shrubs supported 88.0% of elevated nests. Twenty-nine species of deciduous trees, shrubs, and vines were used, but supported only 12.0% of nests. The most frequently selected species used for nesting were spruces (90 nests), pines (80 nests), junipers (48 nests), white cedar (37 nests), hawthorns (30 nests), balsam fir (15 nests), and elms (12 nests). Many nests in gardens were in hedges. Nests in vines or roses were often on trellises or against a wall. Single nests were found among the branches of a fallen pine, on a willow stub, on an apple tree stump, on the ground in a clump of red clover, in a clump of goldenrod, in an implement shed, in a notch in the side of an upright timber, and in the corner of a barnyard rail fence. Tree and shrub nests were on lateral branches or in crotches and were more often away from the trunk than near it. Distances from trunks were 0.5-4.6 m, with most nests 0.9-2.4 m from the trunk. Heights of elevated nests were 0.2-15 m with most 0.9-2.2 m from the ground (Peck and James 1987). Reynolds and Knapton (1984) described 22 nests from Algonquin Park: 19 were in white spruce and 1 each were in hemlock, balsam fir, and red pine. Usage of spruce (86.4% of nests) was greater than its availability (42.5% of trees). The median height of nest trees was 2.5 m (range 1.1-13.7 m) and this did not differ significantly from nearby trees. The median height of nests was 1.1 m (range 0.4-2.5 m). Successful nests averaged 1.51 m in height (range 0.64-2.46 m); unsuccessful nests averaged 0.69 m in height (range 0.38-1.30 m). Orientation of successful nests averaged 158.1°, significantly different from unsuccessful nests (28.7°). Successful nests averaged 4.8° from the mean whereas unsuccessful nests averaged 124.6° from the mean; mean orientation was 153.3°. Most nests were positioned so that they were exposed to the early morning sun. Prevailing winds were from the northwest and the southeastern orientation may have offered some protection. In Muskoka and Parry Sound districts, the Chipping Sparrow nested mainly in conifers at heights of 0.3-12 m. Average nest height was 1.5 m but those in white pine were higher. Nests were also in white elm, juneberry, and a deciduous shrub in a gravel pit (Mills 1981). Middleton (2020) summarized the characteristics of 224 nests on the University of Guelph campus. Conifers supported 87.9% of nests and 12.1% were in deciduous trees and shrubs. Spruce was the preferred nesting substrate, supporting 32.7% of nests, followed by pine (23.0%), juniper (20.6%), white cedar (5.5%), yew (4.3%), and larch (1.7%). The most preferred deciduous tree was crabapple (3.9% of nests), followed by maple (2.0%), and a variety of ornamental trees, shrubs, and vines (3.6%), including hawthorn, beauty bush, currant, and English ivy. Mean nest height was 2.6 m (range 0.5-10 m). There was a tendency for nest height to increase with the season, but this trend was not significant. No preference for orientation was exhibited at Guelph where trees were often sheltered by buildings. Overhead cover was not essential for nests. Those in pine and spruce were often uncovered; those in cedar, juniper, and deciduous species were covered. In 15 years at Guelph, there were no records of the same nest being used more than once in a season (Middleton and Prescott 1989). In Michigan, there were 2 cases of the same nest sites being used in the same season after the first nests were intentionally removed, and the same nest site may be

used in subsequent years. Many nests are abandoned during the nest-building and egg-laying stages and materials from them may be used to construct a new nest.

Where available, conifers are highly preferred for nesting; in deciduous stands in Colorado, 77% of nests were in oaks. Spruces, pines, cedars, firs, junipers, and yews are most frequently selected for nesting. In addition to the nest-species reported in Ontario, the Chipping Sparrow has nested in spiraea bushes, rose bushes, horse chestnut, pear, apple, grape, cottonwood, birch, willow, and red-osier dogwood. Nests in ornamental trees and shrubs are often very close to human dwellings. Nests are usually 1-2 m from the ground. In Michigan, mean nest height in suburban areas was 1.09 m in May, 1.53 m in June, and 2.29 m in July. In a Michigan Christmas tree plantation, mean nest height was 1.43 m, significantly higher than for Clay-colored and Field sparrows. In Colorado, the Chipping Sparrow tended to nest at one third of the pine height two thirds of the way out the branch. Mean nest height was 2.55 m. Nests were in clusters of pine needles on outer branches an average of 1.36 m from the trunk and 0.58 m from the tip of the branch. Average orientation of nests was 155.7°, almost identical to what was reported for Algonquin Park, and nests were significantly clumped around the mean. In a Vermont Christmas tree plantation, nests in trees 1.5-2.0 m tall averaged 0.8 m from the ground (range 0.3-1.1 m). All these nests were next to the tree trunk, which probably provided shelter from the wind. In British Columbia, nests were 0-9 m from the ground, but mostly 0.8-2.2 m up. In Minnesota, 61.5% of nests were less than 1.8 m from the ground and 13.3% were higher than 3.4 m. In a Minnesota bog, it nested in tops of black spruce at heights of 16.6 m and 17.2 m. The highest nest reported was 19.1 m up in the top of a maple overgrown with vines in Pennsylvania. Most Yukon nests were about 0.5 m from the ground (range 0.1-4.5 m). The Chipping Sparrow rarely nests on the ground. In green ash woodlands in South Dakota, all nests were on the ground, and many Alberta nests were on the ground. Unusual nest locations include on a mowing machine in a semiopen tool shed, on the sides of old stacks of straw, in a moss-filled hanging basket, in pepper plants hung to dry, and 10 cm down from the opening of a Hairy Woodpecker winter roost hole. Some British Columbia nests were in fallen trees, against a rock, or on the ground sheltered beneath a clump of vegetation (Allen 1939; Buech 1982; Campbell et al. 2001; Fillmore and Titman 1977; Harrison et al. 2005; Hughes and Hudson 1997; Leighton et al. 2002; Middleton 2020; Ortega and Ortega 2001; Rumble and Gobeille 1998; Sinclair et al. 2003; Stull in Austin 1968; Swanson et al. 2004; Walkinshaw 1944, 1952, 1959).

Males commence territorial defence as soon as they arrive in spring. In Algonquin Park, males sang from conspicuous perches, usually in white spruce or balsam fir. The female may defend an area around the nest tree and occasionally assists in territorial defence. Territorial disputes were frequent in mid-May in Algonquin Park but declined progressively thereafter. No territorial behaviour was observed after mid-August in a Michigan suburb. Even during the height of territoriality, 2 males may sit on opposite sides of a tree. Pairs may share feeding areas outside territories and feed close to each other, yet each male defends a discrete territory. In natural areas, territories tend to be compact and contiguous. In settled areas, territories tend to be discontiguous with boundaries imposed by urban landscaping. In suburban Michigan, territories were 0.4-0.6 ha. Most territories are 0.2-1.0 ha but 1 Georgia male had a territory of 3.1 ha during nest building and incubation that declined to 1.1 ha during the nestling stage. Home ranges are larger but there is no information on their size. In addition to wandering off territories to forage, males frequently make

extra-territorial forays early in the breeding season when females are receptive (Middleton 2020; Middleton and Prescott 1989; Odum and Kuenzler 1955; Reynolds and Knapton 1984; Stull in Austin 1968; Walkinshaw 1944).

Natal philopatry rates are low. At Guelph, 1 of 229 nestlings (0.4%) returned as a breeding female 2 years later. A juvenile banded in Pickering in September was recovered in July at the same location almost 4 years later. In Michigan, 0 of 28 nestlings returned (Middleton 2020; Speirs 1985; Walkinshaw 1952).

Adult females tend to return to their previous breeding areas but males vary in their fidelity. Return rates at Guelph were 25.6% for females and 15.6% for males. In Minnesota, 21.0% of females and 10.5% of males returned. In Michigan, 50% of both sexes returned, but only 6 females and 4 males were banded. At Guelph, there was 1 record of a male on the same territory in 2 consecutive years and 4 females were documented in 3 successive years. One Michigan female was present in 5 years and her 12 nests were within an area of 0.08 ha (Middleton 2020; Middleton and Prescott 1989; Walkinshaw 1952).

Limiting Factors

Peck and James (1987) reported eggs in Ontario nests from the beginning of May until mid-August, with most present in the first 3 weeks of June. In Algonquin Park, nests are under construction from late May to late June, eggs are present from late May to mid-July, nestlings are present from early June to mid-July, and dependent fledglings have been observed from late June to mid-August (Tozer 2012). The modal date for nest initiation in Algonquin Park was 31 May. Reynolds and Knapton (1984) concluded that the few nests started through early July were probably replacement nests. At the University of Guelph, the earliest egg date was 7 May, the mean was 12.8 May, and the latest egg was laid on 15 July (Middleton 2020).

Pairing occurs 1 or 2 days after the females arrive. Most birds are paired by late May in Algonquin Park. In Algonquin Park, nests took 4 days to build. The mean time to construct nests at the University of Guelph was 4.1 days (range 2-8 days). Later nests were built significantly quicker: mean times to build nests were 4.4 days in May, 3.6 days in June, and 2-3 days in July. In Colorado, nests took an average of 4.1 days to build. In Michigan, nests took an average of 3.4 days to complete (range 2-5 days); July nests took only 2 days to build. One Michigan nest took 15 days to build, but no work was done on it for an 8-day period. In most cases, the first egg is laid the day after the nest is complete. As many as 7 days have elapsed between nest completion and laying of the first egg, with longest intervals occurring early in the season. One egg is usually laid per day, but laying may be interrupted by cold and wet weather. Laying may resume 2-3 days later with no apparent effects on the original eggs. Incubation may start with the laying of the penultimate egg, the night before the last egg is laid, or after the final egg is laid. Incubation periods of 7-14 days have been reported in Ontario, with most eggs hatching in 10-11 days. In Algonquin Park, the incubation period was 11-12 days; the mean incubation period at both the University of Guelph and University of Western Ontario was 11.9 days. Elsewhere, the typical range for the incubation period is 10-15 days. The mean incubation period in Michigan was identical to that at Guelph and London (11.9 days, range 10-14 days). The mean incubation period in Colorado was 10.4 days. Nests have no insulative properties and cool temperatures result in longer incubation periods. Hatching may be synchronous or spread over 24

hours, depending upon when incubation started. Most young in Algonquin Park fledged when they were 9 days old. The nestling period is 7-12 days, mean nestling period was 9.85 days at 52 nests, and the mean nestling period at Fort Simpson, Northwest Territories was 9.6 days. In Colorado, the mean nestling period was 8.5 days. Nestlings that leave the nest before they are 9 days old have greatly reduced chances of survival (Allen 1939; Ball and Bayne 2012; Middleton 2020; Ortega and Ortega 2001; Peck and James 1987, 1998b; Reynolds and Knapton 1984; Scott and Lemon 1996; Stull in Austin 1968; Swanson et al. 2004; Walkinshaw 1944, 1952).

As many as 3 broods have been raised by the Chipping Sparrow in Ontario and other locations, but 2 broods is usually the maximum. In Algonquin Park, there was no evidence of second broods being attempted. The same was true at the University of Guelph where the maximum number of nests in a season was the original nest and 2 replacement nests. At the University of Western Ontario, 8 of 27 pairs (29.6%) raised 2 broods with an average of 1.26 broods per pair. Only a single case of 3 broods has been reported in the province, with all raised in different nests. Some second broods were raised in the same nest, but nest reuse appears to be rare. In Michigan, 1 female attempted 5 nests in a year; 2 failed and 3 broods of 1, 2, and 3 young were raised. This female had 12 nests in 5 years. Despite the occasional pair raising 2 or even 3 broods, most pairs are successful in raising only a single brood a year. Twelve to 24% of pairs raise a second brood. The time between fledging of the first brood and building the next nest averages 11 days (range 3-24 days). When more than 1 brood is raised, the male cares for earlier broods while the female is incubating the next clutch. It regularly initiates replacement clutches if the first one is lost or abandoned, usually the day after the loss. Clutches of 2-5 eggs have been reported in Ontario; 1 nest contained 7 eggs. Two-egg clutches were uncommon, but some were incubated and produced young. The average clutch size of 396 Ontario nests was 3.36 eggs; the most frequent clutch size was 4 eggs. In Algonquin Park, clutches of 3-5 eggs were reported. The mean clutch size 1 year was 3.8 eggs and the mean was 4.3 the following year for an overall average of 4.0 eggs. At the University of Guelph, 377 unparasitized nests had a mean clutch size of 3.7 eggs (range 2-5 eggs). The normal range of clutch size is 2-5 eggs, but there are rare records of 6- and 7-egg clutches. Most clutches contain either 3 or 4 eggs and clutch size declines with the season; second and replacement clutches are smaller than first clutches. Average clutch sizes were 3.62 in Michigan, 3.00 for unparasitized nests in Minnesota, 3.08 in Colorado, and 3.79 in Pennsylvania (Allen 1939; Buech 1982; Campbell et al. 2001; Middleton 2020; Mousley 1916a; Peck and James 1987; Reynolds and Knapton 1984; Scott and Lemon 1996; Stull in Austin 1968; Swanson et al. 2004; Walkinshaw 1944, 1952).

Yearlings are probably capable of breeding and older birds breed every year. Originally considered strictly monogamous, recent research demonstrated that the Chipping Sparrow employs a variety of reproductive strategies, including polygyny, intraspecific parasitism, and extra-pair copulations. Of 9 pairs nesting on the University of Guelph campus, polygyny was presumed in 1 case and strongly suspected in another. In North Dakota, 1 of 32 pairings (3.1%) was polygynous. Low rates of polygyny have been documented in New York, North Dakota, and Michigan. In Michigan, 2 cases occurred where 2 females contributed eggs to a single nest, with resulting clutches of 8 eggs and 7 sparrow eggs and a cowbird egg. In the first case, both females were mated with the same male and 3 adults attended the nestlings. At Guelph, there were 6 instances of 493 nests (1.2%) where more than 1 female contributed eggs to the same nest. Extra-pair copulations

appear to be common and are sought by both sexes. During nest building and egg laying, the male maintains close contact with the female and is probably guarding her from other males. Once incubation begins, males frequently wander off their territories, apparently to seek extra-pair copulations. Most territories at the University of Guelph contained dense stands of conifers where males could trespass on other territories without being detected. Pair bonds may persist for the entire breeding season or change as the season progresses. If a mate is lost, new pair bonds are formed quickly (Middleton 2020; Middleton and Prescott 1989; Walkinshaw 1959).

During the breeding season, the Chipping Sparrow forages either individually or in pairs. In Algonquin Park, foraging occurred on the ground along edges of wooded areas, gravel roads, and parking lots. Most foraging occurs on the ground or in low vegetation, predominantly in open areas such as lawns, fallow fields, along hedgerows, and in forest litter. In Michigan, most food for nestlings was obtained in a woodland adjacent to the nesting field. It may scratch through accumulated plant litter in search of fallen seeds, invertebrates, and grit. It feeds directly on ripened seed heads of low grasses and herbaceous species. It sometimes feeds by reaching out from a perch in brush piles, fallen trees, low shrubs, or fences and by eating seeds directly from tips of stems within 1 m of the ground. It hunts insects by searching from a perch 30-40 cm from the ground and peering into the vegetation, never spending more than 10 seconds on a single perch. When it detects prey, it descends from the perch and attempts to capture it in the bill. It occasionally takes insects on the wing. It may follow flying moths and cabbage white butterflies for several metres, making several attempts to capture them, but is seldom successful (Evans 1964; Middleton 2020; Reynolds and Knapton 1984; Stull in Austin 1968; Walkinshaw 1944). In the Clay Belt of Ontario, 68.0% of foraging was in conifers, 69.0% was in foliage, 26.1% was by aerial attacks, 1.4% by hanging, 3.5% by hovering, 12.1% by reaching, at an average height of 7.2 m which was 54.0% of tree height. In the Mackenzie District, 94.0% of foraging was in conifers, 91.0% was in foliage, 11.6% was by aerial attacks, 1.0% by hanging, 3.3% by hovering, 32.0% by reaching, at an average height of 10.2 m which was 69.3% of tree height (Greenberg et al. 1999). Hebrard (1978) compared the foraging tactics of Chipping and Field sparrows in South Carolina. Both fed mostly in old-field habitat and almost always on the ground regardless of habitat type. Both species frequently flycatched during warmer months and they increased the amount of foraging in treed habitat in April. The Chipping Sparrow occasionally foraged briefly along pine branches. During nonfeeding periods, the Chipping Sparrow perched more frequently in treed habitat; the Field Sparrow remained in the old field. In Texas, Allaire and Fisher (1975) compared the foraging strategies of the Chipping and Field sparrows. Both species foraged mostly within 1 m of the ground and took seeds that had not yet fallen to the ground, as well as those that were on the ground. Both hunted from a perch 30-40 cm from the ground. The Field Sparrow made more frequent use of perches in brush piles, fallen trees, low shrubs, and fences than the Chipping Sparrow. Chipping Sparrows were most common in a grazed pine stand. They typically perched in the upper half of a pine and slowly, one by one, flew down to the ground among the grasses. After a while, they flew up into the trees, moved to another area, and repeated the process. Chipping and Field sparrows were very similar in the types of seeds and arthropods that they ate, but were very flexible in their diet. Flexibility enhances chances for survival if a particular type of food becomes scarce. They may not compete for food because it is so abundant. Benkman and Pulliam (1988) observed that the Chipping Sparrow ate seeds that were about an order of

magnitude smaller than finches of approximately the same size. Consequently, it must spend much more time foraging than finches and is not able to spend as much time searching for food. As a result, it is much more sedentary and restricted to areas of dense seed concentrations.

Younger nestlngs appear to be fed mostly seeds with the amount of invertebrates fed them increasing as they mature. They have been fed grit, small caterpillars, grasshoppers, aphids, and beetles. In Michigan, the percent occurrence of food items in nestlings' feces and gizzards consisted of 24% odonates, 92% orthopterans, 20% true bugs, 96% soft-winged bugs, 60% beetles, 96% lepidopterans, 52% flies, 44% hymenopterans, 92% spiders, 4% snail shells, and 52% plant material. Larvae or nymphs of lepidopterans, beetles, orthopterans, and bugs were preferred to adults. Adults feed on seeds most of the year but add invertebrates to their diet during the nesting period. Seeds of grasses and annual plants are most important in the diet, with fruits infrequently consumed. The summer and autumn foods of birds collected throughout the range consisted of 62% plant matter and 38% invertebrates, which were mostly insects. The Chipping Sparrow prefers seeds of hairy crabgrass and yellow foxtail, but eats seeds of many other grass species including those of timothy and orchard grass. Dandelion is an important food early in the breeding season. It eats many other seeds including those of black bindweed, sweet clovers, knotweeds, lamb's-quarters, oats, chickweeds, amaranths, purslane, ragweeds, wood-sorrels, and wild and cultivated cherries. All life stages of insects are eaten, with lepidopterans, beetles, and orthopterans most important. In June, 93% of the diet consists of insects, including 36% grasshoppers, 25% caterpillars, and 6% leaf beetles. Other beetles consumed include weevils, ground beetles, dung beetles, click beetles, and June beetles. Less frequently, the Chipping Sparrow feeds on bugs, flies, hymenopterans, termites, and spiders. One was observed pecking at a block of salt (Allen 1939; Beal and McAtee 1912; Evans 1964; Judd 1901; Middleton 2020; Stull in Austin 1968; Walkinshaw 1944). In summer in Texas, 68 seeds eaten by 5 birds consisted of 77.5% crabgrass, 8.9% foxtails, 5.3% spinifex grass, 6.5% marshelder, and 1.8% spurges. They had consumed 8 invertebrates including 5 orthopterans and 3 beetles. Chipping and Field sparrows ate similar species of seeds and the same orders of insects. The Chipping Sparrow tended to eat seeds that were slightly larger than those consumed by the Field Sparrow (Allaire and Fisher 1975). The diet of 8 Chipping Sparrows in spring in Michigan by percent occurrence in gizzards consisted of 37.5% orthopterans, 62.5% true bugs, 62.5% soft-winged bugs, 75.0% beetles, 75.0% lepidopterans, 25.0% flies, 37.5% hymenopterans, 62.5% spiders, 62.5% plant material, 25.0% wiregrass seeds, 25.0% Indian grass seeds, 25.0% unidentified grass seeds, and 12.5% smartweed seeds. The percent occurrence of food items in 41 gizzards of adults and fledglings in summer consisted of 51.2% orthopterans, 82.9% true bugs, 82.9% soft-winged bugs, 85.4% beetles, 36.6% lepidopterans, 2.4% flies, 36.6% hymenopterans, 39.0% spiders, 46.3% plant material, 2.4% quack grass seeds, 12.1% poverty oat grass seeds, 9.8% wiregrass seeds, 4.9% panic grass seeds, 7.3% bluegrass seeds, 2.4% foxtail seeds, 2.4% Indian grass seeds, 2.4% wood-sorrel seeds, 2.4% smartweed seeds, 2.4% dock seeds, and 43.9% seeds of all kinds. Beetles were represented in the diet mostly by ground beetles and weevils in spring. Leaf beetles and click beetles were common in the summer diet. The lepidopterans consisted mostly of hairless owlet moth and brush-footed butterfly caterpillars. Adult grasshoppers became frequent in the diet in summer. Ants were the primary hymenopterans consumed, but small ichneumonid wasps and other parasitic wasps were also eaten (Evans 1964). In Michigan, some did not feed on jack pine budworms; others readily ate

larvae, pupae, and adults. It concentrated feeding on the most abundant life form of the budworm, but did not start eating them until they reached the fifth instar. All budworms consumed contained hymenopteran parasites. It was estimated that the Chipping Sparrow ate only 0.92% of the available budworms even through it was the most abundant of 60 species of birds present and represented 37.7% of the avifauna (Simmons and Sloan 1974; Sloan and Simmons 1973). In Maine, 3 stomachs collected during a spruce budworm outbreak contained 71% and 67% budworm larvae and pupae by volume in 2 years (Mitchell 1952).

Evans (1964) compared the diets of the Chipping, Field, and Vesper sparrows in Michigan, and the diets of nestlings and adults of individual species. Nestlings of Chipping and Field sparrows consumed significantly higher frequencies of odonates, orthopterans, lepidopterans, flies, and spiders than adults, and significantly lower frequencies of true bugs. Nestling Chipping Sparrows consumed significantly fewer beetles than adults. The frequency of rapidly flying insects and sluggish larvae was much greater in food provided to nestlings than was eaten by adults. Insects that spend most of their time on the surface of the ground or on low-growing vegetation appeared with equally high frequency in the diet of both age classes. The results suggested that, while searching for food for nestlings, adults spent less time on open ground and more time in active flight or in taller vegetation. The Vesper Sparrow consumed orthopterans more frequently than Field and Chipping sparrows (but the difference was significant only for the Field Sparrow) and fewer true and soft-winged bugs (difference significant only for the Chipping Sparrow). The Chipping Sparrow ate significantly more lepidopterans than the other 2 sparrows. Chipping and Field sparrows ate seeds much less frequently in summer than the Vesper Sparrow. The only difference in the diet of nestlings among the species was that Chipping Sparrow nestlings were fed true bugs significantly less than Vesper Sparrow nestlings. There was no shortage of food within the study area and no apparent competition for it; food did not appear to be a limiting factor.

The Chipping Sparrow is a common host of the Brown-headed Cowbird. At the University of Guelph, 35.3% of 381 nests were deserted, with many desertions coinciding with the appearance of a cowbird egg, particularly during nest building or early egg laying. Desertion was likely if there were 2 or fewer sparrow eggs in the nest and unlikely if there were 3 or more sparrow eggs. Data from the Ontario Nest Records Scheme (ONRS) south of the French and Mattawa rivers and Lake Nipissing indicated that parasitized nests were significantly more likely to be deserted (52%) than unparasitized nests (7%). Acceptance rates of cowbird eggs did not differ before (53%) or after (44%) the peak of nest initiation, or in singly parasitized (52%) or multiply parasitized (45%) nests. Desertion may be triggered if the female encounters a cowbird near the nest. Cowbird eggs deposited before the nest is complete may be buried in the nest. At Guelph, 37.5% of cowbird eggs were laid before the first sparrow egg, 37.5% with the first egg, 15% with the second egg, 7.5% with the third egg, and 2.5% with the fourth egg. At the University of Western Ontario, most nests were parasitized when 2 sparrow eggs were present followed by when 3 sparrow eggs were present; more than 50% of nests were parasitized in those 2 days. In Colorado, significantly more parasitized nests were abandoned (29.4%) than unparasitized nests (5.1%). The female cowbird may remove sparrow eggs with the result that parasitized nests have smaller clutch sizes. At Guelph, mean clutch sizes were 3.7 eggs for unparasitized nests and 2.5 eggs for parasitized nests. In unparasitized nests, 81.3% of sparrow eggs produced fledglings compared with 28.0% of eggs in parasitized nests (3.0 fledglings

produced per unparasitized nests and 2.0 in parasitized nests). In only 3 cases did no sparrows fledge. Similarly in Colorado, clutch size of unparasitized nests was significantly higher (3.7 eggs compared with 2.9 eggs) and parasitized nests produced significantly fewer sparrow fledglings. In Minnesota, the clutch size of unparasitized nests was 3.00 eggs compared with 2.33 eggs for parasitized nests. Despite the lower fledging success rate, all parasitized nests produced some sparrow fledglings. The abandonment rate due to parasitism was 30%, but it is likely that many of these birds renested. At Guelph, nests in deciduous trees were more commonly parasitized than those in conifers and nests 1.5-2.5 m from the ground tended to be less heavily parasitized than others. Similar studies in Michigan showed no such differences. In Colorado, there were no significant differences in parasitism rates related to nest height or concealment (Buech 1982; Earley 1991; Graham 1988; Middleton 2020; Ortega and Ortega 2001; Rothstein 1975; Scott and Lemon 1996; Strausberger and Hauber 2017). Parasitism rates vary dramatically geographically, even within Ontario. Peck and James (1998b) reported that 484 of 1,600 nests (30.3%) reported to the ONRS were parasitized. In Algonquin Park, 0 of 22 nests were parasitized (Reynolds and Knapton 1984). At the University of Guelph, 40.6% of 374 nests were parasitized (Middleton 2020); 23 of 25 nests (92.0%) were parasitized at the University of Western Ontario (Scott and Lemon 1996). In Quebec, Perreault and Barrette (in Gauthier and Aubry 1996) reported that 12% of nests were parasitized. In British Columbia, 10% of 508 nests were parasitized (Campbell et al. 2001). In 2 studies in Michigan, 3 of 66 nests (4.5%) and 1 of 18 nests (2.6%) were parasitized (Stull in Austin 1968; Walkinshaw 1944). In Minnesota, 3 of 12 nests (25.0%) were parasitized (Buech 1982). In 2 Colorado studies, 6 of 83 nests (7.2%) and 17 of 77 nests (22.1%) were parasitized (Ortega and Ortega 2001; Swanson et al. 2004). In the first study area, the parasitism rate was low despite the fact that the Chipping Sparrow was the most abundant species, suggesting that it may not have been a preferred host. The Plumbeous Vireo was scarce yet experienced a 49.6% parasitism rate. In Illinois, 33 of 49 nests (67.3%) were parasitized (Strausberger and Hauber 2017).

McLaren et al. (2006) examined the ONRS to analyze Ontario parasitism rates from the 1870s to the 1990s. They reported that 509 of 1,749 nests (29.1%) were parasitized and 139 of 509 nests (27.3%) were multiply parasitized with more than 1 cowbird egg. There was a significant increase in multiple parasitism in the century prior to 1970 but a nonsignificant decline in multiple parasitism after 1970. Results supported the hypothesis that intensity of parasitism is related to cowbird density and that multiple parasitism is a recent phenomenon associated with increases in cowbird density. The cowbird has been declining in Ontario and this may explain why the rate of multiple parasitism decreased after 1970. Peck and James (1998b) observed that only 33 of 188 nests (17.6%) were parasitized in the decade prior to their publication compared with an overall rate of 30.3%.

There appear to be no major limitations to the Chipping Sparrow, which benefits from most human activities. Development of subdivisions was previously beneficial but modern high-density housing may not provide adequate habitat. In many cases, the roofs of the houses are almost touching and it would probably need several adjacent lots with suitable landscaping in order to set up a territory. Because it is often abundant around human settlements, it and its nests are highly vulnerable to being preyed upon by cats (Middleton 2020).

The Chipping Sparrow responds positively to forestry activities that open up the forest canopy yet retain some tree cover. In the Boreal Forest Region of Ontario, it increased by 50% when 30% of trees were removed (Vanderwel et al. 2007). In the Canadian Shield of Ontario, there were no differences in its abundance in early successional and mid-successional clear-cuts and burns of the same ages. It was significantly more abundant in early successional than mature stands and equally abundant in mid-successional and mature stands (Zimmerling et al. 2017). In partial cuts in Alberta, it increased significantly when 80% of trees were removed in deciduous forests with a coniferous understorey and when 50% of trees were removed in mixed stands (Harrison et al. 2005). In Idaho, it exhibited a significant increase due to single-tree selection logging in coniferous forests (Medin and Booth 1989). Tittler et al. (2001) compared the abundance of the Chipping Sparrow in Alberta mature mixed forests and clear-cuts with varying amounts of residual tree cover. In 1 of 3 years, it was significantly more abundant in clear-cuts than controls, but there were no significant differences in other years. It exhibited no significant response to clear-cutting and was unaffected by the amount of residual tree cover. In New York northern hardwoods, it was absent in uncut forest and occurred in low abundance where 25%, 50%, 75%, or 100% of merchantable timber was removed (Webb et al. 1977). In British Columbia, density of deciduous vegetation in coniferous plantations was manipulated by cutting in some treatments and by cutting and spraying stumps with herbicide in other treatments. Because of its reliance on deciduous vegetation for nest patches in this area, it was negatively affected by the management. It compensated by finding patches of untreated or recovered vegetation to nest in (Easton and Martin 2002). In Pennsylvania, it was significantly more abundant in woodlots where snags were retained as part of timber stand improvement. Where snags were retained, there was significantly more woody plant material 0-1.5 m from the ground that probably provided nest sites (Stribling et al. 1990).

In Alberta and West Virginia, the Chipping Sparrow was significantly more abundant at seismic lines, pipelines, access roads, and well pads than in forest interior adjacent to these features (Bayne et al. 2016; Farwell et al. 2019).

Forest fires are either beneficial for the Chipping Sparrow or have no discernible effect; fires in savannahs may be detrimental. In a mature California coniferous forest, it nested in areas that had been burned 6-8 years previously, but was absent in unburned forest (Bock and Lynch 1970). In a mixed forest in Oregon, its density 1 year before fire and in each of 9 years postfire showed no clear response to the fire (Stephens et al. 2015). In Indiana savannahs, it occurred at maximum density when the fire frequency was 0 per 15 years. Density dropped from 35 per km^2 with a fire frequency of 0 in 15 years to 20 with 1 fire in 15 years and to 10 with 2 fires in 15 years (Grundel and Pavlovic 2007a).

The Chipping Sparrow declined significantly shortly before the turn of the 20th century. Competition with the House Sparrow and parasitism by the Brown-headed Cowbird were considered responsible. These relationships were never confirmed and by the 1950s the Chipping Sparrow was common in many areas where the other 2 species were abundant. It declined from the 1900s to the point where it was very rare in Illinois in the 1950s. The explanation for this was unclear but was possibly related to pesticide use (McIlwraith 1894; Middleton 2020; Stull in Austin 1968; Walk et al. 2011). Nichols (1946) suggested that its decline in the 3 decades prior to his publication was

because of decreasing availability of horsehair that was used to line essentially all nests. This seems implausible as the Chipping Sparrow readily uses hair from other mammals and occasionally does not use hair in the lining.

Organophosphates used in orchards and other agricultural uses have been demonstrated to be harmful to the Chipping Sparrow (Middleton 2020; Perreault and Barrette in Gauthier and Aubry 1996).

Nests in exposed trees and shrubs facing prevailing winds are often worked loose and tipped by wind action. Wind caused 1.6% of nest failures at the University of Guelph (Middleton 2020).

In Minnesota, the Chipping Sparrow spent more time on or near the ground where the Song Sparrow was not regularly present than where both species were present. Interference competition was likely responsible because the Song Sparrow frequently chased the Chipping Sparrow from mutually occupied areas (Howe 1979).

In Alberta, there was no significant difference in the abundance of the Chipping Sparrow at noisy compressor stations and quiet well pads. It did not appear to be affected by chronic noise (Bayne et al. 2008), but negative responses to noise have been detected during autumn migration.

In Minnesota, extremely low-frequency electromagnetic fields produced by a hydro transmission facility had no apparent effect on the Chipping Sparrow (Hanowski et al. 1996).

Status

Prior to European settlement, the Chipping Sparrow probably inhabited open woodlands, prairie-forest ecotones, and clearings created by fires, watercourses, water bodies, and First Nations. Forest clearing created considerably more habitat for it and it is more abundant now than prior to deforestation by Europeans. Much new habitat was created by the initial expansion of agriculture and forestry followed by naturalization of associated weeds and insects. Its population probably peaked around the mid-1850s and then declined due to reversion back to forest, more intensive farming, cowbird parasitism, competition with the House Finch and House Sparrow, and predation by cats (Middleton 2020; Stull in Austin 1968).

McIlwraith (1894) stated that the Chipping Sparrow occurred throughout the province. Prior to the arrival of the House Sparrow, it was the most familiar bird around dwellings. He noted that it was then in a minority to the House Sparrow. Weir (2008) stated that the Chipping Sparrow was common in the mid-19th century in the Kingston area and that habitat changes over the past 150 years had helped increase its numbers. Baillie and Harrington (1937) considered it one of the most common breeding birds south of the Albany River and the southern end of James Bay. They concluded that it probably ranged westward to Lake of the Woods. The first atlas demonstrated that it ranged almost throughout the entire province except in the northeast portion of the Hudson Bay Lowland. In that physiographic region, it was found mostly along the James Bay coast. It was among the most abundant species in the province (Middleton in Cadman et al. 1987). James (1991) considered the Chipping Sparrow a common summer resident throughout the province, north to Big Trout Lake and Moosonee and rare north to Fort Severn and Attawapiskat.

The second atlas demonstrated that there had been no change in the range of the Chipping Sparrow since the first atlas. There was no significant change in its probability of observation province-wide. A significant decline occurred in the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region, although the number of squares it was documented in was essentially the same. The decline in this region may have been due to forest maturation and in-filling. The decline was most apparent in Algonquin Park, consistent with this hypothesis. It increased significantly in the Boreal Forest Region where it was seen in more than twice as many squares during the second atlas. It increased at a nonsignificant rate in the Hudson Bay Lowland where it is predominantly confined to settlements and riparian habitat along major rivers. It was most abundant south of the Canadian Shield and in the northwestern portion of the Great Lakes–St. Lawrence Forest Region in the Shield. It was one of the most abundant species in the province; over 50% of the population was in the Boreal Forest Region (Cadman in Cadman et al. 2007).

The Breeding Bird Survey (BBS) may not adequately sample the Chipping Sparrow because there are no routes in the northern portion of its range or within urban habitats. BBS data indicate that the Chipping Sparrow decreased at annual rates of 1.42% in Canada and 1.26% in Ontario 1970-2021. The annual rates of decrease 2011-21 were 3.43% in Canada and 5.27% in Ontario. All results were of medium reliability except for the short-term trend in Ontario, which was highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

When leaving the nest, young may move gradually out into the branches of the nest tree. If nestlings fall to the ground, they are led by an adult into a shrubby area. By age 10 days, they can hop onto the lower branches of shrubs where they sometimes remain for long periods on 1 perch. By age 12 days, they can fly short distances and are capable of sustained flight. Young may cross territorial boundaries and, at first, the adults lead them back. As soon as the young of the final brood are independent, both the young and adults leave the territory. Young are usually independent when they are approximately 3 weeks old but adults occasionally feed young as old as 35-40 days (Middleton 2020; Walkinshaw 1944, 1952).

Initially family groups remain discrete. In a Michigan suburb, 3 pairs and their young roamed over the same area but remained separate from each other. Eventually, young gather into small flocks of 5-15. These flocks grow as summer progresses and they are joined by postbreeding adults. Both adults and juveniles remain in flocks until autumn migration; these flocks may be joined by Field and Song sparrows (Middleton 2020; Stull in Austin 1968; Walkinshaw 1944).

Premigratory flocks usually inhabit weedy areas where there is an abundance of seeds for foraging (Middleton 2020; Stull in Austin 1968). In Pennsylvania, Stoleson (2013) netted birds in 3-6-year-old clear-cuts and adjacent mature forests during the postfledging period. He caught 15 adults and 8 juveniles in clear-cuts and 1 adult and no young in forests. In the same state, postbreeding adults were rare on transmission line corridors and absent in the adjacent forest; no family groups were observed (Yahner et al. 2002).

In Algonquin Park, adults and juveniles may forage in flocks of 200 or more where grass and weed seeds are abundant (Tozer 2012).

MIGRATION

There is evidence for the Chipping Sparrow migrating both during the day and at night. It is possible that it makes short-distance movements diurnally and long-distance movements nocturnally. It migrates in stages with many feeding stopovers along the route, particularly in autumn. It migrates in small to large flocks that often contain other species such as Field and Song sparrows. In spring, many birds moving through Long Point travel northwest. In autumn, Ontario birds move south or southeast and at least some birds that breed in Ontario winter in Florida (Allen 1939; Brewer et al. 2018; Campbell et al. 2001; Middleton 2020; Stull in Austin 1968). Gesicki et al. (2016) monitored nocturnal calls of Chipping Sparrows during spring migration on the Ohio coast of Lake Erie and at sites within the lake. Sparrows migrating in the western basin of the lake were more likely to engage in a lake crossing than those in the central basin. The central basin of Lake Erie may inhibit water crossing by the Chipping Sparrow.

Males usually arrive on the breeding grounds 1 week before females but in Michigan the first female arrived 14 days after the first male. The earliest birds arrive about 2 weeks before the peak of migration (Middleton 2020; Perreault and Barrette in Gauthier and Aubry 1996; Walkinshaw 1944). In Ontario, the Chipping Sparrow usually arrives in mid-April and migration continues until mid-May; early migrants may arrive in the last 1-2 days of March (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008). Wilson and McRae (1993) concluded that single birds at Ekwan on 13 and 16 June and one at Longridge on 14 June were either late migrants or unmated birds following the coast.

In the Yukon, adults departed south ahead of juveniles. The latest an adult was observed was 1 August but groups of juveniles were encountered until the end of August (Sinclair et al. 2003). Overall, birds may depart from the breeding grounds from July to November, but peak migration in Ontario occurs in September until mid-October (Middleton 2020) with stragglers into early November or even later.

In Massachusetts, Ellwood et al. (2010) examined spring arrival dates of the Chipping Sparrow from 1851 to 2007. It arrived earlier in warmer springs.

During migration, the Chipping Sparrow may inhabit a variety of open habitats, particularly grassy and weedy areas that provide ample food. It may occur in roadsides, hedgerows, open grassy areas, old weedy fields, suburban and rural yards, forest edges, upland thickets, urban parks, shoreline thickets, field borders, hydro transmission line corridors, grain fields, gardens, villages, open forests, and edges along rivers, lakes, and wetlands. In spring, it appears to prefer upland well-drained areas. During spring in Wisconsin and Minnesota, about 2.5 times more were observed in upland oak and elm stands than in floodplain forests dominated by silver maple and green ash (Campbell et al. 2001; Kirsch et al. 2013; Middleton 2020; Sinclair et al. 2003; Stull in Austin 1968; Walkinshaw 1944).

In spring, the Chipping Sparrow forages singly or in small flocks but tends to occur in larger flocks in autumn. Foraging strategies in the nonbreeding season are similar to those used during the breeding season except that large rolling flocks may occur in autumn. Birds fly to the front of the flock, scratch for seeds where they land, then fly again to the front of the flock which bypasses them as they forage. Autumn flocks often contain 25 to more than 200 birds, or even as many as

1,000 (Allaire and Fisher 1975; Middleton 2020). In Texas, 695 seeds eaten by 15 birds included 42.9% crabgrass, 9.2% foxtails, 8.2% panic grasses, 13.9% unidentified grasses, 22.9% spurges, and 2.9% marshelder. They also ate 9 lepidopterans and 6 termites (Allaire and Fisher 1975).

The Chipping Sparrow collides with television towers and other tall structures during both migration periods (Middleton 2020).

During autumn migration in Idaho, McClure et al. (2013b) created a phantom road through a forest by playing recordings of traffic noise. The Chipping Sparrow was significantly negatively affected by noise with an average of 0.8 birds present under quiet conditions and 0.25 at noise levels of 55 dB(A). Although it does not appear to be adversely affected by noise during the breeding season, it may choose to avoid noisy areas during migration. Noise has the potential to reduce the quality of stopover areas.

James (1991) considered the Chipping Sparrow a common migrant in Ontario.

Hussell et al. (1992) reported that captures of the Chipping Sparrow at Long Point Bird Observatory increased significantly at a rate of 3.3% per year 1961-88. Trends by period included: 1961-70, +2.2% per year; 1970-79, –8.4% per year; and 1979-88, +15.3% per year.

WINTER

Root (1988) concluded that the Chipping Sparrow appeared to winter where the American Tree Sparrow is absent, where the average minimum January temperature rarely drops below –7°C to –1°C, and where pines, scrub oaks, or both are present. It is uncertain if the American Tree and Chipping sparrows restrict each other's range. The Chipping Sparrow does not normally winter in large numbers north of the North Carolina coast (Stull in Austin 1968). There are many records of stragglers lingering beyond normal autumn departure dates, often well into winter. There is evidence of an increasing tendency to overwinter in northern breeding areas (Middleton 2020). Ontario continues to be well north of the normal wintering range.

Winter habitat is similar to breeding habitat, but the Chipping Sparrow may be more common in riparian forests than coniferous forests in winter. In the Hamilton area, it may occur in sheltered valleys. It commonly shares its habitat with other sparrows in winter where their differing behaviours and microhabitat use may allow them to coexist, often in flocks (Curry 2006; Middleton 2020).

The Chipping Sparrow is readily attracted to feeders. A high proportion of Ontario winter birds are seen at feeders. Under harsh weather conditions, it may depend upon feeders for survival. Presence of other species may inhibit its usage of feeders. Favourite feeder foods include mixed seeds, millet, hulled sunflowers, and canary seeds. Infrequently consumed foods include black oil and striped sunflowers, cracked corn, niger, suet, bird puddings, milo, popped corn, and water (Dunn and Tessaglia-Hymes 1999; Middleton 2020). A total of 13,312 Chipping Sparrow foraging bout observations indicated that it preferred white proso millet in tube or hopper feeders (Horn et al. 2014).

Arizona is at the northern extent of the winter distribution of the Chipping Sparrow. Pulliam and Dunning (1987) added grass seeds to experimental plots in oak woodlands. Its abundance was lower when seed production was very low but there was no further increase in its abundance once seed

production exceeded 10 or 15 kg per ha. The authors concluded that food density limited local abundance of Chipping Sparrows when food was scarce but competition limited density when food was abundant. In winter in Texas, 9 birds ate 583 seeds and no arthropods. Seeds consisted of 35.2% crabgrass, 6.5% foxtails, 5.2% windmill grass, 1.7% panic grass, 48.1% unidentified grasses, and 3.3% spurges (Allaire and Fisher 1975).

James (1991) considered the Chipping Sparrow a rare winter resident in the south, north to Ottawa. It is rarely seen in winter in Elgin County (Lancaster et al. 2004). In the Hamilton area, it is observed in winter about every other year (Curry 2006). In the Kingston area, single birds were seen during 14 of 35 winters (40%) since 1972 (Weir 2008).

Clay-colored Sparrow

Spizella pallida

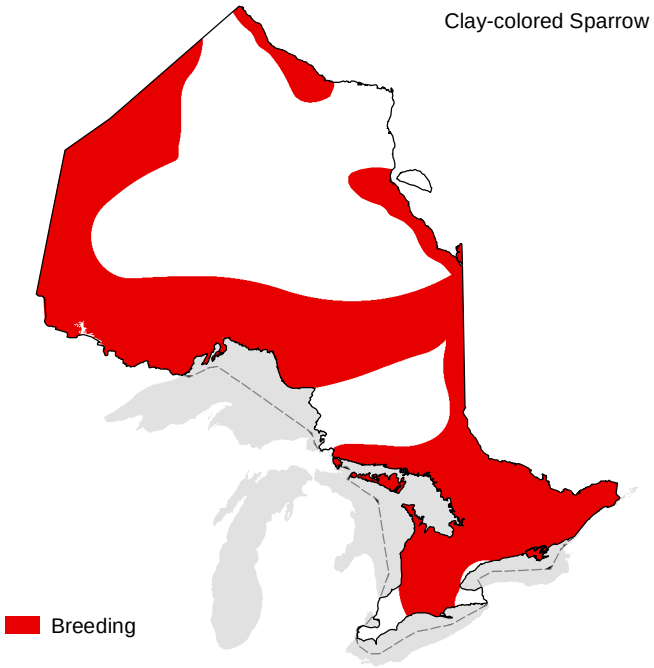
BREEDING SEASON

Habitat Requirements

In Ontario, the Clay-colored Sparrow has nested in Christmas trees and other coniferous plantations in grassy fields (65.5% of nests), in shrubby overgrown fields and pastures (24.1%), in a cottage area (3.4%), in a dried-up muskeg burn with some tree regeneration (3.4%), and in a graminoid opening in willow scrub near a salt marsh (3.4%; Peck and James 1987).

In the Hudson Bay Lowland, the Clay-colored Sparrow nests along the Hudson Bay coast, in the southern James Bay area, and often around settlements (Wilson and McRae 1993). Within this region, it nests predominantly in open willow and birch thickets (Rising in Cadman et al. 2007). It is rare in the Boreal Forest Region where it probably nests in forest clearings and openings, burns, clear-cuts, and shrubby areas near wetlands, watercourses, and water bodies.

In the Canadian Shield in the Great Lakes–St. Lawrence Forest Region, the Clay-colored Sparrow is most abundant in Rainy River District and southern Kenora District near Lake of the Woods. It is



rare in the eastern portion of this forest region. In this area, it nests in abandoned rough pastures with low willows (Rising in Cadman et al. 2007). James and Peck (1995a) observed one in jack pine stands near Gogama. It was most likely associated with very open areas where pines were less than 10 years old. Breeding habitat near Sault Ste. Marie consisted of grassy fields with clusters of willows 3 m tall interspersed with 6-m tall aspens. The fields were flooded to a depth of 30 cm early in spring due to melting snow. When birds first appeared, the water was still ankle deep but the area was completely dry by mid-June (Warburton 1952). In Algonquin Park, breeding habitat included young pine plantations and a hydro corridor (Tozer 2012). In Muskoka District, it nested in an abandoned pasture and in areas of open bedrock outcrops with young trees and shrubs and scattered mature pines, hemlock, and oaks (Mills 1981).

In the Great Lakes–St. Lawrence Forest Region south of the Shield, the Clay-colored Sparrow is commonly associated with alvars such as the Flamborough Plain, Carden Plain, and the Frontenac Axis. It nests in open, shrubby fields with scattered trees in these habitats. Red cedar and junipers on limestone pavement is favoured habitat near Kingston on the Frontenac Axis. Christmas tree and other coniferous plantations are favoured on the Flamborough Plain (Curry 2006; Knapton in Cadman et al. 1987; Rising in Cadman et al. 2007; Weir 2008). It is widespread on the Oak Ridges Moraine where it nests in young plantations and old-field habitat (personal observation). Near Ottawa, it nested in open bogs and willow thickets and at the airport (Godfrey 1966; Knapton in Cadman et al. 1987). Near Craigleith and Merrickville, it nested in old shrubby pastures overgrown with hawthorns, roses, apples, raspberries, gooseberries, cedars, and snowberries with herbaceous species such as ragworts, St. John's-worts, and cinquefoils (Mitchener 1956; Terrill 1952).

In the Carolinian Forest Region near London, the Clay-colored Sparrow nested in an old field on sandy soils grown up with hazel and young scrubby oaks (Dale 1927).

The core of the Clay-colored Sparrow's range is in the prairies of southern Canada and the northern United States. It may be the most abundant passerine of low shrub communities in the southern portions of the Prairie Provinces. It is associated predominantly with shrubs there, especially snowberry and silverberry. In addition to shrubby prairies, it commonly nests in old fields with shrubby growth, pastures, wet meadows, forest edges, burns, and planted grasslands. Less frequently, it nests in hayfields, particularly those planted to alfalfa and sweet clover. These clovers are taller than other species in this family and may function as singing perches in the absence of shrubs. Another habitat used on the prairies is young aspen stands with an open canopy; it may

occur in a variety of open deciduous woods. This habitat is avoided in the east. It rarely nests in croplands other than hay and in urban areas such as parks, vacant lots, and yards. Away from the prairies, it is associated predominantly with areas that have a mixture of shrubs in open grassy and herbaceous areas. These may include old fields and meadows, ungrazed or lightly grazed pastures, shrubby areas bordering these habitats or agricultural fields, overgrown utility corridors, clear-cuts, regenerating burns, dense herbaceous and grassy cover around margins of wetlands where there is some shrub coverage, pine and oak barrens, and open parkland habitat with scattered copses of aspens, willows, or shrubs. It also nests in Christmas tree farms and young coniferous plantations (Askins et al. 2007; Buech 1982; Campbell et al. 2001; Davis 2003; Dechant et al. 2002c; Faanes and Andrew 1983; Flack 1976; Fox 1961; Grant and Knapton 2020; Hill and Sealy 1994; Knapton 1979a, 1980; Mossman et al. 1991; Paquin and Letourneau in Gauthier and Aubry 1996; Root in Austin 1968; Salt 1966; Tews et al. 2013; Tittler et al. 2001; Walkinshaw 1939a; Watts and Albin 1996; Winter et al. 2004).

Some information is available on landscape preferences of the Clay-colored Sparrow. In Saskatchewan woodlots, it was more common in small forest fragments in landscapes with low forest cover (Hobson and Bayne 2000). In the same province, it was the only species that Johns (1993) studied that increased significantly with increasing isolation of woodlots. It occurred in all sizes of woodlot studied (range 0.04-36.7 ha). In 1 Saskatchewan study, its abundance was unaffected by the amount of cropland or wetland within 1.6 km. In another study, its presence was negatively correlated with the number of wetlands 2.8 km^2 around point counts, but it was observed in wetlands and wetland margins within all farmland types. It was more frequent along roadside routes passing through cultivated land than through areas of more native grassland (Dechant et al. 2002c). Grant and Knapton (2020) concluded that population densities were highest in grass-dominated landscapes and lower where the proportion of cropland was greater. Fedy et al. (2018) used Breeding Bird Survey (BBS) data for the Prairie Pothole Region of Canada to determine that it was associated with native and nonnative grasslands and shrubland areas at the 3,200-m scale. Erskine (1977) stated that it was a species of open shrubby areas rather than forest and considered it characteristic of prairie-forest ecotone and poor fields or areas of old-field succession. In North Dakota, it preferred landscapes that were 6-32% forested (Cunningham and Johnson 2019).

Although the Clay-colored Sparrow nests in woodlots and open grasslands devoid of woody cover, highest densities are associated with shrubs near grassy or herbaceous areas. In the Prairie Provinces, snowberry is highly preferred and silverberry is another preferred shrub. In North Dakota, these 2 shrubs and sumac are preferred. In 1 North Dakota study, it was abundant in shrubby fields and absent in grassy and herbaceous plots without shrubs. In Alberta, it is most abundant in habitats with more than 50% shrub coverage. It prefers a mix of vegetation types and is negatively associated with plant communities dominated solely by shrubs, native grasses, or wet-meadow vegetation. In Manitoba, grassy areas, treed bluffs, areas of standing water, marshes, and pure stands of silverberry were not defended. Large territories had proportionately less dense ground cover by snowberry than smaller territories suggesting that snowberry represented higher quality habitat. In Wisconsin, there was significantly more willows and meadowsweet within territories than in unoccupied areas. Near Edmonton, areas of pure grasses were not included in territories, and each territory contained at least 1 clump of poplar and willow; cultivated wheat fields were also not included in territories.

Territories contained grassy areas, patches of roses and snowberries, and shrubs bordering a woodlot. In Minnesota, its density was predicted to increase as woody cover increased (Arnold and Higgins 1986; Campbell et al. 2001; Dechant et al. 2002c; Knapton 1979a, 1979b; Munson 1992; Root in Austin 1968; Salt 1966; Thompson et al. 2014). Leston and Koper (2017) studied Clay-colored Sparrow usage of hydro transmission rights-of-way (ROWs) in the Winnipeg area. It was less abundant along ROWs with more wooded or urban habitat within 100 m. It declined as woody plant cover increased and increased as litter cover increased, including within hayed ROWs.

In western aspen stands, the Clay-colored Sparrow is a forest-edge species. It is significantly more likely to occur in groves with open canopies than those with closed canopies. Open canopies allow development of understorey species such as snowberry, grasses, bedstraws, and wild sarsaparilla. It is associated with very young aspen stands on moderately moist sites that are mid-range between nutrient-poor and nutrient-rich. In Saskatchewan, it demonstrated no preference for forest size. It was significantly negatively related to forest size in North Dakota. It is possible that presence of an open canopy and understorey is more important than forest size (Faanes 1987; Grant and Berkey 1999; Hobson and Bayne 2000; Johns 1993; Kirk et al. 1996).

Some studies compared the habitat quality of native grasslands and planted grasses. In Manitoba, nonnative vegetation included spurges, Kentucky bluegrass, and smooth brome; these were absent in native grasslands. The Clay-colored Sparrow was negatively correlated with native vegetation and positively correlated with nonnative vegetation, but not significantly (Wilson and Belcher 1985). In Saskatchewan grasslands, it preferred pasture in native habitat to planted pastures, possibly because native pastures supported more shrubs, predominantly snowberry and silverberry. Its abundance was associated with native grassland characterized by increased cover by shrubs, standing dead vegetation, and narrow-leaved rhizomatous grasses (Davis et al. 2016). In Alberta, its frequency was similar in native and tame pastures. In native pastures, it used areas of high cover diversity. In tame pastures, it used areas of high herbaceous biomass, moderate height variability, and a high forb to grass ratio. Highest densities occur in grasslands that have been ungrazed for more than 11 years and not burned for more than 80 years. Its use of idle grasslands decreases after mowing and as snowberry cover decreases. In Alberta, it was absent from tame grasslands less than 2 years old; abundance increased until the grassland was 5 years old then decreased (Dechant et al. 2002c). In Saskatchewan waterfowl management areas, percent occurrence of the Clay-colored Sparrow was 93.7% in planted dense nesting cover, 88.9% in native grasslands, and 10.5% in wheat fields (Hartley 1994). In Minnesota, Thompson et al. (2014) concluded that improving the quality of grass cover by increasing litter depth, grass height, and grass extent would lead to only a marginal increase in its density. Increasing the extent of grasses by 11.6 ha within a 500-m radius would lead to a 10-20% increase in this sparrow. Removal of woody vegetation within 100 m would result in a 5% decrease. In Saskatchewan, it was more abundant in brome-dominated plots than those dominated by Kentucky bluegrass (Dale et al. 2000).

Considerable information is available on microhabitat preferences of the Clay-colored Sparrow. In Wisconsin, the five most important plant species by frequency in territories were goldenrod, meadowsweet, Canada bluegrass, reed canary grass, and butter-and-eggs. The respective coverage by these species was 35%, 20%, 29%, 20%, and 12%; coverage was greater than 100% because leaves

overlapped. Some plants of lesser dominance may have been critical elements of territories based on high preference for them. Plant species significantly more abundant within than outside territories included sandbar willow, meadowsweet, reed canary grass, and sedges. Species more abundant outside territories included Canada bluegrass and timothy. Woody species richness, vegetation height (186.3 cm within and 88.9 cm outside), plant species diversity, and vertical density were all higher within territories. Habitat features of high value included sandbar willow and meadowsweet occurrence and stem density, woody species richness, vegetation height, plant species richness, and vertical density. None of the habitat features that were more abundant outside territories had high value as nest cover. The percent coverage of 44 additional plant species, stem density of 7 additional woody species, and frequency of occurrence of 53 additional plant species were similar within and outside territories. It selected territories containing dense stands of woody vegetation and avoided open grasslands. Only 22 of 118 habitat features (18.6%) available to sparrows had high value as nest cover, yet 8 of 11 habitat features (72.7%) that were more abundant within territories were of high value. Because it forages outside the territory, nest cover may be the dominant influence on territory selection (Munson 1992). In Minnesota and North Dakota, the substrate at nests consisted of 0.2% bare ground, 8.9% grasses, 10.4% forbs, 33.2% litter, and 42.9% shrubs (Winter et al. 2004). It increased with increasing amounts of tree and shrub coverage within 200 m. Nest success was unaffected by the amount of woody vegetation (Winter et al. 2006). In North Dakota, maximum vegetation height, amount of shrubs, amount of aspen within 100 and 500 m, and amount of Kentucky bluegrass were significantly greater where it was present than where it was absent. There was significantly less native herbaceous vegetation within 100 m of sites where it occurred than where it was absent (Grant et al. 2004). In Manitoba, nests were more often in a 5-m wide band around the edge of the territory than in the centre of the territory. Many territories encompassed a complete patch of snowberry. Nests were at edges of these patches rather than in the interior (Knapton 1979b). In Minnesota and North Dakota, its density increased with density of trees and shrubs in the landscape. In North Dakota, vegetation was taller and denser at nest sites than within a 30-m radius around nests or within the nest fields, which were 41-69 ha. Nest sites were closer to shrubs, had greater shrub coverage, and greater vegetation heterogeneity than areas within 30 m or the fields. Nests in snowberry had smooth brome as the least-preferred understorey species; native grasses or Kentucky bluegrass were preferred. In recently burned fields, litter depth and amount of residual vegetation were greater at nests than within 30 m or the fields (Grant and Knapton 2020). Dechant et al. (2002c) summarized the results of several studies. In Saskatchewan, its occurrence was negatively correlated with distance from the nest to a shrub and positively associated with narrow-leaved (less than 5 mm) grasses 10-30 cm tall. In North Dakota, its abundance was positively correlated with the density of low-growing shrubs (snowberry and silverberry) and introduced grasses (smooth brome, Kentucky bluegrass, and quack grass). It was negatively associated with plant communities dominated solely by shrubs, native grasses, or wet-meadow plants. The strongest predictor of its abundance was increasing coverage by low-growing shrubs. In Conservation Reserve Program (CRP) lands in North Dakota, it was positively correlated with alfalfa and sweet clover which may substitute for shrubs. In Alberta, hayfields mowed after 15 July were preferred to fields mowed earlier, but use of idle land was greater than hayfields. Lightly to moderately grazed grasslands are often used for nesting, but shrub cover is probably a more

important factor in determining habitat suitability than grazing intensity. Cropland is rarely used for nesting but may provide sparser shorter vegetation that is suitable for foraging.

In grasslands and shrubby areas, the Clay-colored Sparrow tends to nest near edges of patches. In Alberta, it decreased in abundance as the distance to a crop edge increased. It demonstrated no clear attraction or avoidance of gravel roads but decreased with distance from wetlands and selected for wetland-edge habitats. It prefers denser vegetation, which occurred at wetland margins, and croplands may provide foraging habitat. Although it was more abundant near edge, it did not avoid the interior of habitat patches. Edges of grasslands are more likely to be invaded by shrubs and therefore be superior habitat. In some cases, density of small-mammal predators is high in the interior of grasslands (Sliwinski and Koper 2012). In Saskatchewan, it was more abundant in irregularly shaped patches with greater density of shrubs (Davis 2004; Davis et al. 2006; Johnson and Igl 2001).

The Clay-colored Sparrow does not appear to be an area-sensitive species. In Ohio, Watts and Albin (1996) reported a territory in a 2-ha field with an adjacent 8-ha grassland. Near Edmonton, Salt (1966) reported 15 pairs nesting within a 2.6-ha patch of habitat, of which only 2.0 ha were used. In Saskatchewan, Davis (2004) did not record it nesting in the smallest patch he studied, which was 8 ha. It tended to occur more often in smaller patches, but this relationship was not significant. Davis et al. (2006) found that patch size and shape had no effect on its density or nest survival rate. In Minnesota, its probability of observation was highest in small patches near a forest edge but nest productivity was greatest distant from an edge (Dechant et al. 2002c). In Wisconsin, its abundance was not related to patch size. In Minnesota and North Dakota, nest density was influenced by patch size but the magnitude and direction of the relationship varied by year and location; patch size did not influence nest success. The patches studied were fairly large, with a mean size of 226.1 ha (range 2.4-1,245.6 ha; Grant and Knapton 2020; Winter et al. 2006). Johnson and Igl (2001) studied fields 2.2-270.5 ha in Montana, North Dakota, South Dakota, and Minnesota. The fields had been recently planted with grasses and legumes so minimal shrub invasion had occurred. They concluded that the Clay-colored Sparrow tended to favour larger grasslands even though it was negatively correlated with patch size at 2 of 9 of their study areas.

Eighty percent of Ontario nests were in living trees and shrubs and the remainder were on or near the ground. Small conifers supported 70.0% of nests in trees and shrubs and 30.0% were in deciduous saplings and shrubs. The most common nest-species included pines (8 nests), spruces (2 nests), and raspberries (2 nests). Nests were well concealed and usually near or against the trunk in a crotch. Some were low enough that they were partially supported by grasses growing through the lower tree branches. Elevated nests were 0.1-1.8 m from the ground with most 0.2-1.0 m up. Ground nests were in grass and forb clumps, often near the base of a tree. One was concealed by an overhanging clump of dead grass and vetch (Peck and James 1987). Warburton (1952) reported 3 nests near Sault Ste. Marie that were 10-36 cm from the ground. They were in willows, anchored to almost vertical stems.

A high proportion of nests in the prairies are in snowberry so the height of nests is generally lower. In Manitoba, 110 of 125 nests (88.0%) were entirely or mainly in snowberry and only 6 nests (4.8%) did not have snowberry as support of the nest. Snowberry represented 58.0% of the

vegetation in the study area but 89.0% of the vegetation in territories was snowberry and 83.7% of nests were in snowberry. Grass stems were incorporated into the nest substrate slightly more than expected, possibly due to the tendency to nest at edges of snowberry patches where grass was more prevalent. Approximately 85% of nests were within 30 cm of the ground or lower. Individual pairs tended to construct their nest at a constant height throughout the season (Knapton 1979a). Near Edmonton, first nests tended to be on the ground in tussocks where snow and wind had matted dead grasses into clumps. Some were as high as 25 cm from the ground (average 12.7 cm). Later in the season, the Clay-colored Sparrow nested in roses or snowberry and the average nest height increased to 33 cm. In other areas near Edmonton, it nested in willow, caragana, spruce, and pine. In 3 of 5 cases, replacement nests were in similar cover to the first nest, but at greater height (Salt 1966). A Saskatchewan replacement nest was 45 cm closer to the ground than the original nest; the first nest was in snowberry and the second was in a tussock of grass. Average nest height from the ground was 8.0 cm (Fox 1961). In Minnesota and North Dakota, the average height of 793 nests was 13.5 cm. Nests averaged 11.0 m to the nearest shrub and 9.2 m to the nearest tree. Litter depth at nests was 4-9 cm and vegetation height averaged 48.7 cm. Clay-colored Sparrow nest sites differed significantly from those of the Savannah Sparrow and Bobolink. Clay-colored Sparrows placed their nests more frequently in shrubs and less frequently in litter, and were higher above ground. Vegetation surrounding its nests had less grass and litter cover and more shrub cover, vegetation was taller, visual obstruction readings were higher, and nests were closer to shrubs and trees (Winter et al. 2004). In North Dakota, the average height of 602 nests was 24 cm (range 0-66 cm). Thirty-three percent of nests were oriented east-southeast and 25% faced south-southwest counter to the prevailing northwest wind (Grant and Knapton 2020). In British Columbia, 64% of nests were in shrubs or low vegetation, 23% were on the ground, and 6% were in low deciduous shrubs. Ground nests were often in a clump of grass at the base of a tree or shrub. Nest height ranged from 0 to 1.8 m, with most nests 0.1-0.5 m from the ground (Campbell et al. 2001). Nests near the ground may be completely covered with grasses, and nest species may include hawthorn, juneberry, and conifers (Root in Austin 1968). In Michigan, nests averaged 50 cm from the ground (range 27-75 cm) in shrubs 1.5-1.8 m tall. Nests were usually in the densest part of the shrub in a crotch or in a natural cupping of the vegetation. Nest shrubs were typically on the slope of a hill and not at the top or in the valley. Six nests were in maples, 2 were in oaks, and 1 each were in juneberry and hawthorn (Walkinshaw 1939a). One Ohio nest was 19.1 cm from the ground in a multiflora rose 112 cm tall (Watts and Albin 1996). Old nests are not reused and they do not survive the winter (Grant and Knapton 2020).

In Manitoba, males started to establish territories the day they arrived. In Alberta, males arrived in the first week of May but did not establish territories until about mid-May. Once boundaries were established, neighbours rarely trespassed and aggressive interactions declined significantly by mid-May in Manitoba. Males returning from previous years had few aggressive encounters among themselves. Most aggression was between old and new birds and among new birds. Once established, territorial boundaries did not change and returning birds used exactly the same territories. Even when birds were removed, neighbours did not encroach into the vacant territory. Interspecific territoriality may occur between the Clay-colored Sparrow and Chipping, Brewer's, and Song sparrows. This involves only singing and song-post displacement. The Clay-colored Sparrow

does not forage in its territory. Territories in Manitoba were clumped together in a small patch but this was best explained by the distributional pattern of snowberry, which provided nesting habitat. Clumping was not related to coloniality. Peripheral territories were significantly larger than those in the centre of the patch, probably due to the greater number of neighbours associated with central territories. Peripheral territories might be superior because adults have less distance to travel to reach foraging areas. There was no difference in nest success in peripheral and central territories. Returning males reoccupied 74.2% of central territories and 72.2% of peripheral territories and new birds claimed whatever territories remained unoccupied. There was no preference for either peripheral or central territories. Nests close together were significantly less successful than those further apart. Internest distances were greater than random distances, so nest placement was affected by the locations of neighbours' nests. Each year at 2 Winnipeg sites, there was a size of territory that was more frequent than others. Overall mean territory sizes were 971 m^2 and 1,053 m^2 on 1 study area over 2 years and 739 m^2 and 676 m^2 on the other. At the first study area, the most frequently defended territories were 800-1,000 m^2 in both years and 400-800 m^2 and 400-600 m^2 on the other site. More young were fledged in the size range of territories that was most abundant. Lower reproductive success occurred in territories smaller than optimal, probably due to predation. Elsewhere, territory size has been estimated at 0.1-0.5 ha. Territory size and arrangement may depend on shrub coverage. It is possible that some of the estimated territory sizes included foraging areas and may be more representative of home range sizes than territory sizes (Dechant et al. 2002c; Grant and Knapton 2020; Knapton 1979a, 1979b; Root in Austin 1968; Salt 1966; Watts and Albin 1996).

Natal philopatry rates are very low, although there are limited data. In Manitoba, 0 of 146 nestlings returned and 4 of 305 juveniles (1.3%) returned (Knapton 1979a).

Males have high site fidelity rates; females do not. Male return rates at 2 Manitoba study areas were 35 of 66 (53.0%) and 85 of 120 (70.8%). Of those that returned, 76% occupied the same territory and often used the same song perches. Occasionally 2 adjacent males exchanged territories. Seven of 10 males involved in these exchanges had not raised any young the previous year; the other 3 had been successful. Female return rates at the same study areas were 12 of 66 (18.2%) and 20 of 120 (16.7%). Returning females usually did not return to the same territory and had a different mate. Three males were translocated. None returned in the same year but 1 returned the following year and reoccupied his original territory (Knapton 1979a, 1979b). In Minnesota, 3 of 52 adults (5.8%) returned. One North Dakota bird was recaptured in the same location 5 years later (Dechant et al. 2002c).

Limiting Factors

Eggs have been reported in Ontario nests from mid-May until the third week of July, but most are present 10-26 June (Peck and James 1998b). Nest construction takes 2-4 days. It appears as though egg laying begins the day after the nest is complete. Normally 1 egg is laid per day but the fourth egg was laid at least 3 days after the third in 1 nest. Incubation begins with laying of either the penultimate or final egg and often when the third egg is laid regardless of clutch size. The incubation period near Sault Ste. Marie was 10-11 days and the incubation period was estimated to be at least 11 days at 3 other Ontario nests. Elsewhere, the incubation period has been reported as 10-14 days.

Because incubation may start before the clutch is complete, hatching may either occur on the same day or be spread over 2 consecutive days. Young leave the nest when they are 6-11 days old. In North Dakota, the age at fledging averaged 8.7 days (range 6.9-10.3 days) for nests monitored by video and an average of 8.2 days (range 6-11 days) for nests visited by humans. The presence of predators or observers may induce young to leave the nest earlier (Fox 1961; Grant and Knapton 2020; Knapton 1979a; Peck and James 1987; Root in Austin 1968; Salt 1966; Walkinshaw 1939a; Warburton 1952).

Second broods are rare, with most pairs raising a single brood in a season. Second broods have not been documented in Ontario. Second broods have been suspected in Michigan, Minnesota, and North Dakota, but not confirmed. One Minnesota male raised 2 broods in a year, but with different females. Double broods have been confirmed only in Manitoba. In 1 year, pairs that successfully raised a brood did not attempt a second one. The following year, 11 of 20 pairs (55.0%) that fledged young prior to 23 June attempted a second brood, and 5 (45.5%) were successful. No birds that fledged young after 23 June attempted a second brood. If the first nest is lost or deserted, replacement clutches are laid. Building of the new nest usually begins the day after the loss. As many as 4 attempts to raise a clutch may be made. Replacement nests are usually close to the original nest. Two Saskatchewan replacement nests were 16 and 23 m from the original nests, and another replacement nest was 3.7 m from the first nest. In 1 case, a replacement clutch was laid 3 m from the original nest. When the replacement nest was lost, a third nest was initiated between the first 2 nests. Clutches of 2-5 eggs have been reported in Ontario, with 4 eggs most frequent (mean 3.89 eggs). Elsewhere, clutches of 3-5 eggs have been reported, with most containing 4 eggs. A review of North American clutches determined that 7% of clutches contained 3 eggs, 82% contained 4 eggs, and 11% contained 5 eggs. In Manitoba, there was no difference in the clutch sizes of early nests (mean of 3.56 and 3.83 eggs over 2 years) and late clutches (3.75 and 3.60 eggs). Replacement clutches have 4 eggs and occasionally 5 eggs; most 3-egg clutches are laid late in the season. In Saskatchewan, later clutches were as large as early clutches; early clutches were larger in Minnesota and North Dakota. Mean clutch sizes reported elsewhere include 3.3 eggs in unparasitized nests in Minnesota, 3.80 eggs in unparasitized nests and 3.77 eggs overall in Minnesota and North Dakota, 3.8 eggs in Saskatchewan unparasitized nests, and 3.83 eggs in Alberta (Buech 1982; Campbell et al. 2001; Davis 2003; Dechant et al. 2002c; Fox 1961; Grant and Knapton 2020; Hill and Sealy 1994; Knapton 1979a; Peck and James 1987, 1998b; Root in Austin 1968; Salt 1966; Walkinshaw 1939a; Warburton 1952; Winter et al. 2004).

The Clay-colored Sparrow is capable of breeding when it is 1 year old and breeds every year thereafter. In 1 year in Manitoba, new pairs took over territories and attempted to breed midway through the breeding season in late June and early July after territories had been vacated by successful pairs. When territorial males were experimentally removed, all were replaced by an unbanded male within 3 days and each replacement male attracted a female. This suggested that there was a surplus of nonterritorial birds. There is a high probability that these are yearling birds and those that breed later where other pairs have successfully nested may also be inexperienced birds. The mating system is monogamous; no evidence of polygyny or extra-pair copulations has been found. Pair bonds remain stable throughout the breeding season and for replacement nests. Returning females usually do not mate with their previous year's male and typically pair with another

male on a different territory. In Manitoba, 29 of 32 returning females (90.6%) did not mate with the same male. One pair occupied the same territory and remained together 3 consecutive years (Grant and Knapton 2020; Knapton 1979a, 1979b).

Foraging and food gathering for the nestlings occurs away from the territory in arable and pasture land, weedy edges, and around margins of ponds and marshes. Individual males appear to forage in specific locations but there was no evidence that these areas were defended. Pairs with peripheral territories foraged adjacent to their territories; those with central territories probably flew to the nearest foraging area. Within pairs, the male flew significantly further from the nest to the foraging location. When both left the territory together, the female alighted first and closer and the male flew further before landing. This suggests that there is spatial partitioning of foraging areas between the members of a pair. Mean foraging distance for 6 males was 32.5-94.7 m compared with 29.9-78.9 m for 6 females. The Clay-colored Sparrow typically gleans from ground vegetation and rarely forages above ground in shrubs. Males may flycatch insects from their singing posts and feed the female while she is incubating (Fox 1961; Grant and Knapton 2020; Knapton 1980).

The Clay-colored Sparrow eats mostly seeds and other vegetable matter. Nestlings are fed invertebrates and adults may also consume them at this time. In Manitoba, food brought to nestlings consisted of 42.8% caterpillars, 18.1% orthopteran nymphs, and 15.6% odonates. Other prey included 9.7% flies, 3.8% adult lepidopterans, 2.0% beetles, 1.8% neuropterans, 0.7% spiders, 0.1% bugs, and 5.4% unidentified invertebrates. There were large differences in the diet of nestlings in different nests. A pair whose territory was close to a pond fed their young narrow-winged damselflies almost exclusively. Another pair fed their young predominantly short-horned grasshoppers and caterpillars dominated the nestlings' diet at 5 other nests. More caterpillars were taken in June, odonates increased in the diet in July, and there tended to be a general increase in the number of orthopteran nymphs brought to young over the breeding season. Similar-aged nestlings in different nests did not receive the same foods, suggesting that adults were not selectively choosing prey according to the age of nestlings. Both adults and young eat a high proportion of grasshoppers. In an area where grasshoppers had been controlled by a pesticide, adults ate twice as many dead as live grasshoppers. In Manitoba, young were fed grasshoppers exclusively for the last 4 days they were in the nest (Forsyth et al. 1994; Knapton 1980; Root in Austin 1968; Walkinshaw 1939a; Warburton 1952). In early spring, adults often eat willow catkins and buds of snowberry, elms, and other trees; geometer moth caterpillars are consumed in spring. Adults also eat leafhoppers, ants and other hymenopterans, adult lepidopterans, and spiders. In late summer, it eats seeds of lamb's-quarters, amaranths, tall tumble mustard, sweet alyssum, pepperweed, Russian thistle, green foxtail, and other grasses. In banding traps operated in autumn, the Clay-colored Sparrow may be attracted by cracked corn, millet, sunflower seeds, bread crumbs, and occasionally berries. Crabgrass seeds are particularly favoured in autumn (Root in Austin 1968; Warburton 1952).

The Clay-colored Sparrow is a common host of the Brown-headed Cowbird. It may either accept or reject cowbird eggs. The rate of parasitism is highly variable, even in locations quite close to each other, and depends upon factors such as nest placement, tree coverage, abundance of cowbirds, and availability of other host species. None of these factors appear to be constant and relationships with them and the rate of parasitism may be positive in 1 area and negative in another. In 2 nearby

study areas in Manitoba, sparrows accepted cowbird eggs in 1 area and consistently rejected them in the other by deserting the nest. Where eggs were accepted, 54 of 93 nests (58.1%) were parasitized compared with 30 of 139 nests (21.6%) where eggs were rejected. The higher parasitism rate in the first study area was thought to be due to higher numbers of cowbirds and fewer nests of other species to parasitize. The parasitism rate in the first area declined in the last 2 years of study, possibly due to cessation of cattle grazing which may have resulted in better nest concealment. Individual pairs were consistently either acceptors or rejecters of cowbird eggs throughout the season. Of 6 parasitized females that returned in a subsequent year, the same 4 were acceptors and the same 2 were rejecters (Knapton 1979a). In another Manitoba study, 22 of 204 nests (10.8%) were parasitized, mostly prior to 21 June. The Clay-colored Sparrow deserted 59.1% of these nests, accepted cowbird eggs at 36.4% of nests, and the outcome at 1 nest was unknown. Cowbirds removed sparrow eggs in a 24-hour period before or after parasitism. Ten of 15 clutches (66.7%) that had the clutch size reduced were abandoned but 100% of 67 clutches that received a real or artificial egg without clutch reduction were accepted. Clutch reduction and not the act of parasitism may trigger nest desertion (Hill and Sealy 1994). In North Dakota, 27 of 246 nests (11.0%) were parasitized. Pietz et al. (2009) compared parasitism rates in areas with differing tree cover, which ranged from 2-41%. The probability of parasitism was negatively associated with the percent tree cover within 2 km. For every 1% decrease in percent tree cover, the odds of a nest being parasitized increased by 15%. Parasitism rates tend to be lower for grassland species nesting in landscapes with more trees, probably due to the higher bird density in treed habitat and greater availability of alternate hosts. Parasitism decreased further from woody edges in Minnesota tallgrass prairies. In a North Dakota area, no nest further than 52 m from a perch was parasitized. Also in North Dakota, 5.1% of 781 nests were parasitized in aspen parkland and 14% of 694 were parasitized in treeless prairie (Dechant et al. 2002c; Grant and Knapton 2020). Trees may provide perches where female cowbirds can watch sparrows to find their nests. In a Minnesota Christmas tree plantation, parasitized nests were better concealed than unparasitized nests, suggesting that female cowbirds detected host nesting activity and then searched for nests (Buech 1982). In addition to removing eggs from sparrow nests that the cowbird intends to parasitize, it may also remove eggs or nestlings from nests that it has no intention of parasitizing. The cowbird may do this to induce renesting, thereby providing additional opportunities for parasitism (Granfors et al. 2001). Because of egg removal, reproductive success of the Clay-colored Sparrow is reduced. In 1 Manitoba study, parasitism accounted for the loss of 2.16% of sparrow eggs and in only 1 case did both a cowbird and sparrow fledge. In all other cases, all sparrow nestlings died if a cowbird was raised. In another Manitoba study, 32 sparrow eggs were removed from 22 parasitized nests, a loss of about 1.5 eggs per nest. In Saskatchewan, no sparrows fledged from 8 parasitized nests, but an average of 2.0 sparrows fledged from successful parasitized nests in another study in that province. This was not significantly different from unparasitized nests. In Minnesota and North Dakota, the clutch size of parasitized nests was 0.7 eggs less than for unparasitized nests. Successful parasitized nests fledged 1.32 fewer sparrows than unparasitized nests. In 26 North Dakota nests, 13 fledged both cowbirds and sparrows and 13 fledged only cowbirds. In Minnesota, 23% of sparrow eggs produced fledglings in parasitized nests compared with 49% in unparasitized nests. Because few sparrows fledge from parasitized nests, it is maladaptive to accept cowbird eggs. The incidence of parasitism decreases with the season so replacement nests are less likely to be parasitized (Buech 1982; Davis 2003; Fox 1961; Grant and

Knapton 2020; Hill and Sealy 1994; Knapton 1979a; Winter et al. 2004). In Ontario, 11 of 35 nests (31.4%) were parasitized (Peck and James 1998b). Results from different areas demonstrate the high variability of parasitism rates: 13 of 40 nests (32.5%) in a Minnesota Christmas tree plantation (Buech 1982); 8 of 9 nests (88.9%) and 26.8% of 82 nests in Saskatchewan (Davis 2003; Fox 1961); 5.1% of 781 nests in tallgrass prairie in Minnesota and North Dakota (Winter et al. 2004); 68 of 492 nests (13.8%); 38% of 42 nests, and 16.9% of 496 nests in North Dakota (Granfors et al. 2001; Grant and Knapton 2020); 2 of 58 nests (3.4%) in British Columbia (Campbell et al. 2001); and 20 of 31 nests (64.5%) and 26 of 52 nests (50.0%) in Manitoba (Root in Austin 1968).

Habitat loss does not appear to be an issue in Ontario, and much potentially suitable habitat is unoccupied. Coniferous plantations may become unsuitable once they mature and the crown closes, killing the understorey vegetation. In the core of its range in the prairies, conversion of grasslands to croplands results in habitat loss and is one of the contributing factors to its decline in that area. Removal of shrubs is also detrimental because the Clay-colored Sparrow is more of a shrub than grassland species. The quality of remaining grasslands has been diminished by fragmentation, invasive plants, fire suppression, certain livestock grazing practices, roads, and energy extraction (Askins et al. 2007; Curry 2006; Grant and Knapton 2020; Paquin and Letourneau in Gauthier and Aubry 1996; Root in Austin 1968; Winter et al. 2004).

Several factors can influence nest success. In Manitoba, nests within 10 cm of the ground were significantly more successful (60.9%) than higher nests (30.5%). Light penetration was significantly lower at successful than unsuccessful nests suggesting that less-concealed nests were more easily found by predators. Nests closer to the ground would have more overhead cover. Males returning to breed for at least the second year had higher nest success than males breeding for the first time. At 2 study areas, returning males had 65.0% and 82.8% nest-success rates compared with 20.0% and 53.8% for first-time breeders (Knapton 1979a). In North Dakota, nest survival was higher near forest edges because predators were more common in the interior of grasslands. Nests with more cover by Kentucky bluegrass and that were better concealed by vegetation had higher survival rates (Grant and Knapton 2020; Grant et al. 2006).

Niemuth et al. (2008) investigated the effects of drought on the Clay-colored Sparrow in North Dakota. It was positively correlated with the number of ponds present in spring. It was possibly responding to vegetation characteristics influenced in the previous year and conditions in the current year. Drought affects agricultural practices, with changes in crops, intensity of grazing, and timing of harvest. During drought conditions, CRP lands are often released for emergency haying or grazing, which alters the structure of grassland vegetation. This may be detrimental to the Clay-colored Sparrow because these practices reduce the shrub coverage that it prefers. In South and North Dakota, Montana, and Wyoming, there was no relationship between its abundance and weather (Gorzo et al. 2016).

Early haying can destroy Clay-colored Sparrow nests (Winter et al. 2004). Tews et al. (2013) estimated that the incidental take of this sparrow in Canada due to mowing and other agricultural practices was 111,071 annually. These numbers represent eggs and nestlings that are potentially destroyed. All incidental mortality due to agriculture was in western Canada. It does not typically nest in hayfields in Ontario.

In Alberta, the Clay-colored Sparrow nested on undisturbed and grazed grasslands and was absent in mowed, fallow, and seeded fields. Territories were always associated with low shrubs such as wolfberry or willow. It occurred on roadside counts in all landscape types and was most abundant where there was a mix of grazed and cultivated land. Agricultural practices did not appear to have affected its distribution and may have had a positive influence. Its preference for shrubby areas allows it to take advantage of ditches which are common in agricultural areas (Owens and Myers 1973).

Robertson et al. (2012) concluded that the Clay-colored Sparrow could benefit from the production of perennial grasses for biofuels. This type of habitat is unlikely to be used in Ontario and may be marginal habitat elsewhere because of the tall dense grasses and lack of shrubs. Use of corn for biofuels does not provide habitat for it.

The Clay-colored Sparrow tolerates light to moderate grazing because this typically results in short grass with scattered shrubs and tall unpalatable herbaceous species such as thistles. Heavy grazing is detrimental because this usually results in the removal of the shrub coverage that it prefers (Dechant et al. 2002c; Pylypec 1991).

Burning of grassland habitat appears to be detrimental to the Clay-colored Sparrow, particularly if the fire is intense enough to kill shrubs. In Wisconsin, spring burning of residual cover resulted in a 94% decline of this sparrow even though shrub density was not decreased. In South Dakota, it avoided burned areas. In North Dakota, it responded negatively to fires in mixed-grass communities and was most abundant in areas that remained unburned for more than 80 years compared with those burned 0.5-8 years ago. Numbers increased with the number of years since fire suggesting that moderate and long fire-return levels would be most beneficial. Some burned areas were used immediately after burning, but by lower numbers (Madden et al. 1999). In North Dakota, nest survival was not related to fire history but declined with increasing prevalence of woody cover in the landscape. Tall woody cover consisted mostly of chokecherries and 3-6-m-tall green ash. The proximity of nests to the nearest patch of tall woody cover or low shrub cover had no effect on nest survival. Murphy et al. (2017) concluded that the use of prescribed fire to reduce patches of tall woody growth does not adversely affect Clay-colored Sparrow nest survival and may improve it. In Saskatchewan fescue grassland, populations were reduced by prescribed burning. Three years after burning, the breeding population was 66% of what it was prior to burning (Grant and Knapton 2020). The effects of fire are likely to vary at different sites depending on how dense and tall the woody vegetation is prior to fire.

Forsythe et al. (1994) analysed the effects of spraying carbofuran to control outbreaks of grasshoppers. There was no evidence of reduced nestling survival for 3 days following spraying in a pasture and there was no mortality of adults that ate grasshoppers killed by carbofuran. This suggested that adults and nestlings are able to tolerate dietary exposure to carbofuran sprayed at the rate of 134 g per ha.

In North Dakota and South Dakota, Shaffer and Buhl (2015) studied the reaction of the Clay-colored Sparrow to turbines in wind farms. There was no significant change in its abundance before and after the turbines were present, but the trend was negative. The magnitude of differences in density of more than 20 birds per km^2 between turbine sites and reference sites suggested that it

may have experienced immediate displacement. After 1 year, it exhibited significant displacement within 200 m of turbines at 1 site and more than 300 m at the other study area. Delayed displacement may have been due to site fidelity with birds not returning in subsequent years, and new birds may be unwilling to settle near turbines. Removal of woody vegetation during road construction and turbine installation may have reduced breeding habitat. The displacement distance for it from turbines was considered to be 200 m. In Minnesota, higher densities of the Clay-colored Sparrow occurred more than 180 m from turbines than within 80 m of turbines (Grant and Knapton 2020).

In Alberta, there was no significant difference in the abundance of the Clay-colored Sparrow along seismic lines and in forest interior. It was significantly more abundant near pipelines and well pads than in adjacent forest interior (Bayne et al. 2016).

Some nests may be lost due to exposure to wind and rain, but this is usually a minor impact. In Manitoba, 1.3% of nests failed due to exposure and 2.9% of abandoned nests failed due to exposure (Grant and Knapton 2020). In Minnesota, 3 storms that produced more than 18 cm of rain in 2 weeks destroyed 82.4% of 17 nests (Root in Austin 1968).

Dechant et al. (2002c) offered recommendations for managing prairie grasslands for the Clay-colored Sparrow: allow grasslands to remain idle for long intervals to encourage shrubby growth, leave patches of shrubs when using fire or herbicides, maintain grasslands with tall forbs and abundant litter, discourage conversion of shrubland to cropland, maintain shrubby areas around cropland, and avoid heavy grazing that removes ground cover or shrubs. Woodland edges, wooded riparian areas, and other linear woody habitats such as windbreaks and shelterbelts could provide habitat.

Price (2004) predicted that the Clay-colored Sparrow could disappear as a breeding species from southern Ontario if the average summer temperature increased by 2°C. Nixon et al. (2016) predicted the area of suitable climate in Alberta would decrease slightly by the 2050s and by 26% by the 2080s. This was due to a northward shift in suitable climate to outside of the province. They projected that the area of suitable habitat within suitable climate regions would be reduced by approximately 20% by the 2050s and 40% by the 2080s.

Status

The Clay-colored Sparrow is a relatively recent arrival in Ontario. Forest clearing followed by regeneration and planting of coniferous plantations allowed it to expand north and east into Ontario. Prior to deforestation by Europeans, it is likely that it was confined to prairie habitat in the central portion of North America. There is some evidence that its eastward extension into Ontario occurred both north and south of Lake Superior (Baillie 1967; Campbell et al. 2001; de Vos 1964; Grant and Knapton 2020; Root in Austin 1968).

The Clay-colored Sparrow was first recorded in Ontario at London in 1894. The first nest was found at Thunder Bay in 1922 (Baillie 1967; Dale 1927). Baillie and Harrington (1937) stated that it occurred not uncommonly in various locations along Lake Superior westward to the Manitoba border. Breeding had been confirmed by then at Thunder Bay and Kenora and it was thought that it could breed in most suitable locations between Lake Superior and Lake of the Woods. Nesting

rarely occurred in the southern portions of the province at that time, with breeding records from Renfrew, Huron, Simcoe, and York. It was not known to nest east of Lake Superior until 1931 when the first record occurred in Algoma District. It first nested in southern Ontario in 1950. By the 1960s, it had nested in the Sault Ste. Marie, Ottawa, Craigleith, Halton, Waterloo, and Hamilton areas and there were scattered records in the north east to Fort Albany (Baillie 1967; Baillie and Harrington 1937; Curry 2006; de Vos 1964; Godfrey 1966; Mitchener 1956; Peck and James 1987; Warburton 1952). The first atlas demonstrated that it was widespread yet sparingly distributed throughout the province, with the exception of the Boreal Forest Region where it was very rare and sporadic in occurrence. Several breeding records were obtained in the Hudson Bay Lowland where it occurred sparingly along the Hudson Bay coast and more commonly along the southern James Bay coast from Moosonee to Attawapiskat. This represented a northward extension to the known breeding range. It was most abundant in the Thunder Bay and Lake of the Woods areas, with minor concentrations in the Ottawa area and along the southern edge of the Canadian Shield (Knapton in Cadman et al. 1987). James (1991) considered it a common local breeder in western Rainy River District; uncommon at Thunder Bay; and rare and local in the south and the north at Moosonee. There were scattered summer sightings north to Fort Severn and Attawapiskat. Wilson and McRae (1993) reported that there was an established breeding population in the coastal regions of the Hudson Bay Lowland.

The second atlas indicated that there had been no substantial change in the breeding range of the Clay-colored Sparrow, although it was slightly more widespread in the Boreal Forest Region than previously. Considerable infilling occurred within its range. Its probability of observation increased province-wide, but not significantly. In all regions, the trend was positive and was significant in the Carolinian, Great Lakes–St. Lawrence, and Boreal forest regions. Highest densities were in the Rainy River area. In the south, it was most abundant on shrub alvars and in old fields on the Carden Plain and the Napanee Limestone Plain between Belleville and Kingston (Rising in Cadman et al. 2007).

The BBS has some limitations for the Clay-colored Sparrow because only the southern portion of its range is sampled in the Prairie Provinces. In Saskatchewan, there was no significant difference in its abundance along roads and trails, so BBS results were representative of its abundance (Sutter et al. 2000). BBS data for 1970-2021 indicate that the Clay-colored Sparrow decreased at annual rates of 1.22% in Canada and 0.272% in Ontario. The trends for 2011-21 were annual decreases of 2.5% in Canada and 2.78% in Ontario. The long-term trend for Ontario and short-term trend for Canada were highly reliable; the other trends were of medium reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Young are incapable of flight when they leave the nest. Fledglings disperse radially and hop through the shrubbery or may be lead by the adults to a safer place. In Manitoba, 8 fledglings initially moved an average of 13.6 m (range 6-21 m) from the nest to shrubbery. Once in dense shrubbery, they usually climb up the base of a shrub and remain motionless, waiting to be fed. When they are a bit older, the young become very active within snowberry or the prevailing shrub cover. Young are fed by the adults for at least 8 days after they leave the nest. By the time the young are 14-15 days old (about 5-6 days after leaving the nest) they are capable of flight. They gather together in small loose flocks and disperse onto adjacent territories where they are shown no aggression. Soon they begin

to wander widely and may appear in habitats such as grain fields, around ponds and potholes, in other shrubby habitats, in gardens, and among trees. Dispersal from the nesting area may be rapid. One bird banded as a nestling was recovered 2 km distant 13 days later. Others may congregate in favourite foraging areas, such as pond margins, a short distance from the nesting area. Nesting areas are usually devoid of birds by mid- to late July, although birds may remain in the general area into August. Little is known of their movements from then until the onset of autumn migration (Dechant et al. 2002c; Grant and Knapton 2020; Knapton 1979a; Root in Austin 1968; Salt 1966).

MIGRATION

The Clay-colored Sparrow migrates both nocturnally and diurnally, with diurnal migration most evident in autumn. It travels in flocks either by itself or in the company of other sparrows. Very large flocks may occur in autumn in the core of its range. In Ontario, where it is seldom seen during autumn migration, only solo birds are typically seen. In the Great Lakes region, spring migrants pass through Point Pelee, Sault Ste. Marie, and Manitoulin Island into western Ontario. It also passes through Manitoba and Minnesota in spring, and lesser numbers pass through Point Pelee in autumn (Grant and Knapton 2020; Root in Austin 1968).

In Manitoba, males arrived an average of 5 days before females in spring (range 3-7 days; Grant and Knapton 2020; Knapton 1979a). In southern Ontario, the Clay-colored Sparrow is usually on territory by mid-May, but birds may arrive in late April, mostly near the beginning of May. In the southern Shield, it arrives in the third week of May. There are few autumn records for Ontario, possibly because it migrates further west in autumn or because it may be difficult to distinguish from the Chipping Sparrow. The latest observation at Longridge was 5 September. The 3 autumn records for Algonquin Park span the period of 30 August to 10 October. In the south, migration extends from early September or very late August until mid-October, with stragglers to early November (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Tozer 2012; Weir 2008; Wilson and McRae 1993).

In Algonquin Park, spring migrants are usually seen along hydro corridors, at old sawmill sites, and in open areas with small trees (Tozer 2012). Elsewhere, migrating Clay-colored Sparrows occur in thickets, copses in open parkland or pastures, weed patches, and grassy areas where it shows a preference for borders of fields, woods, roads, and streams. During autumn migration, it may occur in urban parks and gardens, and sometimes comes to lawns, bird baths, and lawn sprinklers. During spring migration in British Columbia, it frequents open landscapes such as open hillsides, clearings, gravel pits, beach edges, dykes, regenerating clear-cuts, and lawns where the plant cover is dominated by grasses, dead forbs, and shrubs. In autumn, most are observed in shrub patches bordering fields, overgrown fields, pastures, hedgerows, and at margins of lakes, ponds, and marshes. Areas where grass and forb seeds are abundant are selected (Campbell et al. 2001; Leighton et al. 2002; Root in Austin 1968).

James (1991) considered the Clay-colored Sparrow a rare migrant in Ontario. Most regional books on Ontario's avifauna classify it as a rare or very rare migrant and it appears to be very rare in autumn throughout the province. Most migration records are of individuals or very small numbers. An exception is the 27 seen on 23 May in the Kingston area (Weir 2008).

Field Sparrow

Spizella pusilla

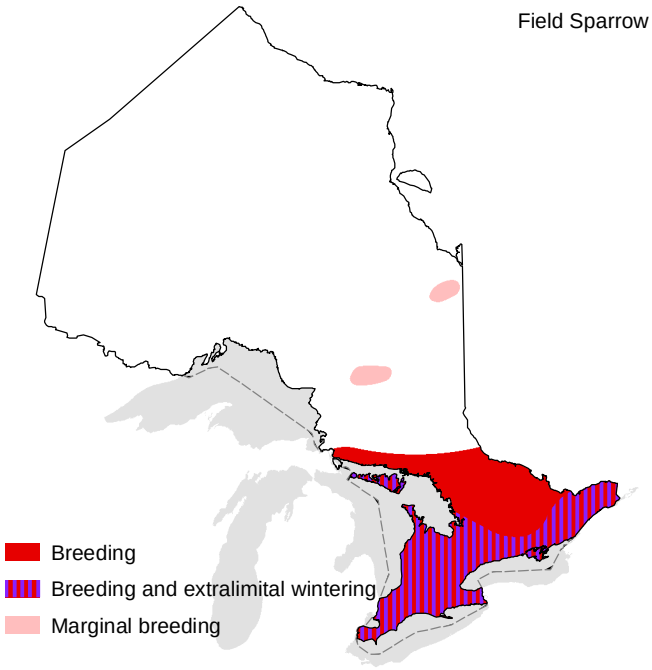
BREEDING SEASON

Habitat Requirements

In Ontario, the Field Sparrow has nested in open and overgrown fields and pastures (33.3% of nests); in Christmas trees and open coniferous plantations with small trees (33.3%); in open woodlands, woodland edges, and clearings (18.3%); in sand dunes with some grass, shrub, and tree growth (10.3%); in old orchards (1.6%); on farm and public lawns (1.6%); on overgrown bedrock outcrops (0.8%); and along railway embankments (0.8%). Most nests were in dry areas, but 4 were in undescribed wet areas, 1 was in a wooded swamp, and 1 was in a shallow marsh (Peck and James 1987).

In the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region, the Field Sparrow nested on abandoned farmland, on hydro corridors, and in young plantations in Muskoka and Parry Sound districts (Mills 1981).

In the off-Shield portion of the Great Lakes–St. Lawrence Forest Region, it preferred open habitat such as shrubby fields, thickets, and overgrown pastures in the Kingston area (Weir 2008). In Durham Region, it was common in a very young red pine plantation dominated by shrub willows with an understorey of meadowsweet. The largest pines were 1.8-2.4 m tall but most were less than 0.9 m tall. It also nested in an abandoned apple orchard that contained hawthorns. The woody vegetation was 4.6-6 m tall with an understorey of grasses. Speirs and Orenstein (1975) considered it an early forest succession species.



The Field Sparrow is an open-country species that nests in a variety of early successional habitats. Taylor and Taylor (1979) characterized it as a species of both large and small openings and forest edges. Presence of shrubs is one of the most critical habitat components. It is most common in shrubby areas with an understorey of grasses and herbaceous species, infrequent in forest edges and forests with open canopies, and rare in grasslands with no woody cover. In Quebec, it occurs mostly in lands reverting to scrub, hedgerows bordering pastures, and young pine plantations (Yank and Dauphin in Gauthier and Aubry 1996). In New York, it nested at the edge of a Scotch pine plantation (Brooks 1980) and in 2-6-year-old clear-cuts. It was most abundant 2-3 years after cutting and declined significantly as the shrub-edge openings that it used largely disappeared (Keller et al. 2003). In New Jersey pine barrens, it was a local but fairly common breeder in recently burned pine forests and in pine plains (Brush 1987). In Maine, it nested in grassland barrens dominated by lowbush blueberry with lesser amounts of grasses and sedges, loosestrifes, and shrubs such as chokeberry, alder, and birch (Vickery et al. 1994). In West Virginia, Margenau et al. (2019) compared its abundance on reclaimed surface mines. The first stage of succession was grassland 5-19 years old dominated by nonnative grasses and forbs. Shrublands were 13-27 years old and supported shrubs and trees as large as 8 cm diameter at breast height (DBH). Other plots were in remnant forests and undisturbed intact forests. It was almost 2 times as abundant in shrublands as in grasslands; it was absent in the forested habitats. In Maryland, it was abundant in an unsprayed apple orchard with an unmowed ground cover and in an abandoned field with a new growth of young pines. It was uncommon in damp deciduous scrub with standing dead trees. In Georgia, it inhabits fields and pastures overgrown with raspberry thickets and deciduous underbrush. It avoided older pine woods but readily inhabited them after they were clear-cut or until they were 25-35 years old and still had a grassy understorey (Johnston and Odum 1956; Walkinshaw in Austin 1968). In North Carolina, it was abundant in fields recently planted with pines and common in pastures regenerating with pine (Carey et al. 2020). Planted pine trees less than 1.8 m tall codominated with Virginia broomsedge

supported a much higher density than where the pines were less than 0.9 m tall and codominant with fescue grasses and bush-clovers. Reproductive success was significantly higher in the latter habitat with larger clutches, more fertile eggs, a higher survival rate, and fewer female desertions. Its density may not be an indicator of habitat suitability (Fretwell 1969a). In North Carolina, Moorman et al. (2017) compared Field Sparrow usage of warm-season grass forage fields (hayed or grazed), nonnative cool-season hayed or grazed forage fields, and fields of native warm-season grasses and forbs. It occurred in all field types but its density was more than 3 times greater in native grasses than those that were hayed or grazed. Preferred fields had taller grass and greater forb density than other field types, had dense litter layers, and were often near woody edges. In Arkansas, it nested in fields dominated by grasses and sedges (Luscier and Thompson 2009). In the same state, as fields became invaded by shrubs and small trees, it became characteristic of the habitat and was among the most abundant species. It occurred in a burned field of Virginia broomsedge with scattered dead trees, in Virginia broomsedge and herbaceous species with clumps of trees, in a sassafras stand where the canopy was not quite closed but the grass layer had been killed out, and in forest edge with dense sumac and blackberry (Shugart and James 1973). In Pennsylvania, it was absent in uncut aspen and oak forests but appeared 2-3 years after 1-ha patches were clear-cut within them. The cuts provided temporary early successional habitat that was good nesting habitat (Yahner 1993, 2003). In the same state, densities declined 58% over a 6-year period in an old field, probably due to natural succession. The Field Sparrow begins breeding in old fields 1-2 years after human disturbance ceases, increases for about a decade, then declines, and by about 30 years of field age the area is not used due to natural succession (Carey et al. 2020). In Pennsylvania, it was common on a power-line corridor passing through deciduous forest but absent in the forest. It was 1 of the 6 most abundant species on the right-of-way (Yahner et al. 2002). In another Pennsylvania study area, breeding habitat consisted of old fields of grasses, herbaceous species (mostly goldenrods) and clumps of woody vegetation averaging 1.5 m in height, particularly dogwood, blackberry, viburnum, meadowsweet, ash, and honeysuckle (Carey 1990). Fields 20-35 years old were dense thickets of shrubby vegetation with only small scattered areas of open grassy habitat. It preferred breeding in open habitat with some woody vegetation (Smith et al. 2017). In Kentucky and Tennessee, its abundance was positively correlated with the amount of shrub coverage within 100 m (Lituma and Buehler 2016). In Illinois in 1957-58, it was most abundant in edge shrubs followed in order of decreasing abundance by hedgerows, along drainage ditches, shrub-grown areas, orchards, pastures, fallow fields, ungrazed grasslands, forest, and wheat. Preferred habitats included shrubs of all types, hedgerows, orchards, and pastures (Graber and Graber 1963). This survey was repeated in the 2000s. It was abundant in shrubs, common to uncommon in idle grass and savannah, and rare in row crops, hayfields, upland forests, floodplain forests, grazed grass, and grass mowed for hay (Walk et al. 2011). On reclaimed strip mines in Illinois, it was common in early shrub succession where the largest trees were 10 years old and in old shrubs where the largest trees were 37 years old (Karr 1968). Best (1977a, 1978, 1979) studied an area in Illinois that consisted of 8.5 ha of shrub-woodland, 9.0 ha of shrub-grassland, and 6.1 ha of grassland. The shrub-grassland was dominated by Kentucky bluegrass, Indian grass, big bluestem, panic grasses, and timothy. The dominant forbs included tall goldenrod, wild carrot, early goldenrod, Canada goldenrod, parsnip, yarrow, asters, and ironweed. Trees and shrubs, all less than 8 m tall, were scattered throughout and included smooth sumac, black raspberry, poison ivy, and black cherry. The shrub-grassland was the preferred habitat with all

available space occupied by contiguous territories. Territories extended into the grassland but were never completely in this habitat. Extension of territories into the shrub-woodland was limited, occurring where the forest canopy was more open. The Field Sparrow occupied transitory seral communities where succession is impeded by processes such as fire. In Ontario, more permanent habitat may occur on alvars or soils that are very nutrient-poor, but eventually even these areas regenerate into unsuitable habitat. In Indiana, Grundel and Pavlovic (2007a, 2007b) considered it the strongest indicator of open habitat in areas ranging from savannah to forest. It was significantly more abundant in open habitat with little woody vegetation than in prairie remnants and areas previously disturbed by farming or strip mining; significantly more abundant in savannahs with a moderate canopy of oak and little woody understorey than in the remaining habitats; significantly more abundant in woodlands, which were similar to savannahs but with more canopy closure than in the remaining habitats; and significantly less abundant in scrub with a high density of black oak saplings less than 5 m tall and in forest with multiple woody layers than in other habitats. It exhibited a high sensitivity to tree density, declining as tree density increased, but tree density alone did not strongly predict its distribution. On Indiana reclaimed surface mines, nests were found in shrublands and savannah areas with many scattered young trees 4-8 m tall, in open grasslands, and in open grasslands with a few areas of shrub or savannah habitat (Galligan et al. 2006). Nolan (1963) reported it breeding in abandoned upland fields separated by small timbered tracts or wooded ravines in Indiana. It was the most abundant species but less common in fields where half the ground was shaded during part of the day, either by saplings 7 m or taller or by densely growing hawthorns. In Michigan, the Field Sparrow nested on a hillside covered with blackberries, young trees, and shrubs; grass-grown meadows; pastures; and weed-grown fencerows. The dry hillside sparsely covered with blackberry was the preferred habitat but young oak trees, hazel shrubs, cinquefoil, or any other dense short vegetation in open fields may provide nesting habitat. Its habitat had tall grasses with patches of blackberry, staghorn sumac, shining sumac, New Jersey tea, and bush-clover and supported scattered small oaks, hickories, and hawthorns (Walkinshaw 1936, 1939b, 1945). Evans (1964, 1978) studied the Field Sparrow in 2 fields in Michigan. One was a grassy area dominated by Canada bluegrass and wiregrass with a rich variety of other grasses and forbs and scattered hawthorns, common junipers, and small trees. The other was grassland from 1949 to 1957, but an increase in the size and number of woody plants made the field less open by 1974-75. By 1975 the field was dotted with junipers, red cedars, and hawthorns several metres tall, there were dense patches of blackberries, and black cherry saplings 60 cm or shorter were scattered throughout. The number of junipers increased from 82 in 1950 to 273 in 1975 and they were also taller. The increase in the number of junipers created additional superior nest sites; density of sparrows increased by 73% from 1956 to 1975. The field gradually became more suitable habitat as natural succession progressed. In Missouri, cropland was planted to swamp white oak and pin oak at 9 by 9 m spacing. One of the 2 areas was planted to redtop, producing a low dense ground cover; no ground cover was planted at the other site. It nested predominantly in control areas and areas with a redtop understorey; significantly fewer nested in oaks where no ground cover was planted (Burhans et al. 2010). In Missouri, it nested in regenerating forests, glades, and forest-pasture edge habitats surrounded by forest cover. Regenerating areas had been clear-cut 3-5 years previously. The glades were burned 4-6 years previously and were characterized by dolomite outcrops with grassy areas and scattered trees and shrubs (Woodward et al. 2001). In Kansas, it nested in shrub thickets in

stream headwaters and along rock outcrops and in the border between grassland and woodland, especially in former pastures and cultivated fields growing up into thickets. It occasionally nested in woodlands where the canopy was open and the understorey was sparse. Open areas were occupied only where thickets were available (Fitch 1958; Zimmerman 1989). In Iowa, it was most frequent in upland woodland followed by woodland edge, herbaceous areas, and floodplain woodland (Stauffer and Best 1980). In Wisconsin, it was abundant in pine and oak barrens. It was abundant in oak savannahs, pine-dominated barrens, diverse barrens, river terraces, and coniferous plantations; common in shrub prairies, nearly forest, and clear-cuts; and fairly common in open-aspect barrens. It was one of the most common species in Christmas tree and forestry plantations. Its relative abundance was 12 in shrub habitat compared with 1 in open areas, heaths, and heaths with shrubs (Mossman et al. 1991). Buech (1982) reported it nesting in a Christmas tree plantation in Minnesota. In South Dakota, Gentry et al. (2006) reported it both in small (3.5 ha) tableland woodlots and large contiguous floodplain forests. In green ash woodlands in the same state, it occurred in both early and late seral stages of forest but was more abundant in young forests. Younger stands had less canopy cover and were patchier than older stands (Rumble and Gobeille 1999). In the northeast, the Field Sparrow has nested in upland deciduous forests, sapling and pole-sized poplar-birch stands, seedling-sapling-stage pine forests, and burned pine forests (Back 1979; Capen 1979; Samson 1979). Additional habitats that may be used for nesting include grassed waterways, untilled and idle cropland, shelterbelts, wooded draws, road and railway allowances, and nurseries. It avoids nesting in the vicinity of human habitation (Carey et al. 2020; Dechant et al. 2002g; Judd 1901).

Some studies examined habitat requirements of the Field Sparrow at the landscape level. In North Dakota in 400-m landscapes with less than 30% tree cover its probability of occurrence increased to 20% at 40% tree cover within 100 m and declined to 10% at 70% tree cover. The response was similar in wooded landscapes with a maximum probability of occurrence of 30% at 35% tree cover, declining to 5% at 90% tree cover. It preferred areas with 32-59% forest cover (Cunningham and Johnson 2016, 2019). In North Carolina, it was negatively correlated with the amount of tree canopy at the 200-m scale. As tree canopy increases, the amount of shrub coverage decreases. It was negatively correlated with the amount of exurban development at the 200-m and 1,000-m scales, although the relationship at the 200-m scale was not significant. It was significantly correlated with the amount of shrubland at the 1,000-m scale (Gilbert and Ferguson 2019). At the 400-m scale in Illinois, it was negatively correlated with agriculture and positively associated with forest (Glass and Eichholz 2023).

Sousa (1983) prepared a habitat suitability index model for the Field Sparrow. He concluded that availability of suitable perches such as shrubs, trees, and fences may be a limiting factor. In Missouri, the primary microhabitat features were canopy height and density of woody stems less than 2.5 cm DBH. Areas with canopy heights of 2-8 m were occupied but the preferred range was 2-4 m. The optimum density of small-diameter stems was 350-500 per ha, but it occupied a range of 25-1,050 per ha. Secondary habitat characteristics included density of stems larger than 2.5 cm and percent ground cover. The optimum range was 25-50 larger stems per ha (range 25-500 per ha) and 95-100% ground cover (range 85-100%). In Virginia, populations in regenerating hardwoods decreased as canopy height exceeded 4.5 m. Habitat in clear-cuts is suitable for 3-5 years on fast-growing sites and 10-15 years on slow-growing sites. Grasslands with no shrubs were considered unsuitable; more

than 75% shrub coverage was considered too dense. Habitats with 50-75% of shrubs shorter than 1.5 m were assumed to provide the optimum mix of tall and short shrubs. Grass coverage less than 50% was assumed to provide less than optimal nesting cover; more than 90% grass coverage may inhibit movement. The optimum height of herbaceous vegetation was 16-32 cm with suitability decreasing with increasing height due to increased difficulty in reaching the ground. The minimum size of habitat patches considered suitable to support the Field Sparrow was 2 ha. Scores on the habitat suitability index ranged from 0 (unsuitable) to 1.0 (optimum). For percent shrub crown cover, scores were 0 at 0%, increasing to 1.0 at 50-75%, and declining to 0 at more than 75%. For percent of shrubs less than 1.5 m tall, scores were 0.2 at 0%, increasing to 1.0 at 15-35%, and decreasing to 0.6 at 100%. For percent coverage by grass, scores were 0 at 0%, increasing to 1.0 at 50-90%, and declining to 0.8 at 100%. For average height of herbaceous vegetation, scores were 0 at 0-5 cm, increasing to 1.0 at 16-32 cm, and decreasing to 0.5 at taller than 40 cm.

Several studies defined microhabitat characteristics of Field Sparrow habitat. In Missouri, percent coverage of vegetation in 1-m^2 quadrants around nests consisted of 31.6% grasses, 52.2% forbs, 17.5% shrubs, and 6.7% bare ground (Burhans and Thompson 1998). In Illinois, territory size increased with the percentage of area covered by Indian grass, tall and early goldenrods, big bluestem, sedges, Kentucky bluegrass, black cherry and other species in the same genus, ironweed, yarrow, wild lettuce, and smooth sumac. Coverage by other species was independent of territory size. The frequency of occurrence of Indian grass and big bluestem increased significantly with territory size. The number of nesting attempts was negatively correlated with the frequency of occurrence of Indian grass suggesting that territories containing this species may become less attractive as the season progresses. Parsnip occurred significantly more in territories of yearlings than older birds. The opposite was true for the frequency of little bluestem and percent coverage by big and little bluestem, black cherry, panic grasses, and sulphur cinquefoil. This related to the extension of territories into a shrub-woodlot. All but 1 yearling territory extended into the shrub-woodland. The proportion of territory in shrub-woodland averaged 36% for yearlings and 20% for returning males. Frequency of male mating was correlated with the area covered by smooth brome, tall goldenrod, ironweed, Indian grass, and cherry. All these were used for nesting except ironweed (Best 1977a). In Pennsylvania, percent ground cover was the best model for predicting nest-site selection, with nest sites having higher ground cover than random sites (Schill and Yahner 2009). In Maine, abundance of the Field Sparrow was positively correlated with habitat patchiness and abundance of shrubs 60-200 cm tall. It was negatively correlated with bare ground. It was infrequent in areas that had been recently mowed or sprayed with herbicides (Vickery et al. 1994). In Illinois, its abundance was positively correlated with vegetation height and negatively correlated with mean grass height (Herkert 1994a). In Iowa, it was positively correlated with horizontal patchiness of saplings, vertical patchiness of trees, slope, grasses, and coniferous trees. It was negatively correlated with sapling and tree density and size, vines, and vertical stratification (Stauffer and Best 1980). In Illinois, daily nest survival was positively associated with grass cover both at the nest site and within a grassland patch (Glass and Eichholz 2023). In Texas, its highest probability of occurrence was at 74% canopy cover by woody species within 250 m (Plappert et al. 2024). Dechant et al. (2002g) summarized other microhabitat requirements. In Illinois, availability of trees, shrubs, or other potential perches was a key habitat component. Birds stayed within or near forest edge, not

venturing deep in the forest or more than 12-15 m into fields. In Wisconsin, density was correlated with percent woody cover, the total number of dead stems, and plant species richness.

Although the Field Sparrow was restricted to edge habitat in Illinois (Dechant et al. 2002g), other studies have not observed that it preferred or avoided edges. In shrub patches adjacent to forest edges in Missouri, areas within 20 m of the forest edge and those 20-40 m and more than 40 m distant from it were all used in proportion to their availability. Distance from edge did not affect predation rates and edges did not function as ecological traps (Woodward et al. 2001). In riparian wooded strips in Maryland and Delaware, there was no difference in its probability of detection in forests 50-800 m wide (Keller et al. 1993). In Tennessee and Kentucky, Lituma and Buehler (2016) found no differences in its abundance at roadsides or on transects 300 or 600 m from roads. In Illinois, nests further from edge had higher survival rates, but Field Sparrows did not avoid roads. It tended to nest near edges regardless of edge type (Glass and Eichholz 2023).

The Field Sparrow is not an area-sensitive species. In Ohio, it nested in patches smaller than 2 ha. In Illinois, it was encountered in patches smaller than 10 ha but was classified as moderately vulnerable to habitat fragmentation because it was encountered more frequently in large than small fragments. It was more strongly influenced by habitat structure than area. Absence from some small grassland areas may have been due to lack of suitable habitat rather than avoidance of small areas (Dechant et al. 2002g). In Maine, it was positively correlated with patch size, but not significantly (Vickery et al. 1994). In both Illinois and Iowa, its probability of occurrence was unrelated to patch size (Herkert 1994a; Stauffer and Best 1980). Near Ayr, 2 territorial males were present in an area of about 1 ha, near Erin a single territorial male was present in an area of 1 ha, and in Hamilton, 1-2 pairs nested annually in an area smaller than 1 ha (personal observation).

Ontario nests were on or very near the ground and elevated in shrubs, trees, plant clumps, and tangles of vines. Deciduous trees and shrubs (11 species) were somewhat preferred to conifers (5 species), with 60.5% of nests in deciduous species. The most frequently selected species were hawthorns (42 nests), spruces (15), pines (12), juniper (11), elms (8), apple (8), and white cedar (8). Nests were mostly in main crotches at the trunk, although 5 were on branches out from the trunk. Ground nests were usually in clumps of grass under small trees or shrubs (Peck and James 1987, 1998b). Mills (1981) reported 1 nest in a bracken fern and another in a red pine.

Nest height increases as the season progresses throughout the Field Sparrow's range. Nest building usually begins before foliage is well developed on trees and shrubs. During the first 1-2 weeks of nesting, nests are placed almost exclusively in dead grass litter from previous years. Once new grass growth overtops the dead grasses, this substrate is avoided. Once leaf-out has occurred, nests are placed in a mix of grasses, forbs, trees, and shrubs. Later in the season nests are predominantly in shrubs and trees. In Illinois, nest heights were 26 cm in May, 38 cm in June, 47 cm in July, and 48 cm in August with an overall range in height of 9-89 cm. Similar increases in nest height with season have been documented in many other areas. Nest height within a given substrate also increases with time. In Indian grass, mean nest heights were 29 cm in May, 34 cm in June, and 47 cm in July; mean heights in trees and shrubs were 27 cm in May, 42 cm in June, 51 cm in July, and 49 cm in August. Overall, nests have been found 0-4.4 m from the ground but most are 1 m or less from the ground. In a Christmas tree plantation in Minnesota, mean nest height was 44

cm in trees that averaged 1.42 m tall. Nests have been reported in a variety of grasses, herbaceous species, shrubs, and trees including Kentucky bluegrass, Indian grass, black raspberry, tall goldenrod, sweet clover, Canada thistle, elderberry, catnip, hawthorn, apple, cherry, oak, sumac, rose, elm, wild lettuce, Manitoba maple, lilac, dewberry, shrubby cinquefoil, red raspberry, bush-clover, black locust, blueberry, Japanese barberry, stiff-leaved goldenrod, hickory, red cedar, common juniper, ash, New Jersey tea, hazelnut, meadowsweet, alfalfa, honeysuckle, and dogwood. In Missouri, 22% of nests were in grasses, 10% were in forbs, 46% were in shrubs, and 22% were in roses. In Illinois, 41.9% of nests were in grasses, 19.4% were in forbs, and 38.6% were in trees and shrubs. Although many nests are not in woody vegetation, few are further than 40 cm from a shrub or tree. Within woody vegetation, most nests are in main crotches at the trunk where they may be supported by 2 to several branches. An exception is in common juniper where nests are often in twigs and foliage distant from the main stem. In Minnesota Christmas trees, there were no significant differences in nest heights of the Field, Chipping, and Clay-colored sparrows. In Missouri, mean nest height of Field Sparrow nests was 0.4 m, significantly lower than those of the Indigo Bunting and Northern Cardinal. In Michigan, the Field Sparrow built 94% of its nests in shrubs shorter than 1.5 m; the Chipping Sparrow built 90% of its nests in shrubs 1.5 m tall or taller. The Field Sparrow nested on the ground and in low shrubs, the Chipping Sparrow nested exclusively in trees and shrubs, and the Vesper Sparrow nested exclusively on the ground. Although Field and Chipping sparrows overlap considerably in their foraging patterns and diet, their nesting habitat is different. Food does not appear to be a limiting factor for the Field Sparrow and presence of suitable nesting locations is probably the most important factor in determining territory location. Nests are typically used only once but 1 Texas nest appeared to have been used twice in a season (Allaire 1972; Best 1977a, 1978, 1979; Buech 1982; Burhans and Thompson 1998; Carey 1990; Carey et al. 2020; Dechant et al. 2002g; Evans 1964, 1978; Judd 1901; Luscier and Thompson 2009; McChesney and Anderson 2015; Nolan 1963; Schill and Yahner 2009; Walkinshaw 1936, 1939b, 1945; Walkinshaw in Austin 1968). In Michigan, 1 nest was in a vacant lot between 2 houses (Walkinshaw 1939b).

Males may initially have larger than normal territories, but these shrink as more birds arrive. Changes in territorial configuration are common early in the season. In addition to shrinking due to new neighbours, territories may be expanded into abandoned areas. Territories in high-quality habitat tend to be contiguous; those in marginal habitat are often separated from each other. One male defended a territory in Michigan for 6 years. His territory size was 0.40 ha in the first year, 0.48 ha the second year, and 0.8 ha in the final 4 years. All 15 nests of this male and his various mates were within an area of 0.36 ha. In Illinois, the mean size of territories of returning males was 0.60 ha in the first year and 0.95 ha in the second year. After 2 or 3 years, males seem to pick an optimum size of territory to defend. Illinois territories averaged 0.76 ha (range 0.31-1.62 ha) before boundaries were changed to include abandoned territories. One male increased his territory to 3.41 ha after 2 of his neighbours abandoned their territories. Habitat quality affects territory size, with smaller territories in high-quality habitat. In Illinois, territories in grassland were significantly larger (1.02 ha) than those in shrubby areas (0.53 ha). Territories in open areas in Kansas were larger than those in shrubs. In Illinois, the best territories contained shrubland and margins of a woodlot where adults obtained much of the food for nestlings. Territories providing the most desirable nesting and foraging sites early in the spring had greater reproductive potential than those becoming desirable

later in the season when clutch size is reduced. Mean territory sizes were 0.6 ha in Indiana, 0.65 ha in Kansas (range 0.32-1.01 ha), and 0.5 ha in Iowa (range 0.3-0.8 ha). In Michigan, Field and Chipping sparrows had overlapping territories and aggression only occurred when a member of the other species approached the nest (Best 1977a; Evans 1978; Fitch 1958; Nolan 1963; Walkinshaw 1945; Yank and Dauphin in Gauthier and Aubry 1996).

Natal philopatry is very low. In Ohio, 1 of 103 banded juveniles (0.9%) returned (Lehnen and Rodewald 2009b), 6 of 1,826 nestlings (0.3%) returned in Pennsylvania, 1 of 514 nestlings (0.2%) returned in Michigan (Carey et al. 2020), and 1 of 100 fledglings (1.0%) returned in North Carolina (Fretwell 1968).

Adult site fidelity rates are high. In many areas, probably all surviving males return to breed and they tend to occupy the same territory each year. Returning males do not arrive significantly earlier than those appearing for the first time. Females have lower site fidelity than males. Some disappear within a breeding season following nest desertion and these seldom return. In Pennsylvania, some females were absent for 1 or 2 years and then returned but males never did this. When birds disperse to a different habitat patch in subsequent years, they usually move to younger patches but do not select areas with more shrubland. Dispersal patches in Ohio averaged 1 year younger than original patches. In New York over 4 years, 33 of 61 males (54.1%) returned the subsequent year. Return rates in individual years were 63.2%, 48.0%, 50.0%, and 57.1%. In Illinois, 11 of 25 males (44.0%) returned to breed in the following year. Only 3 females returned (the sample size was not specified). Females appeared to have a strong tendency to reoccupy the previous territory regardless of which male was defending it. In Ohio, 39 of 97 adults (40.2%) returned. In Pennsylvania, an average of 53% of males returned to breed in a subsequent year with annual rates of 18-80%. An average of 36% of females returned with annual rates of 18-48%. For both sexes, the rate of return was similar regardless of age. One male returned for 8 years and 1 female returned for 7 years. One study summarized results from several areas and calculated an overall return rate for adults of 49% (Best 1977a; Carey et al. 2020; Lehnen and Rodewald 2009b; Nelson 1992; Schlossberg 2009; Smith et al. 2017).

Limiting Factors

Eggs have been reported in Ontario nests from the beginning of May until mid-August, with most present from the last week of May until the third week of June (Peck and James 1987). Females usually pair with their mate 1-2 days after they arrive, but in Michigan, this occurred 9-32 days after the males arrived (average 22 days). First nests take 3-7 days to build but mostly 4 or 5 days. Later nests may be built in 2 or 3 days with some lining material occasionally added on the fourth morning. In Michigan, females invariably laid the first egg in a replacement nest 5 days after the first nest was lost or deserted. The first egg was laid in second-brood nests 6-16 days after the first young fledged (average 10.8 days). The first egg is laid the day after the nest is complete or the following day. In Pennsylvania, the first egg was laid 1 day after the nest was complete in 63.6% of cases. One egg is laid per day. The onset of incubation may occur with the laying of the first egg, the day the third egg is laid, or late in the day that the second egg is laid. During cold weather, some females delay the start of incubation for as long as 4 days after the last egg is laid. The incubation period of 1 Ontario nest was 12 days. Incubation periods of 10-17 days have been reported with most eggs

hatching in 11 or 12 days. The young usually hatch on the same day. In Michigan, 2 young usually hatched in the same hour, the third young hatched in the next 24 hours, and, if there was a fourth young, it hatched sometime the next day. Young leave the nest when they are 5-10 days old, with disturbed birds leaving earlier. In Michigan, disturbed young left the nest when they averaged 6.4 days old (range 5-7 days); undisturbed young fledged at an average of 7.5 days (range 6-8 days). In Indiana, the nestling period was 7-9 days and mostly 9 days; Pennsylvania young fledged when they were 9-10 days old (Carey 1990; Carey et al. 2020; Nolan 1963; Peck and James 1987; Walkinshaw 1936, 1939b, 1945; Walkinshaw in Austin 1968).

Ontario egg dates suggest that 2 broods may be raised. This has not been confirmed, but McIlwraith (1894) stated that 2 broods were raised. The Field Sparrow is capable of raising 3 broods in a season, but rarely does so because of predation and parasitism. In Michigan, only 2 pairs successfully raised 3 broods over an 11-year period. In Pennsylvania, 60% of nests fledged young and second broods were common. Forty-eight of 160 females (30.0%) successfully fledged 2 broods and 1% successfully raised 3 broods. Where snakes are abundant, predation rates are very high with few birds raising 2 broods and some not raising any young. It is a persistent renester, starting replacement nests 1-2 days after a nest is depredated or abandoned. One Illinois female initiated 10 nests in a season, all of which were lost due to predation and parasitism. Clutches of 3-5 eggs have been reported in Ontario (mean 3.75 eggs). Four-egg clutches were most frequent and comprised 66.3% of clutches; only 4.1% of clutches contained 5 eggs. Elsewhere, clutches of 2-6 eggs have been reported, with a normal range of 3-5 eggs. Four-egg clutches are the most abundant; most other clutches contain 3 eggs. Clutch size declines with the season. Mean clutch sizes in Michigan were 3.85 eggs in May (range 3-5 eggs), 3.54 eggs in June (range 2-5), 2.99 in July (range 2-4), and 2.75 in August (range 2-3). In Kentucky and Tennessee, clutch size was significantly reduced by 0.5 egg every 52 days; clutches of second broods averaged 0.5 egg less than first nests. Five-egg clutches usually do not occur after mid-June. Mean clutch sizes from other locations include 2.9 eggs in unparasitized nests in Minnesota, 3.53 in Michigan, 3.6 in Kentucky and Tennessee, 3.69 in Pennsylvania, 3.43 and 3.56 in 2 habitats in North Carolina, 3.4 and 3.8 in 2 years in West Virginia, and 3.96 in Missouri (Best 1974; Buech 1982; Carey 1990; Carey et al. 2020; Dechant et al. 2002g; Evans 1978; Fretwell 1969a; Giocomo et al. 2008; Nolan 1963; Walkinshaw 1936, 1939b, 1945; Walkinshaw in Austin 1968; Wray et al. 1982).

The age at first breeding is 1 year and breeding occurs every year thereafter. The presence of unmated males suggests that some yearlings may not nest. In Pennsylvania, 11.9% of territorial males were unmated. Some Illinois males remained unmated all summer. In Michigan, 2 males did not initially attract a mate but continued to defend their territories. They finally acquired mates in mid-June and nested. The mating system is predominantly monogamous but a few males are polygynous. In Pennsylvania, 4 of 156 males (2.6%) were polygynous and 1 was polyterritorial. Many pairs remain together for the entire breeding season, often through multiple nesting attempts. In Pennsylvania, 199 of 379 pair bonds (52.5%) formed at the beginning of the season remained stable throughout the season. Females may abandon their territories part-way through the breeding season in response to parasitism or predation, or after the first brood fledges. These females leave the habitat patch and probably attempt to breed in another location. Males that have been abandoned continue to defend their territories and are frequently successful in attracting another

mate. One Illinois male was mated with 5 different females in a single season. No male that was previously mated abandoned his territory if a female was in the area. All males that abandoned territories before the end of the season were unmated. Mates rarely pair again in subsequent years. In Pennsylvania, 17 of 312 pairs (5.4%) reunited in a subsequent year, significantly less than expected if surviving mates always paired with each other (Best 1977a; Carey 1990; Carey et al. 2020; Walkinshaw 1945).

Extra-pair copulations may be an important component of the Field Sparrow's mating system, and both sexes may seek them. A Michigan female copulated with her mate and 2 neighbouring males in quick succession. In Ohio, 10 of 52 nestlings (19.2%) had genotypes that were inconsistent with 1 or both behavioural parents and 5 of 17 broods (29.4%) showed mismatches. In Pennsylvania, 98 of 1,051 nestlings (9.3%) had DNA that did not match the attending male and 36 of 175 males (20.6%) had at least 1 extra-pair young in their nest. Eighty-two of 98 extra-pair nestlings (83.7%) were in nests in which the entire brood was extra-pair. Eighteen males had such broods; 13 (72.2%) were first-time breeders and 78% of their mates were also first-time breeders. Many were also late arrivals on the breeding grounds. Nesting chronology tends to be highly asynchronous with nests in varying stages. This provides opportunities for extra-pair copulations. The male does not incubate so he has 11 days to seek extra-pair copulations while the female incubates. In Pennsylvania, the frequency of extra-pair young declined steadily from 20% in 1990 to 0% in 2000-02, coincident with a decline in the population (Carey et al. 2020; Petter et al. 1990; Walkinshaw in Austin 1968). Intraspecific nest parasitism appears to be a rare behaviour. In 2 cases in Ohio, nestlings were unrelated to the social mother. In Pennsylvania, 2 of 469 nests (0.4%) received 2 eggs in 1 day and 1 of 152 nestlings (0.7%) was mismatched with the attending female. Unmated females or those that had their clutches depredated may potentially lay eggs in other females' nests (Carey et al. 2020; Petter et al. 1990).

During the breeding season, the Field Sparrow typically forages solitarily or with its mate within the territory. Some exceptions occur. In North Carolina, adults foraged for nestlings' food in adjacent alfalfa fields and shrubs bordering a watercourse. During rainy weather in Kansas, birds appeared to be reluctant to forage in the tall grasses within their territories where they usually foraged. Instead, several pairs foraged within a few square metres in open habitat along a road. No hostility was observed among these birds even though the area was within the territory of 1 pair and beyond the boundaries of the other pairs. When the weather cleared, they returned to their territories and normal aggression was resumed. In Illinois, it avoided grasslands for foraging; all foraging occurred in shrubby meadows and at the edge of a woodlot. Wooded areas provided a greater abundance of nestlings' food early in the breeding season. More open areas with low herbaceous vegetation became the preferred foraging area later in the season. The suitability of a territory for nesting and rearing young may change markedly over the breeding season. In Texas, both Chipping and Field sparrows foraged mostly within 1 m of the ground, predominantly from perches 30-40 cm up. They peered into the vegetation below and, when a non-flying insect was seen, quickly descended from the perch and tried to capture it. Field sparrows were somewhat more active than Chipping Sparrows and never spent more than 10 seconds on a perch. The Field Sparrow exhibited a greater variety of seed-gathering techniques and was more acrobatic in procuring seeds. It often flew to the top of grasses, letting its weight carry itself and the stems to the ground where it ate the seeds while

still holding onto the grass stems. It spent more time foraging from low perches than the Chipping Sparrow. It often used brush piles, fallen trees, low shrubs, and fences as perches where it reached out and ate grass seeds from the tops of stems. In South Carolina, Field and Chipping sparrows both foraged in a disturbed field of grasses, shrubs, and brush piles. The Field Sparrow foraged among the emerging flowers of a willow on 1 occasion, but all other foraging was on the ground. It spent more time flycatching than the Chipping Sparrow and did so almost invariably from the ground. In April, both species fed equally in trees and in the field, but usage of trees was very low to zero in other months. A comparison of the diet of adults and nestlings in Michigan suggested that adults spent less time on the ground and more in active flight or in higher strata when foraging for nestlings′ food. In Maryland, the Field Sparrow occasionally fed in tobacco fields with Chipping Sparrows and individually in corn fields from the time that the corn became tasselled until it was harvested. In Ohio, the Field Sparrow foraged in grasses more than their availability. In August, it visited stubble fields, feeding on oats in oat stubble and insects and weed seeds in wheat stubble, but not on wheat. All researchers agreed that food is abundant and well distributed in the breeding season and is not a limiting factor (Allaire and Fisher 1975; Best 1977a, 1977b; Carey et al. 2020; Dechant et al. 2002g; Evans 1964, 1978; Fitch 1958; Fretwell 1969a; Hebrard 1978; Judd 1901).

The nestling diet consists almost entirely of insects, with some spiders consumed. Walkinshaw (1939b) observed young being fed insects, particularly grasshoppers and caterpillars. He reported another study where nestlings were fed 154 geometer moth caterpillars, 45 grasshoppers, and 24 moths. Carey et al. (2020) reported that 237 nestling food items consisted of 65% caterpillars, 19% grasshoppers, 10% adult moths, and 6% unidentified matter. In Iowa, the nestling diet consisted of 71% caterpillars, 16% adult flies and bees, 10% adult moths, and 3% beetles. In Pennsylvania, 1,853 food items in nestlings′ diet consisted of 80% caterpillars, 10% adult flies and bees, 6% orthopterans (mostly katydids), 3% adult moths, and 1% spiders. The golden-backed snipe fly comprised a large portion of the nestling diet, but only during its emergence in early June. In Michigan, the percent occurrence of food items in the diet of 5 nestlings in spring was 20% odonates, 80% orthopterans, 40% true bugs, 80% soft-winged bugs, 60% beetles, 100% lepidopterans, 80% flies, 80% spiders, 20% snail shells, and 60% plant material. The percent occurrence of food items of 20 nestlings in summer was 30% odonates, 85% orthopterans, 100% soft-winged bugs, 60% beetles, 95% lepidopterans, 45% flies, 60% hymenopterans, 95% spiders, 10% snail shells, and 50% plant material. Larvae of lepidopterans, beetles, orthopterans, and soft-winged bugs were preferred by adults for feeding nestlings, and spiders were also important. Nestlings had significantly higher frequencies of odonates, orthopterans, lepidopterans, flies, and spiders in their diet than adults and significantly lower frequencies of true bugs and beetles. Nestlings were fed more rapidly flying insects and sluggish larvae than adults ate. Adults and free-flying fledglings ate by frequency 20.7% rapidly flying insects, 20.7% sluggish larvae, and 86.2% insects from the ground. Nestlings ate 44.0% rapidly flying insects, 96.0% sluggish insects, and 100% insects from the ground. There was no significant difference between the diets of Field and Chipping sparrow nestlings (Evans 1964). Best (1977b) examined the diet of nestlings in 2 years in Illinois. In the first year, the diet consisted of 37% caterpillars, 18% other insects, 16% soft-winged bugs, 15% orthopterans, and 14% spiders. In the second year, the diet was comprised of 30% caterpillars, 22% soft-winged bugs, 22% spiders, 18% orthopteran nymphs plus 2 adults, and 8% other insects. There was an increase in the abundance

of soft-winged bugs in the second year due to the emergence of 13-year cicadas that provided an extremely abundant food source from the end of May throughout June. In both years, caterpillars were the most important food in May and June, reached their lowest level of consumption in July, and increased again in August. Orthopterans were absent in the diet in May both years, were of minor importance in June, and the most important food item in July and August. In the first year, spiders were important in the diet but decreased to negligible use after June; usage of spiders was constant in the following year. Spiders consistently declined in the diet as nestlings aged and orthopterans increased. The larger size of orthopterans probably restricted their usage by young nestlings. Soft-winged bug usage was nearly constant as nestlings aged whereas usage of caterpillars fluctuated erratically. The size of food provided ranged from less than 0.005 cc to 0.38 cc in volume with the upper size increasing with age. The importance of items smaller than 0.005 cc decreased as nestlings grew, but even old nestlings were fed items of this size, predominantly soft-winged bugs. Nestlings were also fed walkingsticks.

Adult Field Sparrows eat predominantly seeds but also consume insects during the breeding season when they are feeding nestlings. Plant material, mostly grass seeds, dominates the spring diet. The diet gradually changes from a predominantly plant diet to a predominantly invertebrate diet in summer, and reverts to a plant diet in autumn and winter. In Texas, seeds eaten in summer consisted of 92.2% crabgrass, 0.5% panic grass, 0.5% spurges, and 6.8% unidentified. Arthropods consumed in summer included 33.3% beetles, 16.7% orthopterans, 25.0% lepidopterans, 8.3% bugs, 8.3% hymenopterans, and 8.3% spiders. Autumn seeds consumed consisted of 42.6% crabgrass, 10.7% panic grasses, 28.2% foxtails, 9.8% spinifex grass, 5.0% flatsedges, 4.5% spurges, and 0.2% unidentified. The autumn arthropod diet consisted of 11.1% termites and 88.9% lepidopterans. In Michigan, frequency of occurrence of items in the diet was 25% orthopterans, 25% true bugs, 12.5% soft-winged bugs, 50% beetles, 25% lepidopterans, 37.5% flies, 37.5% hymenopterans, 25.0% spiders, and 100% plant material including 37.5% wiregrass, 25% panic grasses, 25% Indian grass, and 12.5% sandworts. Frequency of occurrence of food items in summer was 4.8% odonates, 42.9% orthopterans, 76.2% true bugs, 90.5% soft-winged bugs, 76.2% beetles, 14.3% lepidopterans, 9.5% flies, 28.6% spiders, and 52.4% plant material including 4.8% brome grass, 19.0% poverty oat grass, 23.8% wiregrass, 4.8% fescue grass, 9.5% bluegrass, 9.5% sandworts, 4.8% thistles, 14.3% wood-sorrel, and 4.8% docks. In summer, odonates first became evident in the diet and leaf and click beetles became common in the diet. Weevils and ground beetles that were prominent in the diet in spring were also important in summer. Prior to the 20th century, the Field Sparrow was reported feeding on aphids, tent caterpillars, and geometer moth and other caterpillars. In Maryland, 175 stomachs contained 41% animal matter and 59% vegetation. Invertebrate food items consisted of 2% weevils; 2% leaf beetles; 9% ground, tiger, click, and June beetles; 4% caterpillars; 6% grasshoppers; 14% leafhoppers, true bugs, sawflies, ants, flies, and spiders; and 4% parasitic wasps. Plant food consisted mostly of grass seeds such as crabgrass, panic grasses, foxtails, broomsedge, wiregrass, and dropseed; other seeds included 4% chickweeds, lamb's-quarters, gromwell, amaranths, purslane, spurges, wood-sorrel, and knotweeds; and 4% oats. It feeds very little on seeds other than grasses and subsists on ragweed less than other upland sparrows. It occasionally shows a marked preference for wood-sorrel, chickweed, purslane, and smaller-seeded species of knotweeds and smartweeds. A flock in September fed mostly on crabgrass, but sparrows occasionally sprung up in the air and

captured a braconid wasp. Plant food of 137 birds in the northeast consisted of seeds of foxtails, crabgrass, broomsedge, panic grasses, oats, and lesser amounts of dropseeds, sheep sorrel, amaranths, ragweed, wood-sorrel, timothy, and lamb's-quarters. Thirty-eight stomachs from the prairie states contained seeds of foxtails, panic grasses, dropseeds, crabgrass, and lesser amounts of vervain, lamb's-quarters, wheat, redtop, and gromwell. In Texas, the diets of Field and Chipping sparrows were very similar but may have been partitioned because the Field Sparrow tended to forage higher than the Chipping Sparrow. The Field Sparrow tended to feed on seeds that were slightly smaller than those selected by the Chipping Sparrow. In Maryland, the consumption of parasitic wasps by Field Sparrows was the principle difference from the diet of the Chipping Sparrow. There was little difference in the diets of Field, Chipping, and Vesper sparrows in Michigan. The Chipping Sparrow ate more lepidopterans than the other 2 species and the Vesper Sparrow ate significantly more orthopterans than the Field Sparrow and significantly fewer soft-winged and true bugs than the Chipping Sparrow. Food appears to be so abundant that there is no competition for it among species (Allaire and Fisher 1975; Evans 1964; Judd 1901; Walkinshaw in Austin 1968). Browning et al. (1981) offered seeds of round-headed bush-clover, blazing-star, and 2 types of sunflowers to Field Sparrows. Bush-clover was the lowest quality food and Field Sparrows ate fewer of these seeds and more of the sunflower seeds, demonstrating that it selects higher-quality seeds.

The Field Sparrow is a common host of the Brown-headed Cowbird. It may either accept or reject cowbird eggs with nest desertion being the method of rejection. In some areas, most foreign eggs, including plastic and blue ones, are accepted; most parasitized nests are abandoned in other areas. In 1 area of Illinois, all eggs were accepted. In another area of Illinois, 14 of 29 parasitized nests (48.3%) were deserted compared with 0 of 21 unparasitized nests. In Missouri, 21 of 47 parasitized nests (44.7%) were deserted compared with 1 of more than 300 unparasitized nests (less than 0.3%). No desertion occurred in nests where a Field Sparrow egg was replaced with a real, an artificial maculated, or an artificial unmaculated cowbird egg. Sparrows may desert nests in response to a decrease in clutch size. Desertion may also occur if parasitism occurs on the first or second day of incubation. Nests may be deserted if a sparrow sees a cowbird near the nest. Of 6 cases where a cowbird was encountered near the nest during egg laying, 5 (83.3%) were deserted. All nests presented with a cowbird model in the nest-building and early egg-laying stages were deserted, 3 of 7 (42.9%) were deserted in the late-laying period, and 0 were deserted during incubation. Desertion appears to be immediate when a cowbird is observed. The reaction of Field Sparrows to cowbird models varies geographically, with higher levels of aggression in areas with higher parasitism rates. Parasitism does not appear to be a significant limiting factor to the Field Sparrow. In Illinois, 5% of sparrow eggs were lost due to parasitism, either through removal by cowbirds or nest desertion. This loss was probably mitigated by renesting. Nestling sparrows appear to be unaffected by the presence of a cowbird nestling, growing normally and fledging provided the nest is not depredated or otherwise harmed. The Field Sparrow is a poor host for the cowbird. In Iowa, only 3.4% of cowbird eggs produced a fledgling; 11.5% of Michigan eggs produced a cowbird fledgling. Parasitism rates vary considerably geographically, from 0-80%. Parasitism rates are affected by local cowbird abundance, landscape characteristics, proximity to woodlands and woody stems, and nest placement. In 2 areas in Missouri, the parasitism rate was 4.6% in an area that was 33.3% forested and 11.3% in an area with 70% forest cover. The cowbird was rare at the first site and an

order of magnitude more abundant at the second site. In Illinois and Missouri, the parasitism rates were 52.1% and 11.1% respectively; the density of cowbirds was much higher in Illinois. The cowbird tends to avoid landscapes dominated by grasslands and is more common in partially forested landscapes. It avoids landscapes that are almost completely forested. The cowbird is often concentrated near wooded areas because there is a greater density of potential hosts and bird density is higher in woodlands than grasslands. In Illinois, the mean distance of parasitized nests from woodland was 13.4 m and all but 2 were within 26 m. In Missouri, the probability of parasitism decreased with distance to the nearest tree, potential vantage points for cowbirds. In Michigan, 39% of nests in common juniper were parasitized compared with 28% in other nest substrates. In Indiana, 2 of 18 nests (11.1%) that were on the ground or in ground cover were parasitized; 0 of 43 elevated nests were parasitized. In Ontario, 63 of 378 nests (16.7%) were parasitized. Three of 10 nests (30.0%) in a Minnesota Christmas tree plantation were parasitized. In 3 Missouri studies, 14%, 11.1%, and 4.6% of nests were parasitized. In Georgia and South Carolina, 0 of 10 nests were parasitized. In extensive grassland habitat in Kentucky and Tennessee, 3 of 276 nests (1.1%) were parasitized. In different Illinois studies, 16 of 147 nests (10.9%), 6 of 93 nests (6.4%), and 37 of 71 nests (52.1%) were parasitized. Other parasitism rates include 69 of 141 nests (48.9%) in Kansas; 0 of 15 nests in New York; 16 of 20 nests (80.0%) in Iowa; 0 of 23 nests in West Virginia; 51 of 159 nests (32.1%) in Ohio; 2 of 946 nests (0.2%), 1 of 96 nests (1.0%), and 9 of 57 nests (15.8%) in Pennsylvania; and 182 of 664 nests (27.4%) in Michigan (Best 1974, 1978; Buech 1982; Burhans and Thompson 1998; Burhans et al. 2001, 2010; Carey et al. 2020; Evans 1978; Galligan et al. 2006; Giocomo et al. 2008; Hahn and Hatfield 1995; Kilgo and Moorman 2003; McChesney and Anderson 2015; Nolan 1963; Peck and James 1998b; Peer et al. 2000; Rivers et al. 2010; Strausberger and Burhans 2001; Walkinshaw 1939b, 1945; Walkinshaw in Austin 1968; Wray et al. 1982).

The most significant limiting factor for the Field Sparrow is availability of suitable nesting habitat, and habitat quantity is declining. Its shrubby habitat is frequently converted to other land uses such as agriculture and urban development. Creation of larger farm fields coupled with removal of hedgerows plus cleaner farming practices that leave minimal undisturbed areas have reduced habitat availability. Habitat suitability may be affected by natural succession; mowing, grazing, and other agricultural practices; and burning. Habitat loss is likely to continue resulting in further declines of the Field Sparrow (Carey et al. 2020; Petter et al. 1990; Walk et al. 2011).

Preferred Field Sparrow habitat is ephemeral in nature due to natural succession. When an agricultural field is abandoned, it remains unsuitable for the first year or 2 when it is dominated by annual plants. Habitat becomes more suitable as grasses and perennial herbaceous plants become established and becomes optimal when the field is invaded by scattered shrubs and saplings. Once woody stem density increases, the area becomes less attractive, and it is unsuitable once shrubs or saplings form a dense canopy. In clear-cuts in New York, the Field Sparrow appeared 2 years after the cut, peaked 3 years after cutting, and was essentially extirpated by 9 years after cutting (Keller et al. 2003). Stauffer and Best (1980) considered it to have low tolerance for habitat alteration. They predicted that it would disappear if all woody vegetation was removed and increase if woody vegetation was reduced to narrow strips, if the woody canopy was partially removed, or if the woody canopy was partly removed and shrubs and saplings were thinned.

The Field Sparrow tolerates light grazing by cattle and native ungulates. Heavy browsing that kills shrubs and saplings or makes the ground flora short and sparse is detrimental and may make the habitat unsuitable (Dechant et al. 2002g).

Cutting hay in fields used for nesting is detrimental. Prior to mowing in Arkansas hayfields, nest survival rates were similar. In fields cut 18-23 May, the nest survival rate was 0% except for 2 nests in corners of fields that were not mowed. Only 2 of 54 nests (3.9%) were destroyed when hay was cut later (7-14 July). Only 3 nests per km^2 were initiated in the 39 days following early mowing compared with 18 per km^2 in unmowed fields and 13 per km^2 in late-mowed fields during the same period (Luscier and Thompson 2009). In Iowa, the Field Sparrow nested in grassed waterways that were mowed the previous year. In Ohio, it used fallow fields, pasture, and small-grain fields grown in strips between idle croplands. In Iowa, it nested in soybean fields that were not tilled in spring or autumn and that contained year-round crop residues. Fields that were tilled in spring were not used. In Illinois, unmowed grasslands were selected over those that were high-mowed, leaving the vegetation more than 30 cm tall. In New York, fields that were mowed annually were avoided; fields were used 2-16 years after mowing (Dechant et al. 2002g). In Illinois, Graber and Graber (1963) observed large declines of Field Sparrows nesting in orchards from 1907-08 to 1957-58. In the earlier period, grasses and herbaceous species were allowed to grow in orchards but there was a tendency to mow understorey vegetation in orchards during the later period.

The effects of fire on the Field Sparrow vary depending upon timing of the burn and the intensity and frequency of burning. Intensive fires that kill woody vegetation are detrimental, unless there was excessive woody growth prior to the fire. Areas that are burned frequently have limited residual vegetation from previous years. Vegetation litter is preferred nesting substrate early in the season. Frequent burns simplify habitat heterogeneity and inhibit growth of woody vegetation. In Illinois, a prescribed burn was undertaken in grassland and shrubland habitat. After the fire, usage of shrubby habitat was higher than expected and the opposite was true for grassland and shrub-woodland habitats. Fire resulted in the preferred habitat being used more intensively. Females showed an aversion to nesting in burned areas due to the lack of cover but plant regrowth occurred in time for renesting. Some females built nests in patches of grass litter that had escaped the fire, some of which were only a few centimetres wide. Adults foraging for nestlings shifted their activities from woodland to open habitat. The fire made more grass seeds available because they were formerly hidden under the grass litter. It was concluded that infrequent fires were beneficial, allowing establishment of shrubby areas, retarding succession to forest habitat, and promoting edges and habitat heterogeneity. Frequent and complete burns would eliminate woody vegetation and the Field Sparrow. In another Illinois study area, it preferred areas that had been burned previously but was absent 5 or more years after a burn. Another Illinois study determined that its abundance was negatively correlated with prescribed burns. It preferred grasslands in later successional stages that had not been disturbed for several years. In Wisconsin, its density was correlated with the proportion of area that had been burned. In Kansas, it was absent in areas that were burned annually, probably because they did not support shrubs (Best 1979; Dechant et al. 2002g; Glass and Eichholz 2023; Walkinshaw 1945).

Predation is a significant limiting factor in the Midwestern United States where snakes are abundant. Many populations in this region do not appear to be sustainable due to high levels of predation. Predation rates have not been studied in Ontario, but are probably considerably lower because the diversity and abundance of snakes is considerably lower here. Nest placement and habitat may affect predation rates, but it is probable that these variables are site specific. In Michigan, nests in common juniper were significantly more successful than those in other locations. Predation rates in junipers were 12% during incubation and 15% during the nestling period compared with 57% and 49% respectively for other nests (Evans 1978). In Kentucky and Tennessee grasslands, predation rates were higher in smaller fields because these had more small trees per unit area that might provide perches for predators (Giocomo et al. 2008). Nest height may affect predation rates. In Indiana, higher nests had lower success rates, but only in grassland habitat. In Illinois, snake predation occurred at all heights but was most prevalent 16-30 cm above ground; predation by mammals was restricted to nests 25-60 cm from the ground. Nestlings fledged most frequently from nests located either close to the ground or at higher heights because of the foraging patterns of predators. In Missouri, higher nests were less likely to be depredated. All nests at heights above 3 m fledged young, but these were unusually high nests (Best 1978; Burhans et al. 2002; Galligan et al. 2006). Habitat type may affect predation rates. In Illinois, mammalian predation was significantly less for nests in grass litter and higher than expected in forbs, trees, and shrubs. Nests in large expanses of tall grasses never suffered from mammalian predators but predation by snakes was constant in all habitat types (Best 1978). In Missouri, higher predation rates occurred in bottomland sites than in upland old fields and pastures. Predation increased with increasing coverage by coralberry (Burhans et al. 2002).

McChesney and Anderson (2015) studied the response of the Field Sparrow to Morrow's honeysuckle. This is a nonnative invasive shrub that grows in open fields and in the understorey of forests. Nests in honeysuckle had lower survival rates as did nests where there was high coverage by honeysuckle. Fecundity decreased rapidly as more nests were built in honeysuckle but the amount of honeysuckle within the general area was a greater factor in reducing nest survival. Increasing use of honeysuckle as a nesting substrate may be because it leafs out much earlier than other shrubs and trees, thus appearing to be a high-quality nesting site.

In Texas, the Field Sparrow decreased where DDT was used to spray ticks. In New York, it did not breed for 18 years in a field where vegetation was removed by a single application of 2, 4, 5-T and kerosene. It appeared to be unaffected when shrubs were sprayed with carbaryl (Dechant et al. 2002g).

In West Virginia, the Field Sparrow demonstrated no significant response to well pads, access roads, and pipelines (Farwell et al. 2019).

Cold, rainy, or snowy weather may result in death of nestlings due to exposure or starvation. The nest is not securely anchored in trees and shrubs and may be tipped over during periods of heavy winds. The Field Sparrow is often killed by cars on roads; females are vulnerable to being killed by cats while they are on the nest (Carey et al. 2020; Walkinshaw 1936; Walkinshaw in Austin 1968).

Dechant et al. (2002g) recommended providing shrub-dominated edge habitat adjacent to grassland or providing grassland with a shrub component, both of which must include dense grass

and moderately high litter cover, and avoiding disturbances that completely eliminate woody vegetation.

Price (2004) predicted that the breeding range of the Field Sparrow might expand in southern Ontario if the average summer temperature increased by 2°C.

Status

The Field Sparrow may have reached its peak of abundance in Ontario and the northern United States during the mid-19th century when Europeans deforested the landscape (Carey et al. 2020; Walkinshaw in Austin 1968). McIlwraith (1894) reported that it was sparingly distributed in southern Ontario, which formed the northern extent of its range. In Elgin County, it was a tolerably common summer resident in 1891 but was uncommon in 1954 and 2000 (Lancaster et al. 2004). It was scarce in the Milton area in 1906. In the late 1920s, it was much scarcer in the Toronto area than it had been in the previous 2 decades. This was attributed to declines at the northern extent of its range. By the 1950s and 1960s, it was common in the Hamilton area, and continues to be so (Curry 2006). In 1909, it was fairly common in the Kingston area, where it continues to be common (Weir 2008). Baillie and Harrington (1937) concluded that the Field Sparrow was an uncommon and local breeder in southern Ontario north to Muskoka District, northern Frontenac County, and Ottawa. Mills (1981) stated that it had recently expanded its range northward to Lake Nipissing. Algonquin Park originally had much more suitable habitat for the Field Sparrow in the form of logged areas, burns, and settlements. It was not documented until 1960 but has been reported regularly since 1967 (Tozer 2012). The first atlas confirmed that the breeding range of the Field Sparrow included the area south of the Canadian Shield and the southern portion of the Shield with scattered records north to Lake Nipissing and Sudbury; there were also scattered records on Manitoulin Island. It was absent from the urbanized area of Toronto and much of the heavily forested portion of the southern Shield. It was common in areas of suitable habitat (Knapton in Cadman et al. 1987). James (1991) considered the Field Sparrow a common summer resident north to southern Georgian Bay and Ottawa, rare north to Manitoulin Island and Lake Nipissing, and a straggler north to the north coast.

The second atlas revealed that the distribution of the Field Sparrow had not changed significantly since the first atlas. Isolated breeding evidence was obtained for areas further north than during the first atlas near Sault Ste. Marie, Chapleau, and 100 km north of Cochrane. These latter 2 records were the only ones from the Boreal Forest Region. Its probability of observation decreased significantly between atlases province-wide, in the Carolinian Forest Region, and the Shield portion of the Great Lakes–St. Lawrence Forest Region. Declines in the south may be due to intensified agricultural practices; those in the Shield may be due to natural succession. There were several areas of high abundance. The most extensive area was along the southern edge of the Shield, including the Frontenac Axis and Prince Edward County. This area contains rock barrens, abandoned farmland, and red cedar savannahs on the Napanee Plain. Other areas of high density included the Carden Plain, the Flamborough Plain and Galt and Paris moraines, river valleys and sand plains from Lake Erie northwest to the Grand Bend area, and the eastern Norfolk Sand Plain (McLaren in Cadman et al. 2007).

Hanberry and Thompson (2019) compared Breeding Bird Survey (BBS) trends and forest composition over time in the eastern United States. They attributed the Field Sparrow's decline in

part to the reduction in the amount of early successional habitats and increase in the amount of closed-canopy forests. BBS results indicate annual decreases of 1.85% for Canada and 1.67% for Ontario for 1970-2021 and 0.514% for Canada and 2.06% for Ontario for 2011-21 (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

If the female initiates a second brood, the male cares for the first fledglings. If both adults feed the fledglings, brood division often occurs. For the first 1-3 days, the fledglings remain near the nest in tall grass cover and 3 or 4 days later may hide in both grasses and shrubs. One brood remained within a few metres of the nest for the first day, was 21 m distant the following day, and 2 were 61 and 82 m from the original location on the third day after fledging. The family group remained intact for the next 2 weeks and often foraged in a dry pond 137 m from the nest. During this period, the young and accompanying adults may trespass in other territories without being challenged. Family groups eventually mingle together to form larger flocks and may join flocks of Song Sparrows and Dark-eyed Juncos. Young become independent when they are 26-34 days old. Flocks tend to gather in dense thickets in the vicinity of the nest and may disperse to other similar habitats. They may also remain in favoured foraging habitat until the onset of autumn migration. Habitat used during this period may be very similar to breeding habitat. The Field Sparrow has been documented in clear-cuts 3-7 years old in Pennsylvania and Ohio. In Pennsylvania, family groups were common on a shrubby hydro right-of-way but absent in the adjacent forest (Carey et al. 2020; Fitch 1958; Stoleson 2013; Vitz and Rodewald 2006; Walkinshaw 1939b, 1945; Walkinshaw in Austin 1968; Yahner et al. 2002).

During the postfledging period in September, birds roosted at night in small trees and shrubs that were still heavily covered with leaves (Walkinshaw in Austin 1968). In Michigan, Adams and Brewer (1981) captured Field Sparrows in autumn in marshes, crop fields, and mature floodplain forest. Of 475 birds, 362 were juveniles, 71 were adults, and the age of 42 was unknown. Nine birds were recaptured during the subsequent breeding season. These included 5 juveniles, with a return rate of 1.4%, greater than reported at natal areas, suggesting that some juveniles select their breeding location prior to autumn migration. If returning adults find that their previous breeding habitat is unsuitable, they may move to sites they explored the previous autumn.

MIGRATION

The Field Sparrow migrates leisurely in both spring and autumn, spending days or weeks in the same area before moving on. In North Carolina, some males remained all winter but all females migrated south, suggesting that males winter further north than females. Birds migrate at night in small flocks but arrive on the breeding grounds a few at a time instead of all at once. Cold weather may delay the timing of spring migration. One banded at Don Mills was recovered in Texas; another banded near Cayuga was recovered in Arkansas (Black and Roy 2010; Brewer et al. 2018; Carey et al. 2020; Fretwell 1968; Walkinshaw in Austin 1968).

Males arrive on the breeding grounds 1-3 weeks before females and the earliest arrivals tend to be the oldest males (Best 1977a; Evans 1978; Walkinshaw in Austin 1968). In Ontario, a few arrive in late March, but most arrive in the second and third weeks of April with most passing through from mid-April to mid-May. Most leave the southern Shield from mid-September to late October. In the

south, migration occurs during the same period, with an influx of northern birds in the first half of October. A few remain into the first week of November (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008).

During spring migration, the Field Sparrow typically occurs singly but in autumn it may congregate in small loose flocks or within flocks of other sparrow species. In spring in Algonquin Park, it is occasionally found among flocks of migrating sparrows along road margins, in fields, and within campgrounds. Migration habitat is similar to that used during the breeding season and winter. It may also frequent some habitats that are avoided at other times, such as suburban yards. During spring migration in Pennsylvania, it was significantly more abundant in shrubby habitats than in forests. Detections per 100 m were 0.002 in forest and 0.130 in shrubs; captures per 1,000 net-hours were 0 in forest and 4.9 in shrubs (Carey et al. 2020; Smith and Hatch 2008; Tozer 2012; Walkinshaw 1936).

Carey et al. (2020) concluded that the Field Sparrow was an infrequent victim at towers during migration, but Walkinshaw (in Austin 1968) noted that it did strike television towers and airport ceilometers beams at airports. Although few may be killed striking tall structures, it is highly vulnerable to striking low structures during migration. Throughout the United States, it was not among the top 20 species that struck low-rises or high-rises, but was highly vulnerable to striking residences 1-3 stories high. It was 48.3 times more likely to strike a residence than average and was the eighth most vulnerable species (Loss et al. 2013).

James (1991) considered the Field Sparrow a common migrant that occasionally wanders north as far as Hornepayne and James Bay. It is a rare migrant in the Canadian Shield but may be a locally common migrant south of the Shield.

Hussell et al. (1992) reported that captures of migrant Field Sparrows at Long Point increased at a nonsignificant rate of 0.9% per year 1961-88. Trends by period were: 1961-70, +1.2% per year; 1970-79, −7.5%; and 1979-88, +8.5%.

WINTER

The winter range of the Field Sparrow is strongly determined by temperature and it can only acclimatize to the cold to a limited extent. The wintering area includes all of the eastern United States where the average minimum January temperature does not fall below −7°C, with some exceptions along major rivers in Nebraska, Colorado, and Indiana. Areas of high winter abundance occur where the temperature rarely drops below the freezing point (Root 1988). Ontario is north of the normal wintering range.

Winter habitat is very similar to breeding habitat; food availability may affect the suitability of an area to support wintering Field Sparrows. In Elgin County, it is typically observed in shrubby habitats. In North Carolina, it wintered in a field dominated by Virginia broomsedge planted with pines less than 1.8 m tall, but not in a nearby field dominated by fescue grass and bush-clover planted with pines less than 0.9 m tall. Birds that bred in the wintering habitat had higher fat levels than those that wintered elsewhere. Elsewhere in North Carolina, it favoured fields dominated by hairy crabgrass or horseweed and moved to other fields once these were depleted. In Maryland, it remained where it had bred and preferred areas with broomsedge. In Virginia, it wintered in an

agricultural field that had been fallow for 3-5 years and was dominated by broomsedge, asters, goldenrods, crabgrass, pokeweed, and deciduous saplings. Brush stations were created by placing 5-7 saplings 2-3 m tall in some plots. Plots with brush were used significantly more than those without brush. In North Carolina, it was found only in unmanaged field edges and not in fallow fields, narrow field borders, or in mowed field borders (Beck and Watts 1997; Carey et al. 2020; Fretwell 1968; Graber and Graber 1963; Judd 1901; Lancaster et al. 2004). In Maryland, its winter density was 0 in areas that had been mowed in autumn and 113 per km^2 in unmowed buffers. In winter, it uses herbaceous areas for foraging, roosting, and escape cover and autumn mowing removes this habitat (Blank et al. 2011). In Kentucky, Arkansas, and Mississippi, there were no differences in its abundance in row-crop fields with or without buffers of native grasses and forbs (Evans et al. 2015).

The Field Sparrow exhibits no territoriality in winter. No information is available on winter site fidelity but nonmigrant birds often stay year-round in the same place. In North Carolina, there was considerable dispersion from field to field. No more than 120 were ever in the studied field at any given time, but 178 were handled overall and less than 40% of birds were banded. In 1 winter, all birds migrated and the wintering birds present were those that had migrated from other areas. In Illinois, probably drifted further south as the winter progressed. Birds move to other fields if food resources become scarce in the original field (Carey et al. 2020; Fretwell 1968; Graber and Graber 1963).

In winter, the Field Sparrow frequently forages in flocks, either with conspecifics or other sparrows. Individuals often occur in Chipping Sparrow flocks and are also often associated with Song Sparrows, American Tree Sparrows, and Northern Cardinals. The Field Sparrow forages on the ground or in vegetation less than 1 m tall, mostly in open grassy or shrubby fields. In Maryland, it foraged almost exclusively from the culms of panic grass. It often foraged in open habitat 50-75 cm from cover. Its distribution on plots in Virginia was highly skewed to areas where brush had been provided. Its relative abundance in plots manipulated by adding brush or food was 80 where there was food and brush, 40 where there was food but no brush, 8 where there was brush but no food, and 1-2 where there was no brush or food. Food provided on trays was depleted at 3 times the rate where there was brush than where there was no brush (Allaire and Fisher 1975; Beck and Watts 1997; Carey et al. 2020; Dunn and Tessaglia-Hymes 1999; Judd 1901; Root 1988).

The winter diet of the Field Sparrow consists almost exclusively of seeds. Seeds found in stomach samples in Texas consisted of 29.1% crabgrass, 2.5% panic grass, 0.2% foxtail, 5.1% spinifex grass, 3.1% windmill grass, 46.0% grass #1, 14.0% grass #2, and 5.0% unidentified. Field and Chipping sparrows had similar diets, but they differed more in winter than in summer and autumn (Allaire and Fisher 1975). Pulliam and Enders (1971) examined the diet of the Field Sparrow from October to March in North Carolina. It consumed seeds 0.5-2.5 mm in length, with most about 1.5 mm. Two thirds of foraging birds fed from a standing plant while they were standing on the ground, one third fed while perched on a plant, and none fed from the ground. As the winter progressed, it initially fed only in horseweed fields, then in aster fields, and finally in broomsedge fields. The most abundant seed in the horseweed field was crabgrass and it fed almost exclusively on it, indicating that it was the preferred seed. Seeds were scarce by mid-March and there was a significant correlation between the abundance of seeds and Field Sparrows. It was concluded that it was

limited by winter food supplies. In winter, it is not a common feeder visitor, either in the number of feeders visited or the frequency of sightings. More feeders are visited in midwinter and spring and its abundance declines somewhat throughout the winter. Favourite feeder foods are mixed seeds, cracked corn, and probably millet. Infrequent choices include striped and black oil sunflowers, water, canary seed, and milo (Dunn and Tessaglia-Hymes 1999).

Graber and Graber (1979) analyzed the effects of a severe winter storm on the Field Sparrow in Illinois. Densities per km^2 prior to the storm were 7.5 in bottomland forest, 0 in upland forest, and 9.5 in urban residential. No birds were observed after the storm and the authors believed that it had suffered 100% mortality.

James (1991) considered the Field Sparrow rare in winter in the south north to Manitoulin Island and there are records of winter vagrants as far north as Lake Superior.

Fox Sparrow

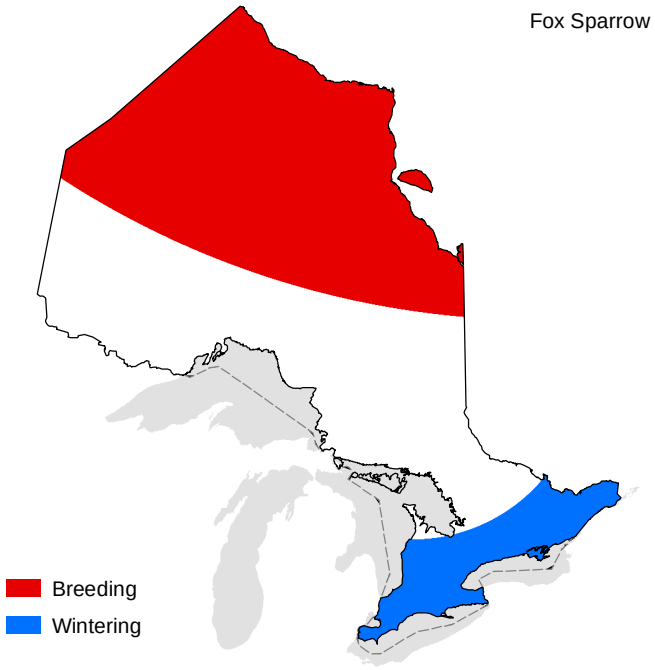
Passerella iliaca

BREEDING SEASON

Habitat Requirements

Ontario Fox Sparrow nests were in a balsam poplar thicket; in a muskeg with stunted tamarack and black spruce; in an open area interspersed with ponds and with growths of black spruce, tamarack, poplar, dwarf birch, and willow; and in a black spruce muskeg with growths of Labrador tea and swamp laurel (Peck and James 1987).

Along the Hudson and James bay coasts, the Fox Sparrow always occurred in deciduous thickets and was common in willow thickets at York Factory (Manning 1952). From the Pickle Lake area northwestward, McLaren and McLaren (1981) observed it in deciduous forest, coniferous forest with an understorey, and mixed, coniferous, and deciduous scrub. It was absent in coniferous forest without an understorey, heath, and tundra. Wilson and McRae (1993) reported several territories in areas of large willow scrub on islands in the Moose River near Moosonee. On the east side of James



Bay in Quebec, it was most frequent where there was a mixture of alder patches and open or stunted spruce, or dry rocky ground. It was not seen in tall patches of alder growing in otherwise barren areas (Manning and MacPherson 1952). Rising (in Cadman et al. 1987) concluded that it nested in Ontario in moist rank growths of black spruce, tamarack, poplar, birch, and especially willow and alder. McLaren (in Cadman et al. 2007) characterized its Ontario habitat as dense stands of stunted conifers in taiga areas and dense thickets of conifers, willows, birches, and alders in regenerating burns along shores of lakes, rivers, and streams. It tends to avoid open tundra, occurring only locally in riparian shrub thickets.

The most important habitat requirement for nesting for the Fox Sparrow is dense shrubby cover where it can nest and scratch for food while remaining concealed. Early in the season, patches of ground that are snow-free are important and are incorporated within territories (Terrill in Austin 1968; Threlfall and Blacquiere 1982). In Newfoundland, it nests in balsam fir–black spruce–white spruce, balsam fir–black spruce, and balsam fir forests; regenerating areas of balsam fir and black spruce; wind-blown stunted forests and scrub forests; successional old fields, clear-cuts and burns; rocky and alpine coastal barrens; brushy forest edges; in mixed farms and wasteland at edges of towns; and historically in gardens in villages. On an island, habitat consisted of climax balsam fir–black spruce–white spruce forest with mountain maple, white birch, American mountain-ash, and alder in open places, with a dense understorey of spinulose woodfern, skunk currant, mosses, bunchberry, and starflower. It used areas with high white birch densities in the shrub layer; it used areas of low birch density on the mainland. Occupied areas on the island were significantly more open with less canopy cover but a taller canopy (8 m compared with 5 m) than mainland habitat. Despite the differences in habitats occupied on the island and mainland, there were no significant differences in its densities in the 2 areas. In 1 Newfoundland study, habitat consisted of harvested and uncut balsam fir and black spruce forest. There was no difference in its probability of occurrence in the 2 landscapes. Its probability of occurrence declined with increasing amounts of forests in both landscapes. In harvested landscapes, it had 80% occurrence at 20% tree cover, 50% occurrence at 40% tree cover, and 20% occurrence at 100% tree cover. In natural landscapes, it had 70% occurrence at 20% tree cover, 90-100% occurrence at 40% tree cover, and 20% occurrence at 100% tree cover. At the landscape level, it was negatively correlated with the amount of tree cover, Within a radius of 12.5 m, it was positively correlated with the amount of scrub, bog, regeneration, recent cut, and dense gnarled conifers. It was considered an edge species. Another study that included both natural and harvested landscapes captured 62% of Fox Sparrows in harvested landscapes.

Other researchers considered it ubiquitous rather than a forest generalist, a forest-interior species, a riparian species, or an open-edge species. Another Newfoundland study in balsam fir stands determined that it was associated with young stands with some deciduous cover on nutrient-poor sites. Young stands (40-60 years old) had a more closed structure with higher tree and small tree density, fewer gaps, more small deciduous trees, less varied tree height profile, taller small trees, and less dead wood on the ground than more mature stands. In Labrador, it preferred scrub spruce and rather open spruce-fir forests, but also occupied pockets of black spruce on barrens, fringes of swamps, and deciduous forests in river valleys (Taylor and Krawchuk 2006; Terrill in Austin 1968; Thompson et al. 1999; Threlfall and Blacquiere 1982; Vassallo and Rice 1981; Weckstein et al. 2020; Whitaker and Montevecchi 1997, 1999; Whitaker et al. 2008).

In Quebec, the Fox Sparrow breeds in coniferous and mixed forests where it prefers thickets and edges; it also occurs in shoreline scrub. It rarely strays from low dense tree and shrub cover, including shrubby woodlands and streamside thickets of willow and alder. It favours rocky shores, particularly on islands and the coast where there is stunted and gnarled coniferous growth that is almost impenetrable. It also occurs in clear-cuts regenerating to conifers. In 1 study area, it was absent in recent clear-cuts and burns where the vegetation was less than 2 m tall, absent in logged areas with saplings 2-5 m tall, significantly more abundant in logged than burned forest where the vegetation was 5-11 m tall, and absent in stands burned 120 and 200 years previously. The eastern part of its Quebec range is characterized by higher elevation, a damp climate, more abundant precipitation, and forest cover consisting primarily of balsam fir with some yellow birch, white birch, white spruce, or black spruce. It is particularly abundant in the stunted coniferous forests of the islands and shorelines of the Gulf of St. Lawrence. On the Magdalen and Anticosti islands, it is associated with dense coniferous growth in the interior and stunted white spruce along the shorelines. In the lower North Shore, it is attracted to the characteristic alternating patches of stunted forests and open rocky areas. In boreal habitat, it is found in edges and clearings and often nests in regenerating rank dense scrub in mountainous areas. In the Great Whale River area, it is abundant in slightly wet areas vegetated with Labrador tea, other low shrubs, and scattered spruce (Bisson and Limoges in Gauthier and Aubry 1996; Imbeau et al. 1999; Terrill in Austin 1968). In Ungava Bay at the extreme northern extent of its range in Quebec, 1 pair nested in a clump of alders in a dry sandy barren on a bluff about 10 m above the Koksoak River. Habitat adjacent to the opening consisted of an open stunted black spruce forest with an understorey of lichens and mosses (personal observation).

Near Churchill, the Fox Sparrow is fairly common in wet willow thickets and wooded areas. It appears to require large blocks of continuous woodland and is absent in clumps of spruce near the coast (Jehl 2004). In the Prairie Provinces, it was associated with riverine sites where there were willows and alders. It occurred in areas with moderate wetness and nutrient status (Kirk et al. 1996). In the Mackenzie Delta in the Northwest Territories, it is one of the most abundant species where it breeds well beyond the limit of trees (Porsild 1943). In the Yukon, it occurs most frequently in shrubby areas of open forests, wetlands, and burns, and along lakeshores and streams. It inhabits white spruce, white birch, and willow along streams and also nests in alder thickets on hillsides and in ravines, alder and willow within spruce forests, and occasionally in black spruce forests (Austin 1968; Sinclair et al. 2003). In Alaska, it was most abundant in hill or bluff habitat followed by subalpine areas, alpine areas, lowlands, and floodplains and terraces where it did not occur in measurable

densities. Floodplains and terraces were highly disturbed with varied vegetation including tall and low shrubs, spruce forests, deciduous forests, and mixed forests. Lowlands consisted of black spruce woodlands and spruce forests. Hillsides were covered with deciduous forest in previously burned areas and mixed forest in unburned areas. Bluffs were steep slopes rising directly from a river with steppe communities, deciduous and mixed forests, scree, and exposed rock. Subalpine habitats included wet sedge and graminoid meadows with low shrub thickets of willow or birch, tall alder thickets, and spruce forests. Alpine habitats consisted of low or dwarf shrubs, wet graminoid meadows, and exposed rock (Handel et al. 2009).

In boreal forest habitat in New York, Vermont, Maine, Nova Scotia, and Newfoundland, presence of the Fox Sparrow was closely clustered in relation to principal components indicating more specialized habitat requirements. It was restricted to colder high latitude sites, suggesting that it could be adversely affected by warming due to climate change (Ralston et al. 2019).

The 3 Pacific groups of the Fox Sparrow use a variety of habitats, many of which do not occur within its eastern range, but presence of dense shrubby habitat is still essential. In 1 region of British Columbia, a requirement appeared to be damp, but not marshy or swampy, ground with a litter of dead leaves rather than a heavy growth of forbs. It required a dense growth of low shrubs that were mostly willows, with occasional elevated perches for singing. Breeding habitat includes sphagnum bogs; subalpine habitats of spruce, willow, and birch; high elevations where forests have been logged or burned; coastal spruce forests; clear-cuts and early stages of regrowth 5-10 years old where it is often confined to this age class; deciduous thickets, alpine spruce, and fir krumholtz; subalpine meadows and forests; dense tangles of willows and alders near streams and lakes; trembling aspen stands with an understorey of Saskatoon and silverberry; tall old-growth balsam poplar with a dense shrub understorey of prickly rose and red-osier dogwood; and drowned muskeg with standing dead snags and black spruce (Campbell et al. 2001). In British Columbia coniferous forests, Wiebe and Martin (1998) considered it a riparian species during the breeding season. Eighty percent of observations were in riparian willow-alder habitat rather than coniferous forest. In Wyoming, it occupied grassy glades surrounded by a circle of willows 3-3.6 m tall. The Fox Sparrow sang from the tall willows and fed in the grass of the glades and the low willows around them (Salt 1957). In Colorado, its abundance was significantly correlated with willow height. Its relative abundance was 0 at 0 cm willow height, increasing linearly to 1.0 at 200 cm height; it preferred to reside and nest in taller shrub habitat (Olechnowski and Debinski 2008). In California, it nested in both burned and unburned forest but was more common in burned areas (Bock and Lynch 1970).

Two Ontario nests were on the ground, one at the base of a sphagnum moss hummock and the other under a small black spruce. Two other nests were 0.5 m and 0.6 m from the ground, with the higher nest in a small black spruce and the other between a balsam fir and a stump (Peck and James 1987).

Nests may be either on the ground or elevated a short distance above it in a shrub or tree. The incidence of elevated nests decreases as the season progresses; earlier nests may be elevated to avoid snow or wet ground. In Newfoundland from 27 April to 13 May, 75.0% of nests were elevated compared with 63.6% 14-30 May, 33.3% 31 May to 16 June, and 0% 17 June to 3 July. Ground nests are under conifers, in clumps of willows or alders, among roots of upturned stumps, on grassy

hummocks, or under herbaceous plants. Most elevated nests are in conifers, especially spruce and balsam fir, but the Fox Sparrow has also nested in willow, yellow birch, currant, and other deciduous species. Most nests are 1 m or less from the ground, but have been reported 4.6-6.0 m up. One nest was on a dead branch leaning against a spruce sapling, 60 cm from the ground. Two nests were in white spruce 1.5 m from the ground. Some females build more than 1 nest before selecting one to lay eggs in (Austin 1968; Burns and Hackett 1993; Campbell et al. 2001; Linsdale 1928; Mailliard 1921; Ryan 1974; Sinclair et al. 2003; Terrill in Austin 1968; Threlfall and Blacquiere 1982; Weckstein et al. 2020).

The Fox Sparrow is territorial but very limited information is available on its territory size. Three territories in regenerating balsam fir–black spruce on the mainland of Newfoundland were about 1 ha in size. Territories on a nearby island averaged 0.25 ha (Threlfall and Blacquiere 1982).

No information is available on natal philopatry and limited information exists on adult site fidelity. In Newfoundland, 12 of 51 adults (23.5%) returned the following year. Nine (75.0%) were recaptured in exactly the same location they were captured the previous year; the other 3 were found within 50 m of their banding locations (Threlfall and Blacquiere 1982).

Limiting Factors

Males establish territories within a day of arriving on the breeding grounds, even when they return 3 weeks prior to snowmelt. Pair formation occurs within a week of territory establishment. Nests typically take 2-3 days to construct, but 1 was built in a single day. Egg laying begins at the rate of 1 a day as soon as the nest is complete. Incubation may begin with the laying of the last egg, start before the clutch is complete, or start with the laying of the first egg. The incubation period has been reported as 12 days 4 hours to 14 days, with hatching spread over a period of at least 35 hours. The nestling period is 9-10.5 days; young may not be capable of flight when they leave the nest (Linsdale 1928; Mailliard 1921; Ryan 1974; Threlfall and Blacquiere 1982; Weckstein et al. 2020).

Double brooding has been confirmed only in Alaska but has been suspected in British Columbia, Quebec, Newfoundland, and the Magdalen Islands. One Newfoundland study concluded that there was no evidence of second broods. The long breeding season and observations of fresh eggs late in the season suggest that double brooding may be widespread. If the first nest is lost, the Fox Sparrow readily renests in a new nest that may be started 2-4 days after the first one is lost. Ontario nests contained either 3 or 4 eggs. Clutches elsewhere may contain 2-5 eggs. In British Columbia, 64% of clutches contained 3 or 4 eggs. Mean clutch sizes were 4.11 eggs in Alaska and 3.24 eggs in Newfoundland (Campbell et al. 2001; Peck and James 1987; Terrill in Austin 1968; Threlfall and Blacquiere 1982; Weckstein et al. 2020).

The age at first breeding is unknown. No information is available on the mating system or duration of the pair bond (Weckstein et al. 2020).

The Fox Sparrow forages predominantly on the ground in either leaf litter or bare ground using a double-scratch technique, moving both feet simultaneously to disturb the substrate. It may also glean insects off vegetation and occasionally flies from a perch to capture flying insects (Terrill in Austin 1968; Weckstein et al. 2020).

Young are fed insects almost exclusively, especially caterpillars. Adults are thought to subsist mostly on insects during the breeding season. The breeding season diet consists of weevils and other beetles, fly larvae, caterpillars, ants and bees, scale insects, spiders, millipedes, and small molluscs. Along the coast of Newfoundland and Labrador, it feeds abundantly on minute crustaceans and may peck at dead and dying fish. Some vegetable matter may be consumed in summer including seeds and fruits of sedges, raspberries, cinquefoils, buttonweed, and juneberries (Terrill in Austin 1968; Threlfall and Blacquiere 1982; Weckstein et al. 2020). On an island off the coast of British Columbia, Hipfner et al. (2013) used stable isotopes to compare the diets of Song and Fox sparrows. The 2 species could compete for food resources because they were the most abundant songbirds and only sparrows on the island and both fed predominantly on insects, fruits, and seeds as well as amphipods captured in the intertidal zone. The Fox Sparrow was dominant to the Song Sparrow in interspecific encounters for food. The Fox Sparrow fed at a lower trophic level, probably consuming more plant material and less animal material than the Song Sparrow. These differences may allow the 2 species to coexist. In May, the Fox Sparrow ate insects almost exclusively in Nevada (Salt 1957). Linsdale (1928) collected 10 stomachs in Nevada. It ate predominantly animal food, with the percentage of animal food in stomachs ranging from 90% to 100% (average 98.1%). The animal food consisted of 70.8% hymenopterans (mostly ants), 15.7% beetles (ground, scarab, and rove beetles, and weevils), 9.9% flies (crane flies and anthomyiid flies), 2.3% small bivalve molluscs, 0.1% spiders, and a trace of caterpillars and millipedes. The vegetation consumed consisted mostly of sedge seeds, but a few cinquefoil and buttonweed seeds were eaten.

There are no records of cowbird parasitism of the Fox Sparrow in the east, where the breeding ranges of the Brown-headed Cowbird and Fox Sparrow do not overlap. There are only 2 records of other subspecies of the Fox Sparrow being parasitized (Weckstein et al. 2020).

There appear to be no significant limiting factors to the Fox Sparrow during the breeding season, but some factors may affect individual birds or local populations. Early nests are vulnerable to being covered by snow during storms. These nests are typically abandoned and a replacement clutch is laid (Threlfall and Blacquiere 1982).

The abundance and distribution of the Fox Sparrow may be affected by logging and human-induced fires (Weckstein et al. 2020). In Newfoundland, breeding season survival rates were slightly lower in harvested than natural landscapes, but not significantly. It appeared to be resilient to moderate levels of clear-cutting (Whitaker et al. 2008). In Alberta, there was no difference in its abundance along seismic lines and pipelines and at well pads than in adjacent forest interior. These energy-sector disturbances appeared to have no effect on it (Bayne et al. 2016).

In the western portion of its range, the Fox Sparrow can be negatively affected by intensive elk grazing, and it may also be affected by moose grazing. Grazing reduces the height of willows, making them unattractive to the Fox Sparrow (Anderson 2007; Olechnowski and Debinski 2008).

In central Quebec and Labrador, DesGranges and LeBlanc (2012) determined that the Fox Sparrow occurred mostly in stands with lower summer temperatures and high rates of summer precipitation. This suggests that it could be adversely affected by climate change in that area.

Status

The first Ontario Fox Sparrow nest was found at Moose Factory in 1860 (Baillie 1958; Peck and James 1987). Manning (1952) considered it common in willow thickets at York Factory. The first atlas demonstrated that it was widespread in the Tundra Zone, Hudson Bay Lowland and the northern portion of the Boreal Forest Region, south to about 70 km north of Cochrane and the Pickle Lake area (Rising in Cadman et al. 1987).

The second atlas indicated that there had been no change in the distribution of the Fox Sparrow. Its probability of occurrence increased significantly province-wide and in the Hudson Bay Lowland and Boreal Forest Region between atlases. The reason for the increase was unclear because there was no significant change in its habitat and northern areas were surveyed by experienced individuals during both atlases (McLaren in Cadman et al. 2007).

POSTFLEDGING PERIOD

All information for the postfledging period is from Newfoundland. Young remain in family groups in or near the natal territory until they are well grown. A male was observed feeding a young in his territory 21 days after it fledged. In late summer, the Fox Sparrow may be seen in groups of 2-6 that include fully grown juveniles and adults. These may feed on dead or dying fish on beaches, or perhaps on insects on the fish (Linsdale 1928; Terrill in Austin 1968; Threlfall and Blacquiere 1982; Weckstein et al. 2020).

MIGRATION

The Fox Sparrow is a nocturnal migrant that usually arrives on the breeding grounds during early morning darkness. Spring migrants may travel together in groups of 8-12 that remain together until migration is resumed. It moves through quickly in spring. It is an early migrant, often appearing when there is still snow on the ground. Snowstorms do not appear to affect the timing of migration; numbers of birds may fluctuate annually but arrival dates are fairly consistent. In Newfoundland, both sexes arrived on the breeding grounds at the same time (Bisson and Limoges in Gauthier and Aubry 1996; Brewer et al. 2018; Terrill in Austin 1968; Weckstein et al. 2020).

In Ontario, spring migrants are often observed in late March but the main movement occurs in the first 2 weeks of April. Migrants may remain south of the breeding range until mid-May, although most leave in late April (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008).

In British Columbia, the median capture date for juvenile and adult autumn migrants was identical, suggesting that both age classes migrate at the same time. Departures began to occur shortly after the young were out of the nest. In Alaska, approximately 10% of birds undertook part of their moult during autumn migration. In Kansas, a flock of autumn migrants remained at 1 site for 13 days (Benson and Winker 2015; Campbell et al. 2001; Evans Ogden et al. 2013; Fitch 1958).

Migrants occur in the southern Shield from late September to late November, with peak numbers in the second and third weeks of October. In southern Ontario, Fox Sparrows usually arrive in early October and depart in early November, with stragglers to late November (Black and Roy 2020; Curry 2006; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008).

At Delta Marsh in Manitoba, Murphy-Klassen et al. (2005) studied spring arrival dates from 1939 to 2001. The Fox Sparrow's arrival was significantly negatively correlated with mean monthly temperature. It arrived 3.3 days earlier in 2001 than in 1939.

The Fox Sparrow prefers shrubby habitat during migration, but may also occur in open hardwood forests with little to no ground cover. It occurs in swampy thickets, streams bordered by dense herbaceous species or shrubs, thickets near ponds, heavy shrub cover along forest edges, clear-cuts in early stages of regeneration, coastal wind-pruned trees, tamarack and spruce muskeg, bogs, treed floodplains, rocky pastures, hedgerows, weedy grain fields, weedy and shrubby roadsides, and urban and rural gardens. It often occurs near water including estuaries, lagoons, ponds, rivers, lakes, sloughs, and bogs and may occur among beach wrack on marine shores. Autumn migrants may feed more often in open weedy areas instead of within thick cover, but seldom stray far from dense cover (Campbell et al. 2001; Fitch 1958; Linsdale 1928; Terrill in Austin 1968; Weckstein et al. 2020). In British Columbia, migrants inhabited willow-alder riparian habitat but not adjacent coniferous forest (Wiebe and Martin 1998).

During the nonbreeding season, the Fox Sparrow is more omnivorous than during the breeding season. In addition to arthropods, it eats a mix of seeds and fruits and occasionally plant buds. It is probable that most fruit is consumed during autumn migration. If snow is on the ground during migration, it often appears at winter bird feeders. In the eastern United States, 127 stomachs collected during the nonbreeding season contained 86% vegetable matter and 14% animal matter. The vegetable matter consumed by the Fox Sparrow differs from that of most sparrows with fewer grass seeds (1%), less grain, and more fruit and seeds of ragweeds and smartweeds, which comprise about 50% of the diet. Twenty-eight percent of the diet consisted of seeds of berries and fruit skin, including those of blueberries, elderberries, grapes, and blackberry. Blueberries may be an important food source for autumn migrants in alpine areas. It also eats berries of red cedar and pokeweed and buds of peach and pear trees. In April, it began eating millipedes, which constituted 20% of the diet for that month; 10% of the April diet consisted of ground beetles. Two stomachs collected during spring migration in Ottawa contained mostly insects, especially beetles, but also spiders, millipedes, and seeds of gromwell. Birds collected in October in Toronto had eaten witch-hazel buds, beetles, firefly and crane fly larvae, spiders, millipedes, and seeds of hound's-tongue. One in Wisconsin had eaten 50 chinch bugs. Ten stomachs collected in Nevada in May contained 71% hymenopterans and 16% beetles. Two April stomachs were almost completely filled with seeds but contained a few ground beetles (Bisson and Limoges in Gauthier and Aubry 1996; Evans Ogden et al. 2013; Judd 1901; Terrill in Austin 1968; Weckstein et al. 2020).

If it snows during migration, the Fox Sparrow leaves thickets to search for food in places such as streambeds and feeders. Mass mortality may occur during severe snow and freezing rain storms. Severe weather during migration and winter may be its greatest limiting factor (Terrill in Austin 1968; Weckstein et al. 2020).

The Fox Sparrow does not appear to be highly vulnerable to striking objects during migration. At the Lennox generating station chimneys near Kingston, no mortalities were detected out of thousands of birds killed (Weir 2008). In British Columbia, 2 Fox Sparrows were killed at a single house out of 118 mortalities (Campbell et al. 2001).

James (1991) considered the Fox Sparrow an uncommon to locally common migrant. Regional bird books concur with this assessment, except that it is a rare migrant in Niagara Region (Black and Roy 2010).

Hussell et al. (1992) reported that captures at Long Point Bird Observatory declined at a nonsignificant rate of 3% per year 1961-88. Trends by period were: 1961-70, –6.7% per year; 1970-79, +3.2% per year; and 1979-88, +9.5%.

WINTER

Wintering Fox Sparrows tend to remain in small groups that stick closely to their particular bit of cover. Winter habitat includes dense thickets and underbrush on edges of woods, dense willows or tall herbaceous species along streams, and rural and suburban yards that have bird feeders. In California, it occurred close to shrubs, roads, and streams, more distant from trees, and far from fields (Kalinowski and Johnson 2010; Terrill in Austin 1968; Weckstein et al. 2020; Wiebe and Martin 1998).

In Indiana, wintering birds roosted overnight in thick red cedar and yew hedges (Weckstein et al. 2020).

In California, Sandercock and Jaramillo (2002) banded 1,139 juveniles and 493 adults over 12 years to determine winter site fidelity. This study was done on a subspecies that does not occur in the east and is a very short-distance migrant. The recapture rate was 60.3% for juveniles and 49.6% for adults. The probability of survival was 10.8% for juveniles after their first capture, 27.4% for adults after their first capture, and 35.2% for adults in later years. Juveniles may have had higher mortality rates because of competition, poor condition, or greater risk taking. Alternatively they may have migrated to different areas in subsequent years. Migratory sparrows are known to change wintering areas after their first year.

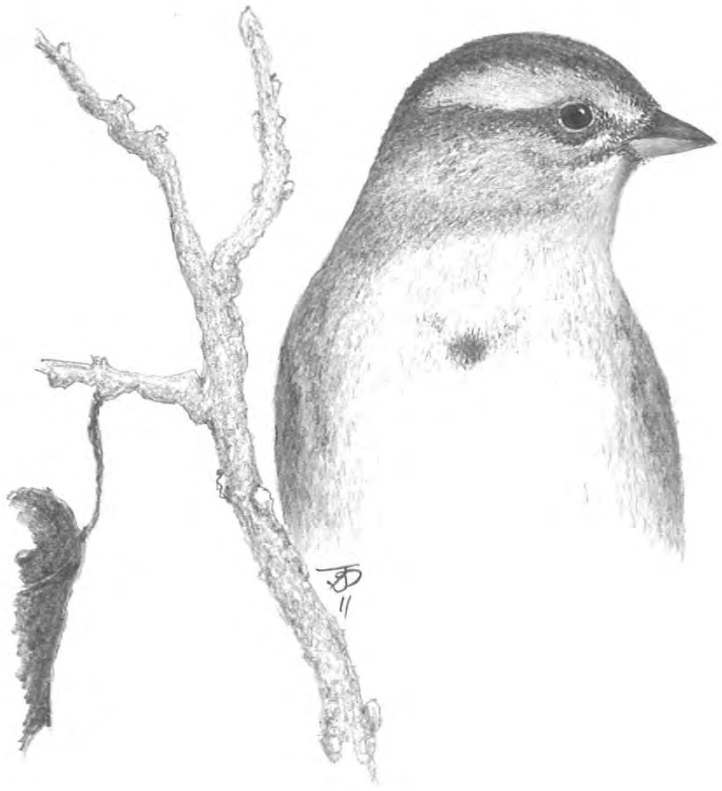
Most observations of Fox Sparrows at bird feeders are of spring migrants with 3 times as many feeders visited in spring than autumn; it also visits feeders in winter. It typically occurs for only a few weeks at a given feeder. It eats numerous berries in winter. At feeders, it often ignores sunflower seeds and selects millet or cracked corn instead. It also prefers mixed seeds and milo. It infrequently takes sunflowers, niger, suet, water, and possibly canary seed and whole corn (Dunn and Tessaglia-Hymes 1999).

Severe weather has the potential to decimate wintering populations. In British Columbia, the population declined 63% during a period of severe weather. The decline was attributed to mortality rather than dispersal (Weckstein et al. 2020). Thousands died in Massachusetts during the severe winter of 1894-95 (Linsdale 1928).

James (1991) considered the Fox Sparrow occasional and rare during winter in the south, north to Bruce and Renfrew counties.

American Tree Sparrow

Spizelloides arborea

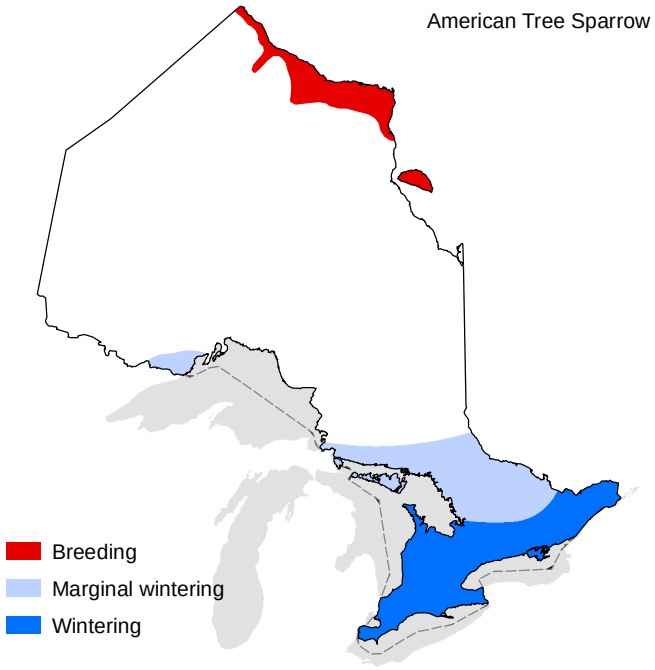


BREEDING SEASON

Habitat Requirements

In Ontario, the American Tree Sparrow nests near the treeline north to the Hudson Bay coast. Nests were in tundra or on old beach ridges covered with lichens, herbaceous species, and small shrubs (Peck and James 1987, 1998b).

In the Boreal Forest Region from North Caribou Lake north to the Manitoba border, it was most abundant in tundra followed by heath, with lesser numbers in deciduous scrub, coniferous forest with an understorey, and coniferous and mixed scrub. It was absent in deciduous and mixed forest and coniferous forest without an understorey (McLaren and McLaren 1981). At Cape Henrietta Maria, it nested in areas of dwarf birch and arctic willow (Peck 1972). It was common in low scrub at the



edge of the treeline along the Hudson and James bay coasts. It also inhabited edges of willow thicket swamps and appeared to nest in patches of dwarf willow and birch (Manning 1952).

Throughout its range, the American Tree Sparrow nests in tundra north of the treeline, in ecotones between tundra and the Boreal Forest Region, and in high altitude subalpine and alpine meadows above the treeline. Less frequently, it nests within spruce forests, but typically in shrubby forest openings. Shrubs, such as willow, birch, and alder, are an important habitat component. Most territories contain water or have water nearby. Erskine (1977) considered it characteristic of tundra and alpine habitats. On the Twin Islands in James Bay, it usually occurred in or near willow thickets where it favoured tall willows; it avoided the shoreline (Manning 1981). On the east side of James Bay in Quebec, it probably nested in considerable numbers along the edge of the treeline and in patches of alders on the barrens. On the barrens, it preferred taller patches of alder and was frequently seen in or near small patches of spruce, but never in the main spruce forest (Manning and MacPherson 1952). Near Churchill, it is common to abundant near the treeline and in willow thickets and is much less common south of the treeline (Jehl 2004; Jehl and Smith 1970). Near Churchill, it is one of the most abundant breeding species in tundra interspersed with patches of scrub birch and willows. Most nests (76.9%) were in dwarf willow–birch thickets, 15.4% were in open tundra near a patch of shrubs, and 7.7% were in spruce near the treeline (Baumgartner in Austin 1968). In the same area, West (1973) reported that melting typically occurred soon after birds arrived, at which time they occurred singly or in pairs around margins of partially melted ponds. Nesting habitat included spruce-tundra ecotones, ponds bordered by alder and willow, and dense willow thickets along a river. Most available habitats were used for nesting except the sea coast, continuous spruce woods, and acid mountain avens tundra. Water or moisture appeared to be important. It occurred most often along margins of small ponds, lakes, marshes, streams, and rivers. In British Columbia, characteristic nesting habitat is near the altitudinal limit of trees in subalpine meadows and marshy wetlands that are interspersed with willow thickets a few cm to 2 m tall. A few conifers or scrub birch are often present in territories. Of 117 nests, only 1 was associated with a building. Seventy-seven percent of nests were in shrub thickets (predominantly willow), 11% were in other low vegetation, and 9% were in unspecified habitats (Campbell et al. 2001). In the Yukon, it is a common breeder in open shrubby habitat at or beyond the treeline. It is the most common species in upland and subalpine shrubs. It typically nests in shrubby tussock tundra with scattered shrubs or a dense cover of shrubs; scattered trees are occasionally present. It also nests well below the treeline in open shrubby habitat with scattered

trees, usually at or near wetlands (Sinclair et al. 2003). In Alaska, it nested in 3 main vegetation types within subarctic tundra: open tundra, low shrubs, and tall shrubs. Open tundra consisted of plants less than 15 cm tall. Low shrubs were predominantly dwarf birch, willow, and bog bilberry 0.15-1.2 m tall. These formed a dense impenetrable mat that was seldom used except along edges or as song posts. Tall shrubs consisted of alder and willow taller than 1.2 m. These thickets often had a herbaceous layer, providing both food and cover; the tall plants also functioned as song posts. Each vegetation type supported isolated spruce trees 3-12 m tall that were used as song perches (Weeden 1965).

During the breeding season, males roost 6-15 m from the nest, often in a conifer. The female roosts on the nest (Naugler et al. 2020).

Twelve of 13 Ontario nests (92.3%) were on the ground; the other was on the lowest branch of a black spruce 30 cm from the ground. Ground nests were at bases of small black spruce or deciduous shrubs such as willows and among grasses near willows. One was under a piece of partially buried scrap metal (Peck and James 1987, 1998b). Schueler et al. (1974) reported 2 nests near Winisk that were on the ground near bases of small deciduous trees. Two nests near Fort Severn were on the ground under small spruces (Baillie 1961).

Throughout the tree sparrow's range, most nests are on the ground, but a few are a short distance above ground, usually in a small coniferous tree or deciduous shrub, but occasionally in a clump of dead grass. In British Columbia, 93% of 94 nests were on the ground; the maximum height above ground was 1.4 m. In the Yukon, 37 of 38 nests (97.4%) were on the ground; the other was 5 cm above ground. In Alaska, most of 200 nests were on the ground, but a few were 0.3-1.2 m up in dwarf willow. A nest near Churchill was 1.5 m from the ground in a small spruce, the highest nest reported. Nests may be partially sheltered by overhanging grasses or leaves, but most are at the base of a shrub or small tree such as Labrador tea, willow, birch, and spruce. Nests may also be in sedge tussocks, clumps of grass, in depressions in mossy hummocks, under grasses, or under debris. One elevated nest was built in an old Redpoll nest. Reuse of nests has not been reported (Baumgartner in Austin 1968; Campbell et al. 2001; Heydweiller 1935; Jehl 2004; Jehl and Smith 1970; Naugler et al. 2020; Sinclair et al. 2003; Walkinshaw 1948b).

Weeden (1965) studied the territoriality of the American Tree Sparrow in Alaska. It is rarely required to defend its territory except in very dense populations. Fights were not confined to birds' typical boundaries and frequently covered an area many times larger than the area in which other daily activities took place. Much fighting appeared to be over females and not a specific area. Frequently-used areas were termed activity spaces rather than territories. Activity spaces included a series of 3 concentric areas: the inner-most core of intensive use, an area of moderate use, and an outer area of low use. Females' activities spaces were always within those of the males' and it is probable that the location of the female dictated the location of the male. Activity spaces occasionally overlapped, usually in areas of moderate or low utilization. Part of the overlap was due to shifts in areas throughout the season, so some of the overlap was not simultaneous. Overlap of activity spaces was 5% for females and 7.2% for males. Where female spaces did not overlap, male spaces overlapped by only 2.6% indicting that overlap of male spaces was more pronounced when female spaces overlapped. Maximum space was used during courtship when males were

establishing territories and acquiring mates. There was a gradual reduction in the size of the activity space through the incubation and nestling phases. Activity spaces were smaller in years of high density. Smaller activity spaces tend to be used more intensively; larger ones had outer cortexes with less intensive use. Females spent much of their time on or near the nest and had smaller activity spaces than males. Nests were frequently not in the centre of activity spaces but were never in areas of overlap with other pairs. Mean sizes of activity spaces for males over 3 years were 1.8, 2.2, and 1.2 ha compared with 0.9, 1.1, and 0.8 ha for females. Mean daily activity spaces were 0.7, 1.1, and 0.7 ha for males. Females wandered throughout the area, stopping in 1 male's territory for a while then moving on to the next. At Churchill, Heydweiller (1935) considered areas occupied by pairs to be territories. Territories ranged in size from 0.29 to 0.65 ha. A pair isolated from other birds had a territory of 2.6-3.6 ha.

No information is available on natal philopatry. In Alaska, 5 of 24 adult males (20.8%) returned in a subsequent year; 3 were present in all 3 years of the study (Weeden 1965).

Limiting Factors

Eggs have been reported in Ontario nests from 21 June to 9 July (Peck and James 1998b). Five to 6 days may elapse after pairing before nest construction begins. At Churchill, nest construction took 9-10 days: 7 days to build it and 2-3 days of rest. The first egg is laid 3-5 days after the nest is complete. Typically 1 egg is laid per day; a day may be rarely skipped. Incubation usually begins with the laying of the last egg, but occasionally with the penultimate egg. The incubation period is 10.5-13.5 days but mostly 12-13 days. All young hatch within a period of 1-30 hours. The nestling period ranges from 8 to 10 days (mean 9.2 days). Undisturbed birds tend to leave the nest when they are 9-9.75 days old, but may leave when they are only 8 days old if disturbed (Allen 1939; Baumgartner in Austin 1968; Heydweiller 1935; Jehl 2004; Naugler et al. 2020; Walkinshaw 1948b; Weeden 1966).

A single brood is raised in a season. At Churchill, there was circumstantial evidence for renesting after loss of a nest, but replacement nests have never been confirmed. In another year at Churchill, all nests were lost during a severe storm and there was no evidence of renesting or resumption of territorial behaviour (Allen 1939; Baumgartner in Austin 1968; Heydweiller 1935; Jehl and Hussell 1966a; Jehl and Smith 1970). Clutches of 5-6 eggs have been reported in Ontario (average 5.25 eggs, mode 5 eggs; Peck and James 1998b). Clutches of 3-7 eggs have been reported, with 5-egg clutches most frequent. Seven-egg clutches have been reported only from Alaska; 4-6 eggs appear to be typical in Manitoba and Ontario (Baumgartner in Austin 1968; Campbell et al. 2001; Heydweiller 1935; Naugler et al. 2020; Sinclair et al. 2003).

The age at first breeding is unknown, but it is probable that both sexes can breed when they are yearlings. The mating system is presumed to be monogamous (Naugler et al. 2020). In Alaska, Weeden (1965) observed numerous unidentified females in territories of mated pairs. Resident males tended to court them and copulation occurred frequently. He assumed that some polygyny and polyandry occurred where activity spaces overlapped. These observations may represent extra-pair copulations rather than polygyny and polyandry. One possible case of intraspecific nest parasitism has been documented, suggesting that female tree sparrows occasionally lay eggs in other females' nests (Naugler et al. 2020).

When feeding on seeds, the American Tree Sparrow usually forages on the ground or a short distance above it in herbaceous plants or shrubs. When feeding nestlings, it gleans insects from tiny leaves of willows and birch, often only 3-4.6 m from the nest. Early in the nesting season, both sexes may feed together in grassy edges of small pools, frequently picking off fresh buds of willow and birch. Buds are obtained by perching on the branch or hopping up a few centimetres from the ground. Occasionally it jumps into the air to hawk mosquitoes or moths (Baumgartner 1937; Heydweiller 1935).

Young are fed almost exclusively animal food until they are 3-4 weeks old, with a trace of leaves from plants in the rose family. Nestlings are fed predominantly caterpillars, but also flies, mosquitoes, and other insects. Once juveniles are capable of feeding themselves, seeds and fruits are taken to a limited extent, with their proportions gradually increasing in the diet. Nestlings are not fed sedge seeds, although these are the main food item of adults throughout the summer and are also important in the diet of juveniles (Baumgartner 1937; Heydweiller 1935; Weeden 1966).

The proportion of animal and vegetable food items in the diet changes seasonally. In winter, the diet is approximately 95% vegetable matter. In late April and May during spring migration, the diet transitions to animal material. The tree sparrow arrives on the breeding grounds to winter-like conditions, and once again reverts to a diet that is almost exclusively vegetation. A staple at this time is sedge seeds from the previous year's production which are typically collected around margins of partially melted pools. The importance of animal material in the diet increases as the season progresses and insects become more available (Baumgartner 1937). Near Churchill, the composition of the diet by period included 64.6% vegetation and 35.4% animals from 25 May to 15 June, 69.15% vegetation and 30.85% animals from 16 to 30 June, 11.59% vegetation and 88.41% animals from 1 to 15 July, 50.83% vegetation and 49.17% animals from 16 to 31 July, 71.2% vegetation and 28.8% animals from 1 to 15 August, and 87.62% vegetation and 12.38% animals from 16 to 24 August. After mid-July, fruits of ericaceous shrubs became available and were important in the diet. For the entire summer, the diet averaged 59.17% plant material and 40.84% animal material. In summer, seeds of 6 species of sedges comprised 46% of identifiable food items. Most other plant foods were heaths and included 7.3% crowberry seeds and 13.2% mountain cranberry seeds and flowers. Of 41 plant taxa available as food, only 9 represented more than 1% of the diet. Seeds (22.1%) and berries (28.4%) of crowberry comprised half the available plant food. Plants that were abundant yet seldom or not used included black spruce, white spruce, 1 sedge species, sweet gale, cloudberry, crowberry seeds and especially berries, and berries of blueberries and cranberries. Bulrushes, 1 sedge species, mustard seeds, and amaranth seeds were consumed roughly in proportion to their availability. Preferred plants included 4 species of sedges, whitlow-grass seeds, blueberry and cranberry seeds, and cotton-grass seeds. It may select smaller seeds that are more easily husked; the large seeds of spruce and cloudberry were not preferred. Only 4 animal orders constituted at least 1% of the diet: 7.6% snails, 3.1% adult flies, 1.2% springtails, and 1.0% beetles; 22 of 53 available taxa (41.5%) were consumed. The tree sparrow was also selective in the animal foods that it ate. The abundant snails and springtails were seldom taken compared with their availability. Scarce items such as beetle larvae and caterpillars were selected. Most other insect taxa and spiders were taken in proportion to their availability. Other animal material consumed included hymenopterans, flies, bugs, adult and larval lepidopterans, and mites (West 1973). Baumgartner

(1937) also studied the diet of the tree sparrow near Churchill. Sedge seeds were the main food item and seeds of 6 different species often occurred in a single stomach. In late July and August, seeds of crowberry and mountain cranberry and bulblets of alpine smartweed became important in the diet. Grass seeds were strikingly scarce in the diet, occurring in only 1 of 39 stomachs in late August. Besides seeds, stomachs contained soft bits of wood or wood chips, fibres, leaf fragments, galls, and unidentified debris. The most conspicuous animals in the diet were spiders, beetles (especially leaf beetles), ichneumonid wasps, lepidopterans, sawflies, and caddisflies. It consumed mostly adult insects, but also eggs, larvae, and pupae.

In a laboratory experiment, Robel et al. (1997) offered tree sparrows different-coloured and different-flavoured food pellets. It preferred brown and yellow pellets and avoided blue and orange ones. Butter- and nut-flavoured pellets were eaten at equal rates and significantly more than lime-flavoured pellets. Flavour discrimination was not as great as visual discrimination.

Water is as essential to the American Tree Sparrow as food (Baumgartner in Austin 1968). This may explain why most territories contain water or have water nearby. Water may also be obtained from succulent plants. Captive birds consumed an average of 29.6% of their body weight of distilled water per day. Birds that were offered salty water increased their water consumption with increasing salt concentrations. Those drinking the 0.15 mole salt solution initially lost weight but recovered. On the 0.2 mole salt solution, 5 of 12 tree sparrows died; the remaining 7 maintained their weight and 2 gained weight. The test with 0.3 mole salt solution was terminated early after 8 of 12 died and the remaining birds exhibited drastic weight loss. It may be able to maintain body weight only on salt solutions that do not exceed 0.15 mole (Ohmart and Smith 1970). Water in oceans averages 0.599 moles of sodium chloride, so it could not survive drinking ocean water.

Habitat loss and degradation on the breeding grounds is not an issue. At Churchill, Sammler et al. (2008) investigated whether intensive grazing by geese affected populations of other bird species. The American Tree Sparrow was 1 of 5 willow-nesting passerines. Over a 15-year period, there was no evidence for a decline of this guild.

Severe weather during the nestling period can result in extensive loss of young. Jehl and Hussell (1966a) reported the effects of a severe wind and rain storm at Churchill that lasted 5 days while young were 3-6 days old. All young died of exposure and there was no evidence of renesting. Prolonged cold and wet weather during the nestling period may result in no young being produced in an entire breeding season.

Status

The American Tree Sparrow was not known to breed in the province until 2 nests were found at Fort Severn on 1 July 1940. Approximately 100 were seen that day on the tundra (Baillie 1961). Manning (1952) considered it common along the Hudson Bay coast. He stated that it was absent at Cape Henrietta Maria although Peck (1972) reported it breeding there. The first atlas demonstrated that it bred throughout the Tundra Region from the Manitoba border east to Polar Bear Provincial Park and south along the James Bay coast almost to Attawapiskat. It was not documented at Cape Henrietta Maria. Some squares supported substantial populations (Knapton in Cadman et al. 1987). James (1991) considered the tree sparrow a common summer resident along the Hudson Bay coast and the northern James Bay coast.

The second atlas revealed little change in the distribution of the American Tree Sparrow. It was rediscovered at Cape Henrietta Maria and nesting evidence was obtained on Akimiski Island, slightly further south than during the first atlas. It is restricted from nesting further south on the mainland due to extensive coverage by forests, bogs, and fens and a general lack of habitat. There was no change in its probability of observation. It was most abundant within 30-40 km of the Hudson Bay coast, particularly between Winisk and Cape Henrietta Maria (Harris in Cadman et al. 2007).

POSTFLEDGING PERIOD

If the nest is not within a dense shrubby area, young are led to one as soon as they fledge. One fledgling took 20 minutes to travel 30 m to a thicket. Once in a thicket, newly fledged young may perch as high as 15 cm from the ground in a small spruce or tamarack. Young are fed by the adults for about 2 weeks after fledging. By the end of July, young at Churchill were flying freely within the thickets. About the third week of August, young emerged from the thick cover and merged with flocks that foraged in open grasses and mosses on river flats. These larger flocks contained both adults and juveniles and remained intact until autumn migration. In Ontario, juveniles were found mostly in patches of dwarf willows and birches, but a few were among spruce. On the eastern James Bay coast, juveniles remained hidden in dense alders (Baumgartner in Austin 1968; Heydweiller 1935; Manning 1952; Manning and MacPherson 1952).

In the latter part of July and most of August after the young had fledged, adults still maintained territories of 0.29-0.65 ha near Churchill. In early August when young were capable of feeding themselves, 3 broods ranged through a 1.4-ha patch of thicket (Baumgartner in Austin 1968).

MIGRATION

Allen (1939) stated that the American Tree Sparrow migrates mostly by day, but other authors concluded that it was a nocturnal migrant (Baumgartner in Austin 1968; Naugler et al. 2020). One bird banded in Edmonton was recovered in Ajax (Brewer et al. 2018). It migrates in flocks of 5-10 or even hundreds, occasionally with other species. At spring migration sites in the Yukon, it initially occurred in small groups of 2-10 and later in flocks of several hundred. As flocks grew, they became multispecies, mostly mixed with Dark-eyed Juncos, but also with Savannah, Fox, Lincoln's, and White-crowned sparrows. No individuals were caught more than 2 days after their initial capture. Migration appeared to be affected by local weather. The initial wave of migrants occurred after a front with heavy wind moved northward. Individuals pursue their own migration schedule and arrive and leave locations independent of each other. Those in the same physiological state probably depart together but the association is transient with some individuals stopping to feed before others. At the Yukon stopover site, the ratio of males to females was 12.3:1. This suggested that females moved along a different route, migrated after 10 May when the bulk of migration was over, or did not stop in the study area. Northward migrating flocks break up before the breeding grounds are reached (Baumgartner in Austin 1968; Naugler et al. 2020; West and Peyton 1972). Morbey et al. (2025) captured tree sparrows during winter and spring at Long Point and Guelph and tracked them using the Motus system. Fifty of 71 departures (70.4%) were nocturnal, with most occurring soon after sunset. The remaining 21 departures were diurnal and 2 of these occurred within 30 minutes of sunrise. Birds were detected nocturnally at Motus stations from 4 February to 4 May and were moving in a northerly direction. Nocturnal movements were strongly associated

with weather conditions, with the likelihood of departure increasing with higher temperatures, higher pressure, and less cloud cover. Departures also increased with more easterly winds, or birds avoided departure during strong westerly winds. Nine birds were detected in southern Ontario in autumn between 17 October and 20 November. Only 1 bird returned to its capture location. Results suggested broad fidelity to the nonbreeding area but limited precise nonbreeding site fidelity. In Alaska, only 8% of the moult occurred during autumn migration, the lowest of the 17 species studied. Because the tree sparrow had the shortest distance to the wintering area and the second-longest duration of time on the breeding grounds, most birds had time to moult prior to migration (Benson and Winker 2015).

In spring, most wintering tree sparrows have departed by mid- to late April in southern Ontario. Some remain until mid-May or rarely into late May or early June. Numbers increase in late March when wintering birds are joined by spring migrants. Northward migration peaks by mid-April. In the southern Shield, it is mostly seen in April during spring migration with stragglers into mid-May (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008). James (1980) saw as many as 6 on 3 occasions in mid-June near Pickle Lake. It is likely that these were unusually late migrants. No information is available on when it reaches its Ontario breeding grounds.

At Delta Marsh, Manitoba, Murphy-Klassen et al. (2005) examined spring arrival times over a 63-year period in relation to temperature. Arrival date was significantly related to temperature in the month of its arrival. The tree sparrow arrived an average of 8.1 days earlier in 2001 than in 1939, but this difference was not significant.

Wilson and McRae (1993) observed 5 tree sparrows at Ekwan in late July, but these had probably been raised nearby. Two seen there on 3 September were the first migrants and 5 seen at Longridge in September were also migrants. In the southern Shield, most arrive in early October, but migration extends from late September to late November. In the south, it typically arrives in mid-October but may occur as early as mid-September (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008).

During migration in forested landscapes in Ontario, the American Tree Sparrow inhabits wet areas such as alder swales, borders of beaver ponds, and margins of marshes. It also uses weedy and shrubby areas; areas dominated by asters and goldenrods may be favoured in autumn (Mills 1981; Tozer 2012). It frequently visits bird feeders in rural and even urban areas during migration. In British Columbia, it frequents a variety of clearings with an abundance of dried herbaceous stems, low deciduous shrubs, and open ground for foraging. These include weedy edges of agricultural fields, willow thickets, around sewage lagoons, abandoned farmsteads, hedgerows, abandoned roadways, utility rights-of-way, stubble fields, grasslands, road verges, and cabin and cottage clearings in forested areas (Campbell et al. 2001). These habitats and marshes may be used during migration in Ontario. In the Yukon, it is widespread during migration in open shrubby lowland habitats where it is associated with wetlands, forest edges, and settlements (Sinclair et al. 2003).

James (1991) considered the American Tree Sparrow a common migrant in Ontario and abundant along the James Bay coast. Wilson and McRae (1993) confirmed that it was a common migrant at Moosonee.

WINTER

Temperature is the main factor determining the winter range of the American Tree Sparrow. The northern limit of its range coincides with the –23°C average minimum January isocline. Factors determining the southern boundary of its range are not as obvious, but may be related to interactions with the Chipping Sparrow (Root 1988). Twomey (1936) compared the temperature and humidity in areas of its breeding and wintering ranges and determined that they were similar in winter in Illinois, Missouri, and Tennessee to conditions during the breeding season at Churchill, Moosonee, and Ungava Bay.

Males winter further north than females. A sample of 16 collected in Ontario consisted entirely of males. In February and March in New York, the male to female ratio was 2:1 whereas there were 3 females for every male during spring migration in April (Heydweiller 1935).

When the ground is covered in snow, the tree sparrow frequently congregates near winter feeders. It is more abundant at rural than urban feeders. It is an open-habitat and edge species in winter, occurring in weedy fields, pastures with some shrubs, cattail marshes (particularly those with some shrub cover), hedgerows, weedy margins of cultivated fields, corn stubble, brush piles, woodland edges (especially those with thickets or weeds), watercourses with weedy or shrubby margins, prairie remnants, and savannahs (Black and Roy 2010; Campbell et al. 2001; Dunn and Tessaglia-Hymes 1999; Fitch 1958; Graber and Graber 1963; Grundel and Pavlovic 2007a, 2007b; Lancaster et al. 2004; West 1967). Smith (2003) considered it a field species in Ontario and used results of Winter Bird-Population Studies to determine its relative abundance in different habitats. Densities per km^2 averaged 10.5 in urban natural parks larger than 10 ha, 7.9 in mixed rural habitat, 4.8 in urban natural parks smaller than 10 ha, 4.4 in rural forests, 1.4 in urban natural areas with open water, and 0 in cities and cropland or pasture with no significant vegetation except hedgerows; differences among the habitats were significant. In Indiana, Grundel and Pavlovic (2007b) reported densities per km^2 of 58 in open habitat with little woody vegetation such as prairie remnants and areas disturbed by farming and mining; 10 in woodland, which was similar to savannah but with greater canopy cover, 4 in oak savannahs, and 0 in forest and dense regenerating oak sprouts following a fire; differences among habitats were significant. It was in the open habitat guild. In Ohio, its abundance was positively correlated with the amount of forest edge. Doherty and Grubb (2000) considered it an edge and generalist species. In Pennsylvania, it was absent in uncut forest and occurred in low density where 50% and 75% of trees had been cut. Cutting created greater availability of early successional vegetation. It preferred edges or brushy vegetation (Yahner 1993).

In winter, the tree sparrow roosts on or near the ground. It mostly roosts solitarily and prefers cattail marshes where they are available. It typically creeps into little cavities in clumps of grasses or cattails in marshes but may also roost in weedy fields and haystacks. It has roosted in dense growths of white pine that offer shelter similar to roosts used on the breeding grounds (Baumgartner in Austin 1968; Heydweiller 1935). During severe weather, it may roost under the snow, either singly or communally. Thompson (1934) observed one near Toronto that burrowed 20 cm into the snow at the base of a small shrub at dusk during a winter snowstorm. McNicholl (1987a) documented communal roosting under snow at Long Point. The overnight temperature was –18°C with a wind chill of –32°C. He observed 18 tree sparrows and a Song Sparrow emerge from 2 small caverns under

the snow formed by the accumulation of snow over arched-over clumps of grass at the base of some red-osier dogwoods. When he retreated, they crowded back into the cavities, filling all the available space. In New York, one roosted in a dense low-growing shrub covered in deep snow (Naugler et al. 2020).

In winter, the American Tree Sparrow typically occurs in flocks. Flocks as large as 250 have been observed in Elgin County and it is likely that flocks of this magnitude occur in many locations. Flocks are often accompanied by Dark-eyed Juncos and occasionally by other sparrow species. Flocks may either remain in 1 general area all winter or wander considerable distances, especially during snow storms. Flocks inhabiting open country wander more widely than those in denser cover such as marshes. A New York marsh supported 2 flocks at either end and there appeared to be an invisible line through the centre of the marsh that flocks never crossed. Birds in the discrete flocks roosted within their diurnal home range; no birds ever roosted in the centre of the marsh. In Kansas, flocks of several hundred tree sparrows mixed with juncos and a few Song Sparrows moved and foraged together. One flock of several hundred stayed within an area of about 11.2 ha all winter. Winter ranges included a weedy fallow field, thickets, a field of milo bordered by an intermittent creek with weeds and shrubs, and debris from a bulldozed hill. Flocks tended to remain together, concentrated in a small part of the range, moving about slowly usually by following shrubs along field edges. Flocks in open habitat may move as far as 10 km during snow storms. Although flocks remain discrete over the winter, their composition may change daily. Individuals may move freely from 1 flock to another. Occasionally large flocks break up into several smaller ones and coalesce later. In New York, 38 birds moved a maximum of 300 m over the winter, 21 moved as far as 600 m, 4 moved 600-760 m, and 17 moved 914-2,073 m. In Kansas, the average distance between successive captures was 115 m indicating a home range of approximately 4.0 ha over the winter. Some birds are fairly sedentary all winter whereas others may wander freely; some birds move as far as 10 km. Winter territories are not defended, but winter flocks may form linear dominance hierarchies (Baumgartner in Austin 1968; Fitch 1958; Heydweiller 1935; Lancaster et al. 2004; Naugler et al. 2020; West 1967).

Many birds exhibit site fidelity to their wintering areas and some return for several years. At a feeder south of Guelph, about a third of birds returned in subsequent years (Brewer et al. 2018). At Prince Edward Point, 34 of 189 birds (18.0%) returned the following year, 9 of the 34 (26.5%) returned the third year, and 3 of 9 (33.3%) returned for the fourth year (Weir 2008). In New York, Brooks (1985) banded a bird of unknown sex and age and recaptured it 41 times over a period of 9 years. In New York, 34% of birds banded the previous year returned, compared with 31.7% in Missouri and 21% in Massachusetts (Dowling 1956; Heydweiller 1935). In Pennsylvania, where the tree sparrow occurs only in the severest part of the winter, Middleton (1943) banded 604 birds over 17 years and 77 (12.8%) returned in subsequent years; 9 were present in 5 winters. Of the 77 that returned, 12 did not return until 2 years after banding, 5 returned 3 years later, 1 returned 4 years later, and 1 returned 6 years later. Of the 77 returning birds, 38 (49.4%) returned a second year. Of the 38 that returned a second year, 15 (39.5%) returned a third year. Of the 15 that returned a third year, 9 (60.0%) returned a fourth year. Of the 9 returning a fourth year, 5 (55.6%) returned a fifth year. Of the 5 returning a fifth year, 2 (40.0%) returned a sixth year.

In winter, the tree sparrow feeds mainly on the ground where it scratches at the substrate or hops up at bent-over herbaceous species. It may also sway from the top of a herbaceous plant and forage as high as 12-15 m in order to obtain berries or catkins. In Missouri, it perched on wild bergamot stems, beat its wings rapidly, and bounced up and down. This dislodged seeds that otherwise would have been unavailable, allowing it to feed on them on the ground. This may be a common foraging technique (Baumgartner 1937; Goldman 1976; West 1967). Gaines (1989, 1990), with a review by Tome (1990), concluded that it did not select high-quality plots and remain in them until high-quality and low-quality patches produced the same energy gain rate. In Pennsylvania, Nastase and Linville (1995) provided seeds at 4 different heights (0, 2, 4, and 6 m). It conducted 16.4% of its foraging on the ground, 20.9% at 2 m, 38.3% at 4 m, and 24.2% at 6 m. It foraged significantly more on the ground than the White-breasted Nuthatch, House Finch, and American Goldfinch and significantly less than the Black-capped Chickadee, Tufted Titmouse, and Dark-eyed Junco. At 2 m, its foraging frequency was significantly different from only the titmouse, junco, and goldfinch, foraging less than them at this height. The tree sparrow foraged significantly more than all species at a height of 4 m. At 6 m, it foraged significantly more than the chickadee, titmouse, and junco and significantly less than the nuthatch and House Finch. The tree sparrow and junco did not differ in their seed choices but differed in their elevation choices, with the tree sparrow preferring to forage at 4 m and the junco preferring to feed at 2 m.

In Ontario, Dance (1986, 2008) observed the American Tree Sparrow eating seeds of black alder, tall goldenrod, gray goldenrod, broad-leaved goldenrod, catnip, Virginia wild rye, and meadow fescue. Mills (1981) observed a flock of 75 feeding on evening-primrose seeds in Muskoka District. Judd (1901) analyzed 517 stomachs collected in the United States in winter. The diet was comprised of 98% seeds, 2% animal matter, and minute amounts of fruit. Grass seeds constituted about 50% of the seeds consumed, with those of panic grasses and foxtails preferred. Other grass seeds in the diet included those of Virginia broomsedge, wiregrass, crabgrass, timothy, bluegrasses, and ensheathed dropseed. Important herbaceous plant seeds included ragweed, lamb's-quarters, amaranths, and smartweeds; these comprised about 40% of the diet. Another 10% of the diet consisted of miscellaneous vegetable matter such as red maple flowers and buds, alder seeds, cultivated grain, a wide variety of miscellaneous seeds, and fruits of red cedar, common juniper, privet, sand cherry, blackberry, blueberry, and nannyberry. Animal foods were predominantly beetles (ground and scarab beetles, and weevils), ants and other hymenopterans, caterpillars, flies, and bugs. Of 549 stomachs examined by the United States Department of Agriculture, 14 (4.3%) contained insects and spiders (Knappen 1934). The animal food of 45 tree sparrows collected in winter consisted of beetles (ground, leaf, rove, and click beetles, and weevils), winter stoneflies, spiders, bugs, leafhoppers, ichneumonid wasps and other hymenopterans, house flies, caterpillars (especially owlet moths), orthopterans, deer flies, and common earthworms (Baumgartner 1937). In Illinois, the winter diet consisted of 98.37% plant material and 1.63% animal material. Grass seeds comprised 77.7% of the identifiable food items. Important grass seeds included those of foxtails (giant, green, and yellow), crabgrass, satin grass, cutgrass, and wheat. Other important seeds included those of lamb's-quarters, amaranths, and asters. It consumed seeds of 36 of 87 available plant species (41.4%). Virginia wild rye, switch grass, Pennsylvania smartweed, climbing false buckwheat, spotted jewelweed, black snakeroot, and giant ragweed were abundant but seldom, if ever, eaten. They may

not be used because of their large size, hardness of the outer seed coat, or unpalatability. Species used in proportion to their availability included wheat, hairy crabgrass, giant foxtail, lamb's-quarters, amaranths, and Pringle's aster. Selected species included nimblewill, rice cutgrass, green foxtail, yellow foxtail, and Pennsylvania pellitory. Approximately 30% of the species consumed were nonnative and most of these were used in proportion to their availability. Animal food consisted of beetles, spiders, and a trace of hymenopterans (West 1967). In Missouri, tree sparrows foraged preferentially in a patch of lamb's-quarters rather than in adjacent plantings of millet and sorghum (Dowling 1956). In New York, a flock fed in the terminal panicles of common reed. No insects were detected in the flower heads so it was concluded that they were either feeding on the seeds or other parts of the dried inflorescence. Seeds of common reed are a rather poor source of food that are rarely consumed by wildlife (Russak 1956). Water remains an essential component of the diet in winter; birds may consume snow to obtain it (Baumgartner in Austen 1968; Naugler et al. 2020).

The American Tree Sparrow may be absent or scarce at feeders when there is no snow on the ground, but common when snow covers the ground. Favoured feeder foods include mixed seeds, millet, and cracked corn. It infrequently selects canary seed, sunflowers of any type, peanut butter mixes, and baked goods (Dunn and Tessaglia-Hymes 1999). Nastase and Linville (1995) offered tree sparrows striped sunflowers, niger seeds, cracked corn, white millet, and canary seed. They ate 46.7% millet, 33.8% canary seed, 12.8% corn, 5.2% niger, and 1.5% sunflower seeds. In a laboratory study, it preferred short and thin sunflowers (less than 12 mm long and 4.7 mm wide) to larger ones (Naugler et al. 2020). A total of 6,644 observations of tree sparrow food selections determined that it preferred white proso millet in hopper or platform feeders (Horn et al. 2014).

Stuebbe and Ketterson (1982) demonstrated that the tree sparrow could survive without eating an average of 30 hours with extremes of 21-40 hours. A bird that ate in late afternoon prior to roosting could be expected to survive overnight and the following day but not a second night. It is highly at risk of starving when severe snow or ice storms make food unavailable. In 1907, 358 were found dead within 3 hours on the shoreline of Lake Huron following an October snow storm (Baumgartner in Austin 1968).

The amount of suitable wintering habitat for the tree sparrow is declining. The old-field habitats that it prefers are being lost as a result of natural succession, tree planting, agricultural intensification, and urbanization (Naugler et al. 2020).

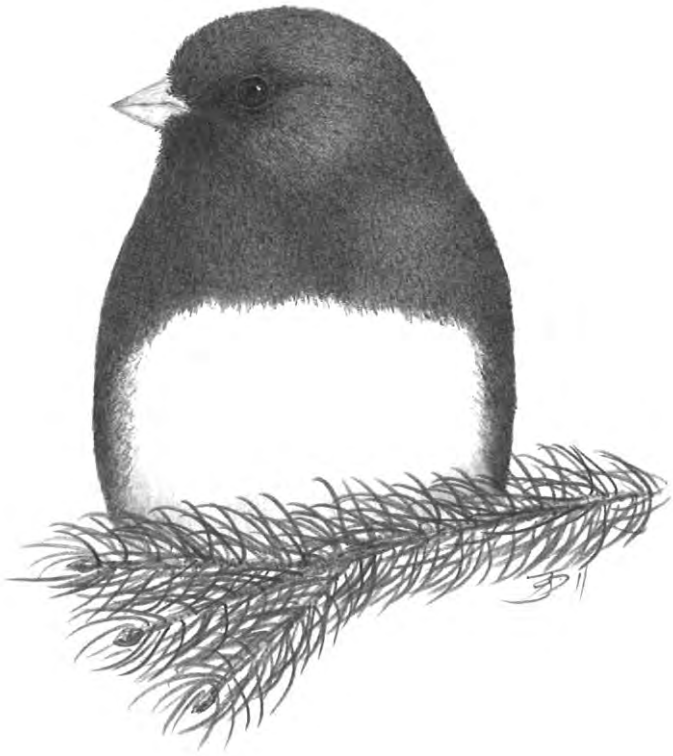
James (1991) considered the American Tree Sparrow common in winter in southern Ontario and rare in the north at Thunder Bay. In Algonquin Park, it is irregular in winter and varies from absent to very common. This is probably due to scarcity of suitable habitat. Early in the 20th century, it was common when many weedy fields were present, but declined as forests matured and eliminated open areas (Tozer 2012). Mills (1981) reported that it was irregular in winter in Muskoka and Parry Sound districts.

It is difficult to determine trends in winter populations due to the American Tree Sparrow's habit of dispersing throughout the landscape when there is no snow and concentrating near feeders when there is snow on the ground. Over the long-term, it is likely that it benefitted from deforestation by the settlers and by the increasingly popular practice of feeding birds. More recently, forest maturation may have eliminated some suitable open habitats, particularly in the southern

portion of the Shield. Results of Christmas Bird Counts are highly variable. Peaks on this survey in 1977, 1980, and 1985 were associated with substantial snow cover. Low counts in 1979, 1984, and 1987 occurred when there was little or no snow. Long-term declines in Pennsylvania were attributed predominantly to the detectability of the species related to snow cover (Hess 1989a, 1989b; Limoges and Barrette in Gauthier and Aubry 1996; Naugler et al. 2020).

Dark-eyed Junco

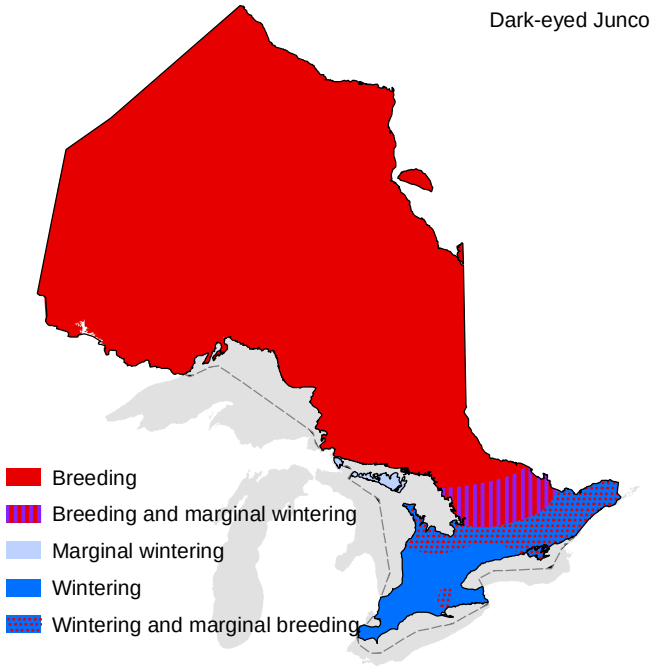
Junco hyemalis



BREEDING SEASON

Habitat Requirements

In Ontario, 59.0% of Dark-eyed Junco nests were in forested habitats, with coniferous (40.0% of nests) preferred to mixed (17.0%) and deciduous (2.0%) stands. Nine percent of nests were in burns or clear-cuts, 19.0% were in bare or sparsely treed bedrock outcrops, 6.0% were in wooded parks or cottage areas, 4.0% were in residential gardens, 2.0% were in open grassy areas, and 1.0% were on a golf course. Wooded areas used for nesting were usually semiopen, or nests were placed at forest edges or clearings. Several nests were at edges with roads and railways, near paths, along shorelines, and in ditches. It preferred to have open areas near the nest. Nesting areas were more often dry than wet. A significant number of nests were on slopes, embankments, and vertical rock faces (Peck and James 1987).



In the Hudson Bay Lowland, the Dark-eyed Junco was very common in burned areas near Hawley Lake (Schueler et al. 1974). Manning (1952) observed it along the Hudson Bay and James Bay coasts, but concluded that it probably nested only in its preferred habitat of dry open spruce forest. Wilson and McRae (1993) also reported it along the northern coasts except at Brant where it did not occur in the tundra habitat.

In the Boreal Forest Region from Pickle Lake northward, the Dark-eyed Junco was most abundant in mixed scrub, followed by coniferous scrub, coniferous forest with an understorey, heath, coniferous forest without understorey, and deciduous and mixed forests. It was absent in deciduous scrub and tundra (McLaren and McLaren 1981). At Pickle Lake, it occurred irregularly in small numbers in disturbed mixed woods or open black spruce stands (James 1980). In jack pine stands near White River, it was most abundant in stands 3-5 years old, but not significantly. It was strongly negatively correlated with vegetation structure 0.5-2.5 m from the ground (Venier and Pearce 2005). In mixed-wood stands near Manitouwadge, it was equally abundant in stands 1-21 and 60-223 years old but absent in 24-36 year-old stands (Venier et al. 2009). Near Hearst, Welsh and Fillman (1980) reported it in a 24-year-old lowland coniferous forest and an upland uncut mixed forest. They did not detect it in deciduous clear-cuts or coniferous clear-cuts younger than 24 years. In the Clay Belt, it was most common in black spruce stands followed by stands dominated by jack pine, tamarack–white cedar, trembling aspen, birch–white spruce, and balsam poplar. It occurred in stands that ranged from wet to dry and nutrient-poor to nutrient-rich (Welsh and Lougheed 1996). Zimmerling et al. (2017) compared its abundance in forests disturbed by fire and logging and in different age classes. It was slightly more abundant in early regenerating stands that were harvested than burned. In mid-successional regenerating stands, it was significantly less abundant in harvested than burned stands. Relative to mature stands, it was significantly more abundant in early regenerating stands and slightly but nonsignificantly more abundant in mid-successional regenerating stands. In the Boreal Forest Region of Ontario, it nested in stands dominated by spruce, balsam fir, hemlock, red and white pine, jack pine, tamarack, and poplar–white birch (Erskine 1977).

In Quetico Park in the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region, there was little difference in the Dark-eyed Junco's abundance in stands 1-23 years old, 67-73 years old, 112-176 years old, and 367-370 years old, although it was most abundant in the oldest and youngest stands (Apfelbaum and Haney 1985). Near Gogama, it was a common and characteristic species of jack pine forests. It first colonized forests when they were approximately 10 years old and attained maximum density when trees were about 20 years old. It avoided deciduous forests and,

to a lesser extent, mixed forests. Territories were in forests that were very uniform with a continuous canopy or where only small openings or gaps were present. Low shrubs were numerous wherever it occurred, but tall deciduous shrubs were sparse to absent (James and Peck 1995a). In jack pine stands near Parry Sound, it occurred in low density in young open stands mixed with a variety of deciduous tree species (James 1979a). In Parry Sound and Muskoka districts, it nested on embankments, among tree root systems, on rock ledges, and on more conventional ground sites (Mills 1981). In Algonquin Park, it was abundant in mixed and coniferous forests, uncommon in sugar maple stands, and rare in settlements (MacLulich 1938). Martin (1960) did not report it in bogs in Algonquin Park, but it inhabited black spruce, black spruce–white cedar, white birch–poplar, poplar and birch mixed with spruce and balsam fir, immature white pine, and hemlock stands. In black spruce–white cedar forests, it occurred from the ground to a height of 18 m, above the top of the cedars but not to the top of the spruce. In white birch–poplar stands, it occupied the ground and shrub layer to a height of 3 m. In hemlock stands, it occurred from the ground to the top of the canopy at 24 m. Also in Algonquin Park, Kingsley and Nol (1999) studied its abundance in white pine stands harvested by the shelterwood method. It occurred in 16.7% of cuts 2-9 years old, 0% and 27.3% of 10-16 year-old cuts in 2 years, and 7.1% and 13.3% of stands with no recent history of cutting. Differences among age classes were not significant. In Algonquin Park, it breeds in open coniferous and mixed forests, often where there is dense ground cover, and favours forest edges, clearings, lake margins, hillsides, and talus slopes below cliffs (Tozer 2012).

Historically, the Dark-eyed Junco was a widespread breeding species south of the Shield. In the Carolinian Forest Region, McIlwraith (1894) stated that it demonstrated a preference for rocky ravines, quarries, and stone piles. Small numbers still nest on talus slopes along the Niagara Escarpment, on the Bruce Peninsula, and in mature plantations (Rising in Cadman et al. 2007).

Throughout its range, the Dark-eyed Junco nests predominantly in forests and appears to prefer coniferous and mixed forests to deciduous forests in most regions. It also nests in treed fens and bogs, subalpine and alpine meadows, and recent clear-cuts and burns. Some western subspecies often breed in open treed natural and landscaped plantings; it may nest on university campuses and in well-treed suburban neighbourhoods. In many cases, it prefers open-canopied forests, small gaps in the canopy, or forest edges.

Numerous studies examined the habitat of the Dark-eyed Junco in Canada and Alaska. In Quebec, it nested in dense spruce forests along the eastern coast of James Bay and in the interior. Most were observed in the drier portions of spruce forests (Manning and MacPherson 1952). Lessard and Limoges (in Gauthier and Aubry 1996) stated that it was one of the most common species in Quebec mixed and coniferous forests where it favoured forest edges, clearings, and other semiopen areas rather than forest interior. It was common in both deciduous and coniferous clear-cuts in Quebec, but absent to uncommon in strip-cuts (Falardeau et al. 1999). In New Brunswick, it occurred in spruce plantations and natural coniferous forests. It tended to be more common in natural forests. In plantations, it was most common in stands 3 years old and those 13-21 years old with lesser numbers in stands 4-8 years old (Freedman and Johnson 1999). In Nova Scotia northern hardwoods, it was most abundant in clear-cuts and was one of the dominant species. It was one of the most abundant and characteristic species in stands 12 years or less in age. It was positively correlated with

young stands with high slash cover and low development of horizontal and vertical plant structure. It was common in strip-cuts in northern hardwoods and mature forests. It was absent in shelterwood cuts (Freedman and Johnson 1999; Freedman et al. 1981; Morgan and Freedman 1986). At Churchill, it nested in drier spruce forests (Jehl 2004; Jehl and Smith 1970). In the same general area, it nested in white spruce–tamarack–black spruce forests and in jack pine stands. These forests had a discontinuous shrub layer of dwarf birch, willows, Labrador tea, crowberry, and blueberries with sedges and lichens. Some of these forests bordered tundra (Gillespie and Kendeigh 1982). In the Prairie Provinces, it exhibited a pronounced gradient of increased abundance from deciduous to coniferous stands. It was associated with dry nutrient-poor sites, mostly with burned areas. It occurred in all age classes of forest, but tended to be associated with older stands (Kirk et al. 1996). In Alberta, it nested in a treed fen dominated by tamarack with a minor component of black spruce. The understorey shrub layer consisted of swamp birch, bog willow, and Labrador tea with a ground flora of creeping sedge, water horsetail, and mosses (Johnson 1988). In Alberta, it preferred coniferous forests. In aspen forests, there was no difference in its abundance in different forest age classes; it tended to be most abundant in old-growth forests (Schieck et al. 1995). Erskine (1977) noted that it tended to be associated with scattered trees or clumps of conifers in deciduous stands, especially white spruce or balsam fir, and was associated with either an open canopy or small trees. In British Columbia, the junco inhabits a variety of forested sites at higher elevations, particularly forest edges and openings, but also occurs deeper in the forest. It nests in alpine meadows and in open subalpine forests interspersed with heath tundra or herbaceous meadows. In the north, it nests in spruce–tamarack bogs and muskeg. In boreal forests, it nests in spruce woodland edges, edges of spruce–hardwood stands, trembling aspen stands, balsam poplar floodplains, black spruce muskeg, and riparian wooded creek areas. In Vancouver Island aspen stands, it was most abundant in clear-cuts and stands 15-20 years old but occurred in all ages of stands except those 50-60 years old. Its abundance was positively associated with elevation and negatively associated with canopy closure. In fir stands, it was most abundant in climax forests dominated by conifers taller than 10 m with an open understorey of scattered snowberry and grasses. It also occurred in young coniferous stands with trees shorter than 10 m and some snowberry and bearberry in the understorey. Other important nesting habitats include recent burns, well-drained shrubby avalanche chutes, and open subalpine fir forests with an understorey of rhododendrons and bilberry. Sixty-nine percent of nests were in forested habitats, 22% were in human-influenced areas, 4% were in alpine areas, and 3% were in riparian areas. Thirty-four percent of forested sites were coniferous, 17% were mixed, and 6% were deciduous. Human-influenced habitats included 10% rural and 7% urban sites; 6% cultivated farmland, orchards, and vineyards; and 4% regenerating cuts and burns and urban and recreational areas. Its abundance was significantly greater in young than old clear-cuts. Presence of slash piles appeared to be an important habitat component of trembling aspen clear-cuts. Riparian sites were associated with swamps, marshes, sloughs, lakes, ponds, bogs, muskeg, and bottomlands (Campbell et al. 2001). In the Yukon, the Dark-eyed Junco is one of the most common song birds. It breeds in a variety of forest types, usually at low altitudes but is occasionally found above the treeline. It nests in dense mixed or coniferous forests, open spruce-deciduous woodlands, edge habitat, trembling aspen–coniferous woodlands, and pine forests (Sinclair et al. 2003). Erskine (1977) stated that it was dominant in all forest types in the southwestern Yukon, whether the site was coniferous or deciduous or successional or climax. It is absent from tundra habitat in this area (Nolan

et al. 2020b). In Alaska forests, it occurred in stands ranging from early succession to old growth and was absent only from stands with a closed dense canopy, low light penetration, and scant ground cover. It was most abundant in shrub-forb growth, sapling-shrub-stage forests, lakeshore old growth, and muskeg (Nolan et al. 2020b). Eaton (in Austin 1968) stated that it inhabited more open woodlands and forest edges or openings in the canopy created by streams, logging roads, or clearings.

Several studies summarized the habitat of the Dark-eyed Junco in the eastern United States. In Maine, it was common in a coniferous forest dominated by balsam fir and spruce with only 7% coverage by deciduous trees. It was absent in a mixed forest dominated by spruce with 38% deciduous tree cover (Morse 1978). In spruce–balsam fir forests in Maine, Titterington et al. (1979) found it only on recent clear-cuts no more than 2 years old and in mature forests. It was absent in mid-successional habitats. Clear-cuts that it used were characterized by dense slash and abundant open ground. Mature stands had a dense coniferous canopy and an open forest floor with some windthrown trees and branches and twigs that had fallen from the overstorey. In subalpine areas of New Hampshire, it occurred mostly in the high krummholz area and extended above this into the tundra (Sabo 1980). In an extensive stand of northern hardwoods in New Hampshire, it was patchily distributed and occurred consistently in areas with a more open understorey and relatively dense herbs and ferns compared with less occupied areas (Holmes and Robinson 1988). Holmes and Sherry (2001) considered this habitat marginal for the junco. It occurred in only 16 of 30 years, predominantly at the start of the study, and may have been attracted to the area by an outbreak of the saddled prominent. In subalpine New Hampshire stands, it was common at elevations of 750-1,150 m in tall mixed, second-growth deciduous, and coniferous forests (Morse 1979). In the White Mountains of New Hampshire and Maine, it was significantly correlated with cover type and structure but not tree-size class. It was most abundant in stands dominated by white pine followed by spruce–balsam fir, white birch, and hemlock stands. It was uncommon in northern hardwoods and swamp hardwoods and absent in aspen stands (DeGraaf et al. 1998). In Vermont, some territories encompassed both northern hardwoods and clear-cuts but it tended to avoid cuts, particularly their centres (Lent and Capen 1995). It was common in New York clear-cuts. It was more abundant in cuts 2-18 years old and declined 24-120 years after cutting (Keller et al. 2003). Several studies summarized its habitat preferences in forested areas of the northeast. In northern hardwoods, it occurred in 10% of plots in mature undisturbed habitats and 37% of disturbed and successional habitats. It occurred at low density in a 3-year-old burn in aspen–white birch but was absent in sapling-pole and pole-mature stands. In red, white, and jack pine forests, it was most abundant in seedling-sapling stands and mature forests; it occurred in low density in pine-hardwood stands and was not observed in pole-sized pine stands. It has not been reported in pitch pine stands. It was associated with small openings, edges, and forests, but not with large openings (Back 1979; Capen 1979; Noon et al. 1979; Taylor and Taylor 1979; Temple et al. 1979). In Wisconsin, it is rare in diverse barrens and absent in other types of pine-oak barrens (Mossman et al. 1991) and rare in northern mesic forests dominated by sugar maple, hemlock, yellow birch, beech, white pine, basswood, and elm. In these forests, it occurs predominantly in coniferous saplings, pole-sized coniferous stands, and mixed forests (Hoffman 1989a). In Minnesota, Niemi and Hanowski (1984a) reported it in closed-canopy spruce forests but not in open spruce stands, low shrubby areas, or

fens. In Virginia, it is the most common breeding species above elevation 1,000 m. It nests there in all available habitats including woodlands, forest edges along hydro corridors and roads, and openings around human habitation (Chandler et al. 1994a).

In Utah, the junco nested in mixed subalpine meadows, trembling aspen forests, and spruce-fir forests (Smith and Andersen 1982). In California, it was the most abundant species in clear-cuts. Large amounts of logs and slash were important in providing cover until shrubby vegetation became established (Hagar 1960). In California coniferous forests, it was common in both unburned and burned forest and comprised more than 50% of the ground-brush nesting guild in unburned forest (Bock and Lynch 1970). In Arizona, it nested in open pine forests and savannahs with an understorey of native grasses (Walsberg 2005).

Some studies characterized habitat of the Dark-eyed Junco at the landscape scale. In Minnesota, it was positively associated with the amount of black spruce within 200 m, the amount of non-forest within 1,000 m, and the density of streams within 200 m. It was negatively correlated with the amount of mortality due to the eastern larch beetle within 500 m. It was associated with black spruce forest and was not common in pure tamarack stands (Zlonis et al. 2017). In Alaska, it was most abundant on hills or bluffs, followed by lowlands, subalpine areas, floodplains and terraces, and alpine areas (Handel et al. 2009). Near Seattle at the 1-km^2 scale, it was most abundant in open developed areas and at forest edges (Marzluff et al. 2007). In Saskatchewan, it was randomly distributed among fragmented and contiguous forested landscapes. It was more common within large forest patches with low percent forest cover within 5 km, but its abundance was not significantly correlated with forest size. It was more common than expected in pure white spruce stands and was uncommon in trembling aspen and mixed stands (Hobson and Bayne 2000). Near Quebec City in second-growth balsam fir forests mixed with black spruce, white spruce, and white birch, it was not significantly associated with forest cover, amount of core area, or edge (Drolet et al. 1999). In Newfoundland balsam fir and black spruce stands, natural landscapes contained a mix of age classes and natural openings created by wetlands and water bodies. Cut landscapes contained these features but at least 5% of the forest had been clear-cut. Its rates of occurrence were 38% in cut landscapes, 34% in natural landscapes, and 36% overall. Its occurrence rate was similar across levels of forest cover within cut landscapes but not within natural landscapes. Lower levels of occurrence in natural landscapes occurred primarily at low levels of forest cover suggesting that natural openings such as bogs and barrens did not provide adequate resources. The proportion of sites occupied in cut landscapes was 20% at 20% forest cover, increasing to 40% at approximately 45% forest cover and remaining constant to 100% forest cover. In natural landscapes, the proportion of sites occupied was less than 10% at 50% forest cover, increasing to 30% at 65% forest cover, and to 40% at 80-100% forest cover. Incidence at the 300-m scale increased with increasing forest cover in natural landscapes but decreased in cut landscapes. Taylor and Krawchuk (2006) concluded that the junco preferred early successional habitats based on its preference for harvested areas and ecotones. In the Boreal Forest Region, Erskine (1977) considered it characteristic of tundra and alpine ecotones with boreal forest. It is one of the most typical boreal species, particularly in black spruce stands. It is common in spruce–balsam fir stands, is found in most jack pine stands, is among the species detected in black spruce and tamarack bog forests with more tree cover than average or taller scattered trees, and is common in burns and clear-cuts.

Several studies detailed microhabitat preferences of the Dark-eyed Junco. In the northeast, it was in a guild that was common in mature upland and lowland conifers; rare to uncommon in alder, mature deciduous upland forests, disturbed shrub areas, young plantations, aspen regeneration, and recent clear-cuts; and absent in grasslands. Its abundance was not associated with the density of low shrubs, saplings, or trees (Niemi and Pfannmuller 1979). In clear-cuts in Maine, it was positively correlated with slash above and below 1 m and the number of conifers larger than 20 cm diameter at breast height (DBH), which was the largest size of trees. It was negatively correlated with raspberries. Its presence was closely associated with dense slash (Titterington et al. 1979). In the White Mountains of Maine and New Hampshire, it was not positively associated with any habitat parameter, but was negatively associated with the percent ground cover and foliage volume of deciduous trees 2-10 cm DBH (DeGraaf et al. 1998). Mean habitat characteristics of territories in subalpine areas of New Hampshire included occurrence on the exposed upper slope of the mountain, usually no water present, mean canopy height 4.0 m, 42% canopy coverage, 72% conifer foliage volume, 38% conifer foliage volume 0-2 m above ground, 15% deciduous foliage volume above 5 m, and average tree DBH 7 cm. It used dense shrub clumps with a rock outcrop or exposed banks for nesting (Sabo 1980). In Vermont, average habitat variables for 6 territories included 84.0% ground coverage by green vegetation, 7.9% coverage by slash, 35.8% canopy cover, 9.5 m canopy height, 6.1 m canopy depth, 8.4 m^2 basal area (BA) of deciduous trees, 4.1 m^2 BA of conifers, mean DBH of deciduous trees 8.3 cm, mean DBH of conifers 6.5 cm, and 20 snags per 0.08 ha. It was in the intermediate canopy–dense understorey guild. The junco was associated with pole-sized hardwoods with a canopy closure of 55-80%, high understorey density, and a mean DBH of 8-15 cm. Plots with these characteristics included a stand that had been clear-cut 20 years previously and stands where recent logging opened the canopy and allowed a dense understorey to regenerate. It preferred denser understorey than other species in the guild (Thompson and Capen 1988). In Vermont northern hardwoods, it was associated with increasing successional age, decreasing numbers of dead trees, and increasing numbers of conifers (Lent and Capen 1998). In New York, it was in an edge-associated guild that was also associated with conifers. It was most abundant in young clear-cuts but also occurred in pole-sized to timber forests. Tree gaps in these forests provided canopy openings that allowed regeneration of the understorey (Keller et al. 2003). In North Carolina, it was significantly associated with the number of houses and buildings within 200 m. It was also associated with an increase in the amount of forest canopy, but not significantly (Lumpkin and Pearson 2013). In western aspen stands, its abundance was correlated with ground cover; it preferred stands with dense herbaceous cover. Despite this preference, few nests were found in areas of dense ground cover. Most occupied stands had an understorey dominated by either grasses or forbs, but it appeared to select habitat on the basis of ground cover density rather than type (Flack 1976). In Colorado, it nested in trembling aspen woodlands bordered by meadows. It was a nonriparian nesting species that was unaffected by proximity to willows, water, or meadows (Glass and Floyd 2015).

The Dark-eyed Junco tends to be most abundant in very young stands and mature forests and less common in intermediate-aged stands. In many forest types, it is most abundant in recent clear-cuts and burns and declines with increasing age of stands. Older forests tend to have gaps in the canopy as a result of treefalls; they provide the microhabitats that it prefers for nesting. In Quebec

black spruce stands, older stages of forest were codominated by the junco and Yellow-rumped Warbler. The junco occurred in all age classes of forest from recent burns and cuts where the vegetation was less than 2 m tall to stands 200 years old (Imbeau et al. 1999). In Newfoundland balsam fir stands, it was most common in 80-year-old stands and significantly more abundant than in 40-year-old stands. The difference in its abundance in 80- and 60-year-old stands was not significant. The 80-year-old forest had a more open structure with lower tree and small tree density, more gaps in the canopy, fewer dead small deciduous trees, a more varied tree-height profile, shorter small trees, larger diameter dead and live trees, and more dead wood on the ground. The junco was associated with communities containing few deciduous species (Thompson et al. 1999). In Pennsylvania mixed woods, it occurred in 100% of old-growth forests, 27.1% of forests statewide, and 52.8% of forests in the Appalachian Plateau. Haney (1999) considered it to have a positive affinity with old-growth forests. Erskine (1977) concluded that it was more common in young than mature coniferous forests in the Boreal Forest Region.

Although the Dark-eyed Junco nests in forest interior, it is more of an edge species. In Newfoundland, it was considered an open-edge species. It was significantly more abundant at nonriparian edges of balsam fir forests where the opening was a clear-cut or a road than in forest interior or riparian edges. It was uncommon in riparian buffers between water bodies or watercourses and clear-cuts but absent within 30 m of riparian edges when the adjacent forest was intact (Whitaker and Montevecchi 1997, 1999). In balsam fir–white cedar forest in Quebec, it occurred in nonriparian stands and riparian stands that included a narrow wetland composed of alder, reed grass, and sweet gale along an aquatic shoreline. There was no difference in its abundance in riparian and nonriparian stands (LaRue et al. 1995). In British Columbia coniferous forests, Wiebe and Martin (1998) studied the influence of a strip of riparian vegetation consisting of a dense understorey of deciduous vegetation that was absent in the main forest. It was negatively associated with the riparian strip, but not significantly. The dense woody vegetation was probably unsuitable nesting habitat. Battin and Sisk (2011) studied its response to edge in coniferous forests in Arizona. The treatment involved a combination of thinning and prescribed burning that reduced basal area by 45% and pine stem density by 80%. It was significantly more abundant in treated than control forests. The junco was the only species that responded to an edge in the treated habitat. Its probability of occurrence peaked at the edge in both habitats. It displayed an edge-exploiting response, seeking out territories that encompassed both treated and untreated forest.

Coniferous trees are used for nocturnal roosts even where deciduous trees are more common. In Virginia, the junco always roosted in hemlock, pine, or spruce trees 2-25 m tall. If trees were tall enough, roosts were several metres above ground. When the female was fertile, both members of the pair roosted together, both on the territory of the male and on those of neighbours. Males usually select a different tree each night for roosting. Over 12 nights, 6 of 13 males (46.2%) roosted on a neighbour's territory rather than their own (Nolan et al. 2020b).

Most Ontario nests were on the ground, often well hidden in depressions in the ground, in hollows in moss, in rock crevices, and various other cavities. Fourteen elevated nests were reported: 9 in crevices on cliff faces, and 1 each in a cedar tree, Labrador tea, a hanging flower basket, a 15-cm cavity in a boulder, and a depression in a stump. Nine nests were 0.2-1.7 m from the ground and 2

nests on cliff faces were 3 and 9 m above water. Ground nests were under shrubs, vines, or trees (27.3% of nests); in or under grass clumps, ferns, and other plants (21.4%); in moss and lichen hummocks (16.9%); beside or under branches, fallen logs, fence rails, and stumps (12.3%); under earthen bank overhangs (7.8%); under rocks (6.5%); in rock crevices (4.5%); beside buildings and walls (1.3%); and 0.6% each in the end of a hollow log, under a metal barrel, and in a vole tunnel (Peck and James 1987). In Algonquin Park, 1 nest was under a dome of dead mown grass on the visitor centre tile bed (Tozer 2012).

Quebec nests are usually on the ground, sometimes in a shallow depression and occasionally in a shallow scrape where the ground is soft enough. They are often at the edge of a forest and usually well concealed under some type of shelter, in dense shrubbery or forbs, or abutting a stump or root. One nest was in a cavity 10 cm underneath a dead stump with the opening concealed by a clump of club-moss (Eaton in Austin 1968; Lessard and Limoges in Gauthier and Aubry 1996). The junco has a tendency to nest on slopes in shallow depressions or cavities overhung by vegetation and sod. It nests on hillsides, talus slopes, cliffs, and road and railway cuts, often under protruding rocks, among roots (especially of windthrown trees), under fallen tree trunks, at bases of saplings or shrubs, and in or at bases of clumps of grasses, forbs, or ferns. Many nests in mountains in the eastern United States are under polypody ferns on the very edges of cliffs. One Alberta nest had a tunnel 10 cm long through the side of a hummock of sphagnum moss to the nest, which was about 15 cm below the top of the hummock and the same distance above water. A small proportion of nests are elevated either in trees or shrubs, or in or on buildings. Most elevated nests were in the west or mountainous areas of the eastern United States. In British Columbia, 86% of nests were on the ground. Nests in trees and shrubs were usually in a crotch or fork of a branch. Maximum nest height there was 10 m but in Virginia, nests were as high as 15 m and were not placed in forks or branches. One nest was 2.1 m from the ground on the back wall of a shallow cave. In the western and eastern mountains, it may nest under, in, or on buildings. It has nested on ledges of buildings, among vines on sides of buildings, on beams and light fixtures, in hanging flower pots, in flats of flowers in a greenhouse, on rafters in barns, under eaves of buildings, and in an attic. There are 3 records of it nesting in old woodpecker holes or tree cavities and 2 records of it using nest boxes attached to sides of houses. There are several records of it relining and using old robin nests. Unusual nest locations include in a bait bucket hanging on a garage wall, in a bicycle helmet, in empty cans lying on their sides, in a bird feeder, in the corner of an empty box, and in discarded rubber tires. It typically builds a new nest for each clutch but there are at least 3 records of nests being reused; 1 was used 3 times (Bailey and Sherwood 2017; Butler 1980; Campbell et al. 2001; Chandler et al. 1994a; Eaton in Austin 1968; Flack 1976; Johnson 1988; Michael 1992; Nolan et al. 2020b; Phelps in Austin 1968; Sinclair et al. 2003; Smith 1964; Sprunt in Austin 1968; Thatcher in Austin 1968; Walsberg 2005). In Arizona, nests were in significantly more open sites with fewer total stems than random sites; predation was less likely at open sites (Nolan et al. 2020b). In Montana, it preferred to orient nests to the north (average 36°); nests with a northern orientation had cooler mean temperatures. This area had been burned at varying intensities. Females were more likely to have burrow nests (with more than 50% of the bowl under a roof of rock or soil) in high-severity burns where canopy cover was the lowest. They were less likely to burrow nests in the second year postfire when the amount of ground cover was significantly greater. Nesting success was unrelated to nest type, orientation, or

burn severity. Birds nesting in postfire sites exhibited a preference for nest sites with the most moderate microclimates: exposed and north facing (Robertson 2009a). In California burned sites, it often placed nests in unburned patches and also used non-traditional nesting sites. Two nests were on mats of pine needles more than 10 m from the ground in trees and many were under overhanging rocks or in burned root holes. These types of nest sites were not observed in unburned areas or in the burned area prior to the fire. Regardless of whether a site had been burned, nests were significantly more likely to be placed in areas of downed wood created by windthrow (J.H. Sperry et al. 2008).

Males sing from the tops of the tallest trees in the territory, often at heights of 15-23 m. Territories often include an opening in the forest canopy surrounding a rock outcrop or exposed soil bank. In Montana, territories occasionally partly overlapped and did not encompass all available habitat (Eaton in Austin 1968; Nolan et al. 2020b; Robertson et al. 2010). North of Lake Nipigon, 3 territories averaged 1.47 ha (range 1.05-1.90 ha; Kendeigh 1947). In Algonquin Park, 19 territories averaged 0.52 ha (range 0.08-1.46 ha; Martin 1960). Eaton (in Austin 1968) reported that territory sizes varied greatly in size, but most were 0.8-1.2 ha. Average territory size reported in Quebec is 1.6 ha (range 1.4-1.9 ha; Lessard and Limoges in Gauthier and Aubry 1996). Average territory size in New Hampshire subalpine forests was 1.1 ha (Sabo 1980). In Maine mainland white spruce forests, 6 territories averaged 1.67 ha; the junco did not nest on adjacent 0.1-4.0-ha islands (Morse 1977). In Minnesota, it nested on the mainland but not on islands 0.04-1.1 ha in size (Howe 1979); most or all these islands may have been smaller than its territory size. In Montana, there was no difference in territory sizes in areas subjected to different intensities of fire, or in the year of the fire compared with the following year. Territory sizes averaged 1.52-1.88 ha (Robertson et al. 2010). The mean home range of 7 females in Virginia during the nestling period was 0.83 ha (range 0.16-2.45 ha). Previous studies determined that the mean home range of females during the fertile period was 2.44 ha, significantly larger than during the nestling period and slightly larger than for males (2.11 ha). During the fertile period, the female seeks copulations, often leaving her mate's territory. During the nestling period, the female focuses on parental care and nest defence, staying closer to the nest. The home range of males during the nestling period averaged 1.31 ha, larger than for females but not significantly. Home ranges of males did not change over the nesting cycle. The large variation in the size of females' home ranges may have been related to differences in the distribution of hemlocks, which were used for roosting (Reichard and Ketterson 2012). In Virginia, Chandler et al. (1994a) implanted some males with testosterone and radiotracked them and control birds. Testosterone males had significantly larger home ranges during both the incubation (6.36 ha compared with 1.96 ha) and nestling (3.31 ha compared with 1.31 ha) periods. The 95% activity core during incubation was 1.51 ha for testosterone males and 0.33 ha for control males; respective results during the nestling period were 0.83 ha and 0.20 ha. Testosterone males often ranged more than 150 m from the nest and were occasionally found 550 m away on neighbouring territories.

Natal philopatry of migratory populations appears to be low. In northern Utah, 0 of 102 nestlings returned (Smith and Anderson 1982). In a resident population in Virginia, 26 of 265 nestlings (9.8%) were in the breeding area the following spring. Twenty-three of 253 nestlings (9.1%) that were known to have fledged and 19 of 123 fledglings (15.4%) that reached independence were present

the following spring (Wolf et al. 1988). Also in Virginia, 99 of 795 juveniles (12.4%) returned. Of 321 additional young first banded as juveniles, 73 (22.7%) returned (Nolan et al. 2020b).

Adult site fidelity rates are considerably higher than natal philopatry rates. In Ontario, 53% of males returned in the following year; at Rutherglen, 1 male returned in 3 years. In Oregon, 7 of 26 adults (26.9%) returned in the following year. In a resident Virginia population, 48 of 77 territorial males (62.3%) were present the following year and reoccupied their former territories; 44 of 104 females (42.3%) returned (Lawrence 1956; Nolan et al. 2020b).

Limiting Factors

Eggs have been found in Ontario nests from mid-April until the end of July, with most present in June (Peck and James 1987). In Algonquin Park, nests are under construction early May to early July, eggs are present mid-May to late July, nestlings are present late May to early August, and fledglings have been seen from early June to early September (Tozer 2012).

Pairing occurs as soon as females arrive. North of Lake Nipigon, this appeared to happen when spring flocks broke up. Severe weather may delay or suspend pair formation, with birds leaving their territories to assemble at feeding areas. During the interval between pairing and nest-site selection, the pair wanders aimlessly while actively feeding. During this period, considerable chasing and fighting occurs, with the male defending an area of 0.9-1.2 m around his mate. A nest site is finally selected during the wandering period; movements of the pair stabilize and they establish a territory. One nest in Algonquin Park took 2 days to build. First nests in Virginia took 3-7 days to build (average 4.5 days). Later nests were usually built in 2 days and occasionally in 1 day. In Virginia, the interval between nest completion and egg laying was 1-11 days for the first nest and 4-5 days for subsequent nests; there is usually no delay between nest completion and egg laying or a maximum of 1 day. Eggs are laid at the rate of 1 a day. Incubation is initiated with the laying of the last egg in 3-egg clutches and with the penultimate egg in larger clutches. Ontario incubation periods were 11-12 days. Elsewhere, incubation periods of 11-14 days have been reported, with most eggs hatching in 12-13 days. Because of when incubation is initiated, hatching of 3-egg clutches is synchronous and hatching in larger clutches is asynchronous. In Utah, 0% of 3-egg clutches, 58.6% of 4-egg clutches, and 77.8% of 5-egg clutches hatched asynchronously. Asynchronous hatching allows brood reduction to occur if food is scarce. Young leave the nest when they are 8-13 days old, with shorter nestling periods usually due to disturbance of the chicks (Allan 1979; Ball and Bayne 2012; Campbell et al. 2001; Eaton in Austin 1968; Kendeigh 1947; Nolan et al. 2020b; Peck and James 1987; Phelps in Austin 1968; K.G. Smith 1988; Smith and Andersen 1982; Sprunt in Austin 1968; Thatcher in Austin 1968; Wolf et al. 1988, 1991).

The Dark-eyed Junco raises 2 broods in Ontario and in much of its range, including northern British Columbia and the Yukon. In alpine areas, only a single brood is raised but in more southern areas, 3 or even 4 broods may be raised. Of 88 cases where the female successfully raised 1 brood in Virginia, 43% had 2 clutches, 44% had 3 clutches, and 13% had 4 clutches. Females usually lay a replacement clutch if one is lost. Clutches of 3-7 eggs have been reported in Ontario, with most containing 4 eggs. Six- and 7-egg clutches are rare. Mean size of 137 clutches was 4.04 eggs. Elsewhere, clutches of 1-5 eggs have been reported but 3 British Columbia nests contained 6 nestlings. Four-egg clutches are most frequent and the normal range of clutch sizes is 3-5 eggs.

One- and 2-egg clutches are rare. Most may be a result of partial depredation but there are some authentic records of single-egg clutches. In most areas, initial clutches contain 4 or 5 eggs and 3-egg clutches usually occur later in the season. Five-egg clutches have lower hatching success rates than smaller clutches but are still the most productive clutch size. Mean clutch sizes from other areas include 4.24 eggs in Colorado and Utah, 4.0 eggs in South Dakota, 4.25 eggs in the Yukon, and 3.92 eggs in California, Oregon, and Utah (Campbell et al. 2001; Eaton in Austin 1968; Nolan et al. 2020b; Peck and James 1987; Phelps in Austin 1968; Robertson 2009b; Sinclair et al. 2003; K.G. Smith 1988; Smith and Andersen 1982; Sprunt in Austin 1968; Thatcher in Austin 1968; Wolf et al. 1991).

Both sexes are capable of breeding when they are 1 year old. In Montana, all males paired successfully but floater males occur in other populations; these are probably all yearlings. Some floater males are successful in obtaining a territory later in the year (Nolan et al. 2020b; Robertson et al. 2010).

The mating system is typically monogamous but some cases of polygyny have been documented. In Virginia, 2 of more than 200 males (less than 1%) were mated to 2 females simultaneously. Polygyny also occurred occasionally when a female lost her mate. In some of these cases, a neighbouring male mated with the female. These males typically retained their existing mate and rarely cared for the young of the secondary female. Most pairs remain together for the entire breeding season. If a female's mate dies, he is typically replaced within a few hours. Replacement males rarely help raise the female's brood but most provide no assistance. When a male loses a mate, it may take weeks to replace her. Some of these males remain unmated for the remainder of the season. In established pairs in Virginia, 2 of 65 females (3.1%) dispersed within the breeding season and mated with another male. In Virginia, most pairs remain mated in subsequent years; 82% of 22 pairs that returned the following year reunited. This population is resident and any migration that occurs is altitudinal. This rate of mate retention in subsequent years may not be typical of migratory populations. In Virginia, 21-56% of young were sired extra-pair. In these studies, males were injected with testosterone so the results may not be typical. There is no evidence of intraspecific parasitism by the junco (Allan 1979; Chandler et al. 1994a; Ferree 2019; Nolan et al. 2020b; Reichard and Ketterson 2012; Wolf et al. 1991).

The Dark-eyed Junco forages predominantly on the ground, but also in low shrubs, saplings, and trees. The male may forage while he sings from treetops; therefore his average foraging height is higher than for females. On the ground, it kicks simultaneously with both feet to disturb the litter area and uncover food items. It often leaps from the ground to capture flying insects. It may forage on skid roads and other areas of bare ground when seeking conifer seeds. It may swarm finch-like at the tops of conifers to feed on seeds. In logged areas, it often forages in fallen slash. Early in spring or shortly after snowfall, it seeks snow-free areas for foraging such as the bases of trees, under dense vegetation, and south-facing slopes (Hagar 1960; Howe 1979; Nolan et al. 2020b; Phelps in Austin 1968).

Several studies described the junco's foraging techniques and substrates and some compared its foraging techniques with other species. In Ontario, foraging occurred 92.0% of the time in conifers, 42.0% in foliage, 29.8% by aerial attacks with an average attack distance of 22.7 cm, 0% by hanging, 10.0% by hovering, 10.7% by reaching, with foraging occurring at 45.0% of tree height at

an average height of 6.2 m. In Mackenzie District, foraging occurred 82.1% of the time in conifers, 66.0% in foliage, 26.1% by aerial attacks with an average attack distance of 35.0 cm, 6.4% by hanging, 0% by hovering, 8.5% by reaching, with foraging occurring at 47.0% of tree height at an average height of 3.8 m (Greenberg et al. 1999). In Vermont, foraging was 95% by gleaning, 5% by aerial attacks, and 0% by hanging and hammering. Foraging substrates consisted of 22% foliage, 0% air, 3% branches, 53% the ground, 0% trunks, and 22% twigs (Lent and Capen 1995). When foraging above ground in Arizona, 84% of observations were at 12 m or below in the lower two thirds of the vegetation (Nolan et al. 2020b). In northern hardwoods in New Hampshire, the junco was in the ground-foraging guild. Its prey attacks were 64.7% 0-0.2 m from the ground, 20.4% on shrubs at heights of 0.3-2 m, 12.5% on saplings 2.1-8 m tall, 3.1% in the subcanopy at 8.1-14 m, and 0.2% in the canopy above 14 m. It directed 37.4% of its prey attacks on the ground or in litter, 18.7% on a forb or fern, 34.6% on foliage, 4.6% on bark, and 4.7% in the air. Prey-attacking manoeuvres consisted of 6.9% probing, 62.7% gleaning, 20.5% jumping and hovering, 5.7% hovering, 0% diving and gleaning, and 4.2% hawking. The forest floor was the most common foraging substrate for all species studied except the Winter Wren which foraged in the shrub layer. All 6 ground-foraging species (Swainson's Thrush, Hermit Thrush, Wood Thrush, Veery, junco, and Ovenbird) differed in one or more aspects of their use of space, foraging behaviours, and diet (Holmes and Robinson 1988). In subalpine areas of New Hampshire, Sabo (1980) classified the junco as a forest-floor forager. Its foraging techniques consisted of 0% aerial flycatching, 17.2% leaf gleaning, 5.0% leaf hawking, 0.3% leaf hovering, 20.2% twig pecking, 21.5% twig gleaning, 5.7% hawking and hovering, 1.5% branch pecking, 1.7% branch gleaning, 0.3% bole pecking, 0.2% bole gleaning, 21.4% litter picking, 3.8% litter gleaning, and 1.4% fallen log manoeuvres. Twenty-three percent of foraging occurred distal to the trunk, 48.1% proximal to the trunk, 57.9% on coniferous tree foliage, 13.6% on deciduous tree foliage, 3.0% on herbaceous foliage, and 25.7% on the forest floor. Foraging height included 13.0% in the understorey at height 0.1-2 m, 35.7% in the midstorey at 2-5 m, 16.8% in the midcanopy at 5-8 m, and 8.8% in the upper canopy above 8 m. Lima (1988) provided juncos with 3 sizes of crushed millet bits and whole millet seeds. Whole seeds took significantly longer to handle, so bits were more profitable to consume. Scanning for predators and handling were mutually exclusive for bits but not for whole seeds. All birds ate both bits and whole seeds. Males ate significantly more whole seeds than females, possibly because males are dominant. The proportion of whole seeds in the diet decreased with an increase in flock size when individuals would not need to be as vigilant. The foraging strategy was a trade-off between the need to be vigilant and to maintain a high rate of energy intake. If predators were not a concern, the junco would be unlikely to eat whole seeds. In an aviary, Goldstein and Baker (1984) offered juncos canary and niger seeds that were natural as well as in pellets and seeds. When offered as pellets, most birds significantly preferred canary seed to niger seed, but natural niger was preferred to natural canary seed. Of 12 birds that had significantly different handling times, 11 preferred the seed (10 niger, 1 canary) that they handled the quickest. Birds did not exhibit an absolute preference for a seed type and usually ate some of the less preferred seed. In an aviary, sparrows, including the junco, were more efficient handling seeds smaller than 0.74 mg; finches were more efficient at handling seeds larger than 1.44 mg (Benkman and Pulliam 1988).

When the male fails to feed the nestlings or dies, the female is capable of raising the entire brood. Although females without assistance can successfully fledge their broods, they may not be able to raise all their fledglings to independence. When nestlings are young, they may be fed regurgitated or partially digested food as well as moths and caterpillars. Older nestlings are fed yellow grubs, owlet moths, spruce budworms, caterpillars, caddisflies, crane flies, soft parts of grasshoppers, and millet. During several hours of observation, young were fed nothing but large numbers of smooth green caterpillars (Eaton in Austin 1968; Nolan et al. 2020b; Thatcher in Austin 1968; Wolf et al. 1988, 1991).

The adult diet consists mostly of insects during the breeding season and vegetable matter the remainder of the year. Eaton (in Austin 1968) reported that adults ate mostly caterpillars, beetles, and ants in the summer, but also wasps, bugs, grasshoppers, other insects, and spiders. In early spring, it feeds on swarming springtails, catches emerging gnats on the snow or in the air, and preys on hatches of winter stoneflies. In late summer and autumn, it eats caterpillars of fall webworms. Seeds the Dark-eyed Junco consumes in autumn and winter include those of ragweeds, foxtails, dropseeds, crabgrasses, amaranths, and goosefoots. Thatcher (in Austin 1968) stated that adults eat dandelion seeds and those of brome grasses and amaranths. In winter, it may feed on spruce seeds in trees with the Pine Grosbeak, Red and White-winged crossbills, and Pine Siskins. Phelps (in Austin 1968) reported that it fed at sapsucker wells, but it was unknown if it was feeding on insects or sap. In spring in Ontario, it has been documented feeding on sugar maple sap icicles (Simpson 2025). In spring, it eats plant galls and seeds of goosefoots, knotweeds, melic grass, and lesser amounts of seeds of pines, catchflies, wheat, annual bluegrass, knapweed, mayweed, scarlet pimpernel, sheep sorrel and wood-sorrel. Twenty-five stomachs collected in the breeding season contained leafhoppers, bugs, beetles, adult and larval lepidopterans, a fly, ants, a spider, and several seeds including those from sunflowers. In California, cultivated and wild oats constituted 10-25% of the autumn and winter diet; seeds of common chickweed were equally important. Cultivated and wild barley comprised 5-10% of the diet during this period; seeds of amaranths were also prominent in the diet. Judd (1901) analyzed the contents of 299 stomachs collected in every month but May, mostly from the Atlantic seaboard but also from the central United States and California. The annual diet consisted of 22% animal matter and 78% vegetable matter. The animal matter consisted of 7% miscellaneous insects that were mostly true bugs, 6% beetles, 3% hymenopterans, 2% orthopterans, 2% lepidopterans, and 2% spiders plus a few snails and other invertebrates. Sixty-five stomachs collected from June to August in California and North Carolina contained 49% animal matter and 51% vegetation. Beetles were important insect food items, including 1% ground beetles, 2% leaf beetles, 8% weevils, 6% click and long-horned beetles, and 16% insects that were mostly small dung beetles and ants. Other animal foods included 4% caterpillars, 5% grasshoppers, and 5% parasitic wasps. The vegetation consisted of 49% seeds and 2% fruits of blueberries, blackberries, strawberries, and elderberries. Important seeds included 9% violets, 8% smartweeds, 5% grass seeds, and smaller amounts of sedges, sheep sorrel, wood-sorrel, purslane, and chickweed. The winter diet consisted of 9% animal matter and 91% vegetation. The vegetable matter could be divided into 3 almost equal parts. The first consisted of seeds of timothy, broomsedge, foxtails, crabgrasses, panic grasses, and paspalum, with small amounts of grain and ensheathed dropseed. The second part consisted of ragweed and smartweed seeds and the third part was comprised of seeds of various

plants, mostly amaranths, lamb's-quarters, chickweed, purslane, tick-trefoil, vetches, gromwell, wood-sorrel, sedges, sheep sorrel, wild sunflowers, and Russian thistle. Seeds of amaranths and lamb's-quarters were by far most important in the diet. Few other sparrows eat as many of these seeds as the junco and it feeds on them mostly in March. Beal and McAtee (1912) analyzed the contents of more than 500 stomachs collected in the United States in all months. They contained 23% animal matter and 77% vegetation; their results also included the stomachs that Judd (1901) analyzed. The principal food was weed seeds (61.8% of the diet) that were eaten in every month and comprised 95% of the September diet. Grain (oats, wheat, barley, and corn) constituted 8% of the diet. Animal foods included 6% beetles, 2% hymenopterans that were mostly ants and a few wasps, 9.4% caterpillars, and 7.3% bugs, grasshoppers, other insects, and spiders. Smith and Andersen (1982) examined the contents of 3 adult stomachs collected during the breeding season in Utah. Major food items included ants, 6 unspecified families of beetles, leafhoppers, and spiders. Juncos also ate lacewings, leaf bugs, and several wasps that were mostly ichneumonids. Only a single beetle larva was found in the stomachs, but they observed adults feeding many beetle larvae, caterpillars, and orthopteran nymphs to nestlings. Hagar (1960) analyzed the contents of 460 stomachs collected in California, mostly from birds foraging in clear-cuts but some were collected in forests. It preferred seeds of Douglas-fir when they were available. In spring, insects, especially small beetles, were a substantial component of the diet complemented by seeds of early successional plants that invaded clear-cuts. By June, these seeds comprised 21-32% of the volume of the food. In summer, the junco depended heavily on seeds of a great variety of weeds and grasses, with the most important being those of bull thistle, fescues, bluegrasses, wiregrass, knotweeds, and willow-herbs. Fruits of raspberries and strawberries were of some importance in late summer. The autumn and winter diet varied considerably annually depending upon the availability of different foods. In 1 winter, fruit of the arbutus tree was used extensively along with forb and grass seeds. Douglas-fir seeds were a minor component of the diet in 1 year but more than 50% of the food volume during 1 autumn and winter and into the next spring. In spring, it also ate germinating seeds and very young fir seedlings. Consumption of fir seeds decreased by June and no new seeds were produced, so it reverted to eating grass and weed seeds. Insects were less important in the diet in the year that fir seeds were abundant, but still comprised 60% of the food volume. Nolan et al. (2020b) reported that 269 juncos collected in California had eaten 24% animal matter and 76% vegetation. In order of decreasing frequency in the diet, the animal food consisted of beetles, moths and butterflies and their caterpillars, ants and wasps, flies, and miscellaneous insects and spiders. The diet was comprised of 62% seeds, with important groups including chickweeds, amaranths, knotweeds, and sorrel. In another sample of 248 stomachs, the diet consisted of 76% vegetation from November to March, 40% in April and May, 93% from June to August, and 92% from September to October. Ragweed and various grass seeds were important in the diet. During the same periods in California, the amount of vegetation consumed was 74%, 52%, 95%, and 91%. Chickweed seeds were important but it frequently ate grama grass and crabgrass seeds. The junco drinks from streams, ephemeral pools, and moisture on vegetation and also eats snow.

The Dark-eyed Junco frequently eats budworms and may or may not increase its population in response to outbreaks. In New Brunswick, it exhibited the highest mean consumption rate of black-headed budworms of the species studied. It was one of the most effective predators of budworms

and increased in density in response to increasing budworm populations (Gage et al. 1970). Near Manitouwadge, Venier et al. (2009) observed no numerical response of the junco to spruce budworm numbers, but it was uncommon within the area. Morris et al. (1958) also observed no response in New Brunswick. In Maine spruce–balsam fir forest, Mitchell (1952) determined that it frequently ate spruce budworms but did not study its population response. In New Hampshire and Maine, Crawford and Jennings (1989) reported that it consumed an average of 1.7 budworms per stomach, a moderate consumption rate for the bird species examined. It responded positively and ate more budworms as their population increased. They did not observe an increase in junco numbers in response to the budworm outbreak but acknowledged that the population could have increased over several years as numbers of budworms increased. In northern hardwoods in New Hampshire, density of the junco was higher during years of an outbreak of the saddled prominent moth (Holmes and Sturges 1975).

The Dark-eyed Junco is an uncommon host of the Brown-headed Cowbird in the east. Parasitism rates may be higher in the west, particularly for populations of juncos that nest near human habitation. The junco accepts cowbird eggs. No detailed studies have been done on the effects of parasitism, but cowbirds in Virginia removed junco eggs in about half the nests they parasitized. An average of 1.7 cowbird eggs were laid in parasitized nests and 1.2 junco eggs were removed by cowbirds. In Ontario, 7 of 177 nests (4.0%) were parasitized, 1 of 75 Quebec nests (1.3%) was parasitized, 25 of 840 British Columbia nests (3.0%) were parasitized, and adults have been observed feeding cowbird fledglings in the Yukon. In the United States, 40% of Virginia nests, 25% of Sierra Nevada nests, 1 of 3 Michigan nests (33.3%), and 1 of 48 California nests (2.1%) were parasitized (Campbell et al. 2001; Nolan et al. 2020b; Peck and James 1998b; Sinclair et al. 2003; Turner et al. 2022).

Extreme habitat loss occurred south of the Canadian Shield due to deforestation around the turn of the 20th century. South of the Shield, the junco is now confined to extensively forested landscapes in areas such as the Bruce Peninsula, the Norfolk Sand Plain, and southeastern Ontario. Populations in these areas may be at risk due to habitat fragmentation.

The junco may exhibit a neutral or positive response to forest management, with positive effects usually associated with the removal of a higher proportion of trees. In California coniferous forests, biomass thinning removed small-diameter low-quality trees, opened up the canopy, and increased understorey cover. There were significantly more nests in thinned plots and they were significantly more successful (Siegel and DeSante 2003). In mature trembling aspen forests in Colorado, it was initially abundant in clear-cuts; 5 years after cutting, it was equally abundant in cut and uncut forest. In British Columbia coniferous forests, it was more abundant in tracts with greater tree removal (Nolan et al. 2020b), and readily colonized 60-100 year-old trembling aspen stands after they were clear-cut (Campbell et al. 2001). In California, it was equally abundant in clear-cut and uncut forest in the first year. Once weedy vegetation became established in cuts, the junco population increased to 2-3 times that in virgin forest, peaking 3-6 years after cutting when shrubs and sapling were the dominant vegetation (Hagar 1960). In the Boreal Forest Region of Ontario, it increased by 50% when 20% of tree cover was removed (Vanderwel et al. 2007). In Maine spruce–balsam fir forests, the junco was most abundant in clear-cuts for 2 years following cutting. It was less abundant in closed-canopy

forest and absent in intermediate stages of forest (Titterington et al. 1979). In northern hardwoods in Nova Scotia and New Brunswick, it was most abundant in clear-cuts, intermediate in abundance in mature forests and strip-cuts, and absent in stands that were thinned by shelterwood or single-tree logging (Freedman and Johnson 1999; Freedman et al. 1981). Falardeau et al. (1999) reported similar findings in Quebec. In Idaho, it was equally abundant in uncut forests and those cut by single-tree selection (Medin and Booth 1989). In New York northern hardwoods, it did not appear to respond to logging where 25-100% of the merchantable timber was removed. Even in 100% removal, residual areas were still forested because non-merchantable timber was retained. The lack of response may have been because it was scarce, representing 2-3% of birds detected in all treatments (Webb et al. 1977). In Pennsylvania, timber stand improvement involves removing dead, dying, diseased, suppressed, or low-quality trees. It was more abundant in improvement stands where snags were retained. Snag-retention areas had a more patchy and open canopy and greater availability of low-growing vegetation and woody plants (Stribling et al. 1990). In Newfoundland, Whitaker et al. (2009) captured 67% of birds in landscapes that contained clear-cuts and 33% in landscapes without clear-cuts. There were no differences in survival rates of birds in cut and natural landscapes. Harrison et al. (2005) studied its response to partial harvest of forests in Alberta. It increased in deciduous stands when 100% of trees were cut, increased in deciduous stands with an understorey when 90% of trees were cut, increased in mixed forests when 20% and 50% of trees were cut, and increased in coniferous forests when 100% of trees were cut. It colonized deciduous forests where it was previously absent when 25-100% of trees were removed but the increase was significant only when 100% of trees were removed. It colonized or increased wherever trees were cut regardless of forest type.

The Dark-eyed Junco appears to be little affected by fire and any effects typically last less than a year (Nolan et al 2020b). In Oregon, Stephens et al. (2015) found that it demonstrated no clear response to fire; its abundance did not vary with fire intensity. In the Sierra Nevada, it was equally abundant in burned and unburned forests (Bock and Lynch 1970). In California, J.H. Sperry et al. (2008) found no difference in its abundance in unburned areas and where prescribed burning removed small-diameter trees. Potentially negative effects due to reduction in litter and an increase in the amount of bare ground were offset by increased food availability and novel nesting strategies such as nesting in small unburned patches and selecting non-traditional nest sites that offered better concealment. In Montana, it was equally abundant in burns of low, intermediate, and high intensity. Nest-predation probability was significantly less in intermediate-intensity burns than in low- and high-intensity burns. Females in intermediate-intensity burns had larger clutch sizes. In high-intensity burns, females were more likely to select nest sites that were concealed by overhanging rocks or turf (Robertson 2009a, 2009b).

In Arizona, grazing by cattle in forests had adverse effects on the Dark-eyed Junco. Grazing resulted in a 75% reduction in fledging success, mostly due to cattle cropping the vegetation overhanging nests; other nests were trampled (Walsberg 2005). On Anticosti Island, grazing by white-tailed deer had no significant effect on the junco (Cardinal et al. 2012). Grazing is unlikely to be an issue in Ontario. The main range of the junco is outside areas of high density of livestock and deer.

Marzluff et al. (2007) examined habitat use by the junco in relation to predator distribution. At larger scales of 1 km and 0.5-70 ha, it was positively associated with corvids and members of the squirrel family but was negatively associated with squirrels in forest patches. Although it co-occurred with nest predators at larger scales, it strongly avoided areas within forests that were rich with a single predator or all predators combined.

The junco responded favourably to energy sector disturbances in Alberta forests. It was significantly more abundant at seismic lines, pipelines, and well pads than in forest interior adjacent to these features (Bayne et al. 2016). In Quebec, Rail et al. (1997) used playbacks of the junco's song to determine the effects on territoriality of gaps 3-100 m wide. Its response did not seem to vary abruptly at any gap width, suggesting that gaps in contiguous forest did not have a strong effect on its territorial response. There was no difference in its probability of crossing different types of gaps, including power lines, roads, ski trails, and clear-cuts. There may have been no discernible effect because the junco nested in most of these gaps.

Gutzwiller and Anderson (1999) studied the effects of human intrusion on juncos nesting in Wyoming subalpine forests. A researcher walked within a 1.0-ha plot for an hour. There was no difference in its abundance inside and outside disturbed areas.

The junco may benefit from reforestation of farmland (Lessard and Limoges in Gauthier and Aubry 1996). This is the case in the Norfolk Sand Plain where reforestation over a century ago resulted in natural-appearing pine-oak forests and stands of mature pine. This area supports one of the few breeding populations in the Carolinian Forest Region.

Birds nesting at high altitudes or in northern areas may experience nest loss as a result of late-season storms (Phelps in Austin 1968). Where the junco raises a single brood, this has the potential to significantly reduce annual productivity. Where more than 1 brood is typically reared, storms may eliminate the possibility of more than 1 brood.

Price (2004) predicted that the Dark-eyed Junco might be excluded from breeding in southern Ontario if the average summer temperature increased by 2°C. In southern and central Quebec and Labrador, it occurs mostly in stands with low summer temperatures and high precipitation. Consequently, it is vulnerable to climate change (DesGranges and LeBlanc 2012; DesGranges and Morneau 2010).

Status

Prior to the 20th century, the Dark-eyed Junco was a common resident that bred throughout the province (McIlwraith 1894). Lancaster et al. (2004) reported that it was a common resident that bred in Elgin County in 1891. It bred in Halton in 1906 and was a scarce nester in Wellington County at approximately the same time (Brewer 1977; Curry 2006). In 1901, it was a common breeding species in Muskoka and Parry Sound districts; it was abundant in southwestern Parry Sound in 1928 and at Lake Muskoka in 1906. By the turn of the 20th century, it was disappearing south of the Canadian Shield as a result of extensive deforestation. There was no evidence of it breeding within the Hamilton area from 1925 to 1956. Baillie and Harrington (1937) considered it a common summer resident of the entire province that nested everywhere except in the extreme southern counties. By 1954, and probably much sooner, it occurred in Elgin County only as a migrant and winter resident

(Lancaster et al. 2004). Mills (1981) reported that it was still widespread in Parry Sound and Muskoka districts, but less common than formerly. Tozer (2012) noted that it had decreased in recent decades in Algonquin Park. It was more numerous in the 1930s in young forests created by fire and logging. The decline was attributed to maturation of trees and filling in of open forests. The first atlas demonstrated that it nested throughout the Canadian Shield to the Hudson Bay coast, with the exception of Cape Henrietta Maria. Its distribution became spotty in the southern portion of the Shield south of Algonquin Park. In the Great Lakes–St. Lawrence Forest Region south of the Shield, it was confined to heavily forested areas such as the Bruce Peninsula, the Oak Ridges Moraine, and scattered areas in extreme southeastern Ontario. The only records from the Carolinian Forest Region were from Long Point and Simcoe where it bred in tracts of conifers (Rising in Cadman et al. 1987).

The second atlas revealed that there had been no change in the range of the Dark-eyed Junco. Province-wide, its probability of observation increased significantly, with significant increases in the Boreal Forest Region and Hudson Bay Lowland, but a significant decline in the Shield portion of the Great Lakes–St. Lawrence Forest Region. Breeding evidence was obtained at Cape Henrietta Maria during the second atlas. Reasons for the decline in the southern portion of the Shield may be related to forest maturation and canopy closure. It was most abundant in the northern portion of the Hudson Bay Lowland. It was also common in the remainder of the Hudson Bay Lowland and the northern portion of the Boreal Forest Region (Rising in Cadman et al. 2007).

In Ontario, the Breeding Bird Survey (BBS) does not cover the area where the junco is most abundant, so it may not be a reliable indicator of population change. During 1970-2021, BBS data indicate that the junco decreased annually by 1.13% in Canada and 2.5% in Ontario. The trends 2011-21 were annual decreases of 0.864% in Canada and 3.96% in Ontario. All results were of low reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Young are poorly developed when they fledge and incapable of flight for 3-4 days. They run or hop from the nest and move upward in the understorey and lower canopy, where they behave cryptically. Until age 23-28 days, brood mates are scattered and do not associate with each other. They become independent 14 days after fledging at age 25-27 days, although feeding by adults may occur until 24 days after fledging. After age 30 days, they increasingly occur in flocks. In Virginia, many fledglings began dispersing from the natal home range at age 30 days. The maximum distance travelled from the natal site before age 40 days was 2.2 km. Nonetheless, many birds 50-60 days old were caught on the natal territory. It was unknown if they had remained there all the time or if they had dispersed and returned. Fledglings 31-40 days old averaged 50 m from the nest, those 51-60 days old averaged 700 m from the nest, and 71-80-day-olds averaged 500 m from the nest (Bailey and Sherwood 2017; Eaton in Austin 1968; Nolan et al. 2020b; Smith and Andersen 1982; Thatcher in Austin 1968; Wolf et al. 1988, 1991).

Thatcher (in Austin 1968) studied a pair that raised 3 broods. Shortly after leaving the nest, young of the first 2 broods moved out of the nesting territory. The third brood remained in the territory until they had almost completed their moult. The adults left the territory together before the fledglings did. Members of the third brood mixed with other broods once the adults left and left the territory together after autumn migration was well underway.

Late summer and early autumn is an important period for juveniles. At this time, they congregate in flocks that wander around on the breeding grounds, with much mixing of flocks. Later in the season, birds that remained near the natal site are joined by juveniles that were raised elsewhere. During this period, young begin familiarizing themselves with potential breeding sites and this makes them more successful in obtaining a territory the following breeding season. In Virginia, 76 of 122 juveniles (62.3%) that had been present in the previous summer or autumn were successful in obtaining a territory compared with 5 of 46 (10.9%) that were not present the previous year. Individuals' status within flocks is determined during the postfledging period. It is possible that this is an important determinant of winter survival (Hagar 1960; Leary et al. 1999; Nolan et al. 2020b).

The junco uses a wide variety of habitats during the postfledging period. In Pennsylvania, Stoleson (2013) captured adults and juveniles in clear-cuts and adjacent mature deciduous forests; both habitats had a dense shrub understorey. Major and Desrochers (2012) captured juncos in young clear-cuts in balsam fir–black spruce stands in Quebec. In Washington, fledglings that had been raised in a nest box on a house in a rural residential area remained around the property for 2 weeks after leaving the nest (Bailey and Sherwood 2017).

Both adults feed the fledglings, although females attempting second broods leave care of fledglings of the first brood to the male once they begin incubation. In Virginia, male care of fledglings was extremely important in raising juveniles to independence. The number of young reaching independence was 2.5 times greater in broods where both adults fed the fledglings than in broods fed only by the female (Wolf et al. 1985, 1991).

MIGRATION

All northern populations of the Dark-eyed Junco are migratory, and breeding and wintering birds do not overlap. In mountainous areas, it may undertake altitudinal migration, moving to lower elevations during the winter. Some western populations are resident. It commonly migrates at night. Kills at towers in December and January in Florida suggest that it makes facultative southward movements to avoid adverse weather conditions. Flocking at night is unlikely, but simultaneous departure of flock mates at dusk has been documented. Members of a diurnal group may gather independently at sites that provide food and shelter, or bottlenecks such as water crossings, then depart as an apparent flock. Family members do not travel together because of dispersal of young and differential timing and distance travelled by the sex and age classes. East of the Mississippi River, sex and age classes winter in different areas. In the northern states, the wintering population is comprised of 20% females; in Texas, 75% of birds are females. The percentage of females at differing wintering areas were 28.0% in Washington, 23.8% in Utah, 19.9% in Michigan, 34.6% in Ohio, 27.9% in Indiana, 53.1% in South Carolina, and 72.5% in Alabama. Females travel further south than males and young of both sexes tend to concentrate further north than adults. Young males are the most prevalent age class at latitude 40°N, adult males have a bimodal distribution, peaking at latitude 40°N and outnumbering juvenile males at latitude 35°N, young females peak and outnumber any other group at latitude 35°N, and adult females are most abundant at latitude 33°N. Temperature was consistently a better predictor of sex ratio than latitude or the amount of snowfall. Spring migration appears to be triggered by photoperiod. Spring migration is usually more rapid than autumn migration, with spring migrants making fewer stopovers and staying shorter periods during

stopovers. In Michigan, average stopover periods were 9.7 days in spring and 13.6 days in autumn. Recaptures of birds in Michigan in subsequent years revealed that certain individuals used the same migration route in spring and autumn (Ketterson 1979a; Ketterson and Nolan 1979, 1982; Nolan and Ketterson 1990; Nolan et al. 2020b; Sprunt in Austin 1968; Stack and Harned 1944). Of birds banded or encountered in winter in Ontario, almost two thirds wintered in the province. The remainder wintered across the Great Lakes states eastward to Pennsylvania and North Carolina. Recoveries indicated a wide range of direction of travel suggesting that Ontario migrants may breed both east and west of the province (Brewer et al. 2018).

Males migrate before females in spring and usually arrive on the breeding grounds 10-14 days earlier than females. At Rutherglen, a female arrived 11 days after her mate. Over a 63-year period in Manitoba, there was no significant change in its arrival date in relation to climate change (Chandler and Mulvihill 1990; Lawrence 1956; Murphy-Klassen et al. 2005; Nolan et al. 2020b). Because the junco is a winter resident in much of southern Ontario, it can be difficult to determine when spring migrants arrive; for some areas, only spring departure times are known. Most depart in late April and early May with some remaining until late May. There is a peak in numbers in April when migrants move through, with migrants arriving in mid-March in the south and late March or early April in the southern Shield (Curry 2006; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008). Manning (1952) observed 3 migrants at North Point north of Moosonee on 6 June. At Shagamu, Wilson and McRae (1993) observed migrants from 28 May to 9 June.

During autumn migration in Indiana, the age and sex classes tended to arrive together. When there were differences in timing, females predominated among early arrivals. In Pennsylvania, females moved south before males and adult females moved before juvenile females. In Indiana, birds that stayed to become winter residents did not arrive earlier than those that continued to migrate. Adults were caught earlier than juveniles. The median capture dates of the sex and age classes were arranged according to the north-south order of their winter destination. Those that had the furthest to travel passed through or settled in for winter the earliest (Ketterson 1979a; Nolan and Ketterson 1990; Nolan et al. 2020b).

Wilson and McRae (1993) observed autumn migrants at Shagamu 20-30 August. In the southern Shield, migration begins in earnest in mid-September and peaks in mid-October, with some birds remaining into early November. Most arrive in southern Ontario in mid-September, with some arriving in early September or as early as mid-August (Black and Roy 2010; Curry 2006; Easton in Austin 1968; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008).

During migration, the Dark-eyed Junco prefers tree or shrub habitat adjoining open areas. In Algonquin Park, it occurs in clearings, roadsides, campgrounds, and around feeders. It may use a variety of habitats during migration, including wetlands, backyards (especially if a feeder is present), alpine tundra, hedgerows, edges of woodlands, cemeteries, brush tangles and piles, riparian vegetation along streams and water bodies, orchards, weedy country roadsides, pastures, fallow fields, beach edges and spits, meadows, clear-cuts, open burns, utility rights-of-way, bogs, marshes, willow thickets, and harvested croplands. The earliest autumn migrants arrive in Kansas when the weather is warm. These birds tend to remain in deep shade in cool and sheltered areas and forage

mostly in open fields when the ground is snow-free (Campbell et al. 2001; Fitch 1958; Nolan et al. 2020b; Phelps in Austin 1968; Sinclair et al. 2003; Tozer 2012).

In Kansas, autumn migrants usually roosted at night in flocks in dense grass, often in smooth brome (Fitch 1958). In Illinois, autumn migrants commonly roost in tall or fallen grass (Gottfried and Franks 1975).

Flocks of migrants form in autumn. At a California site, 2 clear-cuts separated by a timbered ridge each supported a flock of 30-40 birds. Birds from each flock readily mixed with birds of the other flock. Some birds left the area entirely and 2 wandered at least as far as 3.2 and 4.8 km. Although wandering and mixing of flocks occurred freely during October and early November, flock sizes in each clear-cut did not change appreciably. Individuals did not become committed to a single flock or foraging area until December. Once this occurred, flocks remained constant through the winter except during periods of heavy snow (Hagar 1960).

There is evidence that at least some individuals exhibit fidelity to migratory stopover sites in subsequent years. In Michigan, 14 of 5,369 birds (0.3%) were recaptured in a subsequent year and 1 bird returned twice. Some birds were banded in autumn and recaptured the following spring and some banded in spring were recaptured in autumn of the same year. One bird was recaptured 3 years after it was banded (Stack and Harned 1944). Michael (1994) reported a bird at a Washington feeder 16-21 March in 1 year and on 19 March the following year.

In Ontario, the junco has been observed eating seeds of giant ragweed and black alder in autumn and winter (Dance 2008; Dance et al. 2012). In Idaho, Carlisle et al. (2012) compared the diet of autumn migrants with the availability of insects. Prey consumed by the junco more frequently than its abundance included, in decreasing order of preference, beetles, ants, hymenopterans, and leafhoppers. Prey consumed less than its availability, in order of decreasing avoidance, included jumping plant lice, true bugs, spiders, stilt bugs, hornets, wasps, flies, stink bugs, lepidopterans, and spittle bugs.

In the east, small numbers are killed during migration by nocturnal collisions with television towers and other tall structures. In 1 night in Kansas, 2,000 were killed at a tower in October, but the rate is typically low at less than 1-2 per year at different locations (Nolan et al. 2020b).

James (1991) considered the Dark-eyed Junco a common to locally abundant migrant. In the south, spring flocks often number 500-1,000 birds; flocks of 2,000 or more occur in autumn (Curry 2006; LaForest 1993; Weir 2008).

Hussell et al. (1992) reported that captures of the junco at the Long Point Bird Observatory decreased at a nonsignificant rate of 0.1% per year 1961-88. Trends by period were: 1961-70, –1.6%; 1970-79, –4.0%; and 1979-88, +4.5%.

WINTER

In the east, the Dark-eyed Junco avoids areas that have a minimum January temperature less than –18°C to –12°C. It is absent in winter from southern Texas, areas along the Gulf Coast, and from peninsular Florida. High concentrations occur throughout much of its winter distribution. The western extent of where it occurs appears to be determined by precipitation, with highest

concentrations occurring where the annual rainfall exceeds 61 cm. Areas of high concentrations extend southward only as far as where the minimum January temperature is less than 4°C. The highest numbers are largely in riparian habitats (Root 1988).

In southern Ontario, Smith (2003) summarized results of Winter Bird-Population Studies to determine the abundance of the junco in different habitats. Densities per km^2 were significantly different among habitats: 27.6 in urban natural areas smaller than 10 ha, 20.5 in larger urban natural areas, 8.7 in urban natural areas with water, 7.9 in forest, 0.6 in urban commercial and residential areas, and 0 in croplands, some of which had hedgerows. In suburbs of California, it occurred far from fields and close to trees and shrubs (Kalinowski and Johnson 2010). In forest fragments in Ohio, it was less likely to be present as woodlots became more isolated (Doherty and Grubb 2000).

Habitat used in winter is similar to that used during migration. The junco is most common in landscapes fragmented by agriculture and urbanization. Within these landscapes, it inhabits weedy fields, utility rights-of-way, roadsides, forest edges, hedgerows, shrubby areas, orchards, fallow fields, grasslands, agricultural fields with waste grain, urban residential areas, and feeding stations in all types of habitats. In Illinois, fallow fields, ungrazed grasslands, pastures, and cornfields were favoured habitats. In British Columbia, it concentrated in urban areas in winter (Black and Roy 2010; Campbell et al. 2001; Fitch 1958; Graber and Graber 1963; Nolan et al. 2020b). In Ontario, birds south of the Canadian Shield occupy a wide range of habitats. Those in the Shield are often restricted to areas with feeders. In Indiana, it was most abundant in savannahs, followed by prairie remnants disturbed by fire, anthropogenically disturbed areas, woodlands, scrub, and forest. Densities per km^2 ranged from 0 in forests to 119 in savannahs but differences were not significant (Grundel and Pavlovic 2007b).

In Colorado, housing density was the greatest factor in determining abundance of the junco. It increased significantly as the density of housing within 100 m increased. It probably benefitted from bird feeders and ornamental seed-bearing plants. Its abundance also increased as the average height of understorey vegetation increased (Miller et al. 2017).

In Maryland, Blank et al. (2011) studied the effects of mowing grassy buffers interspersed with wildflowers on numbers of wintering juncos. The buffers were between forested wetlands and row-crop fields and were mowed to heights of 10-15 cm in late summer or autumn. Mowing significantly reduced winter junco populations from 34 per km^2 in unmowed buffers to 7 in mowed buffers. In Arkansas, Kentucky, and Mississippi, it was more than 3 times abundant in fields with buffers than those without buffers. It was more abundant in buffers wider than 23 m than in narrower buffers, but not significantly (Evans et al. 2015).

Most juncos remain in fairly stable flocks over winter. In North Carolina, birds inhabiting open weedy fields remained in large stable flocks. Birds in mature woods occurred in small groups or individually (Fretwell 1969b). Flocks tend to maintain a stable home range but do not defend them from other flocks. Home ranges may shift in response to snow accumulations or other factors, and individuals may switch flocks (Nolan et al. 2020b). In Illinois, Gottfried and Franks (1975) observed 2 winter flocks. Flock 1 of 11 birds remained within an area of 27 ha. Flock 2 used 2 home ranges. The first was 33 ha that was used from flock formation in mid-December until 30 January when the flock broke up due to an accumulation of 10-15 cm of snow. The birds reunited a month later when the

snow melted. For the first week after the flock broke up, members stayed in 5 groups of 2-4 birds, with each group occupying a non-overlapping foraging area within the original home range. After the first week, 4 of the groups abandoned their foraging area and congregated with other sparrows at nearby cattle pens where food was available. The fifth group remained where a large tree prevented the accumulation of deep snow. All 3 winter ranges had specific areas used day after day for certain activities. Each contained an area where intensive feeding occurred in the morning and late afternoon and an area where most non-feeding activities occurred at midday. Scrub areas were used for intensive feeding by 1 flock; the other flock used short-grass pasture. Midday activities occurred in trees and shrubs adjacent to cultivated fields. Birds usually fed in areas with trees, shrubs, or tall forbs, including short-grass pastures and soybean fields bordered by shrubs. Birds flew to shrubs when disturbed and perched there between foraging bouts. The occurrence of such vegetation probably determined to some extent which feeding areas were used within the home range. Areas lacking taller vegetation, such as hayfields and centres of large cultivated fields, were rarely used and tallgrass pastures were never used. Flocks spent most of the day in scrub and short-grass pastures. Flock 1 spent about 82% of its time in scrub and 18% in cultivated fields. The second flock spent 58% of its time in scrub, 21% in short-grass pasture, 16% in cultivated fields, and 4% in woods while it was intact. After it broke up, it spent 35% of its time in scrub, 51% in short-grass pasture, 5% in woods, and 4% in hayfields. Daily movements in each home range followed a consistent pattern, especially on clear cold days. Flocks perched on trees adjacent to the roost shortly after sunrise. After leaving the roosting area, birds followed a feeding circuit that extended 0.5-1 km from the roost. The furthest locations from the roost were used from midmorning until late afternoon. Birds followed a similar route back to the roost. On days with snow accumulation, high winds, or low temperatures, movements from and to the roost were irregular because many birds left the flock for varying amounts of time. In flock 1 and the dispersed flock 2, birds gradually worked across a large field as they moved from the roost, although there were some reverse movements. In the intact flock 2, birds fed for about an hour in a short-grass pasture each morning after leaving the roost then flew 600 m to an area where they remained most of the day. There were 13 ha of this route that lacked tall vegetation and was never used for feeding. Birds changed where they fed in agricultural fields over the season. During autumn migration, large flocks were usually widely dispersed in a harvested soybean field, often flying directly into its centre. In midwinter, birds fed mostly near trees at the field's edge, gradually moving into the centre of the field, possibly due to depletion of food near the edges. In the largest home range of 33 ha, only the 2 ends were used and the remainder was simply flown over. The second flock used most of its 17-ha range. The area actually used by both flocks was similar indicating that the needs of a flock of 11-13 birds could be provided by about 16 ha.

In Kansas, 57 males had an average distance of within-winter movement of 184 m, a home range of about 10.5 ha. Females moved an average of 132 m, a home range of about 5.3 ha. These calculations applied only to areas used for foraging and did not include nocturnal roost sites (Fitch 1958).

The Dark-eyed Junco occupies the same roost all winter. Roosts are often outside the diurnal home range. The same roost continues to be used even if the home range shifts. Flock members often roost near each other but do not huddle together. When it roosts in trees, the portions of trees

that have the densest vegetation are selected for roosting. In Illinois, the temperature within roosts was only 1°C warmer than outside the tree but the wind velocity was substantially reduced from 29 km per hour in the open to 1 km per hour in the roost. Conifers are highly selected for roosting where they are present, but there must be enough present to support the entire flock. In Illinois where conifers were scattered or absent, juncos roosted in tall grass or brush piles. In grass, it roosts on or near the ground, presumably to obtain maximum protection from the wind. It has roosted in red cedars, 82-142 cm above ground in jack pine plantations, in Osage orange thickets, in yews, 0.9-2.4 m from the ground in dense Norway spruce, and 0.6 m up in a hemlock hedge. Where there is no suitable vegetation, it may roost in crevices in road cuts and in protected niches beneath overhanging banks along ditches and gullies. In New Jersey, it roosted in old Barn Swallow nests on and in barns (Allen 2025; Eaton in Austin 1968; Fitch 1958; Gottfried and Franks 1975; Nolan et al. 2020b; Phelps in Austin 1968).

The need for territorial defence is avoided by establishing a winter dominance hierarchy. Males are dominant to females and adults are dominant to juveniles. Dominance is established by timing of arrival on the wintering grounds, with earlier birds being dominant. The need for conflict over food resources is further lessened by the sex and age classes wintering at different latitudes. Individuals that move to a different flock lose their dominance class and become subordinate. If they return to their original flock, they resume their original status, but only after 1-2 days of aggression. When a dominant bird moves to another flock, other birds that move with it retain their status relative to it and may have a higher rank in the new flock than in the one they left. Dominance interactions are infrequent in small dispersed groups of birds that are in inferior habitat. These birds may have better access to food resources than lower ranked birds in large flocks. Aggressive encounters are still frequent despite the dominance hierarchies, but losers simply move aside and resume feeding so that little energy is expended during conflicts. At feeders, males control the central portion of the feeding area and females are confined to the periphery. Dominant birds accumulate more fat and are in better shape than subdominant birds. Dominant birds may have a better chance of survival and arrive on the breeding grounds in better condition. Extremely hungry birds that are normally subdominant may become dominant for about a day, helping to alleviate the effects of food deprivation (Balph 1979; Balph et al. 1979; Cristol 1992, 1995a, 1995b; Fretwell 1969b; Ketterson 1979a, 1979b; Nolan and Ketterson 1990; Nolan et al. 2020b).

Winter site fidelity in migratory eastern populations is variable and highest in more southerly locations. In Ontario, approximately 66% of birds were encountered at the same location in a subsequent year (Brewer et al. 2018). Return rates were 6.3% in Michigan, 5.3% in Indiana, 9.4% in North Carolina, and 17.6% in Alabama, and the difference between the north and south was significant. Adult males returned significantly more frequently (10.7%) than juvenile males (5.6%). The rate of return of northern males (11.4%) greatly exceeded the rate of return of southern males (3.5%). In Michigan, female return rates were 2.3% for adults and 3.1% for juveniles. In Indiana, 0% of adult and 2.5% of juvenile females returned. In the north, 11.4% of males and 1.7% of females returned. Young birds of both sexes returned more frequently to the south than the north: 3.5% of males in the north and 17.4% of males in the south; 3.0% of females in the north and 13.8% of females in the south. Return rates of adults were 11.4% for males in the north, 8.5% for males in the south, 1.7% of females in the north, and 8.0% of females in the south. In cases when a bird returned

to a different location in a subsequent winter, it usually spent its first winter in the north and shifted further south (Ketterson and Nolan 1982). Nolan et al. (2020b) reported that site fidelity in Indiana was complex with a return rate of 20% at best. Once birds exhibited site fidelity, 50% returned in the third year, 50% in the fourth year, etc. This suggests that all surviving birds returned. In Kansas, Fitch (1958) documented 1 bird returning in 4 consecutive winters, but each winter most birds captured had not been present in previous years. Movements of 5 birds recaptured after an intervening summer averaged 262 m.

In Illinois, the Dark-eyed Junco fed on seeds on the ground except during periods of high snow accumulation. Then it fed on seeds that were still on the plants, either by pulling the seed head to the ground or pecking on the plant (Gottfried and Franks 1975). In North Carolina, foraging habitat use by the junco was 0% in bare fields, 9% in crabgrass, 14% in horseweed, 21% in fennel, 43% in asters, 10% in tall mixed weeds, 0% in pure broomsedge, 3% in broomsedge with pines, 0% in pines, and 0% in deciduous trees. Its overlap in habitat utilization was 73% with the cardinal, 67% with the Field Sparrow, 75% with the Song Sparrow, and 93% with the White-throated Sparrow. Seed sizes selected by the junco were: 0.5 mm, 45%; 1.5 mm, 40%; 2.5 mm, 10%; and 3.5 mm, 1-2%; mean size of seeds eaten was 2.4 mm. The seed size selected by the junco was the same as for the Field Sparrow but smaller than for the cardinal and Song and White-throated sparrows. Only the junco fed to a large extent on the ground: 35% of feeding was on bare ground, 8% by standing on the ground and feeding from a standing plant, and 57% perched on a plant. In late January, it fed mostly on lawns (Pulliam and Enders 1971). In Pennsylvania, Nastase and Linville (1995) provided a feeding station with food at heights of 0, 2, 4, and 6 m. Junco feeding heights were 24.5% on the ground, 38.3% at 2 m, 23.8% at 4 m, and 13.4% at 6 m. Foods consumed included 9.3% niger seed, 34.4% canary seed, 42.1% millet, 13.4% corn, and 0.8% sunflowers. In addition to the vegetative items consumed in the breeding season, the junco eats hemlock and yellow birch seeds in winter (Root 1988).

The junco is a very common visitor to bird feeders. Dunn and Tessaglia-Hymes (1999) reported that it visited 80% of feeders across North America, more than any other species. Despite this, it probably prefers natural foods to those presented at feeders. It is nearly twice as abundant at rural than urban feeders. Favourite feeder foods include mixed seeds, millet, hulled sunflowers, and cracked corn. It infrequently eats canary seed, striped or black-oil sunflowers, safflower, whole corn, milo, wheat, niger seed, hulled peanuts or hearts, oats, canola, peanut butter mixes, bird puddings, baked goods, and water. Horn et al. (2014) analyzed 27,502 junco feeding bouts. It preferred white proso millet and platform feeders.

During severe winter weather, the Dark-eyed Junco may move to different habitats and may suffer mortality. After a severe storm in Illinois, populations declined by more than 80% in bottomland and upland forests and increased 8.1% in urban habitat. Although some birds moved to urban areas, the overall population declined and several dead juncos were found (Graber and Graber 1979). Abundance of breeding juncos in New Hampshire northern hardwoods declined in years following severe winters in the northeast and southeast states (Holmes and Robinson 1988; Holmes and Sherry 2001).

James (1991) considered the Dark-eyed Junco a common winter resident in the south that was occasional and rare north to Thunder Bay and Moosonee. McIlwraith (1894) stated that only a few remained over winter in the Hamilton area; more recently, Curry (2006) considered it a very common winter resident. In the Kingston area, only a few overwinter annually, mostly at feeders and around white cedar stands (Weir 2008). In Simcoe County, it is fairly common, although most birds move further south to winter (Devitt 1967). On Manitoulin Island, it is rare and irregular in winter (Nicholson 1981). It is rare in Parry Sound and Muskoka districts and appears to reach the northern extent of its winter distribution at Magnetewan, Parry Sound, Baysville, Huntsville, Bracebridge, and Bala (Mills 1981). In Algonquin Park, it is irregular in winter, varying from absent to very common (Tozer 2012).

Freedman and Riley (1980) analyzed southern Ontario Christmas Bird Counts (CBC) for 1929-77. They noted an upward trend, with numbers doubling during that period. Population peaks were of low magnitude and did not correspond with those of other seed-eating birds. CBC trends for Ontario were annual increases of 4.69% 1970-2021 and 5.36% 2009-21 (National Audubon Society 2022).

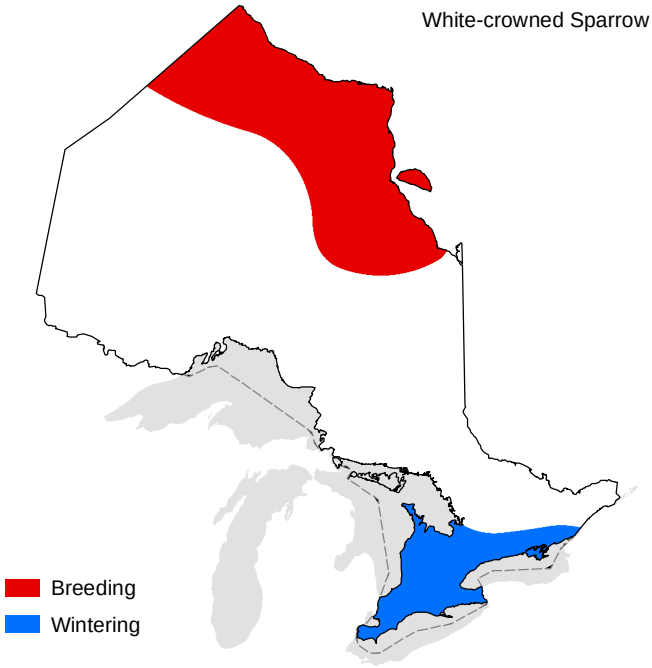
White-crowned Sparrow

Zonotrichia leucophrys

BREEDING SEASON

Habitat Requirements

In Ontario, the White-crowned Sparrow breeds in the Tundra Region and the Hudson Bay Lowland, with a few scattered records in the extreme northwestern portion of the Boreal Forest Region. It is characteristic of tundra and taiga habitats. Nests were in open stands of black spruce and tamarack in burns, bogs, and fens, often with associated stands of willow, poplar, and alder. In heath-lichen tundra, it nests both in the open and near growths of dwarf birch and willow (Peck and James 1987). At Moosonee, all occupied territories were in yards within the town (Wilson and McRae 1993). Three nests near the Hudson Bay coast were on raised tundra ridges covered with lichens, herbaceous plants, scattered shrubs, and small spruce. A nest on Akimiski Island was on a vegetated coastal ridge (Peck and James 1998b). On the Twin Islands in James Bay, it appeared to nest in willow thickets (Manning 1981). Along the Ontario Hudson and James bay coasts, Manning (1952) usually saw it among spruce trees.



In Quebec, the White-crowned Sparrow nests in taiga and tundra habitats, including in open lichen woodlands, lichen tundra, forest tundra, arctic tundra above the treeline, open spruce forests, and regenerating burns. In taiga, it occurs in thickets and scrub in open areas such as burns, open spruce woodlands, and clearings. Further north in the forest tundra, it inhabits alder, dwarf willow, and scrub birch along margins of rivers and streams, and peatlands. It also occurs in clumps of prostrate or stunted spruce on windswept coasts and in mountain-side shrubbery. In the Great Whale River region, it nests in a variety of habitats but is most abundant in recent burns and lichen heath. On the North Shore of the St. Lawrence River, stunted conifers are a typical habitat component (Breton in Gauthier and Aubry 1996). On the east coast of James Bay, it inhabited isolated scrubby spruce but was more common on barren peninsulas and islands where it frequented alder and scattered spruce (Manning and MacPherson 1952). At La Grande Reservoir, it was typical of shrub stands. It appeared in burns after the falling of dead trees about 15 years after fire and disappeared progressively as forests matured (Crête et al. 1995). In the western Ungava Peninsula, highest counts occurred in burned areas. It appears to do best where disturbance of the surface by fire or mechanical means has increased diversity and the shrub growth is still young. It is attracted by stunted tree growth and shrubs and is found in more southern areas only where summer conditions approximate those found in subarctic regions. In central Labrador, it breeds mostly in open lichen woodlands, the most extensive vegetation community. At Goose Bay, it nested only in the often-burned black spruce and dwarf birch on the high sandy delta of the airport. In more productive sites, it was replaced by the White-throated Sparrow (Clement in Austin 1968).

Erskine (1977) considered the White-crowned Sparrow characteristic of boreal forest ecotones with tundra and alpine habitats. In the interior of British Columbia, it occurs at lower densities in open woodlands and forest edges. Near Churchill, it was abundant along the treeline but also nested in small forest clearings; it is typically associated with small spruce in these habitats. It also nests in shrubby areas along roadsides and well above the treeline in isolated clumps of shrubs on the Hudson Bay shore (Jehl 2004; Jehl and Smith 1970). In northeastern Manitoba from the Hudson Bay Lowland north to the forest-tundra transition, it was most abundant in deciduous scrub followed by coniferous scrub, mixed scrub, coniferous forest with a shrub understorey, and heath. It was present in very low densities in coniferous forest without an understorey and tundra and absent in deciduous and mixed forests (McLaren and McLaren 1981). In the Churchill area, it was in the willow-nesting passerine guild (Sammler et al. 2008). In northern Manitoba, it nested in forests with

a mix of white spruce, black spruce, and tamarack as well as jack pine at 1 site. These were usually open stands with an understorey of dwarf birch and willow. Edges of these forests bordered tundra or rocky ridges. It also nested in riparian strips with very dense coverage by 2.3-m tall alder, birch, and willow (Gillespie and Kendeigh 1982). In the Northwest Territory, it nested in isolated spruce stands smaller than 0.01 ha to 12.3 ha with an understorey of mosses, dwarf birch, Labrador tea, willow, green alder, and bilberry. These stands were surrounded by shrub communities 0.3-1.5 m tall dominated by dwarf birch, willow, Labrador tea, bilberry, and green alder. The dwarf birch community was the principal nesting habitat, but it only nested near margins of isolated spruce stands (Norment 1992, 1995a). In the Yukon, it nests in a variety of habitats that usually have patches of shrubs, open grassy or tundra areas, river or lake shores, and occasionally scattered trees, open forest, or forest edge. It inhabits shrubby habitats from lowlands to subalpine areas and may be associated with tall shrubs (Sinclair et al. 2003). In Alaska, it was most abundant in subalpine habitats, followed by alpine habitats, hills or bluffs, floodplains and terraces, and lowlands. Subalpine habitat consisted of wet sedge meadows, low shrub thickets of willow and dwarf birch, spruce forests, and alder thickets. Alpine sites were covered with low or dwarf shrubs and contained some wet graminoid meadows. Hills and bluffs had gentle to moderately steep slopes with dry rocky soils covered with deciduous woods (Handel et al. 2009). In another Alaska study, it nested in a narrow strip along the Yukon River. Essential habitat components included bare ground, grass or grass mixed with short herbaceous plants, and extensive clumps of dense shrubbery. The bare ground was used for foraging and was not always incorporated into the territory. For some pairs, the nearest open ground was 1.6 km distant. These birds regularly flew unchallenged through other territories between the foraging and nesting areas (Oakeson 1954). DeWolfe (in Austin 1968) concluded that these 3 habitat features were characteristic of all western populations, and Chilton et al. (2020) concluded that they were essential range-wide for the White-crowned Sparrow. In at least the west, many territories have standing or running water in or near them with tall coniferous trees on their margins. Sites appear to be more favourable if bare ground, grass, and shrubs are patchily distributed. In central British Columbia, it nests along edges of deciduous woodlands in dense vegetation of young trembling aspen, willow, prickly rose, and fireweed. It also nests in sapling-stage trembling aspen clear-cuts, edges of coniferous woods, balsam poplar woods, riparian habitats, and pockets of dense shrubs in subalpine areas (Campbell et al. 2001).

In the Northwest Territories, Norment (1993) compared nest sites of White-crowned and Harris's sparrows. Within 1 m of the nest, nests of the 2 species differed significantly for 3 variables: shrub height was 62.1 cm at White-crowned Sparrow nests compared with 47.6 cm at Harris's Sparrow nests; the distance to the edge of the nearest stand of trees was 7.2 m for the White-crowned Sparrow compared with 27.9 m for the Harris's Sparrow; and vegetation density was almost 2 times greater at White-crowned Sparrow nests. At 1-10 m from the nest, significantly different parameters for the White-crowned and Harris's sparrows respectively were: shrub cover, 27.5% and 16.1%; average shrub height, 69.2 cm and 50.1 cm; ground cover, 98.7 and 88.6%; number of tree stems larger than 3 cm diameter at breast height, 12.7 and 5.7; foliage density within 5 m of the nest, 108.7 and 58.9 hits; foliage density within 10 m, 210.2 and 112.9 hits; and vertical vegetation density within 10 m, 0.64 and 0.31. Nonsignificant habitat variables for the White-crowned Sparrow that did not differ from those of the Harris's Sparrow included: within 1 m of the nest, 38.6 cm to the nearest

shrub, and orientation 106.5°; at 1-10 m from the nest, 21.8 hits for horizontal foliage diversity. A model that included percent shrub cover, foliage density within 10 m, horizontal foliage density, and percent ground cover significantly discriminated between nests of the 2 species. White-crowned Sparrow nests were closer to the edge of spruce stands in taller denser vegetation, with greater shrub and ground cover, and greater horizontal heterogeneity of cover than Harris's Sparrow nests.

Considerable information is available on the population of the White-crowned Sparrow that nests in alpine and subalpine areas in the Rocky Mountains in the western United States. In Oregon, it nested in alpine meadows in or near riparian vegetation at elevations as low as 800-1,500 m. It strongly preferred to nest near watercourses; 46 of 77 nests (59.7%) were 10 m or less from running water and 59 (76.6%) were within 30 m. The furthest a nest was from water was 175 m. When the population declined, all 12 nests were within 20 m of the creek and 10 were within 10 m. With a further population decline, all males occurred along creeks at elevations above 1,860 m (King and Mewaldt 1987). In Colorado, Glass and Floyd (2015) considered it a riparian species. It nested in aspen groves and meadows on slopes above and alongside streams. The stream banks were dominated by shrubby vegetation, especially willows growing in clumps ranging in size from 10 m^2 to more than 1 ha. Most willow clumps were surrounded by meadows bordered by aspen stands 5-600 m from the willow patches. In Arizona, it nested in alpine meadows with scattered clumps of currants and willows that gradually graded into meadows with low stunted trees near the timberline. The meadows were interspersed among coniferous forests and aspen groves. The nearest populations were 328 km distant, separated by unsuitable habitat (Balda et al. 1970). Another Oregon population nested in riparian strips dominated by trembling aspen or willows; 30 nests were in aspen habitat and 4 were in willow habitat (Heltzel and Earnst 2006). Populations in western and central United States reached their greatest abundance in montane sites. It occurred in alpine meadows and was positively correlated with the percent coverage by forbs. These meadows are often thickly carpeted with wildflowers in the spring. Birds may be responding to other features in the environment, but their association with the forbs was significant (Rotenberry and Wiens 1980). In western aspen forests, it occurred only in montane meadows and the foothills, with many pairs well within forests of large mature well-spaced trees (Flack 1976). At a Wyoming mountain, the White-crowned Sparrow was confined to subalpine habitats with dwarf shrub willow and boggy meadows. The habitat it selected differed significantly from random. It was positively correlated with shrub density and foliage density of the low understorey and was negatively correlated with high foliage at midcanopy or shrub-height. It used areas with fewer than 10 trees per 100 m^2, dense shrub cover less than 2.0 m tall, more than 70% coverage by willow, and high shrub foliage density (Finch 1989b, 1991a). Morton et al. (1972) reported that the meadows it used were typically wet with standing or running water. Habitats it used included grasses, bare ground, dense shrubs or scrub conifers, water, and tall conifers on the periphery. Suitable sites were often very small and widely separated; their suitability may change year to year.

In British Columbia, White-crowned Sparrows nested on Vancouver Island in all forest age classes except for old growth, but were consistently present only in stands that were 15-20 and 30-35 years old. Forty-one percent of nests were associated with human-altered habitats. Habitats associated with humans included rangeland, industrial sites, hydro transmission line corridors,

recreational areas, cultivated agricultural lands and pastures, and suburban, rural, and urban residential habitats. Twenty-seven percent of nests were in residential backyards and gardens, 24% in second-growth forest, 23% in forest edges, 11% in burns, and in open fields, roadsides, clear-cuts and early regenerating forests, riparian habitats, subalpine meadows, beach spits and jetties, orchards, and airports (Campbell et al. 2001). It has nested in margins of shopping centre parking lots, at ferry terminals, on university campuses, in villages, and in open grasslands with sparse shrub coverage. Nests may be placed in ornamental shrubs and vines along walls, fences, or buildings (Banks 1959; Blanchard 1936; Chilton et al. 2020; Ralph and Pearson 1971; Patterson and Petrinovich 1978; Pitelka 1942).

At night, males roost in dense vegetation (King 1986).

All Ontario nests were on the ground and most were at bases of small willows, black spruce, tamarack, and Labrador tea. Some were in dense grass or lichen in the open. They were in well-concealed and often deep depressions in mossy hummocks and in grass and lichen clumps. One nest was under a willow root and 1 nest depression was 15 cm deep in reindeer lichen (Peck and James 1987).

In Quebec and Labrador, most nests are on the ground, typically sunk into a moss-lichen or moss-crowberry mat and partly concealed by overhanging branches of dwarf birch or Labrador tea. Nests are commonly tucked into the lower side of a moss or crowberry mound. Much less frequently, they are built into moss hummocks on a string of heath shrubbery extending out into a sphagnum bog. A few nests are in small balsam firs and one was 0.9 m from the ground in brush thrown over a boat (Clement in Austin 1968). Most nests in the north and alpine areas are on the ground, but they may be elevated in shrubs and trees if snow cover and melting make suitable nesting sites scarce. At Churchill, nests were on the ground, always at the base of a small shrub or tree that offered protection. In the Northwest Territories, all nests were on the ground: 85.7% in dwarf birch habitat and 14.3% in open spruce forest. Of 14 nests, 64.3% were concealed by dwarf birch, 7.1% by spruce, and 21.4% by bog bilberry. In the Yukon, all 22 nests were on the ground. Fourteen were at the base of a shrub (mostly willow), with 1 nest each under alder, birch, and rose; 2 were in a tuft of grasses or sedges (Jehl and Hussell 1966a; Norment 1992; Sinclair et al. 2003). There is a greater tendency for nests to be elevated in alpine areas. In 2 years on a California mountain, more than 60% of nests were on the ground in 1 year but only 22% were on the ground in another year. This occurred because much of the ground was snow covered when nesting was initiated and grass was still not tall enough to conceal nests in thawed areas. Many birds placed their nests on the lowest suitable limbs in willow and scrub pine 21-40 cm above ground; there were few suitable nest sites below 20 cm. In 2 late springs, there was a greater tendency to build nests at heights above 60 cm, usually in pines at the periphery of meadows. The White-crowned Sparrow preferred to nest on the ground in thick grass clumps at the base of shrubs and in crowns of willows 41-60 cm from the ground, especially if they had leafed out. If insufficient sites are available, it will nest on fairly wet open ground in willow that is not leafed out and at the edge of preferred habitat in pines. In a dry year, 11% of nests were elevated compared with 72% in a year with deep snow pack. This adaptability allowed it to reduce delays in nesting due to heavy snow cover or inclement weather. Nests occurred at heights of 0-1.2 m with means over 3 years of 15.5, 38.4, and 18.2 cm. In alpine meadows in Oregon,

65 of 77 nests (84.4%) were on the ground in low grasses or beneath sagebrush and 12 (15.6%) were elevated in sagebrush or grass tufts. In other Oregon areas where the ground was too wet for nesting, nests were elevated 8-200 cm from the ground, with an average of 127 cm (King and Mewaldt 1987; Morton 1994; Morton et al. 1972). Sixty-six percent of British Columbia nests were on the ground; 20% were in shrubs such as rose, steeplebush, willows, and vines; and 14% were in living trees. One nest was in a garage. Seventy-two percent of ground nests were beneath a clump of vegetation or among ground cover, 27% were at the base of trees or among tree roots, and 1% were beside a log or rock (Campbell et al. 2001). Nests have been reported in a fencerow at a height of 1.27 m, in young pines and spruce, scrub oak, willow, alder, dwarf birch, rose, lupine, sagebrush, raspberries, ornamental exotic shrubs, bracken fern, and rarely in annual plants. Nests have been documented as high up as 10.7 m in a tree, in ivy growing on the side of a building, and in shrubs planted along walls, fences, and buildings (Banks 1959; DeWolfe in Austin 1968; Lewis 1973). Nests in subarctic and alpine areas are nonrandomly oriented so they face away from the prevailing wind. In the Northwest Territories, nest entrances were oriented at an average of 106.5° (south to southeast) and the mean wind vector was 329° (north to northeast). In California, northeastern sides of shrubs were selected and southwest orientations were avoided. Cold winds in early mornings and storms came from the south during the nesting season. Nest placement on the northeast side may provide shading and ameliorate heat stress during midday. Exposure of the nest interior to direct sun averaged only 58% at midday (Norment 1993; Zerba and Morton 1983). Females in colder areas locate nests such that solar heating is increased, but all nests are shaded more at noon than at any other time of the day. Nests are situated within natural windbreaks that significantly reduce wind velocity at the nest. In the warmest areas where it nests, some nests are depressed into cool, marshy ground (Clement in Austin 1968; Kern 1984; Morton et al. 1972; Webb and King 1984).

In California alpine meadows, females occasionally arrive before their mates. In these cases, the female takes up territorial residence and sings from elevated perches and flies at intruders to displace them. Upon spring arrival when much of the habitat may still be covered in snow, territorial defence may be weak. In Alaska, males often left their territories for hours, flying as far as 1.6 km. More traditional territorial defence occurred later when incubation began. In montane areas of California, males maintained singing perches in tall conifers bordering the meadows used for breeding until snow-free patches appeared. As soon as a patch of snow-free habitat appeared, a lone male or pair moved into it and defended it. The defended area tended to conform to the thawed area despite its fluctuating size and shape. At this time, adjacent pairs foraged for insects on snow patches between territories. Once the snow disappeared, an overlap in feeding areas continued with their extent depending upon the vegetation. In the Northwest Territories, territorial chases were infrequent and peaked during territory establishment and nest construction. Chases and singing decreased in late June when most pairs were feeding nestlings. Few chases or complete songs occurred after 7 July. In areas disturbed by fire or mechanical intrusions in Quebec and Labrador, territories were 0.36-0.75 ha. In large alpine meadows in California that had 70-80% open ground, there was little or no overlap in feeding areas. Pairs occupied 1.5-2.0 ha but actively defended only a radius of about 50 m (0.79 ha). Where only 20-30% of the meadow was open, territories were as small as 0.15 ha. In these cases, adjacent pairs commonly foraged in the same small grassy areas, with as many as 4 birds using the same 450 m^2 simultaneously. Nests were seldom

at the centre of territories; nests of adjacent pairs were as close as 13 m to each other (Chilton et al. 2020; Clement in Austin 1968; Morton 1992; Morton et al. 1972; Norment 1992; Oakeson 1954). Territories remain fairly constant throughout the breeding season and averaged 1,127 m^2 at 1 site. Another study determined that mean territory sizes were 3,460 m^2 for older males, 1,640 m^2 for yearling males, 2,520 m^2 for older females, and 2,220 m^2 for yearling females. Territory sizes of older males were significantly larger than those of yearling males but there were no differences in territory sizes of the female age classes. There was no difference in the territory sizes of successful (2,760 m^2) and unsuccessful pairs (1,770 m^2). Some aberrant territorial behaviour was observed in this population. Birds of 2 pairs frequently foraged together with no particular arrangement of individuals, and there was mutual use of approximately 80% of territories (Patterson and Petrinovich 1978; Petrinovich and Patterson 1982; Ralph and Pearson 1971).

Natal philopatry rates vary considerably across the White-crowned Sparrow's range. They appear to be very low in subarctic populations but high in western alpine habitats and along the Pacific coast. In the Northwest Territories, Norment (1992) reported that no fledglings returned. The most definitive studies on natal philopatry were conducted in alpine meadows in California. Because these habitats are isolated and separated by several kilometres of unsuitable habitat, they may function similar to islands which tend to have higher than average natal philopatry rates. During the postfledging period, there was an influx of juveniles later in the season from other locations. If males remained longer than 28 days, their return rates increased significantly from 11.1% to 28.5%. After more than 20 days, males became imprinted to the site but there was no difference in return rates of females that remained in the area for long or short periods. Local males returned at a significantly higher rate (18.3%) than females (11.4%) that were hatched on site. For nonlocal juveniles that entered the study area later, a significantly higher proportion of males (11.7%) than females (9.5%) returned to breed. Overall, 15.1% of local birds returned, significantly more than nonlocal birds (10.7%). Significantly more males (13.7%) than females (10.1%) returned. With the sexes combined, 188 of 1,555 birds (12.1%) returned including nonlocal birds. Seventy-three of 482 birds (15.1%) that hatched within the study area returned to breed. Local males that returned spent significantly more time on site as a fledgling (30.7 days) than males that did not return (22.3 days). The same was true for nonlocal males: 12.4 days for returning birds and 8.6 days for non-returning birds. There was no difference in duration of stay for returning and non-returning females: 23.2 days for returning local females, 23.7 days for non-returning local females, 9.6 days for returning nonlocal females, and 8.4 days for non-returning nonlocal females. There appeared to be 2 periods when final selection of breeding sites occurred: the postfledging period and the prebreeding season. The postfledging period was most important to males. It is possible that all surviving males that remained for more than 20 days returned. The prebreeding season could last a month depending upon the snowpack. This period was most important for yearling females in selecting a breeding site, and they moved greater distances than males. Some males dispersed during this period and selected their first breeding site. No individual bird bred in its natal territory. The mean distance of yearlings' first nest from their natal nest was 1,172 m for males (range 150-3,430 m) and 1,134 m for females (range 189-4,340 m). Young of both sexes that hatched in mid-July were more likely to return as yearlings than those hatched earlier or later. The later that young hatched after this, the less likely they were to return. Prior to mid-July, females were significantly less likely to return than males (Morton 1992,

1997; Morton et al. 1991). In the resident population in California, 55 of 706 nestlings (7.8%) returned to breed. There was no difference in return rates of the sexes. Of these, 73.7% entered the local breeding population as yearlings, 14.0% in their second year, 8.8% in their third year, 1.8% in their fourth year, and 1.8% in their fifth year. The median distance of their breeding territory from the natal territory was 110 m (range 0-586 m; Petrinovich 1988). In this population, some yearlings bred on their natal territory (Petrinovich and Patterson 1982).

Adult site fidelity rates are fairly consistent throughout the White-crowned Sparrow's range. In the Northwest Territories, 33% of adults returned (Norment 1992). In California alpine meadows, 22 of 43 males (51.2%) and 21 of 27 females (56.8%) returned to breed, with an overall return rate of 53.8%. Most birds moved a maximum of 2 or 3 territories between seasons. Females dispersed significantly greater distances (119.5 m) between seasons than males (72.5 m). Some riparian territories were long and narrow, so nests in the same or adjacent territory could be several hundred metres apart. The maximum distance between the first nests of subsequent years was 500 m. Breeding dispersal distances in both sexes was greatest between the first and second years, then decreased and remained stable thereafter. Almost all age-related movements occurred between the first and second breeding season, probably because yearlings may be forced to occupy territories of poorer quality. In their second year, they move in an attempt to occupy better habitat. Age effect was significant for females but not for males. Between their first and second years, some females made unusually long movements of 2.7-2.8 km to completely different meadows, something that males did not do. If a female switched mates between seasons, the median dispersal distance between nests in successive years increased significantly from 60.5 m to 119.5 m. Male dispersal distances increased nonsignificantly with a mate change from 60.0 m to 72.5 m. Nesting within 50 m of the previous year's nest was about 2 times more likely for males than females (Morton 1997; Morton et al. 1972). In a sedentary population in California, 105 of 211 males (49.8%) and 67 of 191 females (35.1%) returned; the difference between the sexes was significant. The overall return rate was 42.8%. Of returning birds, 84 of 105 males (80.0%) and 41 of 67 females (61.2%) remained on the same territory; the difference was significant. Overall, 72.7% of adults returned to the same breeding territory. Males remained on territory a mean of 1.7 years compared with 1.4 years for females (Petrinovich 1988; Petrinovich and Patterson 1982). In Oregon, 37% of adult males and 31% of females returned. Those that returned usually settled in their previous territory or nearby. Subsequent territories used by 71 males averaged 113 m apart compared with 160 m for 16 females. Both sexes strongly tended to nest in the same tenth of the creek's riparian strip that they had occupied the previous year (King and Mewaldt 1987).

Limiting Factors

Eggs have been found in Ontario nests from the second week of June until the third week of July, with most present in late June (Peck and James 1998b). In subarctic and alpine populations, the nesting period is compressed and nesting is highly synchronized. In Pacific Coast populations, the nesting period is extended and nesting is less synchronized. At 2 sites in California at approximately the same latitude, 43.4% of females were fertile at the same time at a high-elevation site compared with 17.1% of females at a coastal site. The nesting cycle took 38 days in Alaska, 90 days in Washington, and 116 days in California. In subarctic populations, time is saved by raising only a single brood and by the fact that both sexes are ready to mate as soon as they arrive. Judging by egg dates,

Ontario populations have a compressed nesting period and nesting is probably synchronous (Class et al. 2011; Oakeson 1954; Peck and James 1998b). In subarctic and alpine habitats, the onset of nesting may be delayed. In Oregon, where the snow melted in late April or early May, completion of initial clutches did not vary annually with only a 5-day difference over the years. In California alpine meadows, the chronology of egg laying differed every year due to the snow pack. Pairs occupied the territory for as long as 1 month before nest building when environmental conditions were unsuitable. Nest initiation dates varied by as much as 33 days in different years (King and Mewaldt 1987; Morton 1992, 1994; Morton et al. 1972). In the Northwest Territories, males began singing within 2 days of arrival, but in 1 year, a storm disrupted pair formation for 4 days, with all birds disappearing during this period. The average length of time between pair formation and nesting was 14 days. The nest is usually constructed in 2-4 days (average 2.7 days) in Alaska. Nest building took 7-8 days in Washington and 7-9 days in coastal California. The interval between nest completion and laying of the first egg was 0-3 days (average 1.2 days) in Alaska and 1-12 days (average 2.5 days) in California alpine areas. The 12-day interval was due to a snowstorm just after the nest was completed; the next longest interval was 5 days. Eggs are normally laid at the rate of 1 per day but occasionally a day is skipped. Incubation usually begins with the laying of the penultimate or last egg, but occasionally the day after the last egg is laid. The incubation period of 1 Ontario clutch was at least 10 days. In areas where snow cover and storms are a factor, the incubation period may vary considerably among individuals and year to year. The incubation period in the Northwest Territories was 12 days. In California alpine meadows, mean annual incubation periods were 10.9-13.4 days (range 9-15 days). Incubation periods from other areas include 13 days in coastal California, 11-13 days at Churchill, 11-12 days in British Columbia and Alaska, and 11-14 days in coastal California with most eggs hatching in 12-12.5 days. Hatching of eggs may be either synchronous or asynchronous. In the Northwest Territories, 80% of eggs hatched on the same day and the remainder hatched the following day. Hatching asynchrony in California increased as the season progressed, accounting for 24% of the variation in the time between hatching of the third and fourth eggs. The last chicks were smaller and died or disappeared with greater frequency when the food supply was artificially decreased. Selective starvation or brood reduction may occur in as many as 14% of successful nests. In the Northwest Territories, the nestling period averaged 9.08 days (range 8-10 days). The nestling period appears to decrease with increasing latitude and altitude. The nestling period was 8-11 days in Alaska with averages of 9.6 and 8.4 days at 2 different sites, 8.7 days at Churchill, 9-10 days in alpine areas of California, 9-12 days in coastal California, 9-11 days in British Columbia, and 7-9 days in the Yukon. Nestlings are capable of leaving the nest 1-2 days earlier than normal if they are disturbed (Campbell et al. 2001; Chilton et al. 2020; Clement in Austin 1968; DeWolfe in Austin 1968; Jehl 2004; King 1986; Mead and Morton 1985; Morton 1994; Morton et al. 1972, 1991; Norment 1992, 1995a, 2003; Oakeson 1954; Peck and James 1987; Petrinovich and Patterson 1982, 1983; Sinclair et al. 2003).

Egg dates indicate that only a single brood is raised in Ontario; single broods are also raised in the Northwest Territories and Alaska. A second brood was suspected at 1 nest in Quebec, but the evidence for this was not conclusive. In alpine areas of California, most birds raise a single brood but some raise 2 broods. Along the west coast, there is no evidence of double broods north of latitude 56°N. In coastal California, most birds attempt to raise 2 broods and a few successfully rear a third

brood. The female begins building a new nest a few days after the young of the previous brood fledge. Nearly all birds renest if the first nest is lost, but at northern latitudes renesting occurs only if the loss occurs early in the season. Nests of multiple broods and replacement nests are all in the original territory. Renesting occurs 4-7 days after the loss. In alpine areas of California, the median distance between subsequent nests of the same pair in the same year was 39.7 m (range 5-150 m). The mean interval between nest loss and the laying of the first egg in the next nest was 6.8 days with a range of 2-16 days (Campbell et al. 2001; Clement in Austin 1968; DeWolfe in Austin 1968; Jehl and Hussell 1966a; Mewaldt and King 1977; Morton 1994, 1997; Morton et al. 1972; Oakeson 1954; Peck and James 1998b; Pérez et al. 2016; Petrinovich and Patterson 1982, 1983). Ontario clutches contained 3-5 eggs, with 55% having 5 eggs (mean 4.50 eggs). The clutch size of the White-crowned Sparrow varies throughout its range depending upon latitude, altitude, time of season, and age of the female. Clutches tend to be largest at higher latitudes and altitudes, and with older females. Clutches of 3-6 eggs (mean 4.24 eggs) have been reported for the eastern subspecies, with 6 eggs rare. In the Northwest Territories, the mean clutch size was 4.50 eggs, with most clutches containing 5 eggs. In Alaska, clutch size was 3-6 eggs (mean 4.58 eggs); 3-6 eggs have been reported in the Yukon. In alpine areas of California, clutch size was 3-5 eggs with 80.4% of clutches containing 4 eggs (mean 3.93 eggs). There were no seasonal differences in clutch size. In British Columbia, most nests in the south have 4 eggs and most northern nests have 5 eggs. Overall, clutches of 3-7 eggs have been reported; 7-egg clutches are very rare and it has not been documented whether all eggs were laid by a single female (Baker et al. 1981; Campbell et al. 2001; Chilton et al. 2020; Clement in Austin 1968; DeWolfe in Austin 1968; Morton et al. 1972; Oakeson 1954; Peck and James 1998b; Petrinovich and Patterson 1983; Sinclair et al. 2003).

Both sexes are capable of breeding when they are 1 year old. In the western United States, some birds, including adults, do not breed. It is unknown if this is the case in northern populations. In alpine areas of California, 43.6% of yearling males and 62.1% of yearling females bred; the difference was significant. A significantly higher proportion of older birds nested: 59.8% of males and 75.3% of females. In an Oregon population, 36% of territorial males were unmated. In the resident California subspecies, 5-10% of males may not breed, including both yearlings and older birds. At another site, there was no difference in the proportion of the sexes that bred; 39.2% of birds entered the breeding population in the year they were banded, 37.4% entered the next year, and 22.0% did not become territory holders until 2-5 years after banding. Territory holders that disappeared were immediately replaced by floaters. Pairs containing a yearling male were significantly less successful in fledging young than pairs with older males. Pairs with yearling females tended to be slightly more successful than those with older females. There was a significant difference in the combined ages of the pairs, with successful pairs having a combined mean age of 3.0 years compared with 2.3 years for unsuccessful pairs (Chilton et al. 2020; Mewaldt and King 1977; Morton 1992; Petrinovich and Patterson 1982; Poesel et al. 2011; Ralph and Pearson 1971).

Most birds mate monogamously, but there are a few records of polygyny. One northern Quebec nest contained 8 eggs and was attended by 2 females and 1 male. In California, females that were mated polygynously subdivided the male's territory and defended their part against the other female by loud singing and fighting (Blanchard 1936; Clement in Austin 1968; DeWolfe in Austin 1968). Pairs remain mated throughout the breeding season, even after a nesting failure, but

individuals remate if their first mate dies. In California migratory populations, a mate change occurred in about two thirds of cases each year due to mortality or mate switching. In California resident populations, 27.4% of males and 53.7% of females that returned the following year to the same territory retained their previous mate. If there was a shift to a new territory, both sexes usually had new mates; only 2.9% of males and 3.4% of females that shifted territories had the same mate as previously. Of 36 possible cases of remating, 69.4% of pairs reunited and 30.6% divorced. Most divorced birds moved to an adjacent territory but 3 moved further. One mated pair moved together to a new territory 1.35 km from the original territory (Morton 1997; Morton et al. 1972; Petrinovich and Patterson 1982). Incestuous matings are rare. In a migratory California population over 13 years and in 473 pairs, there were no cases of parent-offspring mating and 1 case of siblings being mated. In a resident California population, there was 1 case of a father-daughter mating out of a possible 10 and no cases of siblings mating (Morton 1972; Petrinovich and Patterson 1982). Extra-pair fertilizations are common in 2 subspecies. In California, 34-38% of nestlings resulted from extra-pair copulations. Males whose nests contained at least 1 chick unrelated to them were significantly older than males with full paternity (Chilton et al. 2020). In an Oregon population, 38.5% of broods contained extra-pair young and 35.4% of young were extra-pair. Fifty percent of males that lost paternity did not father any young in their brood; the remaining males lost paternity of 25-75% of their offspring to extra-pair sires. Thirteen males that sired young with an extra-pair mate increased their reproductive success by an average of 2.5 offspring (range 1-5). For 8 unmated males and some males who lost their mates, this was the only reproductive success that they had. The sex ratio in this population was strongly male biased, which may have favoured extra-pair copulations (Poesel et al. 2011). Extra-pair copulations are unlikely to be common in northern and high-altitude populations where nesting is highly synchronized.

The White-crowned Sparrow forages predominantly on the ground where it scratches with both feet simultaneously to uncover food items. It often forages in bare or grassy ground, but may forage in spruce, tamarack, bog meadows, and tundra. It most often hops or runs along the ground, pecking or scratching at each stop. It often moves slowly over tops of boulders, gleaning from the surface, and moves through tops of shrubs and short trees when consuming buds. It may catch flying insects by leaping short distances into the air, but this is an incidental method of foraging typically conducted on warm sunny afternoons. It may capture insects from a perch similar to flycatchers. It may run through water up to its knees, raising its tail and flashing its wings to flush insects from moss in a bog (Chilton et al. 2020; Clement in Austin 1968; Morton 1967; Morton et al. 1972).

In Alaska under 24-hour daylight conditions, adults fed the brood more than 20 hours a day. In California, active feeding lasted 14.5 hours per day (King 1986; Laubach et al. 2015; Norment 2003; Petrinovich and Patterson 1982). Nestlings are fed mostly insects plus a few spiders. In the Northwest Territories, nestlings were fed a diet of 98.4% arthropods. They were also fed some bog bilberry flowers, but no fruit. On the California coast, young are also fed an introduced species of terrestrial amphipod and isopods. Young have been reported catching and consuming flies, mosquitoes, and spiders (Clement in Austin 1968; DeSante and Baptista 1989; Norment and Fuller 1997; Petrinovich and Patterson 1982).

Adults eat arthropods during the breeding season and vegetable matter the rest of the year. For birds nesting in subarctic and alpine areas, spring arrival on the breeding grounds is a critical period. At this time, arthropods may be scarce and seeds may be buried under snow. In Quebec and Labrador, the green capsules of the juniper haircap moss are an important food item early in the season. Birds may gorge on these and eat new catkins of willows and black flies, which emerge early in spring (Clement in Austin 1968). Near Kuujjuaq, Quebec, adults regularly fed on maggots on fish bodies (personal observation). In Alaska, it fed on moss capsules, willow catkins, poplar sap, tiny horsetail stalks, fresh blossoms and leaves, and mosquitoes at water's edge. It also ate bread scraps and seeds of thistles and knotweeds (DeWolfe in Austin 1968). Fruit was important in the spring diet in the Northwest Territories. Crowberry, mountain cranberry, alpine bearberry, and occasionally bog bilberry produced fleshy fruits that persisted over winter. Spring fruits of the first 3 species were still plump and juicy; those of bilberry were little more than shrivelled skins and seeds. The fleshy fruits were an important component of the diet in early spring throughout the prenesting and incubation periods. Fleshy fruits were an abundant, nutritious, and easily obtained food source that allowed it to remain in good physiological condition when other food items were scarce (Norment and Fuller 1997). The White-crowned Sparrow drinks frequently and dies within a week if fed a dry diet with no water (Chilton et al. 2020). Judd (1901) reported that stomachs collected in California in summer contained 43% animal matter and 57% vegetation. Animal matter included 23% parasitic wasps, 9% beetles (fireflies, weevils, and click, dung, and leaf beetles), 7% leafhoppers and other bugs, and 4% caterpillars. From October to February, the diet consisted of 90% grain and weed seeds, but no grass seeds. Thirty-five percent of food items were seeds of lamb's-quarters and amaranths; it also ate seeds of purslane and plants in the pink family. Grain comprised 39% of the diet during this period, predominantly oats, but also corn, wheat, and barley. Grain was taken from newly sown fields, from standing grain, and in stubble.

The White-crowned Sparrow is a host of the Brown-headed Cowbird only along the Pacific Coast from British Columbia southward. The ranges of the 2 species do not overlap elsewhere. It is only recently that parasitism has occurred on the west coast, but the incidence of it is increasing. In the San Francisco Bay area, 5% of nests were parasitized in 1978. At that time, it was concluded that parasitism did not affect desertion, predation, or fledging success rates. By 1993, 40-50% of nests were parasitized and it was concluded that the White-crowned Sparrow could not maintain its population when the parasitism rate exceeded 20%. In British Columbia, 9 of 469 nests (1.9%) were parasitized. Parasitism was documented in Washington and Oregon (6 of 42 nests, 14.3%) in the early 1970s and mid-1980s. Most records of parasitism come from urban habitats (Baptista 1972; Campbell et al. 2001; Chilton et al. 2020; Heltzel and Earnst 2006; Lavers 1974; Lewis 1973; King and Mewaldt 1987; Petrinovich and Patterson 1978; Trail and Baptista 1993).

In northern and alpine populations, severe weather during the breeding season is the greatest limiting factor. In years of deep snow pack, there is less suitable habitat available at the beginning of the breeding season. This may result in fewer pairs nesting or later initiation of nests which decreases opportunities for renesting. In an alpine population in California, fewer juveniles were captured during the postfledging season in a year preceded by a winter of heavy snows and a summer with storms that diminished fledging success. At an Oregon alpine site, snowstorms resulted in significant nest losses in 4 of 20 years. In 1 year, 95.5% of nests were destroyed and

renesting occurred; in another year, 85.7% of nests were lost and no renesting occurred. This population suffered a significant decline due to a combination of bad weather and high predation rates. Widespread nest losses may occur during hail storms and heavy rains accompanied by wind and cold temperatures. At Churchill, all nests containing young were lost during a rainstorm and no renesting occurred. In Alaska, nestling growth rates decreased with increasing precipitation and also with later nest initiation. During inclement weather, adults spent more time on self-maintenance and less time caring for nestlings (Jehl and Hussell 1966a; King and Mewaldt 1987; Morton 1992; Morton et al. 1972; Pérez et al. 2016).

Rivers et al. (2019) studied the effects of forest herbicides applied to clear-cuts on the White-crowned Sparrow. The herbicide reduced deciduous vegetation density and was applied at light, moderate, and intensive levels. Herbicide application had no influence on daily nest survival or postfledging survival. Although increased herbicide application intensity resulted in extensive reductions in vegetation cover at the stand and nest-patch scales, there was no difference in vegetative cover at nest sites among treatments and controls.

Dietz et al. (2013) studied the effects of a gravel road on the White-crowned Sparrow at an alpine site in Colorado. The road was 6.5 m wide and a mean of 35.5 vehicles used it daily in June and July. Nests were initiated before the road was opened to traffic. Nests were 1-223 m from the road (median distance 27.5 m). More nests than expected were within 10 m of the road and fewer than expected were at other distance categories from the road. Although areas near the road were selected, there was a significantly higher desertion rate at nests within 20 m of the road that was related to higher stress responses of males nesting in this area. The road was an ecological trap; the road and areas within 20 m of it were of reduced quality habitat.

Near Churchill, Sammler et al. (2008) studied the effects of intensive grazing by geese on other bird species. The White-crowned Sparrow was in the willow-nesting guild and this habitat was not affected by the geese. In western United States populations, livestock grazing reduces ground and shrub cover and is associated with lower populations of White-crowned Sparrows and higher rates of nest predation (Earnst et al. 2012; Heltzel and Earnst 2006).

The density of a California population declined over 30 years due to natural succession. Over this period, the vegetation changed from early successional scrub to later successional scrub and coniferous forest. The White-crowned Sparrow selected the earliest successional habitat and avoided later successional areas (Porzig et al. 2018).

DesGranges and LeBlanc (2012) reported that the White-crowned Sparrow occurred in stands with low summer temperatures and precipitation in central Quebec and Labrador. Consequently, it may be vulnerable to climate change in this area.

Status

The White-crowned Sparrow was first described as a species at Fort Severn (Forster 1772). Breeding was first documented for the province at this location in 1940 (Peck and James 1987). Baillie and Harrington (1937) stated that it was only known to breed along the Hudson Bay coast and along the James Bay coast north and west of the Albany River. During the first atlas, its breeding distribution included most of the Hudson Bay Lowland, although greatest abundance occurred within 100 km

of the coastlines with few records beyond 200 km. The transition area between tundra and boreal forest appeared to be its preferred habitat. It was uncommon along the James Bay coast and at Kerine Lake; fairly common at Fort Severn, Winisk, and Cape Henrietta Maria; and common at Hawley Lake. Highest abundance was on the tundra and along the treeline (Rising in Cadman et al. 1987). James (1991) considered it uncommon in the northern Hudson Bay Lowland south to Big Trout Lake and along the James Bay coast south to Moosonee. Wilson and McRae (1993) reported that it was most common along the north coast, becoming scarcer further south. It was common at Shagamu but considerably less abundant at Brant, possibly due to the scarcity of shrubs. It was uncommon at Ekwan and there was no evidence of breeding at Longridge. Several territorial birds were present within the Moosonee town limits.

The second atlas revealed a similar range for the White-crowned Sparrow as during the first atlas. It was somewhat more widespread throughout the Hudson Bay Lowland and breeding evidence was obtained in 4 squares in the northwest portion of the Boreal Forest Region. Its probability of observation increased significantly in the Hudson Bay Lowland. Highest densities occurred in the northern Hudson Bay Lowland from Fort Severn east into Polar Bear Provincial Park and inland from Peawanuk along the Winisk and Fawn rivers. Its abundance decreased with distance from the Hudson Bay coast (Rising in Cadman et al. 2007).

POSTFLEDGING PERIOD

Newly fledged young cannot fly or can fly weakly for short distances of 5-20 m. On the day of fledging or shortly thereafter, brood division occurs with each adult caring for 1 or 2 fledglings. They remain relatively sedentary, perched in dense vegetation near the nest and can fly 7-10 days after leaving the nest. Fledglings 9-10 days old averaged 20 m from the nest in California alpine meadows (range 0-50 m). This distance corresponded closely to the area that was defended as a territory. By day 30, they averaged 200 m from the nest. If a second brood is initiated, the male takes over feeding the first brood when they are about 20 days old, and the young begin to feed on their own when they are 16-20 days old. Family groups begin to dissolve once fledglings are about 25 days old; juveniles become independent when they are 28-35 days old (Chilton et al. 2020; DeWolfe in Austin 1968; Morton 1992, 1997; Morton et al. 1991; Petrinovich and Patterson 1983). Baker et al. (1982) studied movements of first-brood fledglings in California. For the first week after leaving the nest, they were extremely sedentary, perching cryptically in shrubs near the nest. The average length of stay in the natal area was 51 days (range 27-63 days). They remained within about 60 m of their first capture site for the first 10 days out of the nest, increasing to 110 m 14 days after fledging. Following that, there was a steady increase to 270 m followed by an apparent drop off in movement. The substantial increase in ranging distance occurred at about 35-40 days of age coincident with when tail growth ceases.

By age 40-60 days and beyond, some juveniles are highly mobile; others are sedentary. Many juveniles leave the natal area at age 30-70 days. Some make exploratory flights of 5 or more km. One female was captured 3.6 km from her natal nest at age 32 days. Fledglings from first broods tended to leave the natal area if second broods were raised. Fledglings of pairs that do not attempt a second brood and those of later broods may either leave or remain within the natal area. Some juveniles remain in the natal area for several weeks and even until autumn migration begins. Approximately

a month after local juveniles become independent, an influx of juveniles from other locations occurs; they outnumber local juveniles 2.5:1. These birds may stay a short period before moving on (with about 35% remaining only a single day) or remain for the remainder of the season. These latter birds may also return to breed (Morton 1992, 1997; Morton et al. 1991; Oakeson 1954; Petrinovich and Patterson 1982, 1983). In Alaska, there was an influx of adults that had not bred in the area in the third and fourth weeks of August indicating that some adults may move away from their breeding areas prior to autumn migration (Oakeson 1954).

Loose family groups were seen in August in an alder fringe along the George River in Quebec. By mid-September when they leave the region, they are usually restricted to dwarf birch thickets on slopes in timberline areas (Clement in Austin 1968).

MIGRATION

All subspecies except one in California are migratory. Birds banded in Ontario and Quebec overlap broadly in winter in an area extending from Missouri east to Kentucky and south to the Gulf Coast from Texas to Mississippi (Brewer et al. 2018). Migration is nocturnal and flocks forage together at stopover sites during the day. Flocks are not cohesive units. Each bird within a flock travels on its own schedule independent of the birds that it accompanies during the day. The rate of spring migration tends to increase with latitude. Spring migration is quick and compressed in time; autumn migration is prolonged. In Maine, the mean passage period was 18 days in spring and 42 days in autumn. Late snow and ice may delay arrival on the breeding grounds in northern Quebec and Labrador by as much as a week. Under these conditions, birds may stack up at Sept-Isles along the north shore of the St. Lawrence River. In Maine, the mean minimum stopover time was 4.5 days (range 1-20 days); there was little variation in stopover lengths between spring and autumn. In New Jersey, the mean autumn stopover period was 5.7 days (maximum 14 days). In the west, stopover times were 4.1 days at latitude 42°N, 2.5 days at latitude 60°N, and 2.1-3.8 days at 3 sites in the Yukon (Brewer et al. 2018; Campbell et al. 2001; Cherry 1982; Chilton et al. 2020; Clement in Austin 1968; DeWolfe et al. 1973; Heinemann 1981; King and Mewaldt 1981; Oakeson 1954; Seewagen and Newhouse 2018).

Males tend to arrive on the breeding grounds about a week before females (range 5-14 days). In Alaska near the Canadian border where the climate was less severe, females arrived about the same time as males. In California alpine meadows, the earliest cohort was predominantly males but a few females arrived with the males. Some females arrived before males and established territories until males were available. Older males arrived significantly earlier than females by 5.8 days; yearling males arrived an average of 5.3 days earlier than yearling females. Yearling males arrived 2.2 days later than adult males and this difference was significant. Yearling females arrived 1.6 days later than adult females, but this difference was not significant. Juveniles that were present in the area during their postfledging period arrived 2 days sooner than those that had not been present previously, but this difference was not significant (King 1986; King and Mewaldt 1987; Morton 1992; Norment 1992; Oakeson 1954; Poesel et al. 2011).

In southern and central Ontario, spring migrants usually arrive in late April or early May and leave by the end of May. The peak of migration is in the first half of May or mid-May in the southern Shield. Stragglers may persist into early June (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et

al. 2004; Mills 1981; Tozer 2012; Weir 2008). Wilson and McRae (1993) considered single birds seen on 6 and 9 June at Longridge to be migrants. The earliest observation on the Twin Islands was 9 May (Manning 1981).

In subalpine meadows in California, juveniles often migrated before adults in autumn (Morton 1992). On the Twin Islands, all birds left before 16 September (Manning 1981). At Longridge, migrants began to appear 4-13 September (Wilson and McRae 1993). In the southern Shield, most autumn migrants occur from mid-September to late October, but some may linger until late November (Mills 1981; Tozer 2012). In the south, migrants usually arrive in early to mid-September and leave by late November, but birds may be present from late August and remain into December (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008).

During migration, the White-crowned Sparrow prefers shrubby areas in open habitats. In the Yukon, these habitats may include wetlands and backyards (Sinclair et al. 2003). Along the British Columbia coast, it occurs in edge habitats, particularly areas of heavy shrub growth adjacent to more open areas. These may include transmission line and transportation corridors, beaches and spits, golf courses, city parks, airports, gardens, backyard feeding stations, shrub-dominated logged or burned areas, agricultural areas and road edges with short grasses and weed patches, edges of bogs, and riparian habitat adjacent to beaver ponds, sloughs, sewage lagoons, creeks, estuaries, and other wetlands. Similar areas are used in the interior, plus sagebrush grasslands, shrubby and weedy fencerows, avalanche chutes, subalpine areas, and grain elevators and sheds where spilled grain provides a food source (Campbell et al. 2001). In autumn in Ohio, it occurs in brushy areas, dense patches of tall weeds, and weedy uncut cornfields (Clement in Austin 1968). In Maine, Cherry (1982) trapped birds in a mixed wood and in an open field with a hedgerow. All White-crowned Sparrows were captured in the hedgerow. In Kansas, migrants occurred only in thickets, especially those at margins of weedy fields (Fitch 1958).

During spring migration in Algonquin Park, birds foraged mostly on the ground but occasionally went high in trembling aspens to feed on catkins. Birds lingering into November typically occurred at feeders (Tozer 2012). During autumn migration in Idaho, Carlisle et al. (2012) compared the White-crowned Sparrow's diet with food availability. Food items consumed in a greater proportion than their availability, in order of decreasing preference, included ants, other hymenopterans, beetles, lepidopterans, larvae, spittlebugs, and leafhoppers. Items that were eaten less than their availability, in order of decreasing avoidance, included jumping plant lice, hornets, spiders, flies, stink bugs, wasps, stilt bugs, and moths. It consumed a moderate amount of fruit but ate more seed matter. Caterpillars were consumed less than their availability, but were not abundant enough during autumn migration to be a major component of the diet.

Weir (2008) reported that only 1 White-crowned Sparrow was killed at the Lennox generating station chimneys and that 2 were killed by cars. It is occasionally killed by flying into windows during migration (DeWolfe in Austin 1968).

Clement (in Austin 1968) reported that juveniles of the eastern subspecies were often blown out over the Atlantic Ocean, where they presumably perished. Adults appeared to be capable of avoiding this.

James (1991) considered the White-crowned Sparrow a common migrant in Ontario. Spring flocks commonly number 50, with larger flocks of 250-500 in the Kingston area. Autumn flocks are larger and may contain 500-1,000 birds (Curry 2006; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008).

At Long Point Bird Observatory, Hussell et al. (1992) reported a nonsignificant decline of 1.0% per year in the number of White-crowned Sparrows banded 1961-88. Trends by period were: 1961-70, +3.8%; 1970-79, –4.5%; and 1978-88, +1.1%.

WINTER

The winter distribution of the White-crowned Sparrow is governed by temperature. It is mostly absent where the average minimum January temperature drops below –9°C. The eastern subspecies is the only one that regularly winters east of longitude 90°W, but it avoids the southeastern states. Dense wintering populations are all west of longitude 100°W; these are typically birds that breed west of Ontario. Highest abundance in these areas occurs along rivers (Clement in Austin 1968; Root 1988).

In winter, the White-crowned Sparrow uses habitats similar to those it frequents during migration: shrubby or weedy areas in open habitat. It seldom occurs much further than 2 m from vegetative cover. It may occur in grain fields, shrubby roadsides and hedgerows, scrub and steppe vegetation, abandoned farmland, riparian areas, grasslands, and anywhere there are clumps of tall weedy growth, shrubs, or saplings. It may occur at feeders in both urban and rural habitats. It is less reliant on water in winter than in the breeding season (Chilton et al. 2020; Clement in Austin 1968; DeWolfe in Austin 1968; Root 1988). In California, wintering White-crowned Sparrows were positively correlated with feeders and the presence of grass and negatively correlated with structures and roads (Kalinowski and Johnson 2010).

The White-crowned Sparrow roosts, often communally, in dense trees or shrubs in winter. It prefers to roost in woody vegetation that retains its leaves in winter. It avoids trees or shrubs that are sparsely foliaged or defoliated. Roosts are most frequently in open habitat and usually consist of isolated clumps of woody vegetation surrounded by open fields or other similar habitat (Barrentine 1991, 1992; DeWolfe in Austin 1968).

The White-crowned Sparrow avoids expending energy on intraspecific competition by each flock occupying an exclusive home range, sex ratios varying geographically thereby reducing intersexual competition, and establishing dominance hierarchies so birds do not have to assert dominance. In different study areas in California, winter flocks occupied areas of 6-8 ha and 20 ha. Flock sizes of 6-150 birds have been reported. Individual flocks consistently remain in the same location with approximately the same number of birds. Home ranges of flocks do not overlap and are frequently separated by unsuitable habitat. There is no evidence of interchange of birds between flocks, although daily movements of individuals may extend as far as 0.9 km. Within flock home ranges, each individual may have favourite foraging and roosting sites (Barrentine and McClure 1993; Chilton et al. 2020; Clement in Austin 1968; Dunn and Tessaglia-Hymes 1999; Morton 1967; Parsons and Baptista 1980; Ralph and Mewaldt 1975). Members of a pair may winter in separate flocks or at different altitudes and latitudes (DeWolfe in Austin 1968). Dominance is established by sex, age, and appearance. Some aggression occurs but subdominant individuals usually back down

without any conflict. Males dominate over females in each age class and adults are dominant over juveniles. When strange individuals meet, dominance is established by the brightness of the crown colours. In an artificial feeding study, adults fed closer to cover than juveniles and juveniles fed further from cover when adults were present than when they were absent (Parsons and Baptista 1980; Slotow and Rothstein 1995).

Most birds return to the same home range and roost in subsequent winters. Overwintering birds are rarely captured outside the 10-minute block where they were originally banded. Both adults and juveniles exhibit greater site tenacity to feeding sites than to roosts. Winter displacement studies indicate that adults have strong site fidelity and that juveniles develop site fidelity in mid-January. In California, birds of both age classes were displaced 4-160 km from the point of capture. No adults returned to where they were released in the subsequent year, but 65 of 384 (16.9%) returned to where they were captured. Twelve of 424 juveniles (2.8%) returned to the release station, but only those that were moved prior to mid-January. All returning juveniles were released less than 60 km from the point of capture. In another California study, birds were released at a roost 3.7 km from the roost where they were captured. Nineteen of 119 displaced birds (16.0%) were recaptured in the next 2 years; return rates were similar for juveniles and adults. One of 6 returning juveniles (16.7%) and 11 of 13 returning adults (84.6%) returned to the home roost; 5 of 6 juveniles (83.3%) and 2 of 13 adults (15.4%) returned to the roost where they had been released. One juvenile was recaptured 3 years after banding 145 km from the banding location. Delaying fixation on a site until midwinter may allow young birds to explore different areas prior to selecting a wintering area. One bird was captured in March 40 km from where it had been banded in January (Barrentine 1993; Barrentine and McClure 1993; Ralph and Mewaldt 1975). At a residential lot in California, 53 of 94 (56.3%) returned as adults; 51.1% of birds returned more than once. Seventy-four of 256 yearlings (28.9%) returned and 39 (52.7%) returned a second time. The lower return rate of yearlings may be due to late site fixation and higher mortality rates than adults (Mewaldt 1976). In California, Sandercock and Jaramillo (2002) banded 6,625 juveniles and 1,967 adults. The recapture rate was 59.7% for juveniles and 60.6% for adults.

In Washington State during high wind or heavy rain, the White-crowned Sparrow tended to avoid open ground and foraged almost exclusively in sheltered locations such as in and around weeds and brushy fencerows. Light rain and intermittent snow did not affect choice of foraging areas (Morton 1967). It seldom forages much more than 2-4 m from cover. Food was placed in bowls 0.3, 0.8, and 1.3 m from an artificial shrub. In 1 treatment, the shrub was removed and too few birds visited the food bowls to do any statistical analyses. More birds used the bowl closest to the shrub; 73-83% of birds were observed at this bowl but only 33.3% would be expected. Ninety-eight percent of birds went to the shrub before they went to the food. Few birds fed at the bowls when no cover was available despite the presence of dense cover 20 m away. It strongly preferred a nearby source of cover before it would feed (Slotow and Rothstein 1995). In an aviary, it handled seeds smaller than 0.74 mg more efficiently than finches; finches were more efficient in handling seeds larger than 1.44 mg. Based on its winter energy requirements, the White-crowned Sparrow must find and consume an average of 1 seed every 1-5 seconds throughout a 10-hour day. Therefore it must occupy habitats containing high densities of seeds to obtain adequate food. Because most of the day must be spent

foraging, it cannot exploit patchy food resources or make long flights in search of new patches (Benkman and Pulliam 1988).

In winter, the White-crowned Sparrow feeds predominantly on vegetable matter but also on arthropods when they are available. In Maryland and West Virginia, Llewellyn (1949) observed flocks feeding under smooth pigweed, presumably on its seeds. Morton (1967) collected 88 stomachs in Washington in winter and spring. Seeds, especially those of amaranths, were the predominant food item in January. In February, there was an increase in consumption of green plant material. Grass blades were ripped off and swallowed end-first. In late March and early April, there was a major shift in diet when the intake of grass decreased and it began to feed extensively on buds, particularly those of hackberry. With the onset of mild spring weather, there was a noticeable increase in invertebrates, especially flying insects. There was a 125% increase in the amount of animal material in stomachs and an increase in insect-chasing activities. Judd (1901) analyzed the contents of 217 stomachs from every month except August. Almost all were collected in the United States, so they represent either wintering birds or populations breeding near the Pacific Coast. Seventy percent of the diet consisted of insects, and it also ate spiders and amphipods. Half the insect diet was comprised of cutworms and other smooth caterpillars. The remainder of the insect diet included beetles (fireflies, weevils, and ground, leaf, and scarab beetles) and wasps. It did not eat grass seeds and only 1 bird had eaten grain. The primary seeds consumed were chickweeds, lamb′s-quarters, wild sunflowers, smartweeds, and docks. It also ate a few violet and mallow seeds. He examined 94 stomachs of the Eastern White-crowned Sparrow, all from central and eastern states from September to May. It subsisted almost entirely on seeds in winter but became somewhat insectivorous during warmer weather. In May and September, 11% of the food consisted of ants, caterpillars, weevils and other beetles, and spiders. Twelve percent of the diet consisted of grain, almost entirely oats but with some corn and wheat. In May, grain constituted 27% of the diet indicating that it was feeding in newly sown fields. It also ate small seeds including those of crabgrass, panic grasses, foxtails, and Johnson grass. Ragweed was important, comprising 20% of the diet; seeds of amaranths, lamb′s-quarters, chickweeds, gromwells, and wild sunflowers were important foods. Only 5 of 94 stomachs contained fruit, including those of elderberries and blackberries; it has been reported to eat grapes. In spring, it may consume blossoms of trees and shrubs. The entire sample of 217 stomachs contained 25% animal matter and 75% vegetation. Caterpillars formed 9% of the diet and a third of the animal food, a higher proportion than found in stomachs of other sparrows. Ants and parasitic wasps constituted 6% of the diet, which was also higher than average. Beetles comprised only 5% of the diet, below average for sparrows. Other animal matter included 1% grasshoppers, and 4% spiders, bugs, and miscellaneous insects. The vegetable matter consisted of 51% weed seeds, 15% grain, 4% grass seeds, and 5% fruit. It ate fewer grass seeds and more fruit than other sparrows. Beal and McAtee (1912) analyzed the contents of more than 600 stomachs collected predominantly in winter in the United States. It is probable that their results included the samples analyzed by Judd (1901). The stomachs contained 7.4% animal food and 92.6% vegetation. Beetles comprised 1.4% of the food, reaching a peak of almost 8% in June but they were insignificant in other months. Hymenopterans contributed 1.9% of the diet, reaching a peak of more than 16% in June but only about 1% in other months. Most were ants with fewer wasps, bees, and parasitic species. Caterpillars were the dominant animal food, comprising

3.5% of the annual diet and 37.5% of the July diet. Other minor animal foods included stink bugs, leafhoppers, and treehoppers. It subsisted predominantly on weed seeds which comprised 74% of the diet; over 90% of stomachs contained weed seeds. The favoured species was redroot amaranth. Grain constituted 8.6% of the diet and was consumed mostly in winter. Oats were the dominant grain in stomachs, but it also ate wheat, barley, and corn. Fruit represented 4.5% of the diet and included cherries in addition to the species mentioned by Judd (1901).

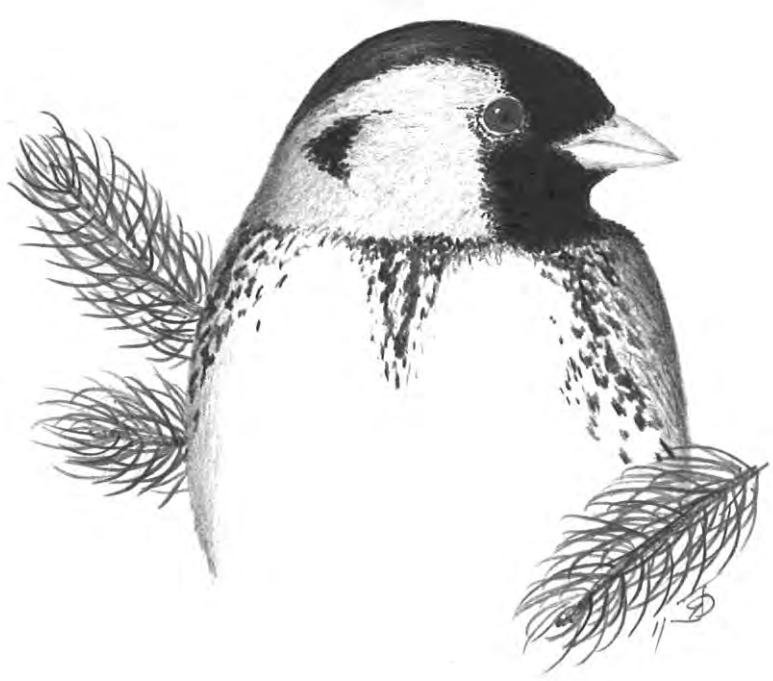
The White-crowned Sparrow is a regular visitor to winter bird feeders. The proportion of feeders visited is lowest in rural areas. Favourite feeder foods include mixed seeds, millet, and cracked corn, and it frequently eats milo, wheat, and hulled peanuts. Infrequently consumed foods include sunflowers, safflower, niger seeds, suet, peanut butter mixes, peanut hearts, baked goods, bird puddings, fresh fruit, and water (Dunn and Tessaglia-Hymes 1999).

James (1991) considered the White-crowned Sparrow a rare winter resident in southern Ontario north to Sudbury.

Clement (in Austin 1968) concluded that the White-crowned Sparrow had extended its winter range eastward and northward since approximately 1950. Possible reasons for its range expansion include climate amelioration, widespread planting of multiflora rose, and greater numbers of feeding stations. Christmas Bird Count data indicate that it increased in Ontario at annual rates of 1.99% 1970-2021 and 6.76% 2009-21 (National Audubon Society 2022).

Harris's Sparrow

Zonotrichia querula

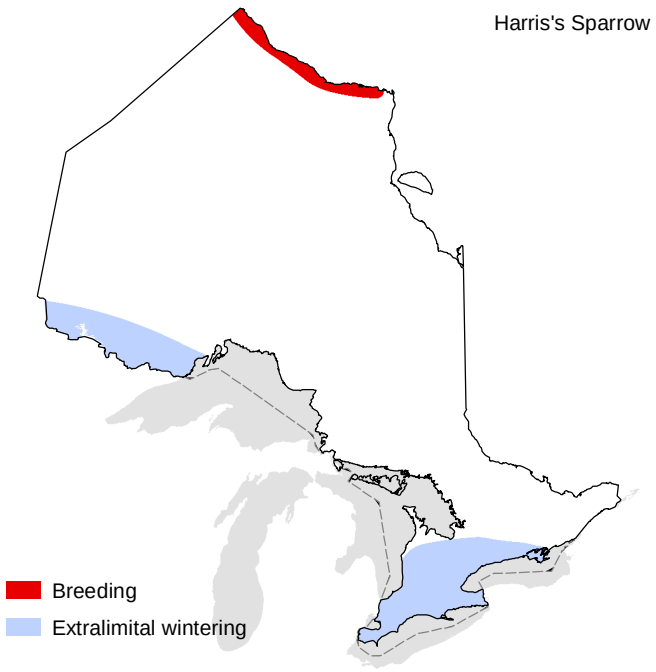


BREEDING SEASON

Habitat Requirements

The Harris's Sparrow is Canada's only endemic songbird. It breeds in the ecotone between tundra and boreal forest from the Northwest Territories to extreme northwestern Ontario.

The first and only Ontario nest was in a coastal fen supporting small tamaracks. The wetland was at a clearing near an airstrip (Peck and James 1987). The nest was in a patch of willow shrubs and stunted spruces in an area with a grassy substrate interspersed with sand and gravel associated with the Fort Severn airport runway. The habitat was predominantly open and the nest was about 10 m from the radio station. The antenna of the station was a favoured singing post (Cadman in Cadman et al. 1987). During the second atlas, birds were observed predominantly in willow thickets surrounding tundra lakes and ponds. Typical breeding habitat consists of patches of stunted conifers with a dense shrub understorey of birch, willow, and alder (Cadman in Cadman et al. 2007).



The breeding grounds of the Harris's Sparrow are confined to the strip of stunted timber along the northern edge of the Boreal Forest Region from Hudson Bay westward (Swenk and Stevens 1929). It prefers small pockets of coniferous trees surrounded by tundra and avoids contiguous boreal forest. The northern extent of its range is limited by the distribution of coniferous forest stands growing beyond the northern limit of the boreal forest. It occasionally nests in tundra. The southern extent of its range is limited by the Boreal Forest Region, which it avoids. Most territories include some coniferous trees. Densities are highest in forests dominated by spruce or tamarack with a shrubby understorey. Low densities may occur in jack pine or white birch with little understorey vegetation; it occasionally nests in areas without trees. Forest stands within territories are typically isolated and small (less than 0.01 ha to 12 ha) with trees less than 3-8 m tall. Most birds occur in areas with less than 30% canopy cover and where the maximum canopy height is 8 m (Norment et al. 2020).

In the Northwest Territories, breeding habitat consisted of a mosaic of small isolated spruce stands and extensive tundra habitat. The tree stands were typically surrounded by shrubby dwarf birch, willow, and green alder 0.3-1.5 m tall (Norment 1995a). Most forest stands had a dense understorey of mosses, dwarf birch, Labrador tea, willow, green alder, and bilberry. There were 4 tundra communities in the area: low sedge meadow, tussock meadow, dry heath, and rock field. Low sedge meadows were poorly drained and vegetated with sedges and cottongrass. Tussock meadows were characterized by cottongrass hummocks. Dry heath areas were dominated by lichens, scattered dwarf birch, and low evergreen shrubs such as alpine bearberry, marsh Labrador tea, mountain cranberry, and crowberry. Rock fields were dry rocky areas with less than 10% vegetation cover. Common plant species in rock fields included those found in dry heath along with prickly saxifrage and mountain avens. Dwarf birch habitat at or beyond the edge of spruce stands supported 89.2% of nests; 4.6% were in spruce stands including one in the interior of a 12.3-ha spruce stand, 3.1% were in tussock meadows, 1.5% were in dry heath, and 1.5% were in rock fields. In this area, the White-crowned Sparrow always nested in dense shrubby vegetation within 25 m of forest edge. The Harris's Sparrow used a wider variety of nesting habitats as far as 127 m from forest edge (Norment 1992).

North of Churchill, the Harris's Sparrow was most abundant in deciduous scrub followed by heath, coniferous and mixed scrub, and coniferous forest with an understorey. It was absent in deciduous and mixed forests, coniferous forest without an understorey, and tundra (McLaren and McLaren 1981). Near Churchill, it was most common at edges of woodlands, in clearings near railway

tracks, and in brushy areas of burned-over areas. It preferred a damp, rather sheltered woodland at the base of a rocky hill. Nests were also in mossy hummocky spruce-tamarack woods with an open canopy (Semple and Sutton 1932). In the same general area, it nested in forest-edge areas where the trees were mostly stunted, densely branched white and black spruce on the sheltered edge of a rocky ridge. The trees averaged 3 m in height with a diameter at breast height of 6.4 cm; tree density was 1,236 per ha. The ground was covered with moss and the shrub layer was comprised of Labrador tea, rhododendrons, blueberries, and bog rosemary (Gillespie and Kendeigh 1982). Also in the Churchill area, it nested mainly in shrubby clearings, old burned-over areas, bogs, and semiopen areas and boggy areas with large hummocks in spruce-tamarack woods (Jehl 2004; Jehl and Smith 1970).

Baumgartner (in Austin 1968) reported that the Harris's Sparrow invariably nested in open areas near Churchill, but always close enough to a spruce to use it as a singing perch. In the Northwest Territories, Norment (1993) characterized microhabitat conditions at nests and determined how they affected nest success and compared them with habitat characteristics of White-crowned Sparrows. Within 1-m of the nest, vegetation density was significantly greater at successful than unsuccessful nests. At 1-10 m from the nest, the amount of shrub cover was significantly greater at successful nests, ground cover was 94.2% at successful nests and 80.4% at unsuccessful nests, the number of hits by vegetation 5 and 10 m from the nest was significantly greater for successful nests, and horizontal vegetation heterogeneity was significantly lower for successful nests. The latter parameter suggested that more uniform distribution of vegetation interfered with the ability of predators to locate nests. Successful nests tended to be in areas with more cover and denser vegetation within 5 m of the nest than unsuccessful nests. The amount of shrub cover within 10 m of the nest was the most useful variable in discriminating between successful and unsuccessful nests. Nest sites of Harris's and White-crowned sparrows differed significantly for 10 of 13 variables tested. Harris's Sparrow nests were further from the edge of spruce stands, in shorter less dense vegetation, and in vegetation with less vertical complexity than White-crowned Sparrow nests. Significantly different parameters of nest sites of Harris's Sparrow and White-crowned Sparrow respectively included: shrub height, 47.6 cm and 62.1 cm; distance from nest to the nearest tree stand, 27.9 m and 7.2 m; ground cover, 88.6% and 98.7%; and vegetation hits, shrub hits, and vertical vegetation diversity significantly less for the Harris's Sparrow. Other Harris's Sparrow average nest-site characteristics included 35 cm from the nest to the nearest shrub and 16.5 cm vegetation height within 0.5 m of the nest (Norment et al. 2020).

All reported nests were on the ground. Most are at the base of a small shrub or tree and well concealed by overhanging vegetation or physical features; rarely nests are unconcealed from above. In the Northwest Territories, 67.7% of nests were concealed by dwarf birch, 7.7% by green alder, 7.7% by spruce, 7.7% by marsh Labrador tea, 3.1% by willow, 1.5% by bilberry, 1.5% by a rock overhang, and 1.5% by a turf overhang. The rim of the bulky nest is sunk into the ground and may be only a few centimetres above water in moss hummocks. In the Northwest Territories, nests were oriented nonrandomly at an average of 140.5°, or southeasterly. The average wind direction was 329°, so nests were oriented about 149° away from the direction of the prevailing wind. There are 2 records of old nest cups being used (Baumgartner in Austin 1968; Jehl and Hussell 1966a; Jehl and Smith 1970; Norment 1992, 1993; Norment et al. 2020; Semple and Sutton 1932).

Territorial chases are infrequent and most common during territory establishment and nest construction. Territorial activity wanes in late June when most pairs are feeding nestlings. Near Churchill, no evidence of territoriality was observed, with birds feeding together for long periods in the morning. The average territory size is approximately 2 ha but males may defend areas with maximum linear dimensions of 200-300 m, or about 6 ha. During the incubation and nestling periods, females remain near the nest but males may wander as far as 500 m from the territory. Females may wander widely during other phases of the nesting cycle (Norment 1992; Norment et al. 2020; Semple and Sutton 1932).

Only 1 study in the Northwest Territories examined natal philopatry. No philopatry was observed, with 0 of 62 nestlings returning (Norment 1994).

Return rates of adults in the Northwest Territories in 2 years were 38.5% and 38.9%. The first-year return rate was 34%; 4 adults (3 males and a female) returned 2 years after banding for a second-year return rate of 31%. Although a higher proportion of males (9 of 22, 40.9%) returned in the first year than females (6 of 22, 27.2%), the difference was not significant. Breeding success appeared to be the greatest factor in determining whether a bird returned. Six of 7 successful males (85.7%) returned compared with 2 of 5 unsuccessful males (40.0%). Two males returned to the same territory. In the following years, 4 of 6 males that had been successful the previous year occupied the same territory, including one that had occupied the same territory 2 years previously. The other 2 returning males established territories 150 m and 750 m from their previous territory. Six of 7 successful females (85.7%) returned the following year compared with 1 of 10 unsuccessful females (10.0%). No female returned to its same territory. The female that returned after nesting unsuccessfully nested 250 m from her original nest. She returned the following year after nesting successfully and again moved 250 m from the previous nest. Another female that had nested successfully nested 75 m from her previous nest (Norment 1994).

Limiting Factors

Peck and James (1987) reported that eggs were most likely to be in Ontario nests from mid-June to mid-July. Males begin singing within 2 days of their arrival. Pairs typically form 5-8 days after arrival, but pair formation may be delayed by adverse weather. During a late snowstorm in the Northwest Territories, all birds disappeared and pair formation was disrupted for 4 days. Both first and replacement nests may be built in about 2.5 days. An average of 3.5 days elapses between nest completion and clutch initiation. The earliest clutches are not initiated until at least 60% of the ground is snow-free. Eggs are laid at the rate of 1 a day. Incubation begins with the laying of the penultimate egg. The incubation period is typically 12.0-13.5 days; eggs at 1 Churchill nest took 15 days to hatch due to inclement weather. Mean incubation periods in the Northwest Territories in 3 years were 12.5, 12.7, and 12.9 days (average 12.8 days). In 61 clutches, 84.7% of eggs hatched synchronously, 14.8% hatched 1 day later than the rest, and 0.5% hatched 2 days later. The nestling period in the Northwest Territories averaged 9.26 days (range 8.5-10.0 days). At Churchill where the young were handled, the nestling period averaged 8.9 days. The nestling period appears to decrease with latitude. Nesting in populations is highly synchronized with all young fledging within 6-10 days in 3 years of study. Nesting phenology is related to food abundance. Hatching in the Northwest Territories began shortly after arthropod abundance began to increase in early and mid-June.

Fledging peaked in the second week of July just prior to the peak of arthropod abundance (Jehl 2004; Jehl and Hussell 1966b; Norment 1992, 1995a, 1995b, 2003; Norment et al. 2020; Semple and Sutton 1932).

A single brood is raised in a nesting season. If a nest is lost, a replacement nest may be initiated soon thereafter. Replacement clutches are laid only if the loss occurs prior to hatching and early in the season. Nests lost before 18 June may be replaced. If nests are lost later, they are not replaced and there is no resumption of territorial behaviour. One pair built a replacement nest 16 m from the original nest and laid the first egg 3 days after the loss. The Harris's Sparrow lays 3-5 eggs. Nests initiated early in spring may contain only 3 eggs, possibly due to lower food availability at this time. Clutch sizes are smaller in years when nest initiation is late due to delayed snow melt. Four eggs is the most frequent clutch size. Clutch sizes increase with latitude with a higher proportion of clutches containing 5 eggs in the Northwest Territories than at Churchill. Mean clutch sizes include 4.26 eggs in the Northwest Territories, 3.88 eggs at Churchill, and 3.50 eggs at Herchmer, Manitoba (Baumgartner in Austin 1968; Jehl 2004; Jehl and Hussell 1966a; Norment 1992, 1995a, 1995b; Norment et al. 2020; Semple and Sutton 1932).

The age at first breeding is unknown but is probably 1 year similar to other sparrows in this genus. The mating system appears to be monogamous. The highly synchronized nesting reduces the possibility of extra-pair copulations. In the Northwest Territories, both members of 3 pairs returned the following year but none retained the same mate. There is no evidence of intraspecific egg parasitism (Norment 1994; Norment et al. 2020).

At Churchill, the Harris's Sparrow was predominantly a ground feeder. It kicked and scratched with both feet simultaneously among fallen leaves and dry herbaceous stalks. It worked its way through grass and moss searching for seeds and insects. It frequently fed in tamarack where it appeared to be feeding on buds, insects, or insect eggs in leaf clusters (Semple and Sutton 1932). In the Northwest Territories, 85% of foraging was by ground gleaning. It plucked food from vegetation or the bare ground, sometimes after kicking the litter away. It also gleaned for arthropods less than 3 m from the ground in trees and shrubs, plucked fresh spruce needles from trees, and pursued flying arthropods by either chasing them along the ground or sallying into the air from the ground. Eighty-three percent of the foraging substrate was the ground, but it also obtained food from snow and the air (Norment et al. 2020). It foraged in more open habitats and further from cover than the White-crowned Sparrow (Norment 1993).

A ligature study determined that the nestling diet was comprised of 15.3% flies other than crane flies, 13.7% caterpillars, 13.1% adult beetles, 12.6% crane flies, 12.6% bilberry flowers, 9.0% adult hymenopterans, 7.4% spiders, and 5.8% seeds (Norment et al. 2020). Of 190 food items that were observed being fed to nestlings, 81.6% were arthropods. They were also fed some bilberry flowers but not fruit (Norment and Fuller 1997).

Six adult stomachs at Churchill contained 66% vegetable matter and 34% animal matter. Vegetable matter included seeds of grasses, sedges, and bulrushes; seeds or fruit pulp of crowberry, cranberry, and blueberry; seeds of birch, amaranths, and lamb's-quarters; and a considerable amount of oats that was gleaned along railway tracks. The Harris's Sparrow ate both larval and adult insects including ground beetles, leaf beetles, wood borers, click beetles, leaf-miner flies, stink bugs, small

moths, horse flies, ants, ichneumonid wasps, and crickets. It also consumed small spiders and fragments of small snails and other molluscs. Miscellaneous foods included short-horned grasshoppers, caterpillars, crowberry seeds, heath seeds, bearberry seeds, fly eggs, and flatsedge seeds (Semple and Sutton 1932). Norment and Fuller (1997) determined that fruit was important in the diet early in spring. Birds arrived almost a month before arthropods became abundant. Crowberry, mountain cranberry, alpine bearberry, and occasionally bog bilberry produced fleshy fruits that persisted over winter. Bilberry seeds were little more than shrivelled skins and seeds by spring but fruits of the other 3 species were still plump and juicy. They made 510 foraging observations of approximately 100 Harris's Sparrows. Fruits, primarily crowberry and mountain cranberry were the most frequently observed food items during the prenesting period (82% of all items) and constituted 66% of food items during the incubation period. Arthropod use increased from 9.4% in the prenesting period to 73.4% in the nestling period. Flowers, mostly of bilberry, were consumed most often during the nestling period. It also plucked and ate spruce needles and buds during the prenesting period. They collected 6 stomachs during each of the prenesting, incubation, and nestling periods. Average mass of food items during the prenesting period was 31 mg fruit seeds, 7.5 mg arthropods, 8.0 mg other seeds, and 0 mg flowers. During the incubation period, averages were 17.5 mg fruit seeds, 10 mg arthropods, 2 mg other seeds, and 0 mg flowers. During the nestling period, averages were 11 mg fruit seeds, 16 mg arthropods, 1 mg other seeds, and 2.5 mg flowers. It consumed bearberry fruit more frequently than its abundance and mountain cranberry less than its abundance. The tendency to eat bearberry fruit more than its availability may have been due to the relatively large mass of this fruit.

One of the greatest limiting factors during the breeding season is the limited range and habitat niche of the Harris's Sparrow. It is confined to a short narrow band along the transition area between boreal forest and tundra, although it occasionally nests in open tundra. It is uncertain how this habitat will respond to climate change. Its habitat in some areas may be adversely affected by forest clearing, mining, and exploration and development for the oil and gas industry (Erskine 1977; Norment et al. 2020; Wells 2007).

Nest loss due to cold rainy or snowy weather occurs frequently. If this occurs early in the season before the eggs have hatched, the adults may initiate replacement nests. If nest loss occurs during the nestling period, renesting does not occur and no young are raised in that year (Jehl and Hussell 1966b; Semple and Sutton 1932).

Status

The first Ontario nest was found at Fort Severn in July 1983. The Harris's Sparrow may have moved into Ontario recently as a breeding species. In 1940, only a single bird was found at Fort Severn with no evidence of nesting. The 1983 record at Fort Severn was the only breeding evidence during the first atlas. The area around Winisk was well covered during this atlas and no Harris's Sparrows were observed. It was concluded that it did not nest as far east as Winisk (Austen et al. 1994; Cadman in Cadman et al. 1987).

During the second atlas, breeding evidence for the Harris's Sparrow was obtained in 4 squares along the Hudson Bay coast. This extended the breeding range eastward to about 120 km west of Cape Henrietta Maria. In all cases, only possible breeding evidence was obtained and none of the birds remained until later in the season (Cadman in Cadman et al. 2007). The Harris's Sparrow wanders

widely during migration and summer and does not reach the breeding grounds until late May (Norment et al. 2020). Some birds detected during the second atlas may still have been migrating or been wanderers rather than breeders.

The Harris's Sparrow has been designated special concern in Canada.

POSTFLEDGING PERIOD

Young are incapable of flight when they leave the nest. By about 4 days after fledging, they can fly short distances of less than 10 m. Young move as far as 100 m from the nest within 5 days of fledging and may be 300 m from the nest after 10 days. Young may be separated by 30-40 m after fledging and appear to be fed by different parents. The adults continue to feed the young for at least 2 weeks after they fledge. The Harris's Sparrow forms flocks in late summer prior to migration, sometimes with other species (Norment et al. 2020).

MIGRATION

Ontario is outside the Harris's Sparrow migration route, except for the Lake of the Woods area which is on its extreme eastern edge. It wanders considerably during migration, so strays have been reported in most provinces and states. In spring, it migrates in flocks, sometimes foraging with American Tree Sparrows and White-throated Sparrows. Inclement spring weather may temporarily halt migration. In North Dakota, southward flights appeared to be driven by the calendar and were not well correlated with weather fluctuations. Southward departures commonly coincided with a temperature increase and a south wind; continued warm weather did not delay departures. The average autumn stopover time over 14 years ranged from 4.3 to 7.6 days with most birds remaining about a week. Spring migrants move faster than autumn migrants. During spring migration, stopover times were 1-5 days (average 1.5 days) (Baumgartner in Austin 1968; Brewer et al. 2018; Norment et al. 2020; Stevens 1957; Swenk and Stevens 1929).

At Churchill and in the Northwest Territories, males and females arrived at the breeding grounds at the same time (Norment 1992; Semple and Sutton 1932). Because the Harris's Sparrow is a rare and irregular migrant in Ontario, limited information is available on the timing of spring migration. This is further confounded by the fact that some early-spring migrants may be birds that overwintered. Southern Ontario spring records range from 10 April to 24 May; northern Ontario records range from 4 to 27 May (Curry 2006; Speirs 1985). At Atikokan, Peruniak (1971) reported that it was fairly common 6-23 May.

At Shagamu, Wilson and McRae (1993) saw single birds on 21 and 25 August and considered these autumn migrants at the eastern extent of their range. Migrants were present at Atikokan 13 September to 23 October and at Hornepayne 22 September to 5 October (Peruniak 1971). In southern Ontario, records range from mid-September until the end of November (Curry 2006; Speirs 1985; Weir 2008). In North Dakota, adults moved southward more promptly than juveniles (Swenk and Stevens 1929).

In northern Manitoba, spring migrants were abundant along the wooded shore of a small lake near a town and in open spruce forest. First arrivals at Churchill occurred mostly in open tundra but they also flocked in areas where they did not breed, including on a ridge near the coast (Jehl 2004; Semple and Sutton 1932).

In autumn, the Harris's Sparrow has been documented taking corn from fallen ears (Baumgartner in Austin 1968).

Storms during migration that result in food supplies being covered by snow or ice probably account for numerous fatalities. The Harris's Sparrow been killed at a television tower in Nebraska during autumn migration, but no information was provided on the number of birds involved or the frequency of kills (Baumgartner in Austin 1968; Norment et al. 2020).

James (1991) considered the Harris's Sparrow a rare migrant in the eastern part of the province and uncommon in the west. Peruniak (1971) considered it a fairly common migrant at Atikokan. Swenk and Stevens (1929) considered it an uncommon to rare irregular migrant in northwestern Ontario. In eastern Ontario, particularly south of the Canadian Shield, it is rare and irregular and is a vagrant outside its normal range. The number of records for the area south of the Shield is low even when wintering birds are included: 3 records from the Kingston area (Weir 2008), 15 from the Hamilton area (Curry 2006), 5 from Niagara Region (Black and Roy 2010), and 5 in Elgin County (Lancaster et al. 2004).

WINTER

The Harris's Sparrow has an unusual restricted winter range of only about 464,000 km^2 that extends from northern Nebraska and central Iowa to central Texas. The winter range is almost entirely south of latitude 41°N and mostly south of 40°N. Highest winter concentrations occur in Kansas, Nebraska, Oklahoma, and Texas. Small numbers occur in South Dakota and throughout the western United States into southern British Columbia and southeastern Alaska. Its prime winter habitat consists of landscapes dominated by tall grasses, oak-hickory woods, and tree and shrub savannahs. It tends to avoid short-grass prairies and areas of dense woods (Norment et al. 2020; Root 1988; Swenk and Stevens 1929).

Where it is common in winter, the Harris's Sparrow may occur in flocks. It is often in the company of other sparrows, American Goldfinches, and Northern Cardinals. During migration and winter, the Harris's Sparrow frequents brushy areas, thickets, edges of woodlots, and weed patches (Baumgartner in Austin 1968; Judd 1901; Swenk and Stevens 1929). One bird in Niagara Region spent 10 weeks in a ditch with some running water where there was dense shrubbery and numerous trees (Black and Roy 2010). In Oklahoma, where it is an abundant wintering species, it occurs in underbrush such as dense shrubbery along creeks and at edges of woods, and particularly favours vine-covered trees. It may also occur in gardens in towns, but only in years when it is particularly abundant (Nice 1929). Typical winter habitat includes shrubby hedgerows, brush piles, thickets bordering watercourses, shrubby ravines, shelterbelts, agricultural fields with weedy patches, pastures undergoing secondary succession, dense shrubs adjoining open land where weeds or cultivated crops provide a food source, patches of sunflowers, shrubby roadsides, raspberry thickets, thistle patches, ornamental hedges in residential areas, and overgrown clearings near grain elevators (Campbell et al. 2001; Fitch 1958; Leighton et al. 2002; Norment et al. 2020; Swenk and Stevens 1929).

In North Dakota, wintering birds congregated in spruces, hedges, and shrub thickets to roost for the night (Swenk and Stevens 1929).

The Harris's Sparrow does not defend a territory in winter but maintains linear dominance within flocks. The dark throat is a sign of dominance and the status of individuals can be changed by altering the throat pattern. Many birds remain within a small home range for 1-2 weeks, then leave and return 1 month or later. Oklahoma birds mostly stayed within an area of 8.1 ha, but also made regular movements as far as 1 km. Birds displaced as far as 3.2 km returned to their usual home range (Baumgartner in Austin 1968; Norment et al. 2020).

Some birds exhibit winter site fidelity and have been detected in as many as 5 consecutive years. In Oklahoma, 121 of 1,361 birds (8.9%) returned in 1 or more years. In Kansas, 2 of 71 birds (2.8%) were recaptured in a subsequent year: one the year after banding and the other 2 years after banding. Other return rates include 8.5% in Kansas and 3.6% in Oklahoma (Baumgartner in Austin 1968; Norment et al. 2020; Swenk and Stevens 1929).

Judd (1901) examined 100 stomachs taken from October to May, mostly in Saskatchewan, Kansas, and Texas. The analysis covered the migration periods and winter. Stomachs contained 92% vegetable matter and 8% animal matter. Vegetable matter included 42% seeds of ragweeds and smartweeds, 25% seeds of wild fruits and miscellaneous plants, 10% grain (more corn than wheat and oats and chiefly waste grain), 9% grass seeds (mainly foxtails, crabgrasses, June grass, paspalum, and Johnson grass), and 6% seeds of amaranths, lamb's-quarters, wild sunflowers, and gromwell. Animal food consisted of insects, spiders, and snails, including an unusual amount (2%) of leafhoppers. Tame birds in Texas ate grasshoppers, moths, beetles, millet, corn, and canary seed. In Oklahoma, it ate poison ivy berries and elm seeds in addition to weed seeds (Nice 1929). One Nebraska bird ate 14 grasshoppers, 5 beetles, and other larvae and seeds. A Wisconsin bird consumed numerous ants, 2 wireworms, moths, spiders, and a small snail (Swenk and Stevens 1929).

The Harris's Sparrow is readily attracted to feeding stations. It prefers more wooded and brushy areas but will come to residential feeders during severe weather. It feeds predominantly on the ground but prefers to be near tall trees where it can rest and take shelter. It is one of few species that readily eats milo. Its favourite feeder foods were mixed seeds, water, and probably striped sunflower seeds. It infrequently consumed black oil sunflower seeds, millet, and cracked corn (Dunn and Tessaglia-Hymes 1999). In Oklahoma, it was particularly fond of canary seeds and sunflower seeds. Other feeder foods it has eaten include hemp seeds, suet, finely chopped meat, and breakfast cereal (Baumgartner in Austin 1968; Nice 1929; Swenk and Stevens 1929).

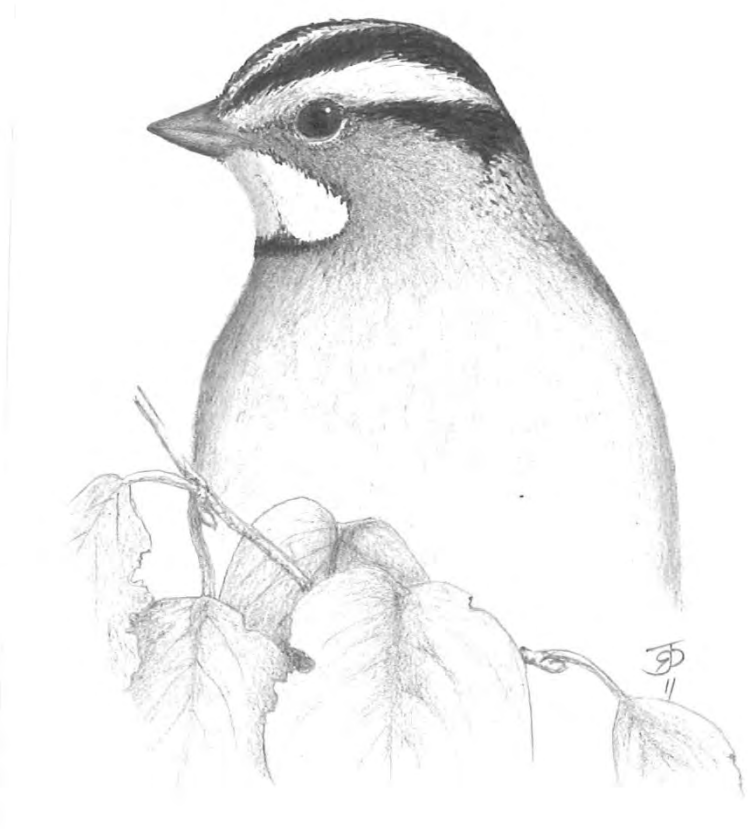
The greatest limiting factor to wintering Harris's Sparrow and probably overall is loss, fragmentation, and degradation of scrub habitats within its United States wintering range. These changes are due to intensification of agriculture (Norment et al. 2020; Wells 2007).

James (1991) considered the Harris's Sparrow a rare winter resident in the south north to Peterborough and in the west at Atikokan and Thunder Bay. In addition to being rare in winter, it is irregular, with Ontario well outside its normal wintering range. Black and Roy (2010) reported 5 winter records for Niagara Region, Curry (2006) reported 4 records for Hamilton, Lancaster et al. (2004) reported 1 record for Elgin County, and Weir (2008) reported 1 record for Kingston.

Christmas Bird Count results from 1965 to 2002 indicated that the Harris's Sparrow declined significantly range-wide at a rate of 1.8% per year (Norment et al. 2020).

White-throated Sparrow

Zonotrichia albicollis



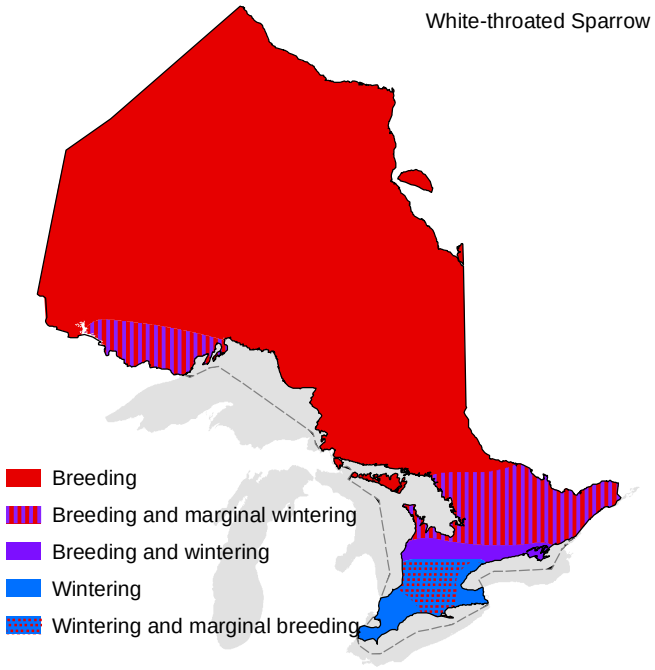
BREEDING SEASON

Habitat Requirements

The White-throated Sparrow has 2 colour morphs of the crown stripe, the white-striped and tan-striped morphs. Birds preferentially mate with birds of the opposite morph. Whether a bird has a white-striped or tan-striped crown affects many aspects of its biology. These may include its aggression and dominance, breeding habitat, contribution to care of young, participation in extra-pair copulations, and timing of spring migration (Falls and Kopachena 2020; Knapton and Falls 1982, 1983; Knapton et al. 1984; Kopachena and Falls 1993a; Lowther 1961).

Most Ontario nests (73.7%) were in woodlands, including 26.6% in coniferous, 20.8% in mixed, 6.9% in deciduous, and 19.3% in unspecified forests. Other nesting habitats included 11.2% in muskeg areas, 5.4% in overgrown fields and shrubby areas, 3.5% in clear-cut and burned forests, 2.7% in swamps and beaver meadows, 2.3% on bedrock outcrops, and 1.2% in bracken fern–

blueberry barrens. The White-throated Sparrow preferred open second-growth woodlands over mature and dense stands. Nests in woodlands were most often at edges, clearings, lake and river shorelines, and along roadsides and survey cuts. It selected dry as well as damp or wet habitats without any clear preference (Peck and James 1987).



In the Hudson Bay Lowland, the White-throated Sparrow nested close to the northern extent of forest along the Hudson and James bay coasts, but was probably more numerous inland. Most observed on Sandy Island in the Moose River were in tall willows and poplars close to the river. Those at the Raft River were among spruce (Manning 1952).

In the Boreal Forest Region, the White-throated Sparrow was associated with open mixed woods with high edge density. In these studies, interfaces between different forest types were considered edge. It was significantly associated with higher amounts of edge and older than average stands. It was also associated with higher levels of disturbance and higher levels of age-class interspersion. It tended to be associated more with conifers than hardwoods and with more intact mature forests (Rempel 2007; Rempel et al. 2007). From Pickle Lake northward, McLaren and McLaren (1981) observed it in all available habitats. It was most abundant in deciduous scrub followed by mixed scrub, coniferous forest with an understorey, heath, deciduous forest, coniferous scrub, mixed forest, coniferous forest without an understorey, and tundra. Near Pickle Lake, James (1980) observed it in open or disturbed woods, bog edges, and about the town. North of Lake Nipigon, it preferred semi-openings and dry alder thickets, but also occurred in dense forest. It used shrubs for refuge and singing, but preferred to sing from trees if they were available, often from the top of 9-m spruce, white birch, or dead trees (Kendeigh 1947). In the same area, it was one of the more common species in immature spruce–balsam fir stands. It frequented the lower crown of the canopy and thickets (Sanders 1970). Near Hearst, Welsh and Fillman (1980) observed it in both uncut and clear-cut upland mixed and lowland coniferous forests. It occurred in all ages of clear-cuts studied, from 3-24 years old. In older clear-cuts, it tended to be more abundant in lowland stands. In young cuts it was equally or more abundant in deciduous stands. In jack pine stands at White River, it was significantly correlated with the earliest stage of succession 3-5 years after clear-cutting. It was a significant indicator of this age class. It was not significantly correlated with any habitat variables that were examined (Venier and Pearce 2005). Welsh (1993) considered it an early successional species throughout the Boreal Forest. Although it occurred in stands 1-200 years old, peak abundance occurred in stands 14 years or less in age. In the Clay Belt, Welsh and Lougheed (1996) found it in all 23 stands they surveyed. These spanned the entire continuums for moisture

regime and nutrient richness. It was most abundant in jack pine stands followed by those dominated by black spruce, trembling aspen, white birch–white spruce, tamarack, balsam poplar, and white cedar.

In white pine forests in the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region, the White-throated Sparrow was equally abundant in mature and old-growth forests older than 130 years. It occurred in about 20% of both age classes of forest (Kirk et al. 2012). In Quetico Park, it occurred in stands 1-370 years old but was most abundant in those 1-23 years old (Apfelbaum and Haney 1985). In jack pine stands near Gogama, it was one of the most ubiquitous species in both pine and mixed forests. Peck and James (1995a) considered it a species of shrub growth in early regeneration or at edges or in openings of older forests. It moved into areas once deciduous shrubs reached a height of 1 m provided that they covered at least 50% of the ground. It was abundant where the pines were less than 10 years old and decreased in successively older stands as the canopy closed. In jack pine stands near Parry Sound, James (1979a) recorded it on all transects. The habitat was open-canopied jack pine mixed with a variety of deciduous species with openings due to wetlands and bedrock outcrops. MacLulich (1938) considered the White-throated Sparrow the most abundant sparrow in Algonquin Park where it was commonly and evenly distributed. It occurred in and near shrubs and was often found far into forest interior. It was more abundant in mixed and coniferous woods than in sugar maple forests. Tozer (2012) reported that it bred in the park in open coniferous and mixed woods, old burns and cutovers, brushy clearings, and borders of bogs, beaver meadows, and old fields. It preferred edges of second-growth coniferous forests with an understorey and an open canopy. In shelterwood cuts in white pine stands in the park, it was observed in 91.7% of 2-9-year-old cuts, 70-83.3% of 10-16-year-old cuts, and 35.7-53.3% of cuts older than 24 years. It was significantly more abundant in young than old cuts. Its abundance was negatively correlated with the deciduous component of the forest, canopy cover, and the extent of herbaceous cover (Kingsley and Nol 1999). In Algonquin Park, Martin (1960) did not find it in bogs or forests dominated by black spruce, black spruce–white cedar, or tolerant hardwoods. In white birch–poplar stands, its activities extended from the ground upward to the lower tree branches above the shrub layer to a height of 4.5 m. It was fourth in abundance in white birch–poplar stands containing balsam fir and spruce. In balsam fir–spruce forests, it was among the most abundant species; it occupied the shrub and lower tree foliage layers. In hemlock stands, it ranged to a height of 6 m, 1 m below the top of the canopy. Lowther and Falls (in Austin 1968) stated that it nested in Algonquin Park most frequently in semiopen stands of balsam fir and spruce and, to a lesser extent, semiopen mixed stands of white birch, poplar, balsam fir, and spruce. It nested in both wet and dry thickets and occurred everywhere except dense spruce forests. Falls and Kopachena (2020) concluded that it was abundant in the park in successional coniferous and mixed forests with openings carpeted with blueberries, but it declined as the forest canopy closed. Males sang mainly from 2-4 song posts that were usually 6-12 m above ground in the outer branches of a spruce. White pines were occasionally used for singing but birches and aspens were avoided. It occasionally sang from a stump or small tree, but never from the ground (Lowther and Falls in Austin 1968). Knapton and Falls (1982) compared the vegetation in territories of pairs of white-morph males and tan-morph females to that of pairs of tan-morph males and white-morph females. In territories of white-morph males, trees were further apart (478 cm compared with 354 cm), there was less wild

sarsaparilla (3.5% compared with 7.0%), less beaked hazel (8.9% compared with 11.3%), less bracken fern (11.2% compared with 13.0%), and more blueberries (12.7% compared with 9.3%). Characteristics that were similar in white- and tan-morph males' territories included: reindeer lichen, 2.1% and 1.4%; grasses, 8.1% and 5.8%; orange hawkweed, 1.2% and 1.6%; American fly honeysuckle, 8.3% and 6.4%; and Canada mayflower, 1.2% and 1.6%. Territories of white-morph males were predominantly in open habitat. Tan-morph males occupied a broader range of habitat from the open habitats occupied by white-morph males to dense habitats not used by white-morph males. Only 3 of 37 plant species differed in their abundance within 30 cm of nests of white- and tan-morph males, respectively: large-leaved aster, 17% compared with 44%; American fly honeysuckle, 25% compared with 48%; and raspberries, 33% compared with 12%. Tree size, distance between trees, and coverage by trees and shrubs near the nest did not differ for the morphs. Trembling aspen occurred more often than expected near nests of tan-morph females, but it was considered unlikely that females chose nest sites based on the species of the nearby trees. Results indicated a greater proportion of tan males inhabiting dense habitat but there was no simple habitat division by the morphs. The morphs foraged in similar manners within and around their territories and did not behave as though they were separate species. The plants that occurred most frequently and with the greatest cover values did not differ between the morphs, and the structural habitat of the morphs was similar. Tan morphs nesting in dense habitat were equally successful as those nesting in more open habitat. Tan morphs may be better adapted to nesting in denser habitat because they are smaller and have shorter wings. They may select dense habitat rather than being excluded from open habitat by white morphs. In Muskoka District and Haliburton County, the White-throated Sparrow was negatively correlated with increasing canopy volume and tree density. It was positively associated with shrubby areas, lawns in highly developed cottage areas, high coniferous composition, and dense understorey. Its preference for an open canopy with a well-developed understorey made it well suited for inhabiting cottage lots in coniferous woods where most of the tree layer had been removed (Clark et al. 1983).

South of the Canadian Shield, the White-throated Sparrow was positively correlated with the amount of forest 100 m or more distant from an edge, woodlot size, amount of forest cover within 2 km, and the amount of regional forest cover. The relationship with the amount of forest core area was the only one that was significant (Austen et al. 2001). In Durham Region in the Great Lakes–St. Lawrence Forest Region, Speirs and Orenstein (1975) observed it in wet forests with open canopies and in a black spruce bog surrounded by a red maple–poplar swamp. They considered it associated with white cedar and mid-succession forests.

In the Carolinian Forest Region, the White-throated Sparrow is confined to isolated patches of conifers, especially white cedar swamps and spruce bogs (Lowther and Falls in Austin 1968). Near Cambridge, McIlwraith (1894) found it breeding in tamaracks surrounding a pond. In Halton Region and the Flamborough area of Hamilton, it nests in white cedar swamps (Curry 2006). It is a rare breeder in Elgin County swamps (Lancaster et al. 2004).

Throughout its range, the White-throated Sparrow nests in a variety of treed and shrubby habitats. Lowther and Falls (in Austin 1968) stated that it normally nests in coniferous forests in the east, preferring spruce and balsam fir, but that it often breeds in clear-cuts. In western Canada, it

breeds in aspen parkland and the Boreal Forest Region, in areas dominated by mature trembling aspen growing in semiopen stands with occasional dense groves of smaller trembling aspen and scattered white spruce and white birch, and groves of willows along seepages and watercourses. In Newfoundland and Labrador, it nests in high rock barrens with clumps of dwarf spruce and tamarack, in black spruce around borders of open sphagnum bogs, in clear-cuts, second growth, open woods, and hillsides. At Churchill, maximum density occurred where spruce forest reached its maximum density and a height of 10.7 m, but only where openings were present such as roadsides and railways. In Maine, highest densities occurred at high elevations on mountains where thin soils supported only stunted and widely spaced trees. Falls and Kopachena (2020) considered it a habitat generalist and an edge species. It breeds in coniferous, mixed, and deciduous forests, especially those having numerous openings with dense low shrubby ground cover. It is abundant in second growth after logging, fires, and insect damage; around margins of ponds, lakes, rivers, bogs, and beaver meadows; in and around clumps of trees near the treeline; where rock outcroppings create openings in the forest canopy; in clearings around cottages and along roads, railways, and utility rights-of-way; and in shrubby field edges and overgrown pastures. It avoids very dense spruce forest. In the east and north, it occurs mostly in coniferous forests of spruce, balsam fir, hemlock, white cedar, tamarack, and pine, often mixed with poplars, white birch, and alder. In the Boreal Forest Region, Erskine (1977) considered it typical of black spruce forest and one of the most characteristic species of the boreal forest. It is common in spruce and balsam fir stands, found in most jack pine stands, and also occurs in tamarack and bog forests. It is more common in young than mature stands and is one of the most regular species in young deciduous stands. Within poplar–white birch stands, it is associated with scattered spruce and balsam fir with an open canopy or small trees. It inhabits both coniferous and deciduous stands, particularly at edges or in or near openings. It is common in burns and clear-cuts where there is nearby shrubbery and a litter layer on the soil that has survived burning. It occurs in bogs where there are more or taller trees rather than open bogs. In Quebec, it was especially common in coniferous and mixed forests, but also abundant in deciduous forests and in urban and agricultural landscapes where small mixed and deciduous woodlots are common and provide suitable habitat. Near the northern extent of its distribution, it frequents shoreline scrub, burns, and black spruce–moss stands. In the Nottaway, Broadback, and Rupert watersheds of Quebec, it was more abundant in old and recent burns than in any other habitat. Shoreline scrub was favoured in the Eastmain River watershed (Spencer et al. in Gauthier and Aubry 1996). In black spruce forest in Quebec, it was associated with younger forest stages. It was most abundant in recent burns and cuts where shrubs were 2-5 m tall, and significantly less abundant in burns and cuts with saplings 5-11 m tall and in forests 120 and 200 years old. Open habitats were dominated by the White-throated Sparrow, with it representing 37% of all birds in young burns and cuts (Imbeau et al. 1999). Also in Quebec, it was abundant in strip-cuts, especially final cuts, and in clear-cuts. It was much more abundant in newly created strips than in older strips where vegetation regrowth created a closed canopy (Falardeau et al. 1999). In New Brunswick, it was one of the dominant species in spruce plantations 20 years or less in age and was uncommon to absent in natural spruce forests. In Nova Scotia clear-cuts in northern hardwoods, it was one of the dominant species. It was characteristic of stands 12 years old and younger, although it occurred in the oldest stand examined (74 years) at very low density. It was significantly correlated with high coverage by slash, abundant ground cover, and high shrub stem density (Freedman and Johnson 1999; Morgan

and Freedman 1986). In the Prairie Provinces, it demonstrated a pronounced increase in abundance from coniferous to deciduous sites. It was associated mostly with mixed or deciduous forests, but also occurred in black spruce and species-poor jack pine stands. Its habitat averaged moderate on the nutrient and wetness scales (Kirk et al. 1996). In boreal areas of British Columbia, it nests in a variety of shrub-dominated habitats. These include mature deciduous, mixed, and floodplain forests with dense shrub growth; recent burns and clear-cuts; and forest edge habitats around beaver ponds, wetlands, and bogs. It prefers trembling aspen stands with dense shrub undergrowth. Along rivers, it is most common in mature deciduous riparian forests dominated by trembling aspen or balsam poplar and birch, followed by mature coniferous riparian forests. Preferred balsam poplar stands often have a dense undergrowth of red-osier dogwood (Campbell et al. 2001). In the Yukon, it is abundant in shrubby old-growth white spruce and mixed forests, shrubby balsam poplar and riparian forests, and shrubby clear-cuts and burns (Sinclair et al. 2003). In the northeast, Taylor and Taylor (1979) considered the White-throated Sparrow a species of small forest openings, edges, and forest edge, but not of large openings. In New Hampshire, Wasserman (1980) reported densest populations in semiopen fields where the dominant vegetation was common juniper approximately 1 m tall and often several metres in diameter. In Indiana, Grundel and Pavlovic (2007b) did not consider it characteristic of any habitat. It nested in open prairie remnants with little overhead canopy or subcanopy, savannahs, scrub, woodlands, and forest. It was most abundant in woodlands that were open forests with more canopy cover than savannahs. The White-throated Sparrow rarely nests in urban habitat. What was possibly the same pair nested in 4 years in the business section of Buffalo in an intensively developed area. The area was completely dominated by buildings, streets, and other paved structures. The birds nested in ornamental plantings along the foundation of a church (Andrle 1974; Andrle and Rew 1971). In Saskatchewan, 1 pair raised young in a Saskatoon yard (Leighton et al. 2002).

Three studies examined habitat preferences of the White-throated Sparrow at the landscape level. In Minnesota, it was positively correlated with the interspersion of habitat types within 1 km^2 (Crozier and Niemi 2003). In Saskatchewan, it was more common in large forest fragments or in areas with high local forest cover within 5 km. It was randomly distributed among fragmented and intact landscapes (Hobson and Bayne 2000). In Newfoundland, it occurred in 83% of landscapes containing some clear-cuts, 76% of natural landscapes, and 79% overall. It declined as the amount of woodland increased in both landscape types, from almost 100% occupancy at 10% forest cover, dropping to 65% at 95% forest cover (Taylor and Krawchuk 2005).

The White-throated Sparrow nests in all age classes of forests, but is most abundant in early successional and old stands; reproductive success is also greatest in these stands (Falls and Kopachena 2020). It is probable that stand structure is more important than its age. It prefers forests with an open canopy and a shrubby understorey. The earliest stages of succession provide this structure as do older forests where treefalls create gaps in the canopy. In Quebec, Rousseau et al. (2012) concluded that it could be considered a generalist because it nested in forest habitats from 1 month-old clear-cuts to mature stands. It was unknown if females preferred mature forests; it might be a generalist species with specialist individuals. In New York, it increased over 35 years in an open agricultural field that became a second-growth forest, but there was no change over 33 years in a mixed forest (Brooks and Bonter 2010). In northeastern northern hardwoods, it occurred on 8%

of plots in mature undisturbed habitats and 23% of plots in disturbed and early successional habitats (Noon et al. 1979). Temple et al. (1979) did not consider it characteristic of any forest age class in northeastern mixed forests. Niemi and Pfannmuller (1979) considered it ubiquitous in early successional habitats in the northeast. Kirk et al. (1996) considered it a very early successional species in forests in the Prairie Provinces. In Newfoundland balsam fir stands, it was most abundant in old stands. These were somewhat more open, had larger dead standing trees, more shrub coverage, and the most large woody debris on the ground (Thompson et al. 1999). In Vermont, it was associated with low successional age (Lent and Capen 1995). In trembling aspen stands in Alberta, it was significantly more abundant in forests older than 120 years than in forests 51-63 and 23-26 years old. It was more abundant in the young stands than in intermediate-aged stands, but not significantly. Old stands had significantly fewer trees per ha than other age classes (Schieck et al. 1995). In British Columbia trembling aspen stands, it was common in mature forests and in clear-cuts 5-20 years after cutting (Campbell et al. 2001).

Several studies examined microhabitat preferences of the White-throated Sparrow. In Minnesota, its abundance was positively correlated with the density of dead trees but was unrelated to habitat complexity (Niemi and Hanowski 1984a). In New Hampshire and Maine, it was associated mostly with poplar followed in decreasing order by white pine, spruce–balsam fir, balsam fir, northern hardwoods, hemlock, and hardwood swamp stands. It was absent in white birch stands. It was positively correlated with coniferous trees larger than 10 cm diameter at breast height (DBH) and number of woody stems per ha. It was negatively correlated with foliage volume of both coniferous and deciduous trees larger than 10 cm DBH and foliage volume of deciduous stems smaller than 2 cm DBH (DeGraaf et al. 1998). In northeastern mixed forests, it was associated with increasing abundance of trembling aspen (Temple et al. 1979). In Saskatchewan, it was more common than expected in trembling aspen stands (Hobson and Bayne 2000). In Newfoundland balsam fir stands, it was significantly more abundant in sites that were nutrient-rich than nutrient-poor (Thompson et al. 1999). In Newfoundland, nests were in areas that were more characteristic of open and harvested areas. There was more downed wood and less tall vegetative ground cover within a 1-m radius of nests than in random areas. Within a 5-m radius, nest-site characteristics did not differ from random sites. Successful nests had a more open canopy and less downed small wood than unsuccessful nests at both the 1-m and 5-m scales. Successful nests had more coarse woody debris than unsuccessful nests at the 1-m scale but there was no significant difference at the 5-m scale. Tall vegetation occurred within the territory and was characteristic of the nest site at a larger scale, but was not selected for at the nest microsite. It did not nest in more open canopy, but success was associated with less canopy cover (Dalley et al. 2008). Lowther and Falls (in Austin 1968) described microhabitat within the vicinity of nest sites. Within 15 m of the nest, there was usually 1 large object or group of objects such as a tree, stump, shrub, or log. There was a positive correlation between the height of the object and its distance from the nest. These objects may provide a lookout prior to flying down to the nest. The amount of cover within 3 m of the nest was similar to the general nesting habitat but there was much less variation within 3 m. It selected nest sites in relation to the amount and dispersion of the nearby cover. The nesting habitat could be described as forest edge. In subalpine areas of New Hampshire, it nested predominantly in high-elevation mixed and coniferous stands, but extended upwards into the tundra zone. Mean habitat

characteristics included exposed upper slope to upper mid-slope, no water or slight wet depressions present, canopy height 5.0 m, 45% canopy coverage, 75% conifer foliage volume, 41% conifer foliage volume at 0-2 m, 12% deciduous foliage volume at 0-5 m, and 8 cm DBH live trees (Sabo 1980). On Wisconsin islands, it was significantly correlated with aspen and preferred pioneer forests of aspen and pine forests. It was the most abundant species in young aspen stands (Beals 1960). In Vermont, it exhibited strong clumping of territories in logged patches and was absent in undisturbed forest. It was associated with low successional age, increasing coverage by conifers, and moderate amounts of dead trees. It was also associated with low coverage by hophornbeam, red oak, sugar maple, and beech; decreasing coverage of red maple; and moderate amounts of poplars and white pine. Its habitat was ephemeral so it may adapt a fugitive strategy as it seeks nesting habitat in the shifting mosaic of habitat patches in spring. Lent and Capen (1995) considered it a gap-specialist species. In Maine spruce–balsam fir stands, it was positively correlated with raspberries, woody stems less than 10 cm DBH and 2.1-4.5 m tall, and slash 0-1.0 m from the ground. It was negatively correlated with woody stems greater than 10 cm DBH and more than 4.5 m tall, slash higher than 1 m, deciduous trees 15-20 cm DBH, and conifers larger than 20 cm DBH (Titterington et al. 1979). In clear-cuts in northern hardwoods in Vermont, mean habitat characteristics were 84.7% green ground cover, 9.1% ground cover slash, 32.0% canopy closure, 9.4 m canopy height, 6.5 m canopy depth, 4.2 m^2 basal area of deciduous trees, 1.0 m^2 basal area of conifers, 7.0 cm DBH for deciduous trees, and 8.5 cm DBH for conifers. It occurred in habitats with dense vegetation less than 3 m tall and no overhead canopy such as clear-cuts with dense hardwood saplings (Thompson and Capen 1986). In Minnesota, it was negatively correlated with tree size and density and the number of different habitats present in the landscape (Crozier and Niemi 2003).

In Alberta, both white- and tan-morph males occurred in forest interior, edges, and clear-cuts but white morphs were most abundant in edge and tan morphs were most abundant in forest interior. In New York, white morphs tended to cluster in contiguous suitable habitat. Tan morphs occurred in more isolated patches. Territories sometimes supported the opposite-coloured morph in different years (Falls and Kopachena 2020).

In subalpine habitat in New Hampshire, the White-throated Sparrow used clearing edges with a lookout for nesting. The Dark-eyed Junco used dense shrub clumps with a rock outcrop or exposed bank. The 5 forest-floor species were separated by the Winter Wren's speciality for fallen logs, the junco's use of twig pecks while foraging and use of the understorey, the White-throated Sparrow using both twig and litter pecks, and the Swainson's and Gray-cheeked thrushes pecking and gleaning in the litter and also feeding in the understorey (Sabo 1980).

The White-throated Sparrow nests in clear-cuts, forest edges, and forest interior, but is commonly termed an edge species because it is often more abundant in this habitat (Freemark and Collins 1992; Taylor and Krawchuk 2005). Along an interstate highway in Maine, it was most abundant within 100 m of the highway (Ferris 1979). In Newfoundland, it was significantly more abundant at clear-cut and access road edges than in forest interior; abundance at riparian edges was intermediate. Whitaker and Montevecchi (1997) considered it an open or edge species associated with early successional openings and edges. In balsam fir–white cedar stands in

Newfoundland, there was no significant difference in its abundance in riparian stands with a narrow strip of alder-grass wetland and in nonriparian stands (Whitaker and Montevecchi 1995). In Alberta stands of trembling aspen, balsam poplar, white spruce, and white birch, density was highest in edge and lowest in clear-cuts. There were no significant differences in settlement dates, but it was slightly earlier in edges and forest interior than in clear-cuts. Fewer territories were abandoned after unsuccessful reproduction in forest interior (5.4%) than in edge (17.2%) and clear-cuts (65.8%). The proportion of territories fledging young was significantly lower in clear-cuts (19-23%) than in edge (32-35%) and forest interior (35-55%) in 2 years. Pairing success was significantly higher in forest edge and forest interior than in clear-cuts; habitat was a significant predictor of pairing success. Territory density was not a useful indicator of habitat quality. Edges had the highest density but were not the highest quality for pairing success, nesting success, or fledgling production. Clear-cuts represented lower-quality habitat and forest interior was higher-quality habitat. Individuals did not select the highest-quality territories first in spring. Body condition indices were higher in edge habitats suggesting that they provided greater food availability. Differences in nesting success may have reflected pairing success because predation and parasitism rates were not significantly different among habitats. Females may opt to mate with males in more intact habitat such as forest interior and edge. Individuals in clear-cuts were apparently unable to effectively evaluate habitat quality during territory establishment and suffered reduced reproductive success (Hannah et al. 2008). In another Alberta study, Villard et al. (2007) predicted that the White-throated Sparrow would be attracted to edges created by clear-cuts, but its response was neutral and nonsignificant. The mean distance to edge averaged 40 m 1 and 2 years after clear-cutting.

The White-throated Sparrow is not an area-sensitive species and may occupy very small habitat patches. Morse (1977) studied the distribution of birds on small islands (0.1-0.4 ha) in Maine. The White-throated Sparrow occurred only on islands that were as large as its mean territory size. The smallest island it occurred on was 0.49 ha, the same size as the mean territory size. The size of the next smallest island was 0.39 ha. Islands with the highest densities of Song Sparrows did not support White-throated Sparrows. In downtown Buffalo, the White-throated Sparrow occupied a small triangle of habitat that was a maximum of 0.18 ha (Andrle and Kew 1971).

Ninety percent of Ontario nests were on or near the ground and the others were elevated in shrubs, trees, brush, or fallen trees. Most ground nests (53.7%) were under low shrubs (commonly blueberries) and trees, and were usually well concealed by grasses, bracken ferns, and other plants; 21.5% were in grass clumps; 14.8% were in mosses with grasses and sedges; 8.1% were in weedy plants and ferns; 0.7% were in leaf litter; 0.7% were under logs; and 0.4% were under roots. Some ground nests were somewhat sunken into the substrate. Approximately equal numbers of elevated nests were in deciduous shrubs and small conifers. Nest heights were 0.2-0.9 m, mostly 0.2-0.5 m. One nest was 2.4 m from the ground in a fallen cedar supported by another cedar (Peck and James 1987). In Algonquin Park, the White-throated Sparrow preferred to nest in clearings large enough to allow direct sunlight to strike the ground vegetation at some time of the day. Of 42 nests, 36 were under blueberries and the remainder were under sweet fern, beaked hazel, hair-cap moss, or mountain-rice grass. Of the 36 under blueberries, 28 were under plants 15-30 cm tall. Two nests were under cover less than 15 cm tall and 13 were under cover taller than 30 cm. Thirty-six nests were on level ground and 2 of the 6 nests on sloping ground were in the middle of 3-m

embankments. Canopies were present over 34 of the 42 nests. Twenty-nine nests were under a mat of dead bracken fern from the previous year, 4 were under clumps of dried mountain-rice grass, and 1 was under the tip of a lower branch of a spruce. The 8 nests without overhead cover were either in vegetation taller than 30 cm or built later in the season in cover lacking an overstorey of live bracken fern. The White-throated Sparrow usually nested on the ground in areas of small trees between which there were clumps of beaked hazel and a ground flora of blueberries and various grasses and forbs. Six replacement nests were all within 33 m of the first nest. Of 197 nests in Algonquin Park, 6 (4.7%) were above ground: 23 cm up on the lower bough of a white spruce, 1 on the bough of a fallen white spruce, 15 cm up in a blueberry, 5 cm up among blueberry and sweet fern stems, 53 cm up in sweet gale, and 76 cm up in bracken fern. Of 54 nests initiated after 15 June, 11.1% were elevated. It was not known to reuse nests (Falls and Kopachena 2020; Lowther and Falls in Austin 1968). In the Hudson Bay Lowland, all nests were on the ground in mixed spruce–deciduous growth (Schueler et al. 1974).

All 34 British Columbia nests were on the ground except for one in a pile of river debris. They were usually well concealed beneath the shrub layer in grass clumps or under other low vegetation. Several were at the base of a deciduous shrub or sapling and one was underneath an upturned root. Most were in or near natural forest openings or human-made clearings such as road or hydro corridors, seismic cuts, clear-cuts, footpaths, and fields. Several were among or near deadfalls or other natural accumulations of woody debris, or near human-created brush piles. The single elevated nest was 1 m from the ground (Campbell et al. 2001). A New Hampshire nest was on the ground under a common juniper. When it failed, the replacement nest was built 15 cm from the ground in a juniper 35 m from the first nest. The first nest was within 10 m of the male's centre of activity. The second one was between the activity centres of 2 adjacent pairs in an area that was infrequently used (Wasserman 1980). An Ohio nest was 0.9 m from the ground well hidden among the branches of a fallen spruce (Davis 1973). In Newfoundland, 32 nests were on the ground and one was 0.5 m from the ground in a balsam fir. Twenty-five nests (75.8%) were in moss (Dalley et al. 2008). In New Brunswick, Philipp and Bowdish (1917) found 2 nests, both of which were elevated in small spruce; 1 was 101.6 cm from the ground. In New York, nests were at the base of a clump of grass or a small shrub. Tan-morph females nested closer to the ground and in brighter light than white-morph females. There was no significant difference in the placement of nests of the morphs for these characteristics in Algonquin Park (Falls and Kopachena 2020).

Territorial activity is greatest in spring and involves singing and chasing of intruders to just beyond the territory boundaries. Interactions with neighbours decrease with time but responses to strangers remain strong. Males establish territories as soon as spring flocks break up. Singing is greatly reduced in early June when nesting is underway but resumes in July for second nestings. Territories are maintained until the last brood fledges. Fledglings that leave the territory are accompanied by only the female. The male remains on the territory but no longer defends it. Singing is concentrated at a few song posts which may influence the territory location and results in uneven usage of the territory by the male. White-morph males are more responsive to other males' songs than tan morphs and are more aggressive in defending their territories. White-morph females may participate in territorial defence but tan morphs do not. In Algonquin Park, females may nest anywhere within the territory or rarely in areas defended by neighbours. In these cases, either the

territory boundaries are shifted or the nest is abandoned. Females in New Hampshire nested predominantly in the centre of the territory and males concentrated their activities within 15 m of the nest site. The area in which males sang ranged from 1,200 to 7,200 m^2 with the least area used during the incubation and nestling periods and the most during the fledgling period. The male spent more than 50% of his time in the same 100 m^2 quadrant as the female when she arrived. The amount of time spent together decreased during incubation, increased during mating activities for replacement or second nests, then decreased. Males appear to conduct all their activities in the territory but females may leave the territory to forage. North of Lake Nipigon, there was no overlap in territories. Territories in clear-cuts were frequently contiguous but those in forest cover were often isolated. One case of polyterritoriality has been documented with the 2 territories 300 m apart (Falls 1988; Falls and Kopachena 2020; Kendeigh 1947; Kopachena and Falls 1993a; Lowther and Falls in Austin 1968; Wasserman 1980, 1982, 1986). There is no significant difference in the size of territories of white- and tan-morph males. In Algonquin Park, 90 territories averaged 0.99 ha (range 0.22-3.26 ha). Territory sizes tended to decrease from the time that females arrived until the young fledged. An earlier study at Algonquin Park determined that average territory sizes were 0.77 ha (range 0.36-1.29 ha) for 20 mated males and 1.01 ha (range 0.61-1.13 ha) for 3 unmated males (Falls and Kopachena 2020; Lowther and Falls in Austin 1968). Another Algonquin Park study determined the average size of 110 territories to be 0.21 ha (range 0.02-1.09 ha; Martin 1960). North of Lake Nipigon, 20 territories averaged 0.47 ha (range 0.20-0.97 ha). Fourteen forested territories averaged 0.49 ha and 6 territories in clear-cuts averaged 0.36 ha (Kendeigh 1947). In Algonquin Park, nonterritorial males wandered through territories quietly and covered areas that averaged 3.6 times the home range of territorial birds (Falls and Kopachena 2020). In Maine, mean territory sizes in mainland spruce forests were 0.35 ha in damaged spruce stands, 0.49 ha in edges of spruce forests, and 1.67 ha in white spruce forests. Mean territory size in white spruce stands on small islands was 0.49 ha (Morse 1977). In subalpine forests in New Hampshire, territories averaged 0.6 ha (Sabo 1980). In Quebec, mean territory size was 0.79 ha in balsam fir forest with scattered white spruce, black spruce, and white birch (Rousseau et al. 2012).

Natal philopatry rates are very low, but few young have been banded. In Algonquin Park, 0 of 65 nestlings returned (Knapton et al. 1984) and 0 of 21 nestlings returned in Alberta (Hannah et al. 2008).

In Algonquin Park, 19 of 47 males (40.4%) and 3 of 30 females (10.0%) were retrapped on the same territory in the following year (Lowther and Falls in Austin 1968). In another Algonquin Park study, the percentage of returning males over 2 years was 50.0% and 47.6% for white-morph and 52.4% and 39.1% for tan-morph males; the differences were not significant (Knapton et al. 1984). The return rate estimates may have been low because a male that returned to an area just outside the study area would not have been detected. In 1 year, 3 of 55 females (5.5%) returned and all were white morphs. Two returned to the same territory but to a different mate. The following year, 4 of 43 females (9.3%) returned. These included 3 white morphs and 1 tan morph, with 2 returning to the same territory. Forty percent of successful males and 54.5% of unsuccessful males returned the following year; the difference was not significant. In New York, 60% of males and 46% of females returned in a subsequent year. Sixty percent of white-morph males and 40% of white-morph females returned compared with 66% of tan-morph males and 50% of tan-morph females. Most

birds reoccupy the same territory but some birds of both sexes move so the estimated return rates are probably low (Falls and Kopachena 2020). In Alberta, 29 of 73 adult males (39.7%) returned: 41.9% in 1 year and 36.7% in another year. In forest interior, the return rate was 44.4% compared with 41.2% in forest edge habitat, and 25.0% in clear-cuts (Hannah et al. 2008). In Quebec, Rousseau et al. (2012) reported adult male return rates of 35% in mature forests and 50% in recent clear-cuts, 90% territory fidelity in forest interior and 100% in clear-cuts, and 33 m median dispersal distance in forest interior and 46 m in clear-cuts. Treatment plots were partially clear-cut in winter after breeding birds had been banded. Return rates were similar between control (35%) and treatment plots (41%). Territory fidelity was significantly higher for control (90%) than treatment (50%) plots. The mean dispersal distance of treatment males (86 m) was significantly greater than for control males (33 m). The higher the proportion of the original territory that was clear-cut, the further the male dispersed. Two males dispersed more than 700 m.

Limiting Factors

Eggs have been reported in Ontario nests from mid-May until mid-August, with most present in June (Peck and James 1987). Almost all information on nesting phenology is from Algonquin Park. Nests are under construction there from mid-May to late July, eggs are present mid-May to early August, nestlings are present from late May to mid-August, and fledglings have been observed from late May to mid-August (Tozer 2012). Pair formation begins immediately upon the female's arrival in tan-morph male–white-morph female pairs and within a few days for pairs comprised of white-morph males and tan-morph females. Most birds are paired before the end of the third week of May in the park. Nest building starts in the third and fourth weeks of May, as much as 2 weeks after pair formation for pairs with tan-morph males and within a few days for pairs with white-morph males. Nest building takes 4-6 days early in the season and 2 days for later nests. Laying usually starts 1-2 days after nest completion. In 1 year in the park, pairs with tan-morph males initiated egg laying significantly earlier by 5 days than pairs with white-morph males but there was no significant difference the next year when all clutches were initiated approximately 9 days later. Most first eggs were laid 21-27 May between 1986 and 1990, with the earliest egg laid on 15 May. First clutches are highly synchronized but synchrony declines with season. One egg is laid per day. Incubation usually starts with the laying of the last egg in clutches of 4 or fewer eggs. Incubation starts with the penultimate egg in 5-egg clutches. The incubation period in Algonquin Park and the remainder of Ontario is 11-13 days, with 12-14 days reported elsewhere. In smaller clutches, the eggs all hatch on the same day but in 5-egg clutches the last egg hatches a day later. The nestling period in the park is 7-12 days, but mostly 8 or 9 days, particularly in the morning of the ninth day (Falls and Kopachena 2020; Knapton et al. 1984; Kopachena and Falls 1991, 1993a; Lowther and Falls in Austin 1968; Peck and James 1987).

The White-throated Sparrow may raise either 1 or 2 broods in a season. Double broods have been confirmed in Ontario at Rutherglen and Algonquin Park. In the park, pairs fledging young before the end of June may attempt a second brood but it is unlikely that a second brood will be attempted after the first week of July. Of 11 pairs that fledged young before 7 July in the park, 6 (54.5%) attempted second broods. Double broods have been attributed to high abundance of food during spruce budworm outbreaks, but budworm populations were not particularly high when this study was completed. It is probably frequently double brooded provided that the first brood fledges

early enough. It is possible that double broods occur only in the more southern portions of its range. In 2 cases in Algonquin Park, females laid the first egg of the second clutch 4 days after the first brood fledged. There was an average of 8.5 days between fledging and incubation of the second clutch. In New York, almost all females have 2 broods. In Quebec, egg dates suggest double broods but this has not been confirmed. Only single broods have been reported in British Columbia (Campbell et al. 2001; Falls and Kopachena 2020; Knapton et al. 1984; Kopachena and Falls 1993a; Lowther and Falls in Austin 1968; Spencer et al. in Gauthier and Aubry 1996). In 1971 and 1972 in Algonquin Park, 24 pairs were double brooded and 1 pair attempted a third brood in 1972. The first brood of 4 fledged on 14 June and both adults were observed tending fledglings on 27 July that appeared to have been out of the nest for about 2 weeks. On the same day, the female was flushed from a nest that contained 3 eggs. The eggs hatched on 31 July but all young perished by 4 August. Poor survival in August is normal due to depletion of food resources and a decline in parental attention. This pair successfully raised 2 broods and hatched a third in 70 days (Loncke and Falls 1973). The White-throated Sparrow commonly renests if the previous nest is unsuccessful. In Algonquin Park, 16 of 50 pairs (32.0%) that lost their nest initiated a replacement nest and 1 pair renested after 2 failures. For 6 pairs, there was an average of 8.7 days between nest loss and incubation of the replacement clutch (Falls and Kopachena 2020; Knapton et al. 1984; Kopachena and Falls 1993a; Lowther and Falls in Austin 1968). Clutches of 2-5 eggs have been reported in Ontario with 4- and 5-egg clutches most frequent; 63.3% of clutches contained 4 eggs. The average clutch size was 4.00 eggs (Peck and James 1987). In Algonquin Park, 41 clutches had an average of 4.1 eggs (range 3-5 eggs). In 2 years in another Algonquin Park study, clutch sizes for tan-morph females were 4.19 and 4.27 eggs compared with 4.50 and 4.11 eggs for white-morph females. There was no significant difference in clutch size of the morphs in either year or any evidence that clutch size declined with season (Knapton et al. 1984; Lowther and Falls in Austin 1968). Clutches typically contain 3-5 eggs with 1 record of a 7-egg clutch from Saskatchewan. It is possible that the large clutch was due to intraspecific parasitism. Mean clutch size throughout the range of the White-throated Sparrow, excluding Ontario, is 4.3 eggs. In Maine, mean clutch sizes were 3.81 for white-morph females and 3.78 for tan-morph females. Mean clutch size in Newfoundland was 3.85; 50% of British Columbia clutches contained 4 eggs (Campbell et al. 2001; Dalley et al. 2009; Falls and Kopachena 2020; Lowther and Falls in Austin 1968).

Both sexes of both morphs are capable of breeding when they are 1 year old. Populations often contain nonterritorial floaters and unmated males, suggesting that some yearling males are unsuccessful in attracting a mate (Falls and Kopachena 2020; Lowther 1961). The assortative mating, whereby a bird of 1 morph typically mates with a bird of the opposite morph, appears to be unique among birds. The differences in plumage are independent of both sex and age. White morphs have a single M chromosome that is lacking in the tan morphs. Because of the assortative mating, neither morph is selected for genetically. Of 110 pairs in Algonquin Park, 79 were white-morph males x tan-morph females (60 expected), 27 were tan-morph x white-morph females (8 expected), 4 were tan-morph males x tan-morph females (23 expected), and 0 were white-morph males x white-morph females. The number of all pair-type combinations was significantly different from random. In Algonquin Park, over 90% of the breeding population consists of 2 pair types: white-morph males x tan-morph females and tan-morph males x white-morph females. In another sample of 180 pairs in

Algonquin Park, 65% were white-morph males x tan-morph females, 33.3% were tan-morph males x white-morph females, 1.6% were white-morph males x white-morph females, and 0% were tan-morph males x tan-morph females. When a bird loses a mate, its replacement mate is usually the same morph as the original mate. There is no difference in the reproductive success of the 2 morphs (Falls and Kopachena 2020; Knapton and Falls 1983; Knapton et al. 1984; Kopachena and Falls 1993a; Kuenzel and Helms 1974; Lowther 1961).

The White-throated Sparrow is typically monogamous, but polygyny occasionally occurs. In Alberta, polygynous matings occurred in forest interior and edge, but not in clear-cuts. Polygynous matings typically consist of 1 white-morph male mated with 2 tan-morph females. One case of polyterritorial polygyny has been reported (Falls and Kopachena 2020; Hannah et al. 2008). Pairs usually remain together for the entire breeding season but not between breeding seasons. If a mate is lost, it is usually replaced until incubation begins and infrequently thereafter. Extra-pair copulations are a common breeding strategy. Tan-morph males spend 67% of their time mate guarding when the female is fertile. White-morph males spend more time seeking extra-pair copulations. In New York, 18 of 89 nestlings (20.2%) were a result of either extra-pair copulations or intraspecific parasitism. Both common pair types are recipients of extra-pair copulations. Seventy-nine percent of intrusions were by white-morph males and 21% were by tan-morph males; 75% of observed extra-pair copulation attempts were by neighbours. In Algonquin Park, there were 2 cases of white-morph nestlings in tan x tan-morph matings, indicating either extra-pair copulation or intraspecific parasitism. Two cases of intraspecific brood parasitism have been confirmed and a clutch of 7 eggs suggests another (Falls and Kopachena 2020). In New York, 31.8% of nestlings were extra-pair and 56.3% of broods from white-morph males and tan-morph females contained extra-pair offspring. These numbers were only 4.4% and 6.3% respectively for tan-morph male and white-morph female pairs. In another New York study, 182 of 1,183 nestlings (15.4%) were extra-pair and 26.6% of nests contained extra-pair young. Extra-pair young were present in 41.7% of nests with white-morph males compared with 8.7% of nests with tan-morph males. The relationship between breeding synchrony and extra-pair paternity was highly significant in nests of white-morph males, but highly nonsignificant in nests of tan-morph males. Neighbours constituted 29.5% of the extra-pair sires, significantly more than the expected 4%. White-morph males are responsible for most extra-pair paternity, but also lose more paternity (Grunst et al. 2017).

The White-throated Sparrow forages on the ground and vegetation, and frequently on small shrubs or lower portions of coniferous trees on the upper surfaces of horizontal branches. Males may forage near treetops between singing bouts. It clears away leaf litter by kicking with both legs simultaneously. It is able to find deeply buried seeds and is adapted to foraging near woody vegetation where the litter is deep. It also flips leaves side to side with its bill. In vegetation, it gleans along stems and through leaves or needles, especially near branch nodes or tips. It pounces on active insects, eats the pulpy part of fruits, and flycatches. It eats only the pulpy parts of fruits and does not eat skins or large seeds. In Algonquin Park, it has been observed chasing and catching dragonflies and may forage aerially on spruce budworm moths during outbreaks. In downtown Buffalo, the male occasionally sallied for insects in ivy growing on a church (Andrle 1974; Falls and Kopachena 2020; Lowther and Falls in Austin 1968). In subalpine areas of New Hampshire, 9.2% of foraging was by leaf gleaning, 0% by flycatching, 0.7% by leaf hawking, 0.2% by leaf hovering, 19.2%

by twig perching, 21.3% by twig gleaning, 2.0% by twig hawking and hovering, 1.4% by branch pecking, 1.8% by branch gleaning, 0.4% by bole pecking, 0% by bole gleaning, 36.3% by litter pecking, 6.2% by litter gleaning, and 1.4% by fallen log manoeuvres. In relation to tree trunks, 18.8% of foraging was distal and 34.9% was proximal. Foraging substrates included 37.2% in coniferous foliage, 16.4% in deciduous tree foliage, 2.4% in forb foliage, 42.7% on the forest floor, 9.4% 0.1-2 m from the ground, 34.2% 2-5 m from the ground, 13.4% 5-8 m from the ground, and 0.3% in the upper canopy above 8 m. It was a high-elevation ground forager (Sabo 1980). In Vermont, 78% of foraging was by gleaning and 22% was by aerial flights. Foraging substrates included 70% foliage, 15% air, 8% ground, and 7% tree trunks (Lent and Capen 1995). In New Hampshire, males foraged mostly on the ground but occasionally jumped from the ground to capture flying insects. Females fed exclusively on the ground. The area where males foraged was significantly larger than where they sang, and significantly larger than the areas where females foraged. Females foraged closer to the nest thereby reducing the amount of time spent off the nest. In 1 pair, the female's foraging areas were initially 5,500-7,000 m^2, 2,200-2,500 m^2 during the incubation and nestling periods, 6,000 m^2 during mating, 3,000 m^2 during incubation, 5,200 m^2 during the nestling period, and 8,000 m^2 during the fledgling period. The male's foraging areas were 6,000-6,500 m^2 during the first mating period, 8,000 m^2 during nest building, 5,200 m^2 during incubation, 4,500 m^2 during the nestling period, 6,500 m^2 during the second mating period, 3,000 m^2 during nest building, 4,000 m^2 during incubation, 5,200 m^2 during the nestling period, and 8,500 m^2 during the fledgling period (Wasserman 1980, 1982, 1986).

The median length of food items brought to Algonquin Park nestlings was 1.34-1.59 cm (range 0.90-2.59 cm), the median width was 0.30-0.45 cm (range 0.23-0.51 cm), and the median proportion of food items that were caterpillars was 54-62% (range 20-98%). The nestling diet consisted of 60.9% caterpillars, 5.1% adult lepidopterans, 3.4% fly larvae, 2.3% adult crane flies, 2.3% odonates, 2.2% beetles, 3.5% orthopterans, 0.6% mayflies, 2.0% winged insects, 1.6% pupae, 1.1% spiders, and 12.6% unidentified animal material. Food provided to fledglings is similar in composition. After the young become independent, their diet is similar to the adults and is dominated by vegetable matter (Knapton and Falls 1983; Kopachena and Falls 1993b; Lowther and Falls in Austin 1968).

In summer, the adult diet is predominantly insects supplemented with fruits and seeds later in summer and autumn. Stomachs collected in Algonquin Park in early May contained about 60% vegetable matter but by late May the diet consisted of 90% insects. In early May, the White-throated Sparrow ate young catkins of birch and beaked hazel. The most important insects in the breeding season diet were adult odonates, hymenopterans, bugs, adult and larval beetles, flies, and lepidopterans. It also eats spiders, millipedes, centipedes, and snails. Fruits important in late summer and fall included those of sumac, grape, highbush cranberry, mountain-ash, rose hips, blueberries, raspberries, bunchberries, and berries of red-osier and silky dogwoods. Other fruits it has consumed elsewhere include those of greenbriers, elderberries, black cherry, and strawberries. Coarse husks of grain are not eaten and chitinous parts of some insects such as wings of beetles and dragonflies are also rejected (Falls and Kopachena 2020; Lowther and Falls in Austin 1968). Judd (1901) analyzed the contents of 217 stomachs collected every month except June. The annual diet consisted of 19% animal matter and 81% vegetation. The animal food was comprised of 5% beetles, 3% bugs and flies, 3% lepidopterans, 6% hymenopterans, and 2% spiders, millipedes, and snails. The most

frequently eaten beetles were weevils and ground, leaf, click, scarab, and clown beetles. The hymenopterans consisted of 2% parasitic wasps, 3% ants, and 1% miscellaneous. Only 2 birds had consumed grasshoppers. Another study reported that White-throated Sparrows had each eaten an average of 18 Rocky Mountain locusts. The vegetable matter consisted of 3% grain, 50% weed seeds, and 28% wild fruits. Its fondness for berries was striking and 25% of its diet from July to November consisted of fruit of blueberries, black cherry, mountain-ash, greenbriers, strawberries, spicebush, wild sarsaparilla, common elderberry, blackberry, and guelder-rose. In July, fruit comprised 44% of the diet. In addition to eating berries, it picks up their dry seeds and cracks them to obtain the inside meat long after the fruit pulp has disappeared. From January to May, it fed on seeds of fruits such as blueberries, blackberries, elderberries, and grapes. Nearly a third of the January and February diet in Texas consisted of bits of seeds or drupes of wild berries. It may consume berry seeds that have been previously eaten by birds whose digestive systems are not strong enough to crush the seeds. It eats grass seeds such as those of foxtails, Johnson grass, crabgrass, panic grasses (approximately 5% of the entire diet), mainly in September when they constitute 25% of the diet. It eats lesser amounts of seeds of amaranths, lamb's-quarters, gromwells, chickweeds, wood-sorrel, sedges, violets, and sheep sorrel, but predominantly ragweeds and smartweeds. Ragweed constituted 9% of the annual diet and smartweeds constituted 25%; in October, 45% of the diet consisted of ragweed seeds.

The White-throated Sparrow usually increases during spruce budworm outbreaks (Falls and Kopachena 2020). Near Manitouwadge, it increased significantly with increasing budworm numbers in stands 1-21 and 24-36 years old but declined slightly in older stands; overall, it increased significantly (Venier et al. 2009). In New Hampshire and Maine, White-throated Sparrow stomachs contained an average of 11.9 spruce budworms, the highest of any species. It consumed significantly more as their density increased but had no discernible numerical response to budworm abundance. Its density was higher than in previous studies so numbers could have increased gradually over several years (Crawford and Jennings 1989). In Maine spruce-fir forests over 2 years, spruce budworm larvae and pupae constituted 18.9% and 16.5% of the invertebrates consumed (Mitchell 1952). In New Brunswick, Morris et al. (1958) observed no response to spruce budworm numbers. In the same province, it increased with increasing populations of the black-headed budworm. It consumed an average of 31 budworms per day, second only to the Dark-eyed Junco. Consumption rate was 0 when budworms were small and in their first instar even though they were most abundant at this time. Consumption increased to its maximum as prey size increased even though prey density was lower and gradually decreased to 0 as prey density declined (Gage et al. 1970).

The White-throated Sparrow is an infrequent host of the Brown-headed Cowbird, probably because the 2 species have different habitat preferences. It accepts parasitic eggs and has not been documented deserting parasitized nests. The effects of parasitism on the White-throated Sparrow are unknown, but it typically fledges both its own and cowbird young from nests. In Ontario, 24 of 449 nests (5.3%) were parasitized; only 1 of 192 Algonquin Park nests (0.5%) was parasitized. In southern Quebec, 20 of 507 nests (3.9%) were parasitized. In British Columbia, 6 of 34 nests (17.6%) were parasitized (Campbell et al. 2001; Falls and Kopachena 2020; Peck and James 1998b; Spencer et al. in Gauthier and Aubry 1996).

Spencer et al. (in Gauthier and Aubry 1996) concluded that the White-throated Sparrow probably expanded its range in southern Quebec in response to forest clearing by settlers. It has declined there since the beginning of the 20th century due to clear-cutting of woodlots for urban development or agriculture. In Ontario, it is uncertain if forest clearing had any positive effects. It has retracted from much of its range south of the Canadian Shield due to agricultural intensification and urbanization. Habitat loss and degradation is not significant for this species in the Shield and northward, although concerns have been raised about the effects of clear-cutting in some areas.

Most researchers concluded that the White-throated Sparrow benefits from clear-cutting and other forest management practices that open up the canopy. Falls and Kopachena (2020) concluded that it was little affected by logging or forest fragmentation. It tends to increase as the forest canopy opens and decrease as the canopy closes. Habitat may potentially be improved by forestry, insect outbreaks, and fire. It demonstrated a positive response to partial harvest of forests in the Boreal Forest Region of Ontario. It was expected to increase by 50% when 100% of the forest was retained, indicating that minor thinning would result in increases. It apparently responds to the short-term availability of suitable habitat within small gaps created by harvesting (Vanderwel et al. 2007). Rempel et al. (2007) predicted that its population would be maintained in Ontario for the next 100 years under natural conditions and forest management under guidelines such as silvicultural guidance for replanting, tending, and harvest objectives. It was expected to increase if timber management guidelines for marten, moose, caribou, and fish were applied. In Ontario in the Canadian Shield, there was no difference in its abundance in early and mid-successional clear-cuts compared with similarly aged stands after fire. Compared with mature stands, it was significantly more abundant in early successional stands and significantly less abundant in mid-successional stands (Zimmerling et al. 2017). At Sault Ste. Marie, it increased in selectively harvested blocks 1-2 years after harvesting; abundance in control forests did not change. In 1 cut, its abundance declined to levels in control forests by 5 years after cutting but it continued to increase 6-7 years after cutting on the other 2 plots. Based on the number of juveniles captured in mist nets, productivity increased on 2 of the 3 harvested areas. It was associated with small deciduous shrubs rather than sugar maple regeneration (Holmes and Pitt 2007). In Algonquin Park, it was significantly more abundant in stands that had been selectively harvested within 1-5 years than in stands harvested 15-20 years previously. Harvesting reduced canopy cover and allowed sunlight penetration to the forest floor, resulting in the establishment of a dense shrub layer of red raspberries and seedlings of sugar maple, beech, and striped maple (Jobes et al. 2004). In Algonquin Park, Tozer et al. (2010) studied the effects of typical and intensive group-selection harvesting that removed 5% and 20% of the tree cover respectively. It increased in both treatments 1 and 2 years after harvest but the positive response was short lived. In Alberta deciduous forests, it increased when 100%, 90%, 80%, and 25% of the forest was harvested but declined when 50% was removed; the increase was significant only when 90% of the forest was harvested. In deciduous forests with an understorey, mixed forests, and coniferous forests, it increased when 25-100% of the forest cover was removed; the only other significant increase was associated with a 90% cut in mixed forests (Harrison et al. 2005). In hardwoods in New York, it increased in abundance with increased intensity of logging, but there was little increase until 75-100% of the merchantable timber was removed (Webb et al. 1977). In Minnesota, it responded more favourably than any other species to harvesting in riparian buffers

(Hanowski et al. 2003, 2005). In Newfoundland, it was significantly more abundant in 30-m buffers to water bodies where the area beyond the buffer was clear-cut; it was only more abundant when birds within the clear-cut were counted (Whitaker and Montevecchi 1999). In New York, Keller et al. (2003) studied the response of the White-throated Sparrow to clear-cutting. The sparrow guild declined significantly as leaf area increased and the shrub-opening edges that they preferred disappeared with time. This guild represented 37% of the total avian population on 2-year-old cuts but only 9% on 6-year-old cuts. The White-throated Sparrow attained its maximum density 2 years after cutting. Its density on 6-year-old cuts was low and was only 13.5% of the density on 2-year-old cuts. In Alberta, Tittler et al. (2001) studied the effects of clear-cutting and of retaining 10%, 30%, and 40% of the tree cover. The White-throated Sparrow declined in the first year after cutting but the population rebounded by the third year to be as common as in uncut stands. It responded negatively to harvesting. The researchers considered it a generalist species that was unaffected by the amount of retained forest. In Maine spruce–balsam fir forests, it was absent in forests with a dense overstorey and an open forest floor, but occurred in clear-cuts from the time of cutting until trees reached a DBH of 10-15 cm and were taller than 4.5 m. Greatest abundance occurred 3-12 years after cutting when regenerating hardwoods were less than 2-4.5 m tall, with a residual raspberry layer and slow-growing softwood regeneration (Titterington et al. 1979). Two Newfoundland studies examined the effects of harvesting at the landscape level on productivity and survival of the White-throated Sparrow. Dalley et al. (2009) determined that nest survival and fledgling production was negatively affected by the amount of harvested area at the 20- and 115-m scales, but positively correlated with the proportion of harvested area at the 1,250-m scale. They found no compelling evidence for negative effects of harvesting but concluded that habitat fragmentation coupled with weather factors could cause dramatic differences in breeding success. Whitaker et al. (2008) found no difference in its survival rates in natural landscapes, where openings were mostly wetlands and water bodies, and landscapes where clear-cutting had occurred. It was resilient to a moderate amount of clear-cutting. In this study area, only about 5% of the landscape was clear-cut.

Two studies cautioned that clear-cutting may be detrimental to the White-throated Sparrow, and these are reinforced by the study by Tittler et al. (2001) in Alberta. In the same province, numbers were lower in clear-cuts than in forest edge and interior, and those nesting in clear-cuts had low productivity and site fidelity. This suggested that populations nesting in clear-cuts were not sustainable and had to be maintained by immigration. Harvesting could reduce habitat quality for decades. In landscapes heavily fragmented by forestry and other disturbances, the remaining habitat may reach a threshold where rates of recruitment, immigration, and site fidelity are reduced to a point that regional population declines occur (Hannah et al. 2008). In Quebec, Rousseau et al. (2012) experimentally clear-cut portions of breeding territories after the breeding season. Treatment males had an average of 69% of their territory clear-cut (range 9-100%). Males that experienced a clear-cut were less faithful to their territories and dispersed 2.6 times further than control birds. Although clear-cuts are a readily used habitat, they were not suitable for most individuals with previous experience breeding in mature forest stands.

Some studies examined the effects of creating gaps in forest habitat on the White-throated Sparrow. In Quebec, Rail et al. (1977) used playback to test the widths of forest gaps that it would

cross. They tested 19 different widths of gaps from 5-95 m at 5-m intervals. A 65-70 m threshold response was apparent, with it reluctant to cross wider gaps. The response was similar among gap types including power lines, roads, ski trails, and clear-cuts. The response at 65-70 m might be an expression of its territory size rather than a gap effect. In British Columbia, seismic lines 8-10 m wide provide edge habitat where it nests among piles of woody debris and in shrubby areas (Campbell et al. 2001). Bayne et al. (2016) determined that it was more abundant at seismic lines and pipelines than in forest interior adjacent to these features. There was no significant difference in its abundance at well pads and in adjacent forest interior.

DesGranges et al. (1987) studied the effects of sugar maple decline in Quebec on the White-throated Sparrow. As a result of tree die-back, the canopy became more open with more growth of shrubs and herbaceous species. It was 4 times as abundant in die-back-affected stands as in healthy stands, a significant difference.

Chemicals associated with forest management may have detrimental effects. Spraying of fenitrothian to control spruce budworms reduced adult populations through mortality and territory abandonment, disrupted normal incubation behaviour, and reduced fledgling success (Falls and Kopachena 2020; Forsyth and Martin 1993). In Nova Scotia, there was a 55% decline in numbers in the second year following treatment of clear-cuts with glyphosate; numbers recovered in the fourth year (Freedman and Johnson 1999). It was not affected by application of this herbicide in Maine. It was second in abundance in untreated clear-cuts, representing 26% of all birds. On treated clear-cuts, it was the most abundant species, comprising 35.7% of the entire bird population. In this area, it was not significantly related to any habitat parameters and did not decline when vegetation complexity decreased (Santillo et al. 1989).

On Anticosti Island, the White-throated Sparrow was unaffected by high deer densities and browsing (Cardinal et al. 2012).

In Alberta, the White-throated Sparrow was 2-4 times more abundant at quiet well edges than at noisy compressor station edges. Bayne et al. (2008) concluded that it was adversely affected by noise from energy sector facilities. Its abundance was not significantly related to noise in Edmonton. Noise in that study was related to urban activities such as traffic. Its focal song is at frequencies of 2.8-4.5 kHz and it is most likely to be affected by noise in this range (Proppe et al. 2013).

Price (2004) concluded that the White-throated Sparrow might no longer breed in southern Ontario if the average summer temperature increased by 2°C. In central Quebec and Labrador, it was associated with warmer summer temperatures and drier stands. At this more northern latitude, it might benefit from climate change (DesGranges and LeBlanc 2012).

Status

McIlwraith (1894) had breeding records for the White-throated Sparrow from the Cambridge and Milton areas but concluded that it did not commonly nest in this portion of the province. Curry (2006) stated that there had been little change in its status in the Hamilton area since that time and that it was absent as a breeder south of Hamilton. Baillie and Harrington (1937) considered it one of the most common and characteristic summer residents, breeding throughout the province but more rarely along the southern boundary. The first atlas confirmed that it bred throughout the Great

Lakes–St. Lawrence Forest Region, except in the urbanized area of Toronto, northward to the Hudson Bay coast. It was uncommon and sparsely distributed in the Carolinian Forest Region and in intensively farmed areas in Huron and southern Bruce counties. In the extreme south, it was confined to isolated coniferous swamps or plantations. Highest populations occurred in the northern part of the province (Falls in Cadman et al. 1987). James (1991) considered it an abundant summer resident throughout most of the province, but rare in the agricultural south and almost completely absent in the Carolinian Forest Region. In the Hudson Bay Lowland, Wilson and McRae (1993) observed that its abundance changed substantially away from the Hudson Bay coast, with the transition area near Ekwan. It was uncommon near the coast and common to abundant further south.

The second atlas demonstrated that there had been no change in the range of the White-throated Sparrow since the first atlas. There was no significant change in its probability of observation province-wide or in any region except the Great Lakes–St. Lawrence Forest Region south of the Shield. It declined significantly there, but the reasons for this were uncertain. Declines may have been related to loss of early successional habitat due to agricultural intensification, urbanization, and natural succession. It was most abundant in the Boreal Forest Region between latitudes 47°N and 51°N. This is where intensive commercial logging occurs. It was considerably more abundant in the Shield and the Hudson Bay Lowland than south of the Shield (McLaren in Cadman et al. 2007).

Breeding Bird Survey data indicate that the White-throated Sparrow decreased at an annual rate of 0.451% in Canada and 1.32% in Ontario 1970-2021. For 2011-21, it experienced annual decreases of 3.09% in Canada and 3.7% in Ontario. All results were of medium reliability (A.C. Smith et al. 2023). Tozer (2012) reported that numbers had declined in Algonquin Park over the past 40 years due to forest succession and the absence of any major spruce budworm outbreaks.

POSTFLEDGING PERIOD

Fledglings cannot fly until 2-3 days after they leave the nest but are strong fliers a week after leaving the nest. As soon as they leave the nest, fledglings move into dense cover. One remained in the lower boughs of a large white spruce 10 m from the nest for 3 days. Young are fed by the adults for at least 2 weeks after they fledge (Falls and Kopachena 2020; Kopachena and Falls 1993b; Lowther and Falls in Austin 1968).

In Algonquin Park, Kopachena and Falls (1991) examined whether brood division occurred. They placed individual fledglings in enclosures that were open at the top so adults could access the young. Brood division occurred, but was characterized by overlapping patterns of parental feeding rather than each parent feeding certain young exclusively. In only 1 of 16 pairs (6.3%) did both parents fail to show preferences for individuals within the brood. In the remaining 15 pairs, there were 2 cases (13.3%) in which 1 parent failed to exhibit preference for individual fledglings. Ten of 27 adults (37.0%) cared for fledglings that were fed only by that parent. In these broods, the remaining offspring was fed by both adults. Of 13 broods in which adults showed preferences for individuals, 84.6% of the fledglings that received the most male feeding trips received the fewest female trips; 76.9% of the fledglings that received the most female feeding trips received the fewest male trips. When fledglings were moved by the researchers, 50% of adults were able to recognize

individual brood members and altered their provisioning behaviour appropriately. Twenty-five percent failed to respond and had therefore keyed in on the location to identify young. The remaining 25% altered their behaviour but failed to match their previous preference for individuals. Most adults started to show preferences for individual fledglings within a few hours of their leaving the nest, but some adults did not establish a pattern until a day after young had fledged.

In Quebec clear-cuts, the White-throated Sparrow was the most abundant species caught by Major and Desrochers (2012). It was more abundant where the researchers had not removed elderberry fruits and results were almost significant. Frugivory contributed to its abundance. It was not entirely dependent upon frugivory because it also occurred in experimental plots where there was no fruit. It was found throughout clear-cuts and did not restrict its movements to edges. In Minnesota, Streby et al. (2011b) captured 81 adults and 87 juveniles in regenerating clear-cuts over 4 years during the postfledging period. During 1 breeding season, they caught 9 adults. The youngest clear-cuts were dominated by red raspberry and aspen saplings 1-2 m tall; older cuts were dominated by aspens 4-6 m tall interspersed with red maple, hazel, and pussy willow. In addition to clear-cuts, many other habitats with dense shrub growth or short deciduous saplings may provide suitable habitat for the White-throated Sparrow during the postfledging period.

In Michigan, Piper (1995) investigated the onset of social dominance in juveniles. Nestling mass was unrelated to their final dominance status and the number of dominance interactions in flocks of brood-mates was not related to dominance status. Social conditions appeared to strongly influence dominance. Birds artificially placed in a flock of 6 for 17 weeks were all of low social dominance, those placed in isolation achieved the top rank, and wild-caught birds were intermediate in dominance. Social conditions experienced by juveniles before they leave the breeding grounds and during autumn migration might have a lasting effect on their dominance status and therefore their winter survival.

MIGRATION

The entire population of White-throated Sparrows migrates. Breeding and wintering ranges overlap in some areas, but different birds are present in different seasons. Although the breeding range extends from British Columbia to Newfoundland, migrants converge to winter in the southeastern United States. Spring migrants arrive when snow melt exposes portions of the forest floor. Timing of arrival in Manitoba was strongly correlated with the mean April temperature. Spring activity increases with high or increasing temperatures, falling barometric pressure, and southern winds. In autumn, birds show random patterns with respect to weather. Latest autumn departures occur prior to the first permanent snowfall. This suggests that it is a weather-dependent migrant, relying on changes in temperature and food supplies to initiate migration instead of endogeneous rhythms and photoperiod cues. Autumn migration is more leisurely than spring migration, with spring migration about a week shorter than autumn migration in Michigan. During both periods, the peak of migration averaged 33 days, but numbers dropped off more quickly after the peak in spring than in autumn. In autumn, there is differential migration with females wintering further south than males, and larger males wintering further north than smaller males. Birds with larger bodies are more likely to survive cold weather and dominant birds force subdominant birds to migrate further from the breeding grounds. There is no evidence that wintering latitudes differ between the 2 colour

morphs (Falls and Kopachena 2020; Fischer and Gill 1946; Jenkins and Cristol 2000; Mazerolle and Hobson 2007; Stack and Harned 1944).

White-throated Sparrows breeding in southern Ontario wintered from Texas east to Georgia and South Carolina. Northern Ontario birds appeared to travel almost directly north-south. Some birds banded in southern Ontario moved strongly in a northeast-southwest direction and probably bred in Quebec. Some birds that breed in Quebec winter in southern Ontario. One bird banded at Mitchell's Bay was recovered in New York the next day, having travelled 673 km overnight (Brewer et al. 2018). Gesicki et al. (2016) concluded that the central basin of Lake Erie was a partial barrier to spring migrants. In the western basin of the lake, more were recorded at West Sister Island than on the Ohio mainland suggesting that it was attracted to the islands when crossing the lake. In the central basin, fewest birds were detected offshore at Cleveland. A higher proportion migrates through the western basin and those in the central basin are less likely to cross the lake.

The White-throated Sparrow migrates at night in loose flocks and forages in flocks during daily stopovers (Falls and Kopachena 2020). Gaymer (1962) observed the initiation of migratory flights in Toronto. In the first half of October, birds moved progressively higher from the ground after sunset, gathering at the top of 25-m tall trees. When it was almost dark, individuals flew straight upwards from an exposed branch to a height of 10-20 m above the trees, circled 2 or 3 times then flew off in a southerly direction. In spring, the northward flight began with many individuals leaving simultaneously and continued with a steady stream of sparrows rather than the entire flock leaving at once. In spring, birds left in a normal flight pattern without the perpendicular upward flight.

In Manitoba, males arrived in spring 4.8 days before females and white-morph birds arrived 4.8 days before tan-morph birds. In New Hampshire, females arrive approximately 2 weeks later than males. At Long Point, the midpoint of migration was 2 May 1977-2000, with males arriving significantly earlier (10.4 days) than females. Males arrived earlier than females north of Lake Nipigon and in Algonquin Park. Most females arrive there between the first and third weeks of May, 1-2 weeks after the first males arrive. White-morph males tended to arrive earlier than tan-morph males in Algonquin Park, but not significantly. White-morph females arrived significantly earlier than tan-morph females but it is possible that the more cryptic tan-morph females were overlooked. At Long Point, white-morph birds arrived significantly earlier (2-15 days) than tan-morph birds when all birds were considered. When sex was taken into account, white-morph females arrived significantly earlier (1.3 days) than tan-morph females, but there was no significant difference in the migration timing of male morphs. Tan-morph females took 7% longer than white-morph females to complete their migration. Tan-morph males took 2.6% longer than white-morph males. Older birds of both sexes arrive in spring earlier than yearlings. At Long Point in autumn, adults of both sexes and juveniles migrate at the same time, but juveniles arrive later in North Carolina (Caldwell and Mills 2006; Falls and Kopachena 2020; Kendeigh 1947; Knapton et al. 1984; Mazerolle and Hobson 2007; Mills 2005b; Wasserman 1980). In Michigan, the average stopover period was 4.5 days in spring and 10.67 days in autumn (Stack and Harned 1944). In Ohio, there was no significant difference in the duration of spring and autumn stopovers by adults and juveniles. In spring, the average stopover period was 5.3 days (5.4 days for adults and 5.1 days for juveniles). Autumn stopovers were significantly longer than in spring, averaging 8.7 days, with means of 8.5 days for adults and 9.1 days

for juveniles (Borror 1948). During spring migration south of Lake Erie in Ohio, birds in good condition began their flight across the lake directly from inland areas. Those in poorer condition staged south of the lake before crossing. There was no difference in body condition between the morphs (Hoh et al. 2018). On islands in the Gulf of Maine, autumn stopover times were 5.6 days on a shrubby island and 3.7 days on a treed island (Suomala et al. 2012). Autumn stopovers could range from 1 day to more than a week (Fischer and Gill 1946).

In southern and central Ontario, migrants move through from mid-April to mid-May, with most passing through by the third week of May (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008). In Thunder Bay, average arrival during 1938-52 was 27 April with extreme dates of 17 April and 6 May. Most White-throated Sparrows leave the Thunder Bay area by early October (Allin 1952). Autumn migration begins in earnest in September in the southern Shield, peaking at the end of the month. Most leave by mid-October, but some remain into late November or December (Mills 1981; Tozer 2012). In southern Ontario, it arrives in mid- to late September, with peak numbers from late September until the second to fourth weeks of October (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008).

Mills (2005a) analyzed banding data for the White-throated Sparrow from Long Point Bird Observatory for 1975-2000. There was no significant change in the date of first arrivals or in spring quartiles and no significant difference for either sex in spring over time. There were no significant differences in the timing of autumn migration. The midpoint of autumn migration was 20 September.

During migration, the White-throated Sparrow seldom occurs far from dense shrub or herbaceous cover. In the Kingston area, it was most abundant in poorly drained areas dominated by dense willows, dogwoods, and buttonbush 1.5 m tall. Similar shrubby habitat is used in other areas but species composition may vary. It also occurs in towns and urban areas where only patches of cover are available (Falls and Kopachena 2020). Most birds seen in November in Algonquin Park are at feeders (Tozer 2012). In southern Ontario, flocks are common in shrubby hedgerows, roadsides, and edges of forests (personal observation). In British Columbia, it is most common during migration in deciduous forests with a dense shrub understorey, but it also occurs in mixed forests and young successional forests such as burns and clear-cuts. It particularly favours forest edges and natural forest openings, as well as shrubby perimeters of lakes, beaver ponds, wetlands, muskegs, and watercourses. In all cases, it exhibits a strong affinity for low dense shrubby vegetation (Campbell et al. 2001). In Kansas, migrants occurred mostly in woodland edge thickets; in spring, this habitat type was used around a pond. Autumn migrants congregated in flocks in woodland edge thickets, brush piles, and weedy margins of a pond (Fitch 1958). During spring migration in Pennsylvania, it was significantly more abundant in shrubs than forest. Detections per 100 m of transect were 0.03 in forest and 0.16 in shrubs; captures per 1,000 mist-net hours were 0.6 in forest and 13.8 in shrubs (Smith and Hatch 2008). During spring migration in Wisconsin and Minnesota, it was equally abundant in upland and floodplain deciduous forests (Kirsch et al. 2013). During autumn migration in New York, it used mature shrublands more than early successional forests (Mudrzynski and Norment 2013).

In both spring and autumn in Pennsylvania, the White-throated Sparrow was significantly more abundant in fragmented than forested landscapes. Fragmented landscapes were 15% forested; forested landscapes supported 40% forest cover. Its abundance was correlated with patch size (Keller and Yahner 2007).

In Ohio, most migrants had home ranges of less than 3.2-4.0 ha, but confined most of their activities to 0.4-0.8 ha. Some moved as far as 400 m during their stopover (Borror 1948).

In many areas, spring migrants may arrive while birds that have overwintered are still present. Winter birds were significantly more dominant than expected based on interactions and the proportion of winter residents and spring migrants that were present. Migrants were significantly less dominant than expected. White-morph birds chased other birds 2 times more than they were chased and tan-morph birds chased half as frequently as they were chased; these differences were significant (Hailman 1975; Harrington 1973).

Based on banding data, Fischer and Gill (1946) concluded that the White-throated Sparrow seldom used the same stopover sites on subsequent migration flights.

In early spring, the White-throated Sparrow moves to the tops of the tallest deciduous trees where it feeds on buds and blossoms of white and red elms, silver and red maples, oaks, beech, and apples (Fitch 1958; Judd 1901; Lowther and Falls in Austin 1968). In downtown Toronto, Lang (1994) observed one feeding on the carcass of another White-throated Sparrow. Food resources may have been depleted forcing it to search for alternative food sources. In Alabama, it eats mulberries during spring migration (Holt 1918). On the Ohio Lake Erie shoreline, MacDade et al. (2011) used stable isotopes to analyze breath samples of White-throated Sparrows to determine their diet. There was a large emergence of midges during the peak of migration. Associations between midge biomass and refuelling performance were not strong. They had breath values consistent with consumption of both aquatic and terrestrial arthropods. There was no significant difference in dietary composition between shoreline and inland sites, possibly due to little difference in midge biomass. Even small shoreline sites of 1.18-2.86 ha often supported high densities of migrants that received energetic benefits from their use. The autumn diet is comprised mostly of grass and weed seeds and fruit. In New York, 19.0% of fecal matter contained evidence of fruit consumption. It ate fruits of Bella honeysuckle and buckthorn but not those of gray or red-osier dogwoods. In Rhode Island, the autumn diet was dominated by fruit which comprised 60% of food items (Fitch 1958; Langlois and McWilliams 2010; Mudrzynski and Norment 2013). In Oxford County, Dance et al. (2012) observed it feeding on giant ragweed seeds.

The White-throated Sparrow commonly collides with buildings and other tall structures during migration. In Toronto, it is among the top 3 of 164 species found killed by striking windows and buildings, and it has a similar rank in other cities (Falls and Kopachena 2020). Weir (2008) reported that 42 were killed at the Lennox generating station chimneys 1972-79.

James (1991) considered the White-throated Sparrow an abundant migrant in Ontario. At Long Point, it is the number 1 banded species, with over 66,000 banded 1960-2010 (Anonymous 2010a). Fischer and Gill (1946) reported that it was the second most abundant species banded in the Atlantic Coast and Mississippi flyways to the Dark-eyed Junco. High spring daily counts in southern Ontario

range from 250 to 2,000. In autumn, flocks may number 1,000-5,000. During a grounding, 10,000 were seen at Prince Edward Point on 2 May (Curry 2006; LaForest 1993; Mills 1981; Weir 2008).

The number of White-throated Sparrows banded at Long Point Bird Observatory declined significantly at a rate of 2.6% per year 1961-83. Trends by period were: –4.0% 1961-70, –2.7% 1970-79, and –2.7% 1979-88 (Hussell et al. 1992). Falls and Kopachena (2020) reported that numbers banded at Long Point 1963-2005 were stable in spring and increased significantly in autumn; since 1987 in autumn and 1991 in spring, the trend was positive.

WINTER

Root (1988) stated that the entire winter distribution of the White-throated Sparrow was limited to areas that receive 102 cm or more of precipitation annually. The western edge of its range stops abruptly where the annual precipitation rate drops below 81 cm. It most often frequents areas with an average minimum January temperature above –1°C. Individual abundance peaks are strongly associated with open water. It avoids snow cover; the longer the snow season length, the less likely it is to be present (Keyser et al. 2023). The bulk of eastern populations winter in North and South Carolina, with its abundance progressively decreasing north and south of these states (Fischer and Gill 1946).

In Pennsylvania, the White-throated Sparrow was equally abundant in winter in landscapes with 15% and 40% forest cover (Keller and Yahner 2007). It inhabits dense shrubby areas similar to what it uses during migration. Birds rarely venture out into the open. Within dense habitats, it seeks areas with minimal snow cover to facilitate its ground foraging. Where snow is deep, it is highly reliant on feeders for winter survival. Winter habitats include edges of woodlots, hedgerows, sheltered ravines with shrubby cover, and dense vegetation adjacent to watercourses, swamps, and cattail marshes. Within thickets, it frequents small openings where leaf litter covers the ground. In Ontario, it winters singly or in small flocks, often with Song Sparrows and other sparrows (Curry 2006; Falls and Kopachena 2020; Fitch 1958; LaForest 1993; Lancaster et al. 2004; Lowther and Falls in Austin 1968; Root 1988; Tozer 2012; Weir 2008). In British Columbia, wintering White-throated Sparrows were found mostly at feeders but also in other anthropogenic habitats such as shrubby edges of fields, utility corridors, foot paths, roads, city parking lots, and in low dense vegetation in city parks and golf courses. It also occurs in shrub thickets along lakeshores and creeks and edges of weedy fields and pastures (Campbell et al. 2001). In Maryland, Blank et al. (2011) investigated the effects of autumn mowing of vegetated buffers between row-crop fields and forested wetlands on wintering White-throated Sparrows. Some buffers were mowed to a height of 10-15 cm; others were not mowed. It was the sixth most abundant species and was significantly more abundant in unmowed than mowed buffers. Densities per km^2 were 16 in mowed and 159 in unmowed buffers. Vertical vegetation density and height and percent coverage by grasses and forbs were significantly greater in unmowed buffers. In Arkansas, Kentucky, and Mississippi, Evans et al. (2015) compared its abundance in fields with and without vegetated buffers. Fields were planted with row crops and buffers were planted to a mix of native grasses and forbs. The White-throated Sparrow was equally abundant in fields with and without buffers and in buffers less than and greater than 23 m in width.

In Arkansas, all roosting habitats were composed of dense stems, vines, or branches and 82% of roosts were 1-5 m from the ground. The species with the most roosts were blackberry and

greenbrier thickets (33% of roosts), autumn olive (28%), red cedar (20%), and privet and Japanese honeysuckle (12%). White-throated Sparrows exhibited strong roosting site fidelity. Habitat at foraging and roosting sites, respectively, was 3.99 cm and 2.74 cm leaf litter depth, 26.21% and 64.4% understorey vegetation density, and 17.74 hits and 17.18 hits horizontal vegetation density. Nocturnal roosting areas and diurnal foraging areas were spatially disjunct and varied significantly in vegetation habitat metrics. Foraging locations had greater leaf litter depth and were concentrated near the forest edge of a hydro right-of-way. Roosts were more dispersed and associated with increased understorey vegetation density (Gonzáles et al. 2023). In Arkansas, a male used the same roosting area in 2 consecutive winters. Its core roost home range in the second year overlapped 100% with its previous year's core roost home range. It roosted in the exact same roost site as it did in the previous year, spending 37 nights in a Japanese honeysuckle shrub (Gonzáles and Ruhl 2025).

In winter, the White-throated Sparrow establishes a small foraging range and may return to it in subsequent years. Home ranges often overlap broadly and individuals frequently join loose flocks when foraging. In Kansas, 1 wintering bird remained within an area of 0.98 ha. Winter home ranges of 0.1-0.4 ha have been reported elsewhere (Dunn and Tessaglia-Hymes 1999; Falls and Kopachena 2020; Fitch 1958).

The dominance hierarchy is established in winter. Dominant birds sing more frequently, feed closer to protective cover, get to access food first regardless of who found it, spend more time foraging, experience fewer interruptions while foraging, accumulate greater stores of subcutaneous fat, and use smaller home ranges than subordinate birds. Dominant birds tend to remain within their home ranges when food levels decline in midwinter; 45-50% of dominant birds return to the same wintering area compared with 30-39% of subordinate birds (Dunn and Tessaglia-Hymes 1999; Falls and Kopachena 2020; Wiley 1991). In New York, Schwabl et al. (1988) concluded that sex and age were important in predicting dominance, but morph colour was not. Adult males held the 2 highest ranks significantly more often than females. Rank was correlated with age in males but not in females. Adult males, but not yearling males, were dominant in more relationships with members of other age or sex classes than expected. All females won fewer contests than expected. Dominance by the 2 morphs varied with season, with white-morph birds dominating in spring and tan-morph birds dominating in autumn. In winter, males were observed in aggressive encounters more frequently than expected and females were in aggressive encounters less frequently than expected (Watt et al. 1984). Ficken et al. (1978) determined that white-morph birds were more frequently the aggressor in interactions during spring migration.

When foraging, the White-throated Sparrow stays within or near cover even if food is more abundant in the open (Dunn and Tessaglia-Hymes 1999; Pearson 1991). As food near cover becomes depleted, birds move increasingly further from cover, but staying within or near cover takes precedence over high food density distant from cover (Schneider 1984). In North Carolina, the main habitats used for foraging were areas of crabgrass, horseweed, asters, mixed tall weeds, and shrubs, with greatest numbers in asters and mixed tall weeds. Fifty-nine percent of foraging occurred while perched on a plant, 41% while standing on the ground but feeding on a standing plant, and 0% on bare ground. Its abundance was not related to food abundance. It ate mostly seeds 0.5-2.5 mm in length but some as large as 6.5 mm. All foods smaller than 3.5 mm were hard seeds (grains, achenes,

and nutlets) and larger ones were soft fruits. Approximately 90% of the diet between October and March consisted of vegetable matter; 13% of the diet consisted of fruit. In Algonquin Park, all birds that survived winter had food provided to them. One subsisted on food pellets given to captive moose (Tozer 2012). In Maryland, Petrides (1942) observed it eating holly berries. Falls and Kopachena (2020) reported that the winter diet included seeds of grasses (including wiregrass), ragweeds, and smartweeds, plus fruits of sumac, grape, highbush cranberry, mountain-ash, and rose hips.

The White-throated Sparrow is one of the more widespread species at winter feeders. Unlike most ground-feeding birds, it is willing to visit raised-platform feeders. Its favourite feeder foods are mixed seeds and millet. It infrequently eats all types of sunflowers, safflower, whole or cracked corn, milo, hulled peanuts or hearts, peanut butter mixes, baked goods, water, and canary seed (Dunn and Tessaglia-Hymes 1999).

During a prolonged period of heavy snow and extremely cold weather in Illinois, Graber and Graber (1979) observed a 99.7% decline in the number of White-throated Sparrows. Densities per km^2 were 249 before the storm and 0.75 after the storm. They found some carcasses and concluded that the decline was due to very high mortality. Falls and Kopachena (2020) reported that populations may decrease after cold weather. Even under normal conditions, birds wintering in Ontario may not survive if they do not have access to a feeder. One that was at a Huntsville feeder until February did not survive until spring (Mills 1981). At Presqu'ile, it was very difficult to find in late February and early March, suggesting that few overwintered successfully (LaForest 1993).

James (1991) considered the White-throated Sparrow a rare but regular winter resident in the south, and occasional and rare in the north to Atikokan, Thunder Bay, and Moosonee. In the Hamilton area, Curry (2006) reported small winter flocks of as many as 10 birds, with 15 birds the most observed. He concluded that more overwintered now than previously.

Freedman and Riley (1980) summarized the results of Christmas Bird Counts (CBC) for southern Ontario for 1929-77. It was recorded in low numbers, but there was a trend to irregular but increasing abundance since approximately 1958. CBC results for 1965-2005 indicated a nonsignificant decrease rangewide of 0.25% per year (Falls and Kopachena 2020). Lepage and Francis (2002) examined CBC and Project FeederWatch data for Ontario. It had low but significant annual variations in population numbers and apparent small peaks every 3-4 years. CBC results for Ontario indicate that it increased at annual rates of 2.15% 1970-2021 and 4.6% 2009-21 (National Audubon Society 2022).

Vesper Sparrow

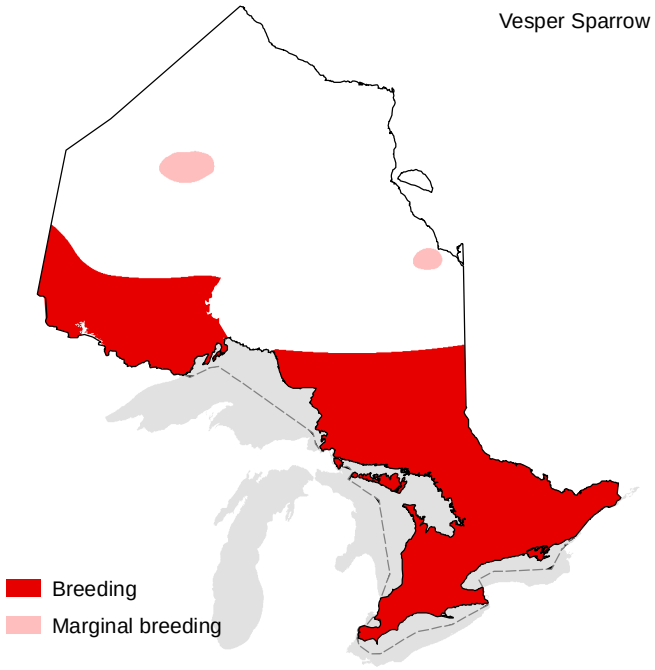
Pooecetes gramineus

BREEDING SEASON

Habitat Requirements

Ontario Vesper Sparrow nests were in grassy fields and pastures that were usually open (62.6% of nests) but 9 (5.7%) were in overgrown fields and pastures; in cultivated grain, vegetable, and berry fields (17.3%); in young open conifer plantations (8.3%); along road and railway rights-of-way (7.1%); in gravel pits (2.0%); in very open woodlands and recent burns (2.0%); in orchards (0.4%); and on golf courses (0.4%). One nest was on soil dug from a pond. Most were in dry locations but 3 were in marshy areas and 5 were in wet areas. Breeding habitats were mostly flat with sparse ground cover; short grass was preferred to long grass for nesting (Peck and James 1987).

The Vesper Sparrow previously nested in the Hudson Bay Lowland area near Moosonee (Manning 1952; Wilson and McRae 1993), but no habitat description was provided. In the Boreal Forest Region, it is restricted mostly to large burns and clear-cuts. It may also occur near settlements and other anthropogenic openings in forests (Rising in Cadman et al. 2007). Near the northeastern



shore of Lake Superior, it was common in large areas of dry open country (Baillie and Hope 1943). Smith (1957) reported that it occurred in agricultural fields in the Clay Belt.

Near Gogama in the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region, the Vesper Sparrow bred where there was a ground cover of grasses or sedges among well-spaced regenerating jack pines. There were few or no tall pines that shaded the ground in inhabited areas. Once pine trees reached 10 years of age, the habitat was no longer suitable (James and Peck 1995a). In the Sudbury area, it was well distributed along the railway right-of-way and in clearings (Baillie and Hope 1947). In Muskoka and Parry Sound districts, it breeds mostly in open scrubby areas and dry pastures (Mills 1981). In Algonquin Park, it was restricted to open areas around old camps and settlements; there were a few birds in barren burns (MacLulich 1938). Tozer (2012) reported that the only recent record in the park was in a burn.

In the Carolinian Forest Region, Sheppard et al. (1936) considered the Vesper Sparrow a very common bird of roadsides and pastures. It now appears to prefer recently fallow fields with hedgerows containing small trees (Black and Roy 2010).

In southern Ontario agricultural fields, the Vesper Sparrow was positively correlated with spring grain, hedgerows, hay, fences, and row crops, but the relationship was significant only for hedgerows. It was significantly negatively correlated with pasture, wooded areas, and road, railway, and hydro corridors. There was no significant difference in its abundance on conventional and organic farms, even though conventional farms had larger fields (Kirk et al. 2011). Dechant et al. (2002a) reported that it was more common on organic than conventional farms and minimal tillage farms, possibly because of greater retained crop residue for nesting.

Throughout its range, the Vesper Sparrow is an open-country bird. It prefers dry areas with sparse, short patchy vegetation, low to moderate shrub coverage, and areas of bare soil. In Ontario, it is 1 of only 3 species that regularly nests in corn and soybean fields along with the Killdeer and Horned Lark. Agricultural fields are widely used for nesting in the Midwestern United States but are rarely used in the Prairie Provinces. Habitats it has nested in include roadsides, grassy fields, abandoned fields, short-grass and mixed-grass prairie, sagebrush and shrubsteppe habitats, hayfields, shrubby grasslands, woodland edges, woodlands with sparse canopy cover and understorey, orchards, shelterbelts, jack pine barrens, fencerows, recent burns and clear-cuts, grazed and ungrazed pastures, grassed waterways in agricultural fields, young Christmas tree farms and coniferous plantations, oak savannahs, shorelines with beach grass, blueberry fields, montane

meadows, airports, and reclaimed strip mines. It often occurs at ecotones between forested or shrubby habitat and open areas such as grasslands and agricultural crops (Askins et al. 2007; Berger in Austin 1968; Beauchesne et al. 2007; Best and Rodenhouse 1984; Camp and Best 1994; Campbell et al. 2001; Dechant et al. 2002a; Faanes and Andrew 1983; Graber and Graber 1963; Graham and Cotter in Gauthier and Aubry 1996; Jones and Cornely 2020; Judd 1901; Leighton et al. 2002; Mossman et al. 1991; Mousley 1916a; Rodenhouse and Best 1983; Rotenberry and Wiens 1980; Swanson 1996; Vickery et al. 1994; Wiens 1969; Wray et al. 1982).

Presence of suitable perches is a critical habitat component and their absence can be a significant limiting factor. In agricultural areas, territories usually extend along the length of a hedgerow or fence. In Iowa, areas in croplands further than 80-110 m from a hedgerow were not used by the Vesper Sparrow. In grasslands, it uses shrubs most frequently as perches. Grasslands without shrubs may be unoccupied. In addition to shrubs, woodland edges and herbaceous vegetation taller than the dominant cover type may be used as perches. In Iowa, birds with territories along hedgerows in cropland used elevated perches heavily. During the preincubation period, males sang primarily from hedgerows, with fence wires, fence posts, or shrubs used most frequently. During incubation, 72% of singing occurred in the field. Song perches used at this time consisted mainly of clods of soil and tall crop residue. Later in the season, 71% of singing occurred in the crops. In soybean fields, males sang from tall weeds and in cornfields they sang from the rows of corn closest to the fencerow; the corn was taller than fence posts and many shrubs. Only 1 of 51 Iowa territories (2.0%) did not include a fencerow. Only fencerows that were entirely herbaceous were unoccupied. In 1 year, the only unpaired male was along a herbaceous-shrubby fencerow and in another year all 4 unpaired males had territories on herbaceous fencerows. Densities along shrubby fencerows were 20% higher than those along herbaceous-shrubby fencerows. The Vesper Sparrow used artificial perches 1.5-2.0 m tall in Michigan, exhibiting no preference for height. The structural diversity of vegetation is important: taller vegetation, such as scattered shrubs or trees, is used for cover and singing perches and areas with shorter sparse vegetation are used for foraging and nesting. Vegetation structure probably is more important than plant species in habitat selection (Beauchesne et al. 2007; Best and Rodenhouse 1984; Dechant et al. 2002a; Harrison 1977; Jones and Cornely 2020; Perritt and Best 1989; Rodenhouse and Best 1983).

At the landscape level, abundance of the Vesper Sparrow is correlated with agricultural land. In Quebec, its distribution corresponded with that of cropland (Graham and Cotter in Gauthier and Aubry 1996). Although it occurs in forested landscapes in Ontario, highest densities occur in agricultural landscapes (Rising in Cadman et al. 2007). In seeded, highly erodible land, its frequency of occurrence was higher in sites surrounded by grassland than sites surrounded by cropland, wetland, woodland, or human settlement (Dechant et al. 2002a). In extensive mixed-grass prairie in North Dakota, it was positively correlated with the amount of aspen woodland within 500 m. It increased as the amount of aspen increased at the landscape level but was unaffected by the amount of aspen at the territory level (Grant et al. 2004). Berger (in Austin 1968) concluded that it appeared to avoid heavy clays and concentrated in areas of lighter soils that contained considerable sand and gravel. This does not appear to be true in Ontario because the heavy clay soils of Essex Counties support high densities of the Vesper Sparrow (Rising in Cadman et al. 2007). In Alberta, its presence was negatively correlated with the number of wetlands within 2.8 km^2 around point

counts (Dechant et al. 2002a). In Colorado, it was more frequent in mixed-grass prairies distant from urban edges (Jones and Bock 2002). In North Dakota, it responded positively to increasing tree cover within a 100-m radius in 400-m landscapes with less than 30% forest cover, but negatively in wooded landscapes. In open habitat, its probability of occurrence was 5% at 0% tree cover, 15% at 20% tree cover, and 20% at 40-70% tree cover. In wooded landscapes, its probability of occurrence was 25% at 0% tree cover, 18% at 40% tree cover, and 10% at 60-80% tree cover. It preferred landscapes with 20-52% tree cover (Cunningham and Johnson 2016, 2019). In the Prairie Pothole Region of Canada, it was positively associated with the amount of cropland within 400 m and the amount of grasslands within 3,200 m. It was negatively associated with the amount of tree and shrub cover within 800 m (Fedy et al. 2018).

The Vesper Sparrow prefers some shrub coverage, short sparse vegetation to tall dense vegetation, and areas that have some bare soil. In Alberta, its presence was positively correlated with woody vegetation around pond margins (Dechant et al. 2002a). In Washington State, it used sites with an average of 32% bare ground with the remaining area covered by grasses and forbs. Beauchesne et al. (2007) concluded that it required some shrub coverage in open habitat. In Washington State, it was most abundant in shrubsteppe habitat followed by Conservation Reserve Program (CRP) fields. It preferred sites with more than 5% shrub cover. Cover of perennial grasses at the site level was positively associated with daily nest survival (Vander Haegen et al. 2015). In South Dakota and Wyoming, it was one of the most abundant species in grass-sagebrush habitat on mines reclaimed 3-10 years previously. Lower densities occurred where sagebrush was absent. In Iowa cropland, pairing success was significantly related to the number of shrub groups and amount of crop residue in territories and almost significantly related to coverage by non-productive areas other than fencerows, such as washes and uncultivated field corners (Best and Rodenhouse 1984). In North Dakota, shrubby plots that were 30-80% covered with shrubs (wolfberry and silverberry) supported 3.5 pairs per km^2 (range 0-17.5). It was absent on plots with less than 10% shrub coverage (Arnold and Higgins 1986). In North Dakota, there was more cover by aspens within 500 m, more shrubs taller than 1 m, and less litter cover where it was present than where it was absent. Invasion by woody vegetation was beneficial (Grant et al. 2004). In Wisconsin, it declined significantly when shrub coverage decreased from 19-24% to 4-12%. Fairly tall woody vegetation was required for singing and perching (Swanson 1996). In Wyoming, Montana, and South Dakota, it was more abundant where black-tailed prairie dogs were absent. Areas without prairie dogs had less shrub cover but more bare ground, less visual obstruction, and low grass cover, conditions favourable for the Vesper Sparrow. Vegetation height and density and availability of bare ground may be more important than shrub density, provided that at least some shrubs are present to provide singing perches (Augustine and Baker 2013). In North Dakota, its probability of occurrence was 70% where there were no woodlands within 500 m and 90% where the area within 500 m consisted of 70% woodland. Probability of occurrence was 50% with no tall shrubs within 100 m and 85% with 35% shrub coverage. Probability of occurrence was 55% with no brush coverage within 100 m and 65% with 50% brush coverage (Grant et al. 2006). In Montana, the Vesper Sparrow occurred where the vegetation was short and dense with a high percentage of ground cover. It was absent where the vegetation was tall and patchy. High amounts of ground cover may be needed for nest concealment and it may be easier for birds to forage in short vegetation (Reed 1986). In Maine, its abundance was

significantly correlated with habitat patchiness and the amount of bare ground (Vickery et al. 1994). In Saskatchewan, its density increased with greater amounts of bare ground (Ludlow et al. 2015). In Wisconsin, it preferred the most xeric, sparsely vegetated sites; its habitat was characterized by the sparseness of vegetation. Unoccupied areas had similar grass and forb coverage but forbs averaged significantly taller in unoccupied areas. Vertical vegetation density and mean effective height were significantly greater in unoccupied sites and light penetration was somewhat reduced. Coverage of low vegetation was greater in unoccupied areas. Litter cover and composition were similar in occupied and unoccupied areas, but litter was significantly deeper in unoccupied areas (Wiens 1969). Rotenberry and Wiens (1980) reported that it reached its maximum density in montane meadows where it was highly correlated with forb cover. These meadows were thickly carpeted with wildflowers early in the season. In Wisconsin, mean vegetation characteristics included 4% woody cover, 68% herbaceous cover, 17% litter cover, 13% bare ground, 62 cm maximum vegetation height, and 21 cm vegetation height density. A significant increase occurred as grass cover increased from 1-4% to 10-57%; densities were positively correlated with percent forb coverage (Swanson 1996).

Comparisons have been made between Vesper Sparrow usage of native grasslands and prairies with planted nonnative, or tame, grasses. In Manitoba, its abundance was negatively correlated with native grasses and positively correlated with nonnative grasses (Wilson and Belcher 1989). In Colorado, it was significantly more abundant in upland mixed-grass prairie than in lowland tallgrass prairie or tame hayfields. In Manitoba, it was negatively correlated with native vegetation and positively correlated with tame vegetation. In Wisconsin, its density was higher in barrens and dry prairies than in old fields, tame grasslands, small-grain fields, cornfields, mesic prairies, planted warm-season grasses, and hayfields. Density was positively correlated with percent coverage by woody vegetation, number of dead stems, low density of prostrate residual vegetation, amount of bare ground, and the proportion of plots that were burned. Density was negatively correlated with vegetation height and percent cover of standing residual vegetation. In Missouri, it used short cover (35% cover at a height of 1 cm and 10% cover at 25 cm) in a heavily grazed abandoned crop field. It was not observed in idle, grazed, hayed, or burned tallgrass habitat. In Iowa alfalfa fields, its abundance was directly related to vegetation density until alfalfa reached a height of 30 cm, when abundance became negatively related to vegetation height and density (Dechant et al. 2002a). On roadside surveys in Alberta, it occurred most often at stops characterized by cultivated lands mixed with native grasslands. Its occurrence was significantly higher at cultivated stops than at grazed or uncultivated stops. Its occurrence at grazed stops was significantly higher than at undisturbed areas. It occurred under both heavy and light grazing regimes, usually in association with shrubs. Uncultivated edges along agricultural lands, fencerows, and roadside ditches provided important habitat that is often lacking in native grasslands (Owens and Myres 1973). In Saskatchewan, the number of Vesper Sparrows observed per stop was 6 times higher in introduced vegetation than in native vegetation (Sutter and Brigham 1998). It was most abundant in planted pastures followed by hayfields and native pastures, and was significantly more abundant in planted than native pastures. Its abundance was correlated with planted grassland with increased cover by bare soil. There were no significant differences in nest survival rates among habitats (Davis et al. 2016).

In Michigan, the Vesper Sparrow avoided permanent pastures and pastures in hayfields. In Wisconsin, it was more abundant in continuously grazed pastures than in rotationally grazed or ungrazed pastures. In Alberta, it occurred in low numbers in early season tame and native pastures and deferred-grazed (after 15 July) native pastures and was absent in continuously grazed native pasture. In native pasture, it occurred in areas with moderate cover diversity and uniformly short grass. In tame pastures, it used areas with moderate amounts of herbaceous biomass, low to moderate variation in herbaceous height, and a moderate to high proportion of forbs relative to grasses. In Saskatchewan, it was equally abundant in lightly grazed mixed-grass prairie and lightly grazed crested wheat grass. Its occurrence was negatively correlated with vegetation height and clubmosses. In mixed-grass prairie, its abundance was positively correlated with forbs and broad-leaved grasses 10 cm or less tall and shrubs 20-100 cm tall. It was negatively correlated with broad-leaved grasses 20-100 cm tall. Its frequency of occurrence in native pasture was unaffected by grazing intensity. Heavy grazing removed virtually all plant and litter material resulting in more than 20% bare soil and more than 40% clubmosses, and presence of short plants with low vigour. Light grazing was associated with less than 10% bare soil and clubmosses, presence of robust and vigorous plants, and abundant litter and plant material. In Alberta, it was most abundant in deferred-grazed grasslands, followed by idle grasslands, continuously grazed grasslands, tame Dense Nesting Cover (DNC) for waterfowl, and idle native parkland. It was absent in idle deciduous upland, conventional hayfields, cropland, native DNC, shelterbelts, and wetlands. In Colorado, Montana, Nebraska, North and South Dakota, and Wyoming, densities were highest in moderately and lightly grazed shrubsteppe-grassland habitat characterized by vegetation averaging 20 cm tall with 9% bare soil (Davis et al. 2016; Dechant et al. 2002a).

In Iowa, the Vesper Sparrow was more common in cropland than CRP lands, which are typically characterized by dense grass cover, but it nested in both habitats. The same preference occurred in Minnesota, Montana, North and South Dakota, Indiana, and Michigan. It did not use CRP lands in Kansas, Missouri, or Nebraska but frequently nested in cropland. In Saskatchewan, it occurred in DNC and in idle grasslands and wheat fields. It was common in low nesting cover of red fescue and Kentucky bluegrass but absent from fallow cropland. In Alberta, it occurred in wetlands and wetland margins within all farmland types, and within DNC. It was present on 1-4-year-old tame DNC but absent in native DNC. In Manitoba, it was present in idle mixed-grass prairie but absent in DNC planted to either native or tame grasses (Davis et al. 2016; Dechant et al. 2002a). In Alberta, it used fields that were 70% cultivated pasture and 30% fescue more than delayed-mowed hayfields. It was absent in conventional hayfields (Jones and Cornely 2020). In Saskatchewan grasslands managed for waterfowl, numbers seen per plot were 0.02 in DNC (12.5% occurrence), 0.03 in native grassland (16.7% occurrence), and 0.02 in wheat (5.3% occurrence; Hartley 1994). In Iowa, CRP lands exhibited average characteristics that included 35 cm vertical cover (range 24-44 cm), 80% grass cover (range 47-98%), 22% forb cover (range 3-53%), 97% litter cover (range 93-100%), 36% vertical patchiness (range 18-56%), and 35% horizontal patchiness (range 6-65%). Density of the Vesper Sparrow was 20 times greater in cropland than CRP land. Nest densities in row crops increased with increasing crop residue from the previous year (Patterson and Best 1996). In Illinois, it occurred at a fairly high frequency in bare-field habitats such as row crops and plowed fields (Graber and Graber 1963). Camp and Best (1994) examined its usage of roadsides adjacent to cropland in Iowa. Strips along

roads were 6 m wide and consisted of a foreslope near the road, dropping to the bottom of a ditch, followed by a backslope up to a fence. All nests were in the foreslope area. Nest densities were positively correlated with the amount of bare ground and negatively correlated with vegetation height and density. Nests were in areas with shorter, sparser vegetation than generally occurred in roadsides, although the immediate nest site contained less bare ground than the area within 1 m of the nest. Vegetation characteristics at nests compared with the area within 1 m, respectively, included: vertical density, 4.1 and 5.1; vegetation height, 32.5 cm and 20.5 cm; grass cover, 52.1% and 40.0%; forb cover, 13.3% and 3.2%; and bare ground, 31.2% and 55.0%. Vegetation was most sparse in the foreslope where all nests were located due to mowing and presence of gravel from the road. Although density in roadsides was higher than in row crops, nesting success was low due to predation.

Other microhabitat preferences have been identified for the Vesper Sparrow. It occurred in green ash woodlands in South Dakota where it was present in early seral stages and absent in late seral stages. Early stage woodlands had less foliage density 1-2 m from the ground, were patchier, and had lower canopy cover (Rumble and Gobeille 1999). In Illinois, it particularly favoured edge shrub habitats, red clover fields, and shrub-grown areas (Graber and Graber 1963). In Wisconsin grasslands, populations were low and dispersed along field edges and fencerows. All territories contained posts and a fence line but none contained wire bales or tangles or trees (Wiens 1969). In the Prairie Provinces, it was in a guild associated mostly with coniferous forests; this study examined forested habitats only. It was associated with dry, nutrient-poor sites that were probably open jack pine stands (Kirk et al. 1996).

Considerable research was conducted on Vesper Sparrow usage of row-crop fields in Iowa. The cropping system there consists of planting corn and soybeans in alternate years. After planting, the area between the rows of crops was periodically cultivated to remove weeds. In Iowa, 58% of the land is in corn-soybean agroecosystems and this rate is 56% in Indiana. These areas provide considerable nesting habitat for the Vesper Sparrow, although nesting success tends to be very low. Within this ecosystem, there are patches that differ in vegetation structure and soil surface litter such as fencerows and weedy areas within cropped land. These provide essential habitat features. With the alternating crop system, soybeans are planted in fields that have corn crop residue from the previous year, and vice versa. Vesper Sparrow activities and early nests were initially in fields with corn residue. Once spring tillage began, most activity and nest placement shifted from 1 side of the fencerow in the territory to the other side that was most recently tilled. It may benefit from having different crops on either side of the fencerow. Agricultural operations on either side of the fencerow are asynchronous in these cases. Nesting sparrows were disturbed regularly and nests were often destroyed by agricultural activities, but only part of the territory was tilled at once, leaving a refuge. On plowed fields with little residual crop coverage, nests were scarce until crop plants began to develop. Later, as the crop canopy closed in mid- to late July, croplands became unsuitable for nesting. Early in the season, nests in crop fields were always in a clump of crop residue. Once the crop was about 10 cm tall, nests were placed at the base of growing plants in the crop row. Early nests were often near non-productive areas such as fencerows, washes, and weed patches, probably because they were the primary source of insect food at that time. Early nests were also in fields with the greatest amount of residual cover from the previous year's crop. Midseason nests were further

from non-productive areas because insect availability in crops greatly increased at that time. After 19 June, nests were closer to non-productive areas than in midseason. These nests were mostly in soybean fields because corn was too tall with a closed canopy by then and was no longer suitable nesting habitat. By mid-June, there was probably greater homogeneity in the distribution of food so birds did not have to nest close to non-productive areas. Although corn fields were unsuitable for nesting at this time, weedy areas under the corn canopy were heavily used for foraging. Having both soybean and corn fields within the territory provided suitable nesting habitat and preferred foraging areas in close proximity during the period when the probability of successful nesting was highest. In the last month of the breeding season, a high proportion of nests were in washes in soybean fields. These areas were open in an otherwise densely vegetated area. In spring, territories where fencerows had a greater number of shrub groups were occupied first. Early occupied territories tended to have greater crop residues in fields and less aerial extent of fencerow coverage. There was little correspondence between habitat characteristics associated with habitat preferences and those related to breeding productivity. This was due to the disruptive nature of agriculture. Radical instantaneous habitat changes may occur such as 100% of the crop residue being buried within a day. Consequently, the Vesper Sparrow may not be able to adjust its breeding behaviour to compensate for habitat changes made by agricultural practices (Best and Rodenhouse 1984; Rodenhouse and Best 1981, 1983, 1994). In contrast to agricultural fields, there is typically no difference in the vegetation at first and second nests in grassland habitat (Wray et al. 1982).

The Vesper Sparrow responds quickly to habitat changes. It colonizes new areas swiftly when habitat becomes suitable but disappears as old fields change into forest cover (Jones and Cornely 2020).

Some studies compared the habitat requirements of the Vesper Sparrow with those of other species. Wiens (1969) conducted a study on the ecology of grassland birds in Wisconsin. In addition to the Vesper Sparrow, the study area supported the Upland Sandpiper, Savannah Sparrow, Grasshopper Sparrow, Henslow's Sparrow, Bobolink, Eastern Meadowlark, and Western Meadowlark. The mean distance of Vesper Sparrow territories was 0 m from fencerows and 69.0 m from cultivated fields (range 5-180 m). Its mean effective vegetation height was low and differed significantly from all species except the Western Meadowlark. Compared with the Vesper Sparrow, vegetation density was greater in areas occupied by other species except in the single Western Meadowlark territory, where it was less. The total vertical vegetation density was significantly less for the Vesper Sparrow than for the Bobolink and Henslow's Sparrow. Light penetration to the ground was high, but not as high as for the Western Meadowlark. Coverage of low lawn-like vegetation was greater for the Vesper Sparrow than for all species except the Western Meadowlark. Forb density was higher and forb height was lower in Vesper Sparrow territories for all species except the Western Meadowlark. Litter depth was similar to that of the Western Meadowlark, Savannah Sparrow, and Grasshopper Sparrow but significantly less than in territories of the Bobolink, Eastern Meadowlark, and Henslow's Sparrow. Vesper Sparrow perches were 14.6% in grasses, 10.8% in heavy-stemmed forbs, 51.7% on wires, and 22.8% on posts. It used wires and posts much more and grass less than other species, and used forbs less than the other sparrows. Habitat was characterized as sparse low vegetation compared with dense low vegetation for the Western Meadowlark and tall dense vegetation for the Bobolink and Henslow's Sparrow. The Vesper Sparrow and Western Meadowlark were associated

with shallow loose litter. Territories often included trees or fence lines for the Vesper Sparrow, Eastern Meadowlark, and Bobolink, but not, or only occasionally, for the Henslow's Sparrow and Western Meadowlark. Species arranged in order of increasing vegetation richness (vegetation density and height and litter coverage and depth) were Western Meadowlark, Vesper Sparrow, Savannah Sparrow, Grasshopper Sparrow, Eastern Meadowlark, Bobolink, and Henslow's Sparrow. The range of difference in this ranking was small. Ecologically similar species performed their basic activities (nesting, foraging, singing, perching) in slightly different manners by differentially using the various substrates or using different vertical layers in the same substrate. In shrubsteppe vegetation, the Vesper Sparrow occupied a habitat niche in montane meadows that was most similar to that of the Savannah Sparrow. Its niche was somewhat similar to those of the Upland Sandpiper, Grasshopper Sparrow, Eastern Meadowlark, and Dickcissel (Rotenberry and Wiens 1980). In Michigan, the Vesper Sparrow was exclusively a ground nester, the Field Sparrow nested on the ground and in low shrubs, and the Chipping Sparrow nested exclusively in trees and shrubs (Evans 1964). In coniferous plantations in Wisconsin, the most common species were the Chipping Sparrow, Clay-colored Sparrow, and Field Sparrow and, to a lesser extent, the Vesper Sparrow. For plantations to be suitable for the Vesper Sparrow, they have to be young with an open canopy (Mossman et al. 1991).

The Vesper Sparrow demonstrates no clear preference for the edge or interior of habitat patches. It is likely that territories are selected based on the suitability of the vegetation structure and density of singing perches. In Colorado, it was significantly more abundant 200 m from edge than closer to edges between suburban development and upland or lowland habitats (Dechant et al. 2002a). In Wisconsin, the mean distance of territories from a wooded area was 246.0 m (range 10-370 m; Wiens 1969). In Alberta mixed-grass prairie, it increased with proximity to roads and exhibited no response to cropland edges. It was neither attracted to nor avoided wetland edges. It may have been attracted to roadsides because of the presence of fence posts for singing perches (Sliwinski and Koper 2012). In row crops in Iowa, it was an obligate edge species. Territories were centred along fencerows and did not extend into fields further than 80 m in 1 study and 110 m in another study. Interior portions of fields were avoided, probably because of the lack of suitable perches (Perritt and Best 1989; Rodenhouse and Best 1983).

The Vesper Sparrow does not appear to be area sensitive, but results are somewhat conflicting. In grassland habitat, it has nested in patches smaller than 4 ha (Beauchesne et al. 2004; Jones and Cornely 2020; Swanson 1996). In Illinois and Missouri, it was found in all sizes of habitat patches and considered highly tolerant of habitat fragmentation. Nonetheless, 10-100 ha was considered the minimum patch size to support a viable population (Herkert 1994a; Swanson 1996). In Maine, its abundance was significantly correlated with patch size. The approximate percentages of incidence were 1-2% in grasslands 1-2 ha in area, 38% at 10 ha, 62% at 100 ha, and 88% at 1,000 ha. Incidence reached 50% at approximately 20 ha. Although incidence increased with patch size, the smallest patches were not completely avoided (Vickery et al. 1994). In Iowa, it nested in 6-m-wide strips in roadsides (Camp and Best 1994), suggesting that it was not area sensitive. In agricultural row crops in Iowa, it was restricted to areas within 80 m or 110 m of edge (Perritt and Best 1989; Rodenhouse and Best 1983), suggesting that large fields would support lower densities than smaller fields. In North Dakota, its probability of detection was significantly negatively correlated with forest patch

size. Its rate of incidence was 80% in 1-ha forests, 55% in 10-ha woodlots, 20% in 100-ha woodlands, and 10% in 1,000-ha woodlands (Grant and Berkey 1999). Johns (1993) reported it being more abundant in large than small woodlots and considered it area sensitive. It occurred in the full range of sizes of woodlots that were examined, from 0.04-30 ha.

Almost all Ontario Vesper Sparrow nests were on the ground, although one was elevated in a grass clump. Many ground nests were in slight depressions or hollows and one was excavated by the bird. Of 129 nests, 68.2% were hidden in or under grass or forb clumps, 20.9% were under or at the base of small trees and shrubs, 6.2% were exposed, 3.1% were beside logs or dead branches, and 1.6% were under dead branches (Peck and James 1987, 1998b).

Almost all nests are on the ground in a small depression, with the exceptions being 1 nest in Ontario and 2 of 176 nests (1.1%) in British Columbia. The 2 British Columbia nests were in shrubs. Nests are frequently near small patches of bare ground or where the vegetation is sparse and low. First nests may be well concealed in an excavation in the ground under cover of prostrate dead herbaceous stems. Nests along gravel roads or in previous year's alfalfa or corn fields are often at the base of a grass tussock, thistle, dandelion, some other plant, or a clod of dirt. Some nests are almost completely exposed from above during egg laying but may be hidden by new growth by the time eggs hatch. Two nests on Vancouver Island were in a mixed forb-grass area concealed in a clump of English plantain and a third nest was in a rocky area against the side of some mowed Scotch broom. In Michigan, nests were oriented toward the north, possibly for protection from the afternoon sun. In British Columbia, there was vegetation on the southwest side of 87% of nests, significantly different from random, and they had a lower ambient temperature. Nests with a southwest orientation are potentially subjected to temperatures that are lethal to embryos for a short time. Nests sometimes have a ramp at the front and nests in sedges have a characteristic awning formed by bent sedge blades (Beauchesne et al. 2007; Berger in Austin 1968; Campbell et al. 2001; Jones and Cornely 2020; Wiens 1969).

The Vesper Sparrow is territorial and most activity is conducted within the territory. Adults frequently forage in nearby shrubs and woodland edges outside the territory. Territories are established shortly after arrival in April but boundaries are rather indistinct initially. The number of birds stabilizes in May. Territory configuration becomes established then and remains fairly constant for the remainder of the breeding season. In row-crop fields where food resources are patchily distributed, territory selection in fields may be related to the abundance and availability of food for nestlings. In Iowa croplands, preferred territories contained more shrubs and crop residue. In agricultural fields, territories typically straddle a fencerow. In grassland, territorial boundaries often follow fencerows or trails for a distance, often resulting in irregular boundaries. In Montana, 1 territory was L-shaped because of a sudden change in vegetation from mixed grasses to broad-leaved forbs. The area of forbs was avoided, possibly because the Vesper Sparrow had difficulty perching on the plants. Territory size is variable and dictated largely by food availability. Territory sizes of 0.29-8.19 ha have been reported; larger territories are often associated with cropland. In Wisconsin grassland, territories averaged 0.89 ha (range 0.61-1.09 ha). Territory size varied over the season and was significantly larger 28 May to 10 June. Average territory sizes in different periods were: 20-26 April, 1.09 ha; 15-25 May, 1.29 ha; 28 May to 10 June, 1.46 ha; and 14-25 June, 0.89 ha. In

Montana grasslands, territories averaged 1.02 ha (range 0.61-1.60 ha). In Michigan, territories averaged 2.59 ha, with averages of 1.53 ha in open fields and 1.03 ha in fields with standing dead trees; territories were 0.48-0.72 ha in cultivated fields. In Oregon grasslands, territories averaged 1.3 ha (range 0.4-5.2 ha). In Montana, 60 territories averaged 1.65 ha (range 0.29-3.04 ha); 3 territories in Montana montane meadows averaged 1.96 ha. In Iowa croplands, territories averaged 3.05 ha in 1 year and 3.57 ha the next year. Another Iowa study in cropland determined that the average territory size was 2.3 ha with a range of 1.8-3.2 ha (Best and Rodenhouse 1984; Dechant et al. 2002a; Jones and Cornely 2020; Perritt and Best 1989; Reed 1985; Rodenhouse and Best 1983, 1994; Wiens 1969).

Based on limited data, natal philopatry rates appear to be very low. Zero of 45 banded nestlings returned in Michigan (Dechant et al. 2002b).

Adult site fidelity rates are variable, based upon limited data. In Michigan, 6 of 8 banded adults (75.0%) returned the following year, and 5 of 16 (31.3%) returned the year after that. One male returned to the same territory in 4 years and 1 adult was recaptured at the same site 6 years later. Combining the returns for the 2 years, 11 of 24 adults (45.8%) returned. In Iowa cropland, 4 of 26 males (15.4%) and 2 of 11 females (18.2%) returned; the total return rate of adults was 6 of 37 (16.2%). All returned to the same fencerow they used the previous year and 2 males occupied the same territory. All returning birds nested successfully the previous year. There appeared to be no apparent advantage to returning to the same area because breeding habitat was abundant. Site fidelity to row-crop fields may be disadvantageous because some birds may return to suboptimal habitat. The amount of crop residue may vary considerably and fencerows may be altered or removed (Berger in Austin 1968; Best and Rodenhouse 1984; Dechant et al. 2002a).

Limiting Factors

Eggs have been reported in Ontario from the last week of April until the first week of August with most present in the last week of May and throughout June (Peck and James 1987). In Algonquin Park, eggs are present from late May to early July, nestlings are present from late June to late July, and recently fledged young have been observed in early August (Tozer 2012).

There is no information on how long nest building takes or if there is a time interval between nest completion and initiation of egg laying. Eggs are probably laid at the rate of 1 per day. It is unknown when incubation is initiated in relation to clutch completion. The incubation period is 11-14 days, but mostly 12-13 days. The incubation period at 4 Ontario nests was 11 to less than 13 days. The normal nestling period is 9-14 days (average 9.6 days in Michigan). If nestlings are disturbed, they may leave the nest when they are as young as 7 or 8 days (Berger in Austin 1968; Evans 1964; Jones and Cornely 2020; Peck and James 1987).

Ontario egg dates suggest that 2 broods may be raised in a year, but this has not been confirmed; the same is true in British Columbia and Quebec. In Ontario, a second clutch was reported in a nest that had contained young a week previously. In Wisconsin, only a single brood was raised. Double-brooding has been confirmed in Michigan, West Virginia, and New York. Michigan birds regularly raised 2 broods and 1 female successfully raised 3 broods. Renesting is common if a nest is lost. In West Virginia, an average of 3.6 nesting attempts were made per year, with averages ranging from 3.4 to 4.1 in individual years. Clutches of 2-6 eggs have been reported in Ontario (average 3.65 eggs). Fifty-nine percent of clutches contained 4 eggs and only 2 clutches

of 6 eggs were reported. Elsewhere, clutches of 3-6 eggs have been reported, with a normal range of 3-5 eggs and a mode of 4 eggs. Mean clutch sizes elsewhere include 3.8 eggs in Alberta; 4.0 in Saskatchewan; 3.8, 3.9, and 3.5 in 3 years in West Virginia; 3.6 in Michigan; 3.75 in Illinois before 15 July and 3.37 later; and 3.7 in Ohio, with mostly 4-egg clutches in May and 3-egg clutches in June and July. The slight but nonsignificant decline in clutch size with the advancing season may be due to shorter day length, diminishing food resources, and tapering off of the endocrine reproductive system (Berger in Austin 1968; Campbell et al. 2001; Dechant et al. 2002a; Gaudet et al. 2020; Graham and Cotter in Gauthier and Aubry 1996; Jones and Cornely 2020; Ludlow et al. 2014; Peck and James 1987; Wiens 1969; Wray et al. 1982).

The age at first breeding is 1 year. No information is available on the proportion of yearlings that nests and if there is a floating, nonbreeding population. The mating system is monogamous. It is probable that the pair bond persists throughout the breeding season, but this has not been verified. Most returning adults do not remate but 1 pair reunited in a subsequent year in Michigan (Dechant et al. 2002a; Jones and Cornely 2020).

In agricultural land in Iowa, food items were obtained mostly from the ground, but the Vesper Sparrow also gleaned the foliage of short plants and hovered to capture insects from vegetation as tall as 25 cm. It occasionally scratched vigorously with both feet at a potential food source, such as crop residue. It often pecked rapidly, suggesting that numerous small items were captured and ingested. It occasionally foraged at a single site for several minutes and walked as far as 50 m between foraging bouts. In Wisconsin grasslands, all foraging was in grasses 5 cm or shorter. Its behaviour of foraging in very short grass differed from that of all other grassland species. The Vesper Sparrow was not observed foraging in medium-stemmed forbs. It forages wherever food is most abundant. In Michigan grasslands, a considerable proportion of food captured for nestlings was obtained from a nearby woodlot rather than being caught within the breeding portion of the territory. Edges and interspersion of habitat types may be important in supporting high sparrow densities. In Iowa croplands, both sexes foraged almost exclusively in their territories. Only late in the season and after an adjacent territory had been abandoned did adults forage off their territories. At this time, flights longer than 300 m were occasionally made. In agricultural cropland, it alters its foraging locations throughout the breeding season in response to the distribution of food. It forages mostly in or near uncropped or weedy areas throughout the season, but proportionately more foraging occurs away from these areas later in the season. In April and May, 68% of foraging observations occurred within 1 m or in an uncropped or weedy area. In June, when insects were colonizing young crops, it walked along rows of corn gleaning insects. In July and early August when insects and foraging activity was more evenly distributed, 50% of foraging still occurred within 6 m of a non-productive area. Foraging was concentrated in a small proportion of each territory. Large areas of cropland, especially more than 50 m from a non-productive area, were rarely used for foraging. Of 21 birds that had the option of foraging in soybean or corn fields, 13 preferred to forage in soybean fields, 7 preferred to forage in corn fields, and 1 had no preference. Soybean fields had greater crop residue from the previous year's corn crop, and the Vesper Sparrow significantly preferred to nest in fields with greater crop residues. Fields with more crop residue had more elevated song perches, more concealing cover, and greater abundance of arthropods. Foraging occurred mostly in open or sparsely vegetated areas in cropland in April and May. In June,

uncropped areas with perennial vegetation, such as fencerows and grassed waterways, became unsuitable for foraging because of dense plant growth, and the proportion of time spent in these areas declined dramatically. During June, crop fields remained sparsely vegetated but provided a source of insect prey. In July and August, annual weeds in washed-out areas and cropland provided both insects and seeds for food. Overall, it tended to forage in field margins during the breeding season. The scarcity of insects in crop fields may contribute to the larger territories that it usually has in croplands (Best and Rodenhouse 1984; Evans 1964; Judd 1901; Rodenhouse and Best 1983, 1994; Wiens 1969).

In Michigan, the frequency of occurrence of food items in nestlings' feces included 30% odonates, 90% orthopterans, 50% true bugs, 60% soft-winged bugs, 100% beetles, 100% lepidopterans, 60% flies, 20% hymenopterans, 90% spiders, and 80% plant material. The frequency of occurrence of items in gizzards of nestlings was 100% orthopterans, 64.3% true bugs, 92.9% soft-winged bugs, 78.6% beetles, 71.4% lepidopterans, 35.7% flies, 42.9% hymenopterans, and 21.4% plant material. Larvae or nymphs of lepidopterans, orthopterans, beetles, and soft-winged bugs were preferred to adults. Nestlings ate significantly higher frequencies of soft-winged bugs, lepidopterans, flies, and spiders and lower frequencies of plants than adults. Nestlings were fed by frequency 58.3% rapidly flying insects, 66.7% sluggish larvae, and 100% insects that are active on the ground compared with 12.5%, 15.6%, and 93.8% for adults, respectively. While searching for food for nestlings, adults spent less time on open ground and more in active flight or in higher vegetation strata than while foraging for themselves (Evans 1964; Jones and Cornely 2020).

Judd (1901) examined the contents of 130 adult stomachs. The diet over the entire year consisted of 69% vegetable matter and 31% animal matter. In winter, the Vesper Sparrow eats vegetation almost exclusively; the summer diet consists of 90% invertebrates. The use of animal foods declines in late summer and early autumn. Vegetation comprises only 10% of the July diet and begins to increase steadily by early August until it comprises the entire winter diet. In addition to seeds, which are the staple of the vegetation part of the diet, it eats fruits of mulberries, blackberries, and strawberries, and buds of beech, maple, and apple. Seeds consisted of 11% grain, 16% grasses, and 42% weeds. The grain included oats and wheat gleaned from stubble fields, horse droppings, or roadsides. It is less partial to grass seeds than other sparrows, but selects much the same species: foxtails and crabgrasses and, to a lesser extent, timothy and paspalum. Weed seeds are more prevalent in the diet, including ragweeds, amaranths, lamb's-quarters, sunflowers, smartweeds, and purslane. Ragweed and amaranth seeds comprised 16% of the entire diet; purslane and sunflowers were preferred over amaranths and lamb's-quarters. The animal food consists almost entirely of insects. The diet included of 12% beetles, 11% grasshoppers and other orthopterans, 5% hairless caterpillars, and 2% bugs, ants, and other hymenopterans. Beetles and grasshoppers formed the bulk of the insect food and constituted a third of the May diet. As grasshoppers become more common as the season progresses, they become dominant in the diet. It is very partial to beetles and still eats them when grasshoppers are abundant and when they are available in winter. Scarab, click, and ground beetles and weevils are preferred to other beetle families. Scarab beetles are very abundant in pastures where it nests and these form 4% of its annual diet. Weevils constitute 4% of the annual diet and 20% of the June diet. Grasshoppers and other orthopterans predominate over all other insect prey from June to September. The Vesper Sparrow eats mostly short-horned

grasshoppers and these constituted 41% of the July diet. In May, 21% of the diet consisted of cutworms, armyworms, and other smooth caterpillars. It also eats leafhoppers, flies, spiders, snails, and earthworms; these collectively represent about 3% of the entire diet. Evans (1964) examined the Vesper Sparrow's diet in Michigan. In spring, the frequency of occurrence in 12 adult gizzards was 41.7% orthopterans, 8.3% true bugs, 25% soft-winged bugs, 66.7% beetles, 25.0% lepidopterans, 16.7% hymenopterans, 16.7% spiders, and 100% plant material (16.7% wiregrass, 58.3% panic grass, 16.7% foxtails, and 50.0% Indian grass). Beetles were represented mostly by ground beetles and weevils. The frequency of occurrence of food items in summer of adults and fledglings was 5% odonates, 80% orthopterans, 65% true bugs, 55% soft-winged bugs, 85% beetles, 5% lepidopterans, 5% flies, 40% hymenopterans, 35% spiders, and 95% plant material (5% flatsedges, 10% wiregrass, 95% panic grasses, and 5% wood-sorrel). Plant material represented 59% of the spring diet and 44% of the summer diet. Among beetles, leaf and click beetles became common in the diet along with ground beetles and weevils. The primary bugs in the diet were leafhoppers, plant bugs, assassin bugs, and meadow spittlebugs. Adult grasshoppers were more abundant in the summer diet. Ants were the main hymenopteran food but it also ate ichneumonid wasps and other parasitic wasps. Plant material remained common in the summer diet, particularly panic grass seeds. Jones and Cornely (2020) reported the results of additional diet studies, and noted that adults frequently ate ants that entered the nest. In Utah, 116 stomachs contained 1,300 insects from 10 orders, 3,158 seeds, and 1 pseudoscorpion. Adult insects predominated in the diet, but larvae, nymphs, pupae, and eggs were also eaten. Dominant animal prey items were soft-winged bugs (about 28.7% of the diet, mostly spittlebugs and aphids), beetles (26.9%, mostly weevils and leaf beetles), hymenopterans (17.0%, mostly ants), true bugs (14.2%, mostly seed bugs), orthopterans (8.5%, mostly locusts), lepidopterans (6.5%, almost entirely caterpillars), and flies (3.1%). Miscellaneous invertebrates in the diet included green lacewings, odonates, caddisflies, and spiders (Knowlton and Nye 1948). In Washington, the diet was predominantly seeds early in the season, but grasshoppers became much more abundant in the diet from June to August. Grasshoppers constituted over half the biomass of food items, but seeds represented 88% of items consumed (Rotenberry 1980). In southeastern Washington State, it was highly insectivorous throughout the breeding season. From June through August, grasshoppers were most important in the diet, often comprising more than 50% of the biomass consumed. Nonetheless, grass seeds dominated the diet numerically and represented 88% of food items. In Minnesota, a third of the diet consisted of seeds, mostly those of ragweeds, purslane, sunflowers, lamb's-quarters, foxtails, crabgrasses, knotweeds, and grain. In Montana, the summer diet consisted of 50.5% insects (grasshoppers, leaf beetles, and weevils) and 20% needle grass. Grasshoppers and beetles formed the bulk of the diet in early summer and seeds were important later in the year. Animal foods included beetles, orthopterans, hymenopterans, true bugs, spiders, caterpillars, flies, soft-winged bugs, thrips, and odonates. Plant seed species in order of abundance were bluegrass, needle grass, lamb's-quarters, satin grass, bush-clover, and Indian grass. Grass seeds predominated in the spring diet with panic and Indian grasses most frequently consumed. It commonly ate seeds throughout the summer, especially those of panic grasses. In western North Dakota, 67% of the spring diet was comprised of grasshoppers. In Montana, the early season diet was comprised of 7% grass seeds, 26% spiders, 11% beetles, 18% ants, 20% caterpillars, and 17% grasshoppers and leafhoppers. After invertebrates became abundant, the diet consisted of 5% grass seeds, 20% spiders, 11% beetles, 22% ants, 26% caterpillars, and 15% grasshoppers and

leafhoppers. The dietary breadth of the Vesper Sparrow declined by 48% after prey became more abundant (Cutting et al. 2016).

Evans (1964) compared the diets of the Vesper, Chipping, and Field sparrows in Michigan. There were very few differences in the diet of the 3 sparrows but he concluded that there was no competition for food because of its abundance. The Vesper Sparrow ate orthopterans more frequently than the other 2 species, but the difference was significant only from the Field Sparrow. The Vesper Sparrow ate true and soft-winged bugs less frequently than the other 2 species, but the difference was significant only for soft-winged bugs. The Chipping Sparrow ate significantly more lepidopterans than the other 2 species. The Vesper Sparrow continued to eat seeds in summer, particularly those of panic grasses. The other 2 sparrows ate seeds less frequently in summer but ate both grass and weed seeds. The only difference in the nestling diet was that Vesper Sparrow nestlings ate significantly fewer true bugs than Chipping Sparrow nestlings.

The Vesper Sparrow is commonly parasitized by the Brown-headed Cowbird. Rothstein (1975) considered it an acceptor of cowbird eggs. Peer et al. (2000) and Klippenstine and Sealy (2008) artificially parasitized Vesper Sparrow nests with real and artificial cowbird eggs painted similarly to real cowbird eggs, and with blue eggs. They also parasitized some nests with undersized eggs that resembled Vesper Sparrow eggs. Real and artificial cowbird eggs were accepted in all nests but 20.75% of blue eggs were rejected by grasp ejection or puncture ejection. Eighty percent of undersized eggs were rejected. Natural and artificial cowbird eggs may not have been ejected due to their close resemblance to Vesper Sparrow eggs and the risk of ejecting one of their own eggs. The Vesper Sparrow does not appear to be significantly harmed by parasitism and both species may fledge from a nest. In Illinois, the mean clutch size was 1.3 eggs in parasitized nests and 3.6 eggs in unparasitized nests. Saskatchewan parasitized nests had smaller clutches and hatched and fledged fewer young. Parasitized nests were significantly closer to field edges than unparasitized nests. Woodlands and thickets may provide perches for female cowbirds watching for activity that will reveal a nest location. One study found that parasitized nests were not significantly closer to edge or significantly less concealed than unparasitized nests. Nests are more apt to be parasitized in April and May when few other species have initiated nesting (Berger in Austin 1968; Dechant et al. 2002a; Jones and Cornely 2020). In Ontario, 52 of 494 nests (10.5%) were parasitized (Peck and James 1998b). From 1966 to 1984, 15 of 44 nests (34.1%) in Grey County were parasitized compared with 3 of 46 nests (6.5%) in Middlesex County from 1877 to 1966 (Peck and James 1987). Throughout the Vesper Sparrow's range, parasitism rates vary considerably from 0 to 61%, but tend to be low. Parasitism rates include 6 of 246 nests (2.4%) and 0 of 53 in North Dakota; 0 of 10, 25 of 41 (61.0%), 1 of 27 (3.7%), and 1 of 6 (16.7%) in Iowa; 13 of 44 (29.5%) in Iowa croplands; 2 of 53 (3.8%) in Alberta; 1 of 181 (0.6%) in Washington; 23 of 195 (11.8%) in Alberta, Saskatchewan, and Manitoba; 0 of 70 in West Virginia; 3 of 74 (4.1%) in southern Quebec; 9 of 112 (8.0%) and 3 of 14 (21.4%) in Ohio; 9 of 89 (10.1%) and 4 of 25 (16.0%) in Michigan; 4 of 52 (7.7%) in Illinois; and 3 of 215 (1.4%) in British Columbia (Berger in Austin 1968; Camp and Best 1994; Campbell et al. 2001; Dechant et al. 2002a; Gaudet et al. 2020; Granfors et al. 2001; Grant et al. 2006; Jones and Cornely 2020; Ludlow et al. 2014; Patterson and Best 1996; Rodenhouse and Best 1981; Vander Haegen et al. 2015; Wray et al. 1982).

Habitat loss and agricultural practices are the greatest limiting factors to the Vesper Sparrow. Conversion of suitable habitat to urban development is linked to its decline between atlases in Hamilton and Niagara Region, and in many areas throughout its range. Abandonment of marginal agricultural land and subsequent natural succession results in loss of suitable habitat. Declines in Algonquin Park and the Kingston area were attributed to natural succession, and much of the farmland in the southern Canadian Shield has reverted to forest (Black and Roy 2010; Curry 2006; Swanson 1996; Tozer 2012; Weir 2008).

Farming practices have changed significantly since the 1950s, and most changes have been detrimental to the Vesper Sparrow. At that time, farms were small with a few head of livestock and some pasture and hayfields. As small farms became less economically viable, harvesting machinery became more efficient, and numerous fencerows were eliminated to create larger fields. This was detrimental to the Vesper Sparrow because its territory is often centred on fence lines and it avoids the interior of row-crop fields. The practice of removing fencerows is still continuing. Fewer farmers continued to raise livestock, so the need for pastures and hayfields declined. Many fields were converted to row crops, habitat that is inferior to pasture and hayfields. Early hay crops were dominated by red clover and other clovers in the same genus. Clover fields were preferred habitat because the vegetation was short and supported abundant invertebrates. These clovers were largely replaced by alfalfa for hay. Alfalfa grows tall and dense and is marginal to unsuitable nesting habitat. The chronology and frequency of hay mowing also changed. Red clover crops were cut only once a year in mid-July. This allowed enough time to raise a first brood. Alfalfa is cut 2 or 3 times a year with the first cut in mid-June or earlier. In Iowa, the Vesper Sparrow was present in both the first and second alfalfa cuts. Its density did not differ significantly before and after mowing, although its overall density was low. Density tended to be higher 2 and 4 weeks after mowing than prior to mowing. Mowed alfalfa fields may be slightly better habitat than unmowed fields. Nests that are initiated in alfalfa fields are typically destroyed by mowing. Approximately 250,000 eggs and young are lost annually in Canada due to mowing, cultivation, and other agricultural practices. The estimated annual mortality rate in the Canadian Carolinian and Great Lakes–St. Lawrence forest regions is approximately 34,000 (Frawley and Best 1991; Graber and Graber 1963; Graham and Cotter in Gauthier and Aubry 1996; Jones and Cornely 2020; Tews et al. 2013). Wolcott et al. (2023) recommended that grassland management be deferred until August to protect both nests and fledglings.

In Iowa, corn and soybean crops are cultivated regularly after they are planted until the crop canopy closes in. Cultivation disturbs the soil between the crop rows and destroys any nests that are not in rows. In Ontario, no cultivation occurs after the crop is planted, and a single herbicide application is applied shortly after crop plants emerge. In both Iowa and Ontario, the first tillage and planting occur after the first nests are initiated. Consequently, almost 100% of first nests in corn and soybean fields fail. In Iowa, nest success rate was 9% prior to 15 June and 28% thereafter. Once the crops were about 10 cm tall, nests were placed in the crop rows and about 50% survived tillage. Since no tillage occurs in Ontario fields at this time, success rates should be higher than reported for Iowa. In Iowa, birds nesting in row crops appeared to represent sink populations, failing to produce enough young to replace themselves (Best and Rodenhouse 1984; Rodenhouse and Best 1983, 1994).

In Wyoming, mowing occurred in sagebrush habitat and was designed to reduce shrub growth and promote herbaceous plant growth. Abundance of the Vesper Sparrow increased by 5.38% for every incremental 10% increase in the amount of the point-count circle that was mowed (Carlisle et al. 2018).

Grazing alters vegetation structure and composition and has the potential to affect habitat suitability. In British Columbia, grazing resulted in significant changes in plant community structure and species composition, but had no effect on Vesper Sparrow abundance. In a second study, grazing converted habitats of robust grasses and shrubs to less robust, mat-forming grasses and forbs, and vegetation height was reduced. Nest sites had greater cover of late-seral bunched and tufted grass species, typical of ungrazed areas, than random sites. Nest survival rates were greater when the nest site had taller vegetation. Nests in shorter grasses had a higher risk of predation. Grazing reduced both the availability of suitable nesting habitat and nesting success (Harrison et al. 2010, 2011). In western native pastures, the frequency of occurrence of the Vesper Sparrow is unaffected by grazing intensity (Dechant et al. 2002a). In Illinois, moderate grazing that left 20-40% of vegetation cover taller than 25 cm was beneficial (Swanson 1996).

Responses to fire by the Vesper Sparrow depend upon the habitat and intensity of the fire. Forest fires are usually beneficial because they may create temporary habitat where none previously existed. Fire suppression may have had limited effects on it in Ontario because the bulk of its population occurs south of the areas that are most vulnerable to forest fires. Fires in shrubby areas may decrease habitat suitability, particularly if the fire is intense and kills shrubs. In shrubsteppe vegetation in Washington, fire converts sagebrush habitat to annual grasslands dominated by the nonnative downy brome. Historically, fires there were probably infrequent, occurring every 50-100 years, patchy, and uneven, resulting in a mosaic of sagebrush and native grasses in different stages of succession. Now fires are frequent, severe, and large, eliminating shrubsteppe vegetation. A fire in 2000 caused more than 90% mortality of shrubs, grasses, and forbs over 85% of the area and only 15% of the area burned in a mosaic pattern. Abundance of the Vesper Sparrow declined in the 2 years following fire, increased in the following 3 years until it approximately reached prefire levels, then declined in the final 2 years of the study (Earnst et al. 2009). Fires in grasslands tend to be beneficial because they reduce the litter depth and eliminate thatch from previous years' growths, making the habitat more suitable. After a fire in native fescue grassland in Saskatchewan, the Vesper Sparrow was the only species that exhibited a preference for burned over unburned prairie in the first year. In Idaho, it was absent from control areas, prior to the burn on the treatment plot and 1-2 years postburn, but appeared 3-7 years postburn. Colonization of grassland areas shortly after a burn or increases in abundance have been observed in other areas (Dechant et al. 2002a; Jones and Cornely 2020; Pylypec 1991; Swanson 1996). In Saskatchewan, its density in mixed-grass prairie was higher 1 year postburn and lower 2-3 years postburn than in an unburned mixed-grass site. In Wisconsin, it appeared on a restored prairie 3 years after it was burned. In another area, it was most abundant 2 years postburn and declined 3-5 years postburn. In Iowa, it was more abundant in burned than unburned roadsides. In Illinois, it was most abundant the first growing season after a burn, absent the second year, and uncommon the third year (Dechant et al. 2002a). In South Dakota, it occurred only on unburned grasslands and avoided burned areas (Swanson 1996). The effects of fire appear to be short lived and are probably initially beneficial by reducing litter depth, dead

vegetation from previous years, and possibly vegetation height and density. Intense fires could potentially kill shrubs and make habitat less suitable.

Some studies examined the effects of edges, vegetation structure, and other factors on nest success. In North Dakota, distance from edge was the most important factor determining nest survival. Percent coverage by tall shrubs was the second-most important factor; percent coverage by Kentucky bluegrass was also important. Nest survival was highest near aspen woodland edges and declined as the distance from woodland increased. Survival increased with increasing coverage by Kentucky bluegrass and tall shrubs. Nest survival was greatest for the best concealed nests. The thirteen-lined ground squirrel was the dominant predator and was most abundant in prairie interior (Grant et al. 2006). Nests near edge in Iowa croplands were significantly less likely to be successful than those distant from edge. Nests destroyed by predators averaged 13.5 m from unproductive areas for crops compared with 25.5 m for successful nests. Few predators search croplands for prey so nests near unproductive areas were more vulnerable to predation. No relationship was found between nest concealment and nest success. No territory characteristics were significantly related to nesting success but the number of washes and amount of crop residue were almost significant. Seventy-five percent of territories without a successful nest did not contain a wash and territories with 2 successful nests had a mean of 1.1 washes (Best and Rodenhouse 1984; Rodenhouse and Best 1983). In Alberta, nest survival was unaffected by temperature or precipitation, and the relationship between nest visibility and survival was highly variable (Ludlow et al. 2014). At West Virginia reclaimed mine sites, percent litter cover was 63.2% at successful nests and 53.7% at unsuccessful nests, percent bare ground was 32.9% at successful nests and 44.8% at unsuccessful nests, and vertical density was 15.3% at successful nests and 11.6% at unsuccessful nests. These characteristics indicate better concealment for successful nests that should be more resistant to avian predation. The main predators were snakes and birds, and snake predation rates appear to be constant in differing vegetation communities. Creating temporary grasslands surrounded by woodlands and pastures tends to concentrate predators and result in sink populations (Wray and Whitmore 1979; Wray et al. 1982). Nest success in relation to edge and vegetative characteristics is variable depending upon the types of predators that are present and where they are most abundant or most likely to search for prey.

Studies have been conducted on the effects of gas and oil development facilities and trails on abundance of the Vesper Sparrow. In Saskatchewan, old oil and gas wells are point sources for nonnative plant species such as crested wheat grass and yellow sweet clover. Nest locations relative to wells did not differ from random but the proportion of nests within 100 m of trails was higher than expected by random. The number of young fledged per nest was higher close to trails but did not vary with distance to wells or gravel roads. It appeared to select nest sites near trails and fledged more young from these nests (Ludlow et al. 2015). In Alberta and Saskatchewan, Sutter et al. (2016) studied the effects of active pipeline construction on the Vesper Sparrow. They compared plots close to the pipeline with those 600 m from it. Nests were evenly distributed in distant plots. In close plots, the number of nests within 50 m of the pipeline was higher than expected. Differences in vegetation near the pipeline may have been an important factor in nest-site selection. Daily nest survival declined slightly with increased exposure to pipeline activity; birds nesting near the pipeline tended to fledge fewer young. In Alberta, its abundance declined with increasing proximity to roads

and as far as 236 m from gas wells. Clutch size decreased with increasing road proximity and nesting success declined as the density of gas wells increased. Noise did not appear to be a factor because results were similar at quiet gas wells and noisy oil wells (Daniel and Koper 2019). In Saskatchewan, Sutter et al. (2000) compared abundance of the Vesper Sparrow along roads and trails. Roads had ditches and often fences. Trails consisted of a single pair of tire ruts through homogeneous habitat. It was significantly more abundant along roads, probably due to the dense grassy vegetation in roadsides and presence of fences that provided elevated song perches. In Colorado, it was significantly more abundant in mixed-grass prairies without trails than along recreational trails (Dechant et al. 2002a).

In North Dakota, the Vesper Sparrow appeared to be unaffected by wind facilities. It demonstrated no avoidance of wind turbines (Shaffer and Buhl 2015).

Declines in eastern populations have been attributed to pesticides. It appears to be unaffected by chemicals used to control grasshoppers (Jones and Cornely 2020). In Ontario cornfields, there was no difference in its abundance before and after treatment of corn rootworm with fonofos and terbufos, or between treated and control fields (Dechant et al. 2002a)

Weather is usually not a major limiting factor except in years of prolonged periods of rain or thunderstorms. This may result in nestlings dying of exposure. It can also affect the timing of agricultural activities which in turn can affect nesting success (Jones and Cornely 2020; Perritt and Best 1989). In Wyoming, all nests were abandoned when a rain storm in the second week of June was followed by 10-15 cm of snow (Schroeder 1972). During extremely hot weather and drought in North Dakota, females abandoned their nests during the incubation period. Populations declined in drought years and increased slightly at the end of the drought but remained 52% lower than prior to the drought (Jones and Cornely 2020). One study correlated the abundance of the Vesper Sparrow for 1980-2005 with the number of ponds present in May and a monthly index of soil moisture. There were no significant relationships between these parameters and its abundance (Niemuth et al. 2008). In South and North Dakota, Montana, and Wyoming, the Vesper Sparrow was significantly affected by weather. It responded negatively to the amount of precipitation received in both the current and previous years (Gorzo et al. 2016).

Dechant et al. (2002a) considered the keys to management of the Vesper Sparrow to be providing areas of dry sparse vegetation or edge habitat between forests and fields and providing elevated song perches. Specific recommendations included burning or mowing roadsides every 3-5 years to maintain vegetation quality, mowing only in early spring or late summer, delaying spraying and mowing in CRP lands to avoid the peak nesting period, leaving more corn residue in fields, and reducing the number of mechanical field operations in crop fields.

Cumming et al. (2014) examined the relationships between climate and Vesper Sparrow distribution and abundance in Canada. The main split between good and poor habitat was vegetation class, with higher abundance in mixed forest and cropland ecosystems. Within good habitat, predicted abundance was higher where the standard deviation around the August maximum temperature was less than 2.4°C. Within poorer habitat, highest abundance was found in areas with a May leaf-area index of less than 13.5 and mean net annual primary productivity less than 0.33. They interpreted this as a description of the open vegetated areas that it prefers. Price

(2004) concluded that the breeding range of the Vesper Sparrow might contract in southern Ontario if the average summer temperature increased by 2°C. In Alberta, Nixon et al. (2016) predicted the response of the Vesper Sparrow to climate change. The area of suitable climate within the province was projected to increase by less than 10% by the 2050s and by about 20% by the 2080s. The projected change in the amount of suitable habitat was 0% in the 2050s but by the 2080s it was projected to decrease by almost 30%.

Status

Prior to European settlement and the subsequent deforestation, the Vesper Sparrow was probably present but rare in the east. The open xeric sites it inhabited were probably maintained by fires, First Nations, erosion of loose sands by wind on sand dunes, diseases, insect damage, flooding, and beaver activity. Native prairies and savannahs probably supported some populations in Ontario. It responded very favourably to forest clearing and the establishment of farmland. By 1900, it was common throughout the eastern portion of its range and was one of the characteristic species where forests had been cleared. Declines as a result of agricultural intensification were apparent as early as the 1930s. Populations continue to decrease due to continued intensification of agricultural lands, natural succession, and conversion of farm land to urban areas. Agriculture is the main reason why the Vesper Sparrow is a common breeding bird in the province, but is also the main reason why populations are declining (Askins et al. 2007; Best and Rodenhouse 1984; Jones and Cornely 2020; Swanson 1986).

McIlwraith (1894) considered the Vesper Sparrow a common summer resident in southern Ontario, and it was found in essentially every grass field in the Hamilton area in 1866. It was still abundant in the Hamilton area in the 1930s and 1940s, but has since declined (Curry 2006). In Elgin County, it was a common summer resident in 1891 and 1954, but an increasingly uncommon breeder in 2000 (Lancaster et al. 2004). In the Kingston area, it was very common in 1909, fairly common in 1973, common in 1989, and common but declining in 2008 (Weir 2008). In Muskoka and Parry Sound districts, it was one of the most common summer residents in 1901 and was still abundant in southwestern Parry Sound District and northeastern Muskoka District in 1928. As late as 1948, it outnumbered the Savannah Sparrow as a breeding species. By 1980, it was only fairly common (Mills 1981). Sheppard et al. (1936) considered it abundant in Niagara Region. Black and Roy (2010) considered it a rare breeder in Niagara Region. Baillie and Harrington (1937) considered it a common breeding species from the southern boundary of the province north to southern Kenora District and Moose Factory. It was uncommon in most of northern Ontario, possibly due to the scarcity of suitable habitat, but its range appeared to extend westward to Lake of the Woods. Smith (1957) considered it uncommon in the Clay Belt portion of the Boreal Forest Region, but common around Timmins. In the Shield portion of the Great Lakes–St. Lawrence Forest Region, it was uncommon in jack pine stands near Gogama (James and Peck 1995a). In Algonquin Park, it is a rare breeder where it has been declining since about 1990, probably due to natural succession (Tozer 2012). The first atlas showed that the range of the Vesper Sparrow included all of southern Ontario north to the Kenora area in the west and Lake Abitibi in the east. No breeding records were obtained from the Moosonee area. It was absent in the urban area of Toronto, the heavily forested landscapes of Algonquin Park, southwest of Lake Nipissing, and in the boreal forest. It was uncommon in the province (Rising in Cadman et al. 1987). James (1991) considered the Vesper

Sparrow a common summer resident north to southern Georgian Bay and Ottawa, rare north to Sioux Lookout and Timmins, and formerly occasional to Moosonee.

The second atlas revealed no change in the overall distribution of the Vesper Sparrow. A breeding observation was obtained in northern Ontario in the Boreal Forest Region near North Caribou Lake. No sightings occurred in the Moosonee area. Its probability of observation declined province-wide and in every region where it occurred, except for the Boreal Forest Region where it is rare. Declines were greatest south of the Shield and in the southern portion of the Shield. Off-Shield losses were probably due to agricultural intensification and urbanization; on-Shield declines were probably related to natural succession. It was most abundant south of the Shield. Highest abundance occurred in the agricultural areas of southwestern Ontario and between the north shore of Lake Ontario and the southern edge of the Shield from Port Hope to Napanee (Rising in Cadman et al. 2007).

Breeding Bird Survey results indicate that the Vesper Sparrow decreased at annual rates of 2.37% in Canada and 3.71% in Ontario 1970-2021. It decreased annually at rates of 2.65% in Canada and 3.48% in Ontario 2011-21. All results were highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Young are incapable of flight when they leave the nest but are quick and agile at moving through the vegetation. After leaving the nest, fledglings remain quiet and hidden in the vegetation. They remain semidependent upon the adults until they are 30-35 days old, usually remaining in the vicinity of the territory during this period. If the female initiates a second brood, the male cares for the fledglings from the first brood (Berger in Austin 1968; Jones and Cornely 2020).

In Oregon at 2 sites, the fledgling survival rates were 47.1-75.0% and 52.0-78.3%, the highest known rates for a grassland species. Fledglings remained in the natal areas an average of 70.4 days and 82.4 days, with an overall average of 78.1 days; 83.8% of 105 fledglings remained on site more than 50 days. Six juveniles (3.1%) dispersed either short distances of 3 km or longer distances of 14 km. The high persistence may be because juveniles undergo a preformative moult that usually occurs on the natal site. Nearly all juveniles that survived the first 2 weeks spent 2-4 months at the natal site (Altman et al. 2024).

Once they are independent, juveniles and adults congregate together, often in the company of other grassland sparrows. In Algonquin Park, approximately 15 were seen on 11 July and 50 on 3 August on an abandoned airfield. In other areas, flocks have been observed congregating along roadsides and fencerows and in weedy and shrubby fields. Birds remain in flocks until autumn migration. Not all families join these flocks. Some late-nesting birds and their families continue to frequent pastures and fields in the vicinity of the breeding area until autumn migration (Judd 1901; Leighton et al. 2002; Tozer 2012).

MIGRATION

The Vesper Sparrow migrates opportunistically, especially in autumn, in response to food availability. In the east, the normal northern extent of the wintering area is South Carolina, Georgia, Alabama, Mississippi, and Oklahoma. It is a nocturnal migrant that moves in small groups, although flocks of

25-300 have been recorded in spring and 50-100 in autumn. Flocks arrive in waves, sometimes in the company of Savannah Sparrows (Jones and Cornely 2020).

In Iowa, females arrived within a week of the first male (Rodenhouse and Best 1983). In southern Ontario, migrants arrive in early April or very late March, with the peak of migration in mid-April and some birds still migrating until the end of April. Migrants arrive in the southern Shield in mid- or late April. Autumn migration occurs throughout September and early October, with peak movements in early October. Some persist in the province into November and rarely into early December (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008).

During migration, the Vesper Sparrow inhabits fields and habitats similar those used during the breeding season. In Algonquin Park, most spring migrants are observed at an old airfield, but it also occasionally occurs on road margins, hydro cuts, at old sawmill sites, and in other clearings (Tozer 2012). During spring migration in Ohio, it inhabited better-drained upland fields and pastures. It was most abundant in sparsely vegetated fields and in close-cropped pastures and meadows. It never occurred in large flocks in spring, with a maximum of 15 in well-organized flocks, and these occurred only early in the season. During the last half of migration, individuals became scattered over fields and pastures (Berger in Austin 1968). In British Columbia, it occurs in open grassy or weedy areas of many types during migration. These include overgrazed pastures and ranges, stubble fields, pastures, prairies, airports, openings in aspen parkland, south- and west-facing unforested or sparsely forested hillsides, road margins, clear-cuts, regenerating burns, dry agricultural fields, playgrounds, sand spits, and dunes (Campbell et al. 2001). Jones and Cornely (2020) described the migration habitat of the Vesper Sparrow as pastures, barren to overgrown fields, grassy or weedy ditches and fencerows, and weedy areas bordering cultivated fields, roadsides, and hedgerows.

The Vesper Sparrow is occasionally killed at communication towers during migration (Jones and Cornely 2020).

In Arizona, both native and nonnative grasslands were burned, reducing the amount of shrubs, eliminating litter, and increasing herbaceous cover. Grass cover was not changed significantly, especially in nonnative grasslands where an exotic love grass still averaged about 90% coverage. The Vesper Sparrow was significantly more abundant during autumn migration in burned portions of both types of grasslands for 2 years postfire, but numbers reverted to prefire levels 3 and 4 years postfire (Bock and Bock 1992).

James (1991) considered the Vesper Sparrow a common migrant in the province. Daily counts seldom exceed 100 birds (Curry 2006; Lancaster et al. 2004; Tozer 2012; Weir 2008).

Captures of migrant Vesper Sparrows at Long Point Bird Observatory declined at a nonsignificant rate of 1.9% per year 1961-88. Trends by period were: 1961-70, –8.2%; no data for 1970-79; and +21.9% 1979-88 (Hussell et al. 1992).

WINTER

During winter, the Vesper Sparrow frequents areas in the east that have an average minimum January temperature of at least –1°C. Within this area, it inhabits patches of cleared land and openings within forests. Abundant populations are restricted primarily to areas with stunted and sparse vegetation (Root 1988).

James (1991) considered the Vesper Sparrow rare and occasional in winter north to London and Kingston. Birds wintering in Ontario are well outside their normal winter range and should be considered extralimital. It is also uncertain if wintering birds successfully overwinter, if they succumb to severe weather, or move further south if weather conditions deteriorate. Limited data suggest that wintering birds are much less frequent than they were formerly. It is probable that the Vesper Sparrow is absent in Ontario in some winters.

LeConte's Sparrow

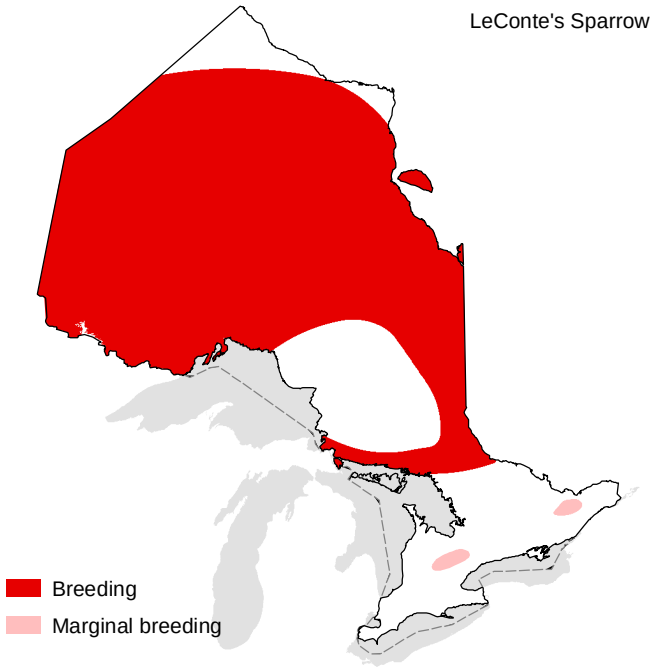
Ammospiza leconteii

BREEDING SEASON

Habitat Requirements

One Ontario LeConte's Sparrow nest was on damp ground at the edge of a swamp and another was on a grassy dyke between stands of wild rice. Near Moosonee, it nested in a graminoid-dominated tidal marsh. In Rainy River District, it nested in a wet meadow bordering a lake. Characteristic nesting habitat appears to be wet areas or their edges (Peck and James 1987, 1998b).

In the Hudson Bay Lowland, 2 nests along the James Bay coast north of the Swan River were in extensive sedge fens (Coady in Cadman et al. 2007). Near Hearst, the LeConte's Sparrow nested in a 5-year-old clear-cut in lowland coniferous forest. There was extensive growth by grey alder in low-lying areas and trembling aspen and beaked hazel on better-drained ridges. The total vegetative cover was 76%: 36% ground cover, 19% low shrub cover, 5% tall shrub cover, and 16% tree cover by balsam fir, trembling aspen, white birch, and white spruce (Welsh and Fillman 1980). Near Wawa, it nested in a sphagnum bog with a few stunted black spruces with areas of nutrient-poor open fen and meadow marsh. It inhabited about 2 ha of the fen, which was bordered by alder thickets with a



few dead balsam poplars and a mixed forest dominated by trembling aspen and white birch. The occupied area had a ground cover of sphagnum moss and was dominated by few-seeded sedge and awl-fruited sedge; Canada bluejoint was also present. The meadow marsh portion of the wetland was flooded to a depth of 0.5 m in late May but the water gradually receded by late June. This area remained damp but without standing water (Patrikeev 2006). One was seen in June in Algonquin Park at the edge of a beaver meadow bordered by alders. This may have been a breeding bird (Tozer 2012). Beaver meadows have the potential to provide suitable habitat throughout the heavily forested Shield.

South of the Shield, Villard and Bracken (1989) reported breeding by the LeConte's Sparrow south of Ottawa. The landscape was agricultural with scattered woodlots. The nest was in a vernally inundated ditch separating 2 cultivated fields. The ditch was 135 m long, 2.5 m wide, and 1 m deep. The adults were seen most frequently around a clump of reed canary grass. The ditch was densely vegetated with tufted vetch, Canada bluegrass, smooth brome, pussy willow, meadow willow, and dark green bulrush. Prior to taking up residence in the ditch, the pair was regularly observed in an alfalfa field, but moved to the ditch after the field was mowed. For at least a decade, LeConte's Sparrows nested in the grassy flats of Holland Marsh, but abandoned this area in the 1940s when it was converted to market gardening. After this, it persisted for a few years in a marsh north of Bradford until it was cultivated (Devitt 1967). In 1985, breeding was confirmed south of Luther Marsh (Sandilands and Campbell in Cadman et al. 1987). The site was an idle agricultural field dominated by rank growth of reed canary grass and smooth brome (personal observation).

Throughout Canada, the LeConte's Sparrow nests in freshwater and salt-water marshes, moist meadows and meadow marshes that are often adjacent to moister wetlands, open fens, prairies and other natural grasslands, idle agricultural lands, and old fields dominated by grasslands. Key habitat components include tall dense grasses and sedges with a deep litter layer. It is not a true grassland species because it also nests regularly in graminoid marshes and fens. In Quebec, it occurs in rather wet habitats such as large marshes of sedges and grasses, including salt-water marshes dominated by cordgrass. It frequents broad open areas thickly carpeted with dead grass and rank herbaceous growth. There is usually a scattering of low shrubs or tall herbaceous plants or grasses such as reed canary grass present. These meadows may be nearly pure sedge communities or mixed communities of grasses and sedges. It also nests in pastures, dense wet meadows, peatlands with abundant grasses and sedges, and fallow or recently abandoned agricultural land where shrub growth is not overly advanced. Although it often occurs in wet habitats, it also inhabits dry areas

(Boulva and Browne 1965; Létourneau and Aubry in Gauthier and Aubry 1996). Erskine (1977) reported that it was associated with fens in the Boreal Forest Region. In the Prairie Provinces, it was in a guild of birds that nested in wet marshy fens or young aspen stands less than 9 years old. It was associated with wetter habitats (Kirk et al. 1996). In Saskatchewan, Hartley (1994) reported 1.34 birds per plot with 100% occurrence in Dense Nesting Cover (DNC), 0.46 birds per plot with 94.4% occurrence in planted native grasses, and 0 in wheat. Near Saskatoon, it was associated with damp areas adjacent to lakes and sloughs where the vegetation was lush. More rarely, it bred in alfalfa fields (Leighton et al. 2002). It bred in native and tame DNC 3-5 years old, including fields planted to intermediate and tall wheat grass, alfalfa, and sweet clover. It occurred in low nesting cover of Kentucky bluegrass and red fescue. In 1 area of Saskatchewan, it was present only in organic farmland and upland DNC and was more abundant in the latter habitat. It was more abundant in wetlands in organic farmlands than wetlands in conventional farmland or DNC. Its density was unaffected by the amount of cropland or wetland within 1.6 km (Dechant et al. 2002i). In Alberta, Tittler et al. (2001) considered it a species of clear-cuts rather than one of unharvested forests. It colonized clear-cuts by the third year after harvest and decreased with increasing basal area of trees. It occurred more frequently in tame than native pastures. In tame pastures, it preferred high grass biomass. In native pastures, it preferred low to moderate cover diversity and moderate to tall grass of uniform height. It was rare or absent in DNC less than 2 years old, increased in abundance through the fifth year, and decreased thereafter (Dechant et al. 2002i). In British Columbia, it nests in patches of sedges emerging from flooded lands. These habitats often contain scattered clumps of low-growing willows. It also inhabits drier sites with grasses, sedges, and willows. One study found that it occupied damp sites ranging from shrub carrs to fields where patches of tall black spruce were prevalent. Sedge meadow–shrub carr edges were the most commonly used habitat. One occupied location was dominated by creeping bentgrass close to a shrub carr complex. Preferred habitat had a plant association that included beaked sedge, horsetails, scrub birch, Labrador tea, sphagnum moss, and willows. It has nested in damp short-grass margins of grain fields, wet sedge verges of black spruce–tamarack muskeg, tall grasses at sewage lagoons, and patches of Labrador tea along shores of muskeg ponds (Campbell et al. 2001). In the Yukon, it nested in open wet meadows with dense and tall (0.5 m) grasses and sedges with scattered shrubs 0.5-1 m tall; the shrubs were used as singing perches. Moisture conditions at nesting sites ranged from wet to standing water (Sinclair et al. 2003).

In the United States, the LeConte's Sparrow nests predominantly in meadows adjacent to marshes, wet or flooded grass and sedge meadows, fallow fields, hayfields, undisturbed pastures, tallgrass prairies, planted cover including Conservation Reserve Program (CRP) lands, and hummocky alkaline fens. Many territories contain scattered low shrubs but others are devoid of shrubs. In territories within or near marshes, common plant species may include soft-stemmed bulrush, willow, prairie sedge, spikerushes, water parsnip, wild mint, and bugleweed. In grassland habitats, it may be associated with cordgrass, river grass, common reed, squirrel-tail grass, smooth brome, Kentucky bluegrass, quack grass, creeping bentgrass, barnyard grass, timothy, reed canary grass, and wheat grass. It occasionally nests in hayfields dominated by timothy and alfalfa and rarely nests in small-grain fields. It occurs most often in moist or wet habitat but also nests in drier areas

(Dechant et al. 2002i; Igl and Johnson 1995, 1999; Lowther 2020b; Murray 1969; Peabody 1901; Walkinshaw 1937; Walkinshaw in Austin 1968; Winter et al. 2005).

Once shrub coverage becomes too dense or taller than about 1 m, habitat becomes unsuitable for the LeConte's Sparrow. In North Dakota, its abundance decreased with increasing tree cover. Its probability of occurrence was 50% when there was 0% woodland cover within a 500-m radius. Its probability of occurrence decreased to 30% at 20% tree cover and to 0% at 60% tree cover (Grant et al. 2004). It tended to avoid areas with extensive woody vegetation (Johnson and Igl 2001). In Minnesota, Winter et al. (2005) found no evidence that it avoided trees when situating its nest. Nesting success increased slightly with increasing distance to trees but percent coverage by trees and shrubs did not affect nest success.

Some studies compared habitat where the LeConte's Sparrow is present to unoccupied sites, or nest sites to the remainder of the territory. In North Dakota where it was present, there was significantly deeper litter (4.3 cm compared with 2.8 cm), taller vegetation (55 cm compared with 51 cm), more smooth brome coverage (22.1% compared with 14.1%), more legume coverage (4.9% compared with 0.2%), less aspen coverage within 100 m (2.1% compared with 6.3%), less native herbaceous vegetation coverage (34.2% compared with 43.9%), and less aspen within 500 m than where it was absent. Its occurrence was greater in areas with taller, lusher vegetation dominated by cool-season nonnative plants such as smooth brome, quack grass, and sweet clover. There were 4 vegetation parameters that did not differ between occupied and unoccupied areas. Mean values for these parameters in occupied areas included 33.7% live vegetation, 14.9% shrubs shorter than 1 m, 2.4% taller shrubs, and 18.9% bluegrass coverage (Grant et al. 2004). In North Dakota in a wet year, it occurred throughout grassy floodplain habitat except in the wetland areas. Its population was densest in cordgrass, less dense in the sparser cover afforded by squirrel-tail grass, and rare in smooth brome in the dry upland habitat. In a dry year, it was confined to the cordgrass habitat. Both cordgrass and river grass provided thicker cover for nest sites. Both grasses are tall and grow in dense stands and most dead stems fall and form a thick mat of litter. Squirrel-tail grass is sparser and shorter and remains upright after drying. The largest patch of squirrel-tail grass was the driest area and was avoided. It typically sang from the concealment of clumps of cordgrass but occasionally from the top of a dock plant. Only 3 used 1-m tall stakes placed throughout the study area, and not until mid-July. Both the LeConte's and Nelson's sparrows nested at this site and both were most numerous in cordgrass, with the LeConte's Sparrow occupying some drier habitats and the Nelson's Sparrow occupying some wetter habitats. The LeConte's Sparrow preferred drier areas than the Nelson's Sparrow. Most areas occupied by the LeConte's Sparrow are flat and may be subject to flooding (Murray 1969). In fields where there is a slight slope, it tends to prefer higher areas (Lowther 2020b; Winter et al. 2005). In Minnesota, it spent most of its time in dense dead grass except in the morning and at sunset when it fed where living grass was sparse. It nested where dead grass was thickest, in lowland sections of prairie with luxuriant growths of denser grasses and vetch (Peabody 1901). In Minnesota, nest sites had significantly less bare ground (0.5% compared with 3.3%), more litter coverage (45.3% compared with 38.7%), less woody cover (0.2% compared with 1.4%), shorter vegetation (37.3 cm compared with 46.8 cm), and lower visual obstruction (19 cm compared with 26 cm) than random areas within the territory. There were 3 parameters that were not significantly different for nests and the remainder of the territory. Mean values for these characteristics at nests

included 37.6% grass cover, 15.6% forb cover, and 6.1 cm litter depth. Compared with random sites, nests were in areas of less bare ground and woody vegetation with higher litter cover. It chose nest sites surrounded by shorter and less dense vegetation. Its density decreased with either high or low amounts of bare ground, increased with taller vegetation at 1 site, and varied among years. Moderate ground cover was probably beneficial because it provided a balance between foraging efficiency and cover from predators. Site-specific vegetation parameters were more important in predicting its density than factors such as patch size and proportion of tree cover in the landscape (Winter et al. 2005). In North Dakota, it was associated with a high amount of grass cover, especially broad-leaved introduced species (Dechant et al. 2002i).

There is some uncertainty as to whether the LeConte's Sparrow exhibits area sensitivity. In Montana, North and South Dakota, and Minnesota, results were inconclusive because it occurred in only 4 of the studied regions and was common enough to analyze results at only 1 site. It showed no evidence of area dependency overall with 2 positive and 4 negative coefficients. Patch size was a positive influence on frequency of occurrence at 1 site, but results were not significant. Johnson and Igl (2001) did not identify any minimum patch-size requirements. Winter et al. (2005) found no evidence of area sensitivity in Minnesota. The mean patch size in their study area may have been too large to detect area sensitivity. Patch size had no influence on nesting success. South of Ottawa, Villard and Bracken (1989) confirmed nesting in a ditch that was only 0.03 ha in area. This strongly suggests that it is not area sensitive, but may just be an example of site tenacity. The pair was originally associated with an alfalfa field of unspecified size. Once the field was mowed the sparrows moved to the ditch. Near Wawa, 2-3 pairs nested in a 5.8-ha wetland and the fen portion of it that they inhabited was only 2 ha (Patrikeev 2006). The existing evidence suggests that the LeConte's Sparrow can adapt and nest in very small patches but more research on its area sensitivity is required.

Ontario nests were either on the ground or 5-17 cm above it, mostly in tall grasses or sedges. One nest was underneath a flattened clump of rushes, one was supported by Canada bluegrass stems, one was well hidden under and inside a clump of dried graminoids and could not be seen from above, one was under an old mouse nest, and one was attached to dried and living sedge stems and a small leatherleaf under loose cover of sedges and grasses (Patrikeev 2006; Peck and James 1987, 1998b).

In dry habitats, the nest is usually on the ground and may be sunk into it. In damp areas, nests are as high as 20 cm above the substrate. In North Dakota, the maximum height of nests was 5 cm. In Minnesota, mean nest height was 2.6 cm; 1 nest was 20 cm from the ground in another Minnesota study. Although 1 nest was scantily concealed, most are well hidden within and under dead plant material. In Minnesota, 96% of 44 nests were within dead plant material; average coverage by surrounding vegetation was 86.9%. The surrounding vegetation is typically grasses or sedges and less frequently rushes or spikerushes (Campbell et al. 2001; Lowther 2020b; Murray 1969; Peabody 1901; Walkinshaw 1937; Walkinshaw in Austin 1968; Winter et al. 2005).

Breeding territories may be clumped leading some authors to conclude that the LeConte's Sparrow is loosely colonial. Apparent clumping of territories in some areas is probably a result of habitat distribution. Males defend territories and all activities by both sexes occur within the territory.

Territories rarely overlap and, when they do, this occurs at different times. Once territorial boundaries are established, they remain fairly stable throughout the season. Any boundary changes are small and typically occur when a neighbouring male disappears. If he is not replaced, some of his territory may be absorbed by the neighbour. If the disappearing male is replaced, there may be slight modifications to the boundary as a result of interactions with the newcomer. In North Dakota, territories were 0.1-0.5 ha (average 0.2 ha). In 1 Minnesota study, 4 birds had territories of approximately 0.2 ha and, in another Minnesota study, mean minimum territory size was 0.47 ha (Lowther 2020b; Murray 1969).

No information is available on natal philopatry. Very few nestlings or fledglings have been banded and no recoveries have been made. It is probable that natal philopatry rates are very low because adults exhibit low site fidelity.

Although adult site fidelity rates are low, few studies banded many birds. In North Dakota, 1 of 7 males (14.3%) returned in the following year and 0 of 6 females returned. In Minnesota, 1 of 93 adults (1.1%) returned, a female (Murray 1969; Winter et al. 2005).

Limiting Factors

Eggs have been found in Ontario nests in the first 3 weeks of June (Peck and James 1987), and probably occur into the first week of July based upon the timing of young in a Wawa nest (Patrikeev 2006). No information is available on how long it takes to build the nest, the amount of time that elapses between nest completion and initiation of egg laying, the egg-laying interval, or when incubation begins relative to the completion of the clutch. The incubation period is probably 12-13 days, but this is uncertain and possibly based upon a single nest. No information is available on the nestling period. One Wawa nest with nestlings was checked on 2 dates and the nestlings were still in the nest when they were at least 7 days old (Patrikeev 2006; Walkinshaw 1937; Walkinshaw in Austin 1968).

Double brooding has not been confirmed and egg dates from most locations suggest that the LeConte's Sparrow raises only a single brood. Renesting has been confirmed after nest loss. All Ontario nests contained 4 or 5 eggs (mean 4.38 eggs). Clutches of 4-5 eggs have been reported throughout its range, with 4 eggs most frequent. In Minnesota, the mean clutch size was 4.51 eggs. Clutch size declined significantly with the season at a rate of 0.03 egg per day (Lowther 2020b; Patrikeev 2006; Peck and James 1987; Walkinshaw in Austin 1968; Winter et al. 2005).

The LeConte's Sparrow is probably capable of breeding when it is 1 year old and breeds annually thereafter. No information is available on the mating system but it is probably predominantly monogamous (Lowther 2020b). Near Wawa, Patrikeev (2006) found 2 nests 150 m apart and thought that they might belong to the same male which would be indicative of polygynous nesting.

Near Wawa, young were fed small green caterpillars, moths, spiders, a sphinx moth caterpillar, and 2 grasshopper abdomens (Patrikeev 2006). The only diet information for adults is based upon the contents of 15 stomachs collected in Missouri in spring and autumn. The diet consisted of 82.9% plant material and 16.9% animal matter by volume. The vegetable matter consisted of seeds including a trace of three-seeded mercury, a trace of redtop, 0.7% bentgrass, 30.2% big and little bluestem and unidentified bluestem, a trace of sedges, 0.7% yellow stargrass, 13.2% early forget-

me-not, a trace of wood-sorrel, 2.9% panic grass, a trace of field milkwort, 16.9% yellow foxtail, 14.7% Indian grass, 2.2% prairie dropseed, a trace of low hop clover, and 0.7% unidentified material. The animal matter consisted of 3.7% spiders, a trace of insect fragments, a trace of beetle fragments, 0.7% leaf beetles, 3.7% weevils, 0.7% stink bugs, 0.7% caterpillars and moths, a trace of ants, and 7.4% leafhoppers (Easterlea 1962). Foraging typically occurs on the ground under cover of vegetation (Lowther 2020b).

The LeConte's Sparrow is an infrequent host of the Brown-headed Cowbird. The effects of parasitism on it have not been determined and it is uncertain if it is able to fledge its own young from parasitized nests. It is probable that clutch size and nest success are diminished in parasitized nests. In Ontario, 0 of 10 nests were parasitized, 0 of 36 nests in Wisconsin were parasitized, 4 of 14 nests (28.6%) were parasitized in Minnesota, 1 of 50 nests (2.0%) in Minnesota were parasitized, and 5 of 5 nests were parasitized in North Dakota (Patrikeev 2006; Peck and James 1987, 1998b; Lowther 2020b; Murray 1969; Peabody 1901; Winter et al. 2005).

It is uncertain if habitat loss is a significant limiting factor for the LeConte's Sparrow in Ontario. The threat of habitat loss in the Canadian Shield northward is low and forest management that involves clear-cutting may provide temporary habitat (Welsh and Fillman 1980). South of the Shield, the amount of suitable habitat has declined significantly since the mid-20th century, but the distribution and abundance of this sparrow within this region is not well known. The field that supported it near Luther Marsh was plowed the year after it nested (personal observation).

In some areas, it is necessary to disturb grasslands periodically to halt invasion by woody growth. Hayfields that are mowed annually are unsuitable habitat. In North Dakota, the LeConte's Sparrow was never observed in fields of squirrel-tail grass that had been mowed the previous year even after the stubble was replaced by luxuriant growth. In addition to removing the litter area, mowing can result in direct mortality of eggs or nestlings. In Saskatchewan, it preferred tame hayfields that were mowed every 3-8 years, management that produced stands of introduced broad-leaved grasses that were attractive to it. At another North Dakota site, highest densities occurred in hayfields that had been mowed 1 year previously, provided that tall grass growth was available for nesting. In a Minnesota tallgrass prairie, idling habitat for more than 1 year allowed too much litter accumulation for the habitat to be suitable. The optimum frequency of mowing is highly variable and site-specific and depends on how fast shrubs invade the habitat and how long the field takes to grow sufficiently tall grasses and accumulate enough litter to be suitable for the LeConte's Sparrow (Dechant et al. 2002i; Lowther 2020b; Murray 1969).

Grazing is another method of retarding natural succession, but it appears to be less effective. In Alberta, Manitoba, and Saskatchewan, the frequency of occurrence of the LeConte's Sparrow was higher in hayed than grazed fields. In North Dakota, it was absent both in grazed prairie and prairie that had been left idle for 5-19 years and had grown up with significant shrub coverage. In Minnesota and Wisconsin, it used both grazed and ungrazed pastures provided that adequate litter was maintained. With grazing, there is also the risk that cattle will trample or lie on nests (Dechant et al. 2002i; Renken and Dinsmore 1987). In most of southern Ontario, grazing intensity is too high to be compatible with the LeConte's Sparrow.

Prescribed burns are often used to kill woody vegetation. In western grassland habitats, the LeConte's Sparrow was absent in areas that were never burned or that were burned in the same year. In North Dakota, it was absent in areas that had not been burned for 7 to more than 80 years, and also in areas that had been burned less than a year previously. Highest density occurred 2 years after fire, declining to half that density 6 years after fire, and disappearing thereafter. In that area, it would probably benefit from a short burn cycle of 2-4 years. In Minnesota, it was absent the year of burning but present the following year after litter and vegetation growth increased (Dechant et al. 2002i; Lowther 2020b; Madden et al. 1999).

The LeConte's Sparrow is adversely affected by drought and is much more abundant in wet than dry years. In Rainy River District, counts were much higher than usual after a prolonged wet period. In Saskatchewan, it was more common in 2 wet years than during a dry year. In North Dakota CRP lands, density per km^2 in 4 drought years was 0.03 compared with 5.4, 21.2, and 21.8 in the following 3 years with above-average rainfall. It was absent in a dry year where the highest counts in the Yukon were made in the previous year. In Texas, it was most abundant during the wettest year of a 3-year study. In Minnesota, it was scarce during a dry year. In North Dakota, it responded positively to moisture and the number of ponds present in May, an indicator of moisture. It is capable of responding quickly to changing habitat quality and this adaptability results in low site-fidelity rates. Other factors that result in the drying of soils and subsequent changes in vegetation have the potential to create local conditions similar to drought. Agricultural drainage may reduce soil moisture and decrease habitat suitability, and these drier areas are more likely to be converted into active agricultural land (Coady in Cadman et al. 2007; Igl and Johnson 1995, 1999; Lowther 2020b; Niemuth et al. 2008; Peabody 1901; Sinclair et al. 2003; Villard and Bracken 1989; Winter et al. 2005).

Nixon et al. (2016) analyzed the projected response of the LeConte's Sparrow to climate change in Alberta. They predicted that its area of suitable climate would shift northward out of the province and that the area of suitable climate would decrease by 12% in the 2050s and 50% by the 2080s. They predicted that there would be a decline of suitable land cover within its area of suitable climate. The decline of suitable cover was projected to be 40% in the 2050s and 80% in the 2080s.

Status

The LeConte's Sparrow is a very unobtrusive species that is easily overlooked. Its song is similar to that of an insect and singing is often done below the vegetation so that it is seldom seen. The weak song is frequently drowned out by other birds' songs but it sings after sunset when it is more easily detected. Its call note resembles that of a small mammal and when disturbed, it tends to run on the ground under the vegetation instead of flying. When it is flushed, it flies only a short distance before diving back into the vegetation. The abundance and distribution of the LeConte's Sparrow is rather poorly known throughout its range because of these behaviours.

McIlwraith (1894) had no records of the LeConte's Sparrow for Ontario although it is probable that it was a breeding species at that time. Baillie and Harrington (1937) stated that, prior to then it was known to occur only north of latitude 48°N in Thunder Bay and Algoma districts. The population along the James and Hudson bay coasts was unknown at that time. In 1937, small colonies were discovered in Waterloo Region, near Toronto, and at Holland Marsh. The latter population persisted for over a decade until its habitat was destroyed (Devitt 1967). Murray (1969) considered the

population along the shores of James Bay and Hudson Bay to be almost disjunct, but acknowledged that it was rare in the Canadian Shield in Ontario east to eastern Quebec. The first atlas revealed that greatest concentrations occurred in the central areas of the James Bay coast and in the northwest in the Boreal Forest Region and Hudson Bay Lowland. It also occurred in Rainy River District and near Thunder Bay with very scattered records in the Shield portion of the Great Lakes–St. Lawrence Forest Region and the Boreal Forest Region. A single record of fledged young near Luther Marsh was the only breeding evidence obtained south of the Shield. The atlas represented the best available information on the LeConte's Sparrow's breeding distribution, but its range and abundance was probably underestimated. Sandilands and Campbell (in Cadman et al. 1987) concluded that it should occur in some inland blocks of the Hudson Bay Lowland and that it should be looked for in marginal farmland in the south and near the southern edge of the Canadian Shield. Villard and Bracken (1989) reported fledged young south of Ottawa. They were uncertain whether its sparse occurrence in the east was actual or an artifact of its discrete mouse-like behaviour. James (1991) considered the LeConte's Sparrow rare to locally uncommon at widely scattered locations in the north from Thunder Bay and Timmins to the north coast. He concluded that it was virtually absent in the south, but with recent records from Dundas and Wellington counties and near Sudbury. In the Hudson Bay Lowland, Wilson and McRae (1993) concluded that breeding undoubtedly occurred from Ekwan south to Moosonee.

The second atlas demonstrated that the LeConte's Sparrow was more widespread and common than was determined during the first atlas. It was observed in many more blocks in the Hudson Bay Lowland and particularly in the Boreal Forest Region and the Shield portion of the Great Lakes–St. Lawrence Forest Region. Despite this, it remained scattered in distribution, with the highest probabilities of observation occurring in the Boreal Forest Region and western portion of the Great Lakes–St. Lawrence Forest Region and the Hudson Bay Lowland. There were only 2 records south of the Shield: 1 east of Orangeville and 1 south of Ottawa. Its probability of observation increased significantly since the first atlas and more than doubled for the entire province, with significant increases in the Great Lakes–St. Lawrence Forest Region, Boreal Forest Region, and Hudson Bay Lowland. Most of the increase was attributed to an improvement in atlasser familiarity with the species. The areas of highest concentrations were in the south-central James Bay coast, western Rainy River District, and in the Dryden area. Despite the significant increase in observations between atlases, Coady (in Cadman et al. 2007) concluded that its range and abundance were still probably underestimated. Patrikeev (2006) confirmed the LeConte's Sparrow breeding near Wawa and concluded that it likely occurred in low densities throughout Algoma District wherever suitable habitat is present.

Breeding Bird Survey (BBS) results suggest that the North American population is declining. During 1966-2015, it decreased at a rate of 2.5% per year rangewide (Lowther 2020b). During 1970-2021, BBS results determined that the LeConte's Sparrow decreased in Canada at an annual rate of 2.17% and increased in Ontario 0.102% annually. During 2011-21, it decreased at annual rates of 5.65% in Canada and 8.53% in Ontario. The short-term trends were of low reliability; the long-term Canadian trend was highly reliable and the long-term Ontario trend was of medium reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Almost nothing is known of the LeConte's Sparrow during the postfledging period. South of Ottawa, 3 fledged young were observed in a drainage ditch where nesting had occurred. They behaved in the same manner as the female, remaining in dense vegetation until they were flushed and then going back to safety a short distance away (Villard and Bracken 1989). Near Luther Marsh, young were observed in the field where the male's territory was located (Craig Campbell, personal communication). In South Dakota, Skadsen (1987) observed an adult with 2 young in dense white clover. The habitat consisted of tallgrass prairie dominated by bluestem, blazing-star, goldenrod, and sweet clover. The young ran through thick vegetation and flew 4.6-6 m when flushed before dropping back into the vegetation.

There appear to be no observations of independent juveniles. It is unknown whether they congregate into flocks and if they remain within the natal area until autumn migration is initiated.

MIGRATION

The LeConte's Sparrow is occasionally killed at towers indicating that it is a nocturnal migrant. Low counts of less than 1 bird per year per site suggest that birds migrate singly or are widely spaced. It is unknown if daytime migration occurs. In South Carolina, 82.8% of specimens collected were female. This may indicate that females winter further south than males (Lowther 2020b; Murray 1969; Walkinshaw in Austin 1968).

The LeConte's Sparrow arrives on the breeding grounds in late April or early to mid-May after a prolonged migration. Near the northern extent of its range, spring migration may be rapid with birds travelling directly to the breeding areas and seldom seen at stopover areas (Campbell et al. 2001; Murray 1969). In Elgin County, there is only a single spring record on 14 May (Lancaster et al. 2004). The 2 Hamilton spring records were on 4 and 14 May (Curry 2006). The earliest record for Simcoe County is 24 May (Devitt 1967). In the Kingston area, there are 4 spring records from 9 to 22 May (Weir 2008). In Algonquin Park, there are sightings from mid-April to late May (Tozer 2012). Near Wawa, singing males were present on 21 May and display flights were observed on 27 May (Patrikeev 2006).

The LeConte's Sparrow leaves the breeding range in September but does not reach the wintering area before early November (Murray 1969). Wilson and McRae (1993) observed one at Moosonee on 1 September. It is observed regularly in Algonquin Park in autumn, mostly from late September to mid-October (Tozer 2012). The 2 autumn records from Muskoka and Parry Sound Districts were on 29 September and 9 October (Mills 1981). One was seen at Luther Marsh on 11 September (personal observation). There are 6 autumn records for the Kingston area: 23 July, 20 August, 1 September, 3 September, 27 September, and 18 December (Weir 2008). The July and August records may be of postfledging birds rather than migrants. The latest autumn record in Simcoe County is 11 September (Devitt 1967). In the Hamilton area, there are 2 autumn records on 6 and 17 September and a winter record on 12 January (Curry 2006).

Habitat selected during migration is similar to breeding habitat. Prime migration habitat in Algonquin Park consists of fields with tall grasses, sedge meadows, drained beaver ponds, marshes, and vegetation at margins of lakes (Tozer 2012). In the Hamilton area, migrants have been observed on the shore of Dundas Marsh, in tall grasses along a creek in Oakville, and in Bronte Woods (Curry

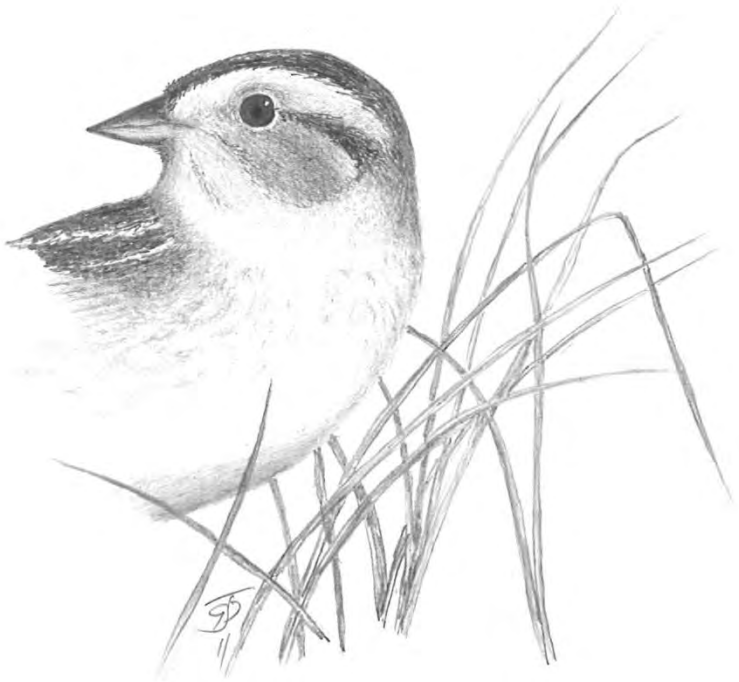
2006). An autumn migrant at Luther Marsh was in an abandoned pasture adjacent to the marsh. It was dominated by goldenrods with an understorey of dead grasses (personal observation). In British Columbia, migrants frequent wet or moist habitats adjacent to marshy lakeshores, wet meadows, patches of sedges, overgrown meadows, tall grasses adjacent to wetlands, and roadside ditches vegetated with dead grasses and willows (Campbell et al. 2001). In the United States, migrants have been observed in tall grasses of dry fields near marshes, open prairies overgrown with ironweed, occasionally on dry bluffs, fields of switchgrass, old fields and weedy areas in Kansas, large open grassy fields and low-lying wet flat areas with rank vegetation in Arkansas, grasslands and marsh edges in Iowa, and stands of cordgrass in a matrix of shorter annual forbs and spikerushes in Kansas (Lowther 2020b; Powell and Nyari 2007; Robertson et al. 2012; Walkinshaw in Austin 1968).

Although the LeConte's Sparrow is occasionally killed during migration by striking television and communication towers and other tall structures, the incidence of this is rare (Lowther 2020b).

James (1991) considered the LeConte's Sparrow a rare migrant. All regional books concur and some regions have no records of migrants. Undoubtedly many migrants pass through undetected because of its reclusive behaviour and the fact that relatively little effort is spent birding in its preferred habitat.

Nelson's Sparrow

Ammospiza nelsoni

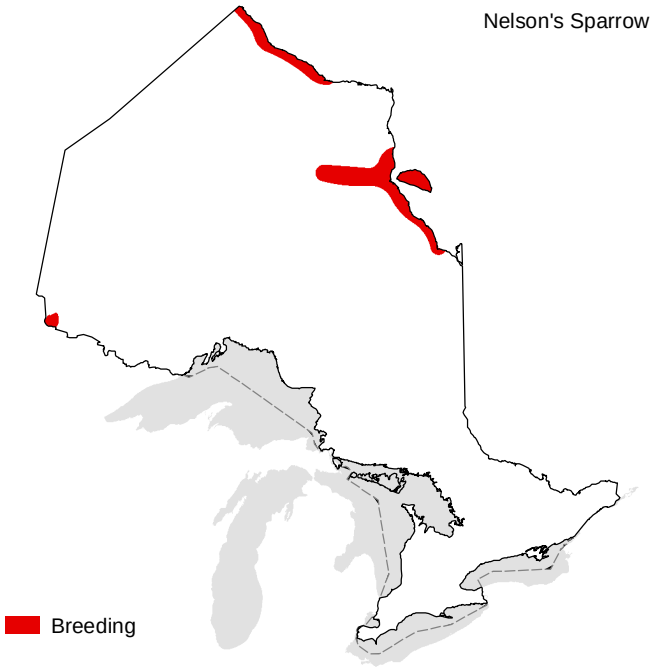


BREEDING SEASON

Habitat Requirements

The Nelson's Sparrow is a highly localized species that occurs as 3 geographically separated subspecies. The prairie subspecies breeds from extreme northeastern British Columbia, northern Alberta, central Saskatchewan, southern Manitoba, and extreme northwestern Ontario (in the Rainy River area) to northeastern South Dakota. The James Bay subspecies breeds on the southern coasts of Hudson Bay and James Bay. The Acadian subspecies breeds along the St. Lawrence River and the Atlantic Coast south to Massachusetts. Its range along the St. Lawrence River extends to almost the extreme western portion of Quebec, but does not include Ontario (Campbell et al. 2001; Murray 1969; Ouellet in Gauthier and Aubry 1996; Shriver et al. 2020). The James Bay subspecies has the best representation in Ontario, but breeding birds in Rainy River District appear to be of the prairie subspecies (James 1991). The northern extent of the James Bay race is uncertain because birds at

Churchill are apparently of the prairie subspecies (Jehl 2004). It is likely that birds along the Ontario coasts of Hudson Bay and certainly James Bay belong to the James Bay subspecies.



All Ontario nests were on the southwest coast of James Bay close to the bay. One was in a grassy area in a clearing along a moist ditch, one was at the edge of a brackish pool on the coast at the mouth of the Nettichi River, and another was in an area of dry grasses, sedges, and forbs 30-40 cm tall (Peck and James 1987, 1998b).

Todd (1963) stated that the James Bay subspecies nested solely in saltwater marsh habitats but it nested in brackish marshes in the Moose Factory area (Murray 1969). During both atlases, it was observed in some inland locations in the Hudson Bay Lowland, indicating that it also breeds in freshwater habitats (Coady in Cadman et al. 2007; Rising in Cadman et al. 1987). This race breeds most frequently in coastal graminoid marshes dominated by saltmeadow rush, meager sedge, chaffy sedge, red bulrush, and common arrowgrass. This habitat is a band approximately 1.6 km wide above the high-water tide. Occupied habitat in Rupert Bay on the southeastern shore of James Bay in Quebec was dominated by Canada bluejoint, northern reedgrass, chaffy sedge, red fescue, sweet grass, bogbean, field horsetail, and Baltic rush. It often breeds where willow and dwarf birch is present (Hill in Austin 1968; Shriver et al. 2020).

The prairie subspecies has the largest range and occupies a greater variety of habitats than the other 2 subspecies. It has been stated that it differs from the other subspecies by nesting in only freshwater habitats (Hill in Austin 1968) but this may not be the case if this is the subspecies that occurs at Churchill. It also nests on margins of salt lakes in North Dakota (Rolfe 1899). It is most frequent in wetlands, particularly marshes, but also occurs in native and planted grasslands and rarely in agricultural lands. In British Columbia, the Nelson's Sparrow nests only in wetlands, including marshes and wet meadows with stands of emergents and willows. It occurs in damp sedge meadows and marshes bordering woodland lakes, among dead and living willows between creeks and grassy meadows, and on willow-covered islets in lakes. In occupied marshes and sedge meadows, clumps of dead and living willows were invariably present interspersed between large areas of grasses or sedges (Campbell et al. 2001). In Alberta, it inhabits marshes in woodland areas and prefers those with scattered willows, and nests in cattails and wet grassy meadows around woodland lakes. In aspen parkland, it was absent in mixed-grass native pastures and uncommon in planted pastures. Planted pastures had lower percentages of grass and shrub cover, higher cover by forbs and bare ground, fewer shrub clumps, and taller grasses and forbs than mixed-grass pastures.

In Alberta pastures subjected to late-season grazing, it was recorded only on a site subjected to the highest intensity of grazing. The biomass lost to grazing was 71% but vegetation height was not reduced significantly. It was more abundant in seeded native Dense Nesting Cover (DNC) than in tame DNC. It was rare or absent in tame DNC less than 2 years old. Its abundance increased with age of DNC until the fifth year, after which abundance decreased. In Manitoba, it nested in unmowed or hayed habitats on hydro transmission line corridors and road rights-of-way that were at least 30 m wide (Leston and Koper 2017). In the Boreal Forest Region, the Nelson's Sparrow also nests in fens. Species that provide nesting cover in marshes include cattails, hard-stemmed bulrush, river bulrush, saltmarsh bulrush, river grass, slough grass, wheat sedge, water smartweed, mints, manna grass, common reed, bluejoint, cordgrass, and water sedge (Campbell et al. 2001; Dechant et al. 2002h; Erskine 1977). In Saskatchewan, Minnesota, and many other areas, the Nelson's Sparrow occupies wetter portions of marshes among cattails, bulrushes, and slough grass. It is uncommon in Saskatchewan grasslands managed for waterfowl, with 12.5% occurrence in DNC, 5.6% occurrence in native grasslands, and 0% in wheat (Hartley 1994; Shriver et al. 2020). Typical habitat in Manitoba consists of a dense mix of cattails, grasses, and tall herbaceous plants with scattered willows. One study found it only in native grasslands and not in tame or seeded native DNC. Another Manitoba study had a single detection in hayfields planted to tame grasses and legumes. It was not observed in native DNC, DNC planted to tame grasses and legumes, or idle native grassland (Dechant et al. 2002h; Shriver et al. 2020). In Minnesota, it nests in prairie marshes and open peatlands that have a permanent water level of a few cm. It is not found in deeper cattail marshes or in marginally wet meadows. Breeding territories contain a low density of shrubs, grasses, and forbs more than 30 cm tall; shorter forbs are more abundant. Some wetlands used were surrounded by bands of tamarack, aspen thickets, and patches of tall grass. At another Minnesota site, it nested in vegetation in damp soil at the edge of a wetland dominated by sphagnum moss and sedges. Another Minnesota study found that graminoid density in territories was high and exceeded 180 stems per m^2. It also occurs in low density Conservation Reserve Program grasslands (Coffin and Pfannmuller 1988; Dechant et al. 2002h; Igl 1996). At 1 North Dakota site, the Nelson's Sparrow nested in a river floodplain. It occurred in wetter areas dominated by cordgrass and was less frequent in stands of river grass and at edges of common reed stands. It never occurred in upland areas dominated by squirrel-tail grass (Murray 1969). In North Dakota, it occurred in low density in fields planted to a mixture of alfalfa and wheatgrass, but was absent in grazed grasslands and idle prairie (Renken and Dinsmore 1987). The Nelson's Sparrow perches on the tallest available sites including fences, shrubs, and trees (Shriver et al. 2020).

The Acadian subspecies nests on islands in the St. Lawrence River not far from the Ontario border. This subspecies is most common in saltwater marshes, but also occurs in brackish and freshwater marshes, fallow fields, drainage ditches, peatlands, hayfields, and grasslands (Hill in Austin 1968; Nocera et al. 2007a; Shriver et al. 2020). In Quebec, the Nelson's Sparrow breeds predominantly in saltwater and brackish marshes, but also in freshwater marshes. It is sometimes found in idle fields and fields of forage crops adjacent to saltwater marshes. In the St. Lawrence River estuary, it occupies the upper level of saltwater marshes dominated by saltmarsh cordgrass interspersed with numerous tidal pools in lower elevations. The upper edges of saltwater marshes are dominated by prairie cordgrass, which is used for cover and perching. In some areas, it occurs in the shrub layer of

saltwater marshes. In a brackish marsh in the Gaspé Peninsula, it nested in a dense stand of hard-stemmed bulrush. At freshwater islands, it occurs in tall grasses of wet meadows. Grasses may include reed grass and rye grass and it may also nest in higher but moist meadows of northern blue flag and marsh cinquefoil (Hill in Austin 1968; Ouellet in Gauthier and Aubry 1996; Seutin and Simon 1988). In New Brunswick and Nova Scotia, it breeds in meadows dyked for the production of hay, especially along ditches where brackish water occasionally backs up. It occurs in the St. John valley in a freshwater environment dominated by arrowheads and white waterlilies. Nova Scotia hayfields that were occupied were dominated by timothy, meadow foxtail, bluegrasses, and reed canary grass. Ditches and wetter sections of hayfields were dominated by prairie cordgrass. The presence of ditches in fields was strongly correlated with its occupancy and reproductive activity, with uncut ditches providing a damp environment with tall coarse grass. It was positively correlated with the height of May vegetation and the abundance of orthopterans, caterpillars, and spiders. It was negatively correlated with the presence of alfalfa. In Prince Edward Island and the St. Lawrence River area, it breeds in short grasses, bogs, and a few ditches. It also nested in a dry marsh grown up to shrubs with scattered dead pine stubs that were remnants of a former forest (Hill in Austin 1968; Nocera et al. 2007a, 2007b; Owen et al. 2025). In Nova Scotia and Maine, the Nelson's Sparrow is associated with coastal saltwater marshes and brackish and saltwater marshes in lower reaches of rivers. These marshes are typically dominated by saltmarsh cordgrass at the lowest elevation, and marsh hay cordgrass and chaffy sedge at middle and higher elevations. Other plants such as saltmeadow rush were patchily distributed at lower elevations. These marshes may contain salt ponds, salt pans (depressions with little or no vegetation and high salinity levels), saltmeadow rush, and saltgrass. In both male and female home ranges, marsh hay cordgrass and vegetated pan habitat was more frequent than at random sites. Saltmarsh cordgrass was less frequent in home ranges than at random sites. There were no differences in the amount of saltmeadow rush, saltgrass, and unvegetated pan habitat in home ranges and random sites, and there were no differences in the vegetation characteristics of male and female home ranges. Mean habitat characteristics in male and female home ranges, respectively, were 28.8% and 18.8% marsh hay cordgrass, 17.8% and 27.6% saltmarsh cordgrass, 21.4% and 14.6% saltmeadow rush, 0.6% and 1.2% saltgrass, 1.3% and 0.5% unvegetated pan, and 20.3% and 18.8% vegetated pan. Many saltwater marshes that support the Nelson's Sparrow contain common arrowgrass. Nests are frequently within patches of saltmarsh cordgrass, with marsh hay cordgrass occurring in drier areas and more important for perching. In other areas, it may nest in marsh hay cordgrass to avoid having the nest flooded by daily tides. Females remain close to the nesting area but males may also use higher elevations of grass, cordgrass, old fence posts, shrubs, stumps, stakes, and spruce trees as perches. Nests tend to be at the upper area that is affected by tides, with full tide flooding only to the roots of the grasses (Hanson and Shriver 2006; Hill in Austin 1968; Norton 1927; Shriver et al. 2010).

Hanson and Shriver (2006) concluded that the Acadian subspecies was not affected by marsh isolation. Proximity of other marshes was not an important variable explaining its density.

Although 1 study determined that marsh size was important in determining density, the Nelson's Sparrow does not appear to be area sensitive. Hanson and Shriver (2006) concluded that marsh area was important in determining density of the Acadian Nelson's Sparrow in marshes as large as 10 ha. Densities in marshes smaller than 5.0 ha and 10.0 ha were lower than in larger

marshes. There was no significant difference in densities in marshes 10-435 ha. Densities increased with the presence of adjacent dykes. Although densities increased with increasing marsh size up to 10 ha, it did not avoid small wetlands. It nested in marshes as small as 1-2.3 ha. In Maine and British Columbia, it nested in very small marshes (Campbell et al. 2001; Hill in Austin 1968). In northern Minnesota, the average size of occupied wetlands was 130 ha (range 15-250 ha). In North Dakota, it occurred in wetlands 5.0-6.4 ha (Dechant et al. 2002h). The prairie subspecies may require larger habitat patches than the other subspecies. Marshes used in Minnesota were quite small and isolated (Coffin and Pfannmuller 1988).

Murray (1968) compared habitat usage of the Nelson's and LeConte's sparrows in a riverine marsh in Minnesota. Both were most numerous in cordgrass but some Nelson's Sparrows were in wetter habitats and some LeConte's Sparrows were in drier habitats. Nelson's Sparrow was never observed in upland stands of squirrel-tail grass but LeConte's Sparrow occasionally nested in this habitat.

Ontario nests were on or close to the ground. Elevated nests were supported by dead coarse grasses (Peck and James 1987, 1998b).

All subspecies place their nests either on the ground or as high as 25 cm above it. Mean nest height is approximately 5 cm. Ground nests may be sunk into the ground or placed on a clump of grasses. Elevated nests are attached to standing grasses or occasionally to a small shrub. Mean vegetation height at nests is 68.1 cm (range 30-90 cm). Nests may be partially or fully domed with dead vegetation from the previous year. A Maine nest was completely covered by a reclining mat of cordgrass and the female entered and left the nest through a narrow passage that was parallel to the culms of the cordgrass. The female may build more than 1 nest but eggs are laid in only a single nest. Nests do not appear to be reused (Campbell et al. 2001; Hill in Austin 1968; Murray 1969; Nordhagen et al. 2005; Norton 1927; Rolfe 1899; Shriver et al. 2020).

Both sexes of the Nelson's Sparrow are nonterritorial. Males may guard receptive females and fight with other males that approach, but no territory is defended. Two to 3 females may nest at the same time within 2-3 m of each other with little or no aggression. Home ranges of all males and females within a population completely overlap with both sexes wandering within the occupied habitat. Males fly from song perch to song perch, crisscross each other's paths, and use common song perches. In North Dakota, males often flew more than 150 m in a single flight but distances travelled in New Brunswick were as far as 800 m. In Maine, the mean size of core home ranges was 18.42 ha for males and 6.15 ha for females. The total home range was 119.68 ha for males and 43.58 ha for females. Twenty-seven percent of females and 45% of males had 2 core areas. The mean distance between core areas was 161.40 m for females and 204.28 m for males. When birds had 2 core areas, they were not used simultaneously and usage of core areas was timed to coincide with separate lunar cycles. At this study area, most nests were flooded during the spring tide and females moved within the study area to construct a second nest during the subsequent lunar cycle. Home ranges of males and the distance between core areas were significantly larger than for females because males attempt to maintain close proximity to females during renesting attempts. In New Brunswick, core areas consisted of patches of isolated wet meadows as far apart as 800 m. At another New Brunswick site, the 95% home ranges averaged 22.17 ha (range 0.30-215.11 ha) and the mean

50% core area was 3.01 ha (range 0.07-29.04 ha). Male home ranges (mean 25.45 ha compared with 9.03 ha) and core areas (mean 29.04 ha compared with 2.95 ha) were significantly larger than those of females (Owen et al. 2025). Birds at a Quebec site had much smaller home ranges, with males restricting their activities to about 1.5 ha and females remaining in an area of 0.4 ha. Male dispersion is related to female dispersion which is influenced by the patchiness of suitable nest-site microhabitat (Murray 1969; Ouellet in Gauthier and Aubry 1996; Shriver et al. 2010, 2020). It is likely that home range size is influenced by the size of habitat patch, homogeneousness of the habitat, and size of the local breeding population. Breeding birds tend to be clumped and adjacent suitable habitat may be unoccupied. This suggests that the Nelson's Sparrow may be colonial but it has been suggested that absence of birds from potentially suitable nesting habitat may reflect chance associated with limited local recruitment. The lack of territoriality and its promiscuous mating system are indicative of true coloniality. If birds were spread evenly throughout habitat, it would be more difficult for individual birds to mate with multiple birds (Murray 1969; Ouellet in Gauthier and Aubry 1996; Shriver et al. 2020).

No information is available on natal philopatry and there is limited information on adult site fidelity. In North Dakota, 1 of 3 males (33.3%) and 1 of 1 female banded the previous year returned (Murray 1969). Shriver et al. (2020) reported return rates of 39% for males and 32% for females based on a sample size of 101.

Limiting Factors

Eggs are likely to be present in Ontario nests from the third week of June until the third week of July (Peck and James 1987). The time it takes to build the nest is unknown. Eggs are laid at the rate of 1 a day and incubation begins with the laying of the penultimate or last egg. Hatching occurs over a 24-36 hour period, suggesting that incubation begins in earnest with the penultimate egg. No information is available on the incubation period. Disturbed nestlings may fledge when they are as young as 8 days, but normally fledge at age 10-11 days. Nest departure is synchronous with all young leaving within a few hours of each other (Shriver et al. 2020).

The number of broods that the James Bay subspecies raises is unknown. The other 2 subspecies are capable of raising 2 broods in a season. Because the female raises the fledglings without assistance from the male, second nests are not initiated until the first brood is independent. Renesting is common after nest loss by the Acadian subspecies. Renesting has not been documented for the prairie subspecies and no information on renesting is available for the James Bay subspecies. In Maine, replacement nests were not initiated until more than 10 days after the initial ones were flooded by spring tides. All Ontario nests contained 4 eggs, but the sample size is small. Clutches of 2-6 eggs have been reported but the normal range is 3-5 eggs; 4-egg clutches are most common (Dechant et al. 2002h; Hill in Austin 1968; Norton 1927; Ouellet in Gauthier and Aubry 1996; Peck and James 1987, 1998b; Rolfe 1899; Shriver et al. 2007, 2020).

Both sexes are capable of breeding when they are 1 year old. The Nelson's Sparrow is polygynandrous, which means that both sexes are promiscuous and may potentially mate with numerous individuals. The mating system is a form of male-dominance polygyny where a small proportion of males perform a disproportionate share of copulations. No pair bond is formed but males may guard specific females for periods ranging from 15 minutes to 43 hours. As a result of

this mating system, offspring in the same brood often have different fathers. The Nelson's Sparrow is the only North American marsh-dwelling polygynandrous species (Greenlaw 1989; Murray 1969; Seutin and Simon 1988; Shriver et al. 2007, 2010, 2020).

The Nelson's Sparrow forages on the ground in dense grasses within marshes or wet meadows, along ditch margins, at edges of shallow pools and mud pans, and around patches of beach wrack. The Acadian subspecies, and probably the James Bay subspecies, forages below the high-water level at low tide around tidal pools and channels. Birds did not move into the grass at higher levels to forage until the mud was submerged. Birds breeding in salt-marsh habitats may visit nearby hayfields to forage. Birds breeding in coastal areas probably feed mostly on marine invertebrates during low tide and terrestrial invertebrates during high tide. Prey items that have been found in the diet are consistent with those found in vegetation and from mud and water obtained by gleaning, pecking, and probing (Hill in Austin 1968; Shriver et al. 2020).

Young are fed invertebrate prey almost exclusively. Eleven Acadian subspecies nestlings had consumed 44.4% insects and 33.3% spiders. The insects in order of decreasing importance consisted of orthopterans, soft-winged bugs, beetles, true bugs, flies, and odonates (Shriver et al. 2020).

Judd (1901) examined 51 adult stomachs collected during the breeding season. It is possible that some of them were Saltmarsh Sparrows; the sample did not include any James Bay subspecies specimens. The diet consisted of 81% animal material and 19% vegetable matter, mostly grass seeds. The animal food consisted of 26% amphipods, spiders, and snails; 14% lepidopterans (a third were owlet moths); 12% bugs (half were leafhoppers); 7% orthopterans (mostly short-horned grasshoppers but some long-horned grasshoppers and crickets); 6% beetles (mostly weevils with some small ground beetles and occasional leaf, rove, tiger, and dung beetles); 5% flies (mainly midges and their larvae and smaller adult horse flies); 3% hymenopterans (ants and ichneumonid wasps); and 8% miscellaneous insects. The Nelson's Sparrow ate a larger proportion of flies than most birds except for flycatchers and shore-inhabiting species of the far north that feed almost exclusively on midges. Amphipods constituted 16% of the diet of saltwater birds but 0% of freshwater birds. Only saltwater birds ate snails and only freshwater birds fed on armyworms. Saltwater birds ate no vegetable matter other than grass seeds but 30.4% of freshwater birds had eaten other seeds, including those of smartweeds, lamb's-quarters, clovers, and dandelions. Saltwater birds fed on the seeds of grasses associated with saltwater marshes and occasionally wild rice. Freshwater birds ate seeds of other grasses, especially panic grasses. Other items it eats include wasps, earwigs, wolf spiders, fiddler crabs, and ribbon worms (Hill in Austin 1968; Shriver et al. 2020).

The Nelson's Sparrow is a rare host of the Brown-headed Cowbird. There are only 2 records of parasitism, both on the prairie subspecies. Based on the results of a single nest, it is possible that parasitism results in complete nest failure (Nordhagen et al. 2005; Shriver et al. 2020). The James Bay subspecies nests north of the range of the cowbird and is unlikely to be parasitized.

Habitat loss and degradation is currently not an issue in Ontario, but is an issue in other areas. It is sensitive to loss of saltwater marshes along the St. Lawrence River and Atlantic coast. In Quebec, 18% of saltwater marshes were destroyed 1945-76 due to agriculture, landfilling, and construction, but the Nelson's Sparrow still continues to inhabit most of its traditional sites. The Quebec James Bay hydro-development has the potential to alter habitat, the movement of ice, and salinity levels.

Along the Atlantic Coast, cutting marshes off from tidal influences by roads and ditching resulted in its decline. Prairie birds have been subjected to drainage of wetlands and fields. Those nesting in managed grasslands may be adversely affected by mowing, grazing, plowing, burning, channelization, recreation, and spraying for insects. In Nova Scotia, delaying hay harvest until 7 July enhanced reproductive success and still provided a good hay crop. Cutting again prior to late August allows a second crop to be harvested and gives time for grass to grow to suitable height for the next year (Campbell et al. 2001; Correll et al. 2016; Nocera et al. 2007a, 2007b; Ouellet in Gauthier and Aubry 1996; Shriver et al. 2020).

The prairie subspecies may be affected by the amount of rainfall received. Responses to wet seasons differed in British Columbia and North Dakota. In British Columbia, it was much more abundant during a very wet summer when water levels were much higher than usual. It was much more widely distributed, nesting in flooded areas such as ponds, densely vegetated ditches, and low fields (Campbell et al. 2001). In North Dakota, it was more abundant during dry years. In dry years, it nested in shallow-marsh and deep-marsh zones of wetlands. In wet years, it nested in cordgrass in wet-meadow zones (Dechant et al. 2002h).

The Nelson's Sparrow is one of few ground-nesting passerines that breed in flooded tidal marshes. These areas have predictable unusually high flood tides that occur every 26-28 days because of the lunar cycle. In Maine, the elevation of nests was a significant predictor of nest success, with successful nests significantly higher than unsuccessful nests. Vegetation parameters did not affect nest success. Second nests were initiated an average of 10.3 days after the flood tide. There was no significant difference in nest initiation dates for birds that had successful or unsuccessful first nests. There were 2 options to achieve successful nesting: constructing nests at high enough elevations to avoid flooding or initiating renesting immediately after nest loss to ensure that nesting was complete before the next flood (Shriver et al. 2007). Flooding of nests has not been documented for the James Bay subspecies, but it is possible that it occurs. The terrain in this area is extremely flat so even a minor increase in water levels could flood extensive areas.

Status

McIlwraith (1894) and Baillie and Harrington (1937) were unaware that the Nelson's Sparrow bred in Ontario. It was first confirmed as a breeder in 1939 when a juvenile was collected at Attawapiskat. Nests were found at Fort Albany and Nettichi Point in 1942; it was most abundant at Fort Albany where 50 were counted on 2 separate dates (Baillie 1960). Manning (1952) concluded that it probably bred in fair numbers in the long grass coastal barrens of the western James Bay coast north to the Albany River. The first atlas revealed that it nested along the southern portion of James Bay and at scattered locations along Hudson Bay. There were 3 records of birds in the north away from the coast. One may have represented a late migrant but the other records were in July, suggesting that these were birds breeding in freshwater habitat. A single bird heard in Rainy River District was likely of the prairie subspecies (Rising in Cadman et al. 1987) and at least 5 were reported there during the 1979 breeding season (Speirs 1985). James (1991) considered the Nelson's Sparrow an uncommon summer resident along the northern coasts where it was most abundant along the southern James Bay coast. He noted that there were summer records from western Rainy River

District. Wilson and McRae (1993) concluded that it was common along much of the James Bay coast but uncommon and local along the Hudson Bay coast.

The second atlas revealed that there had been no significant change in the probability of observation of the Nelson's Sparrow since the first atlas. There was also no significant change in its abundance. Breeding evidence was found again far inland along the Attawapiskat River confirming that it breeds away from the coast in freshwater habitat. A bird singing in early June at Cat Lake may have been a late migrant of the James Bay subspecies or a nesting bird of the prairie subspecies. It was once again documented in the Rainy River area, but breeding of this population has yet to be confirmed. Thirty-five singing males were heard in a small area near Shegogau Creek on the James Bay coast north of Moosonee (Coady in Cadman et al. 2007).

POSTFLEDGING PERIOD

Young can run on the ground and climb in vegetation upon leaving the nest, but are not capable of flying short distances until they have been out of the nest for 3-5 days. They initially disperse in grass a few metres from the nest. In the Bay of Fundy, fledglings remain in grass above the high-tide level while adults forage for food items for them at lower elevations. Small flocks of juveniles and adults form once the juveniles are independent, and juveniles predominate in these flocks. Along the Atlantic coast, these flocks typically contain 10-40 individuals, but flocks in excess of 100 commonly occur. There appears to be some wandering in autumn prior to migration (Hill in Austin 1968; Shriver et al. 2020).

MIGRATION

The Nelson's Sparrow is thought to migrate only at night. All races overwinter along the Atlantic coast from North Carolina to Florida and around the Gulf of Mexico to southern Texas. The James Bay subspecies winters in South Carolina, Georgia, northern Florida, and Alabama. The migration route from the breeding grounds tends to be north-south to the southern Great Lakes area, with numerous records of migrants in the Toronto area and central New York (Hill in Austin 1968; Shriver et al. 2020).

The Nelson's Sparrow is a late spring migrant and the last sparrow to arrive in the Churchill area (Jehl 2004). Because males are nonterritorial, they do not need to arrive early on the breeding grounds to vie for the best territories. There are few records of spring migrants in the province. The single spring record for Hamilton is 20 May (Curry 2006) and Fleming (1907) had a record for Toronto on 10 June. The 4 spring records for the Kingston area span the period 20 May to 5 June (Weir 2008). Wilson and McRae (1993) observed a singing male at Brant on 26 June. It leaves the breeding grounds in September and the peak of migration in southern Ontario is from late September to mid-October. Movement is often associated with strong cold fronts (Pittaway 1997). Wilson and McRae (1993) last saw it at Ekwan on 9 September and on 12 September at Longridge.

In Algonquin Park, autumn migrants occur in wet sedge and marshy areas where they favour extensive stands of sedges, grasses, bur-reeds, bulrushes, and beggarticks but not cattails. Habitats are typically large marshes and wetlands along rivers and lakeshores where the water is as deep as 30 cm (Tozer 2012). In the Kingston area, migrants are found predominantly in cattail marshes (Weir 2008). In Renfrew County, migrants were observed in grasses and sedges that were waist high. In Dundas, most birds occur in a narrow band of waist-high manna grass bordering cattails between a

small pond and the open water of the bay. Autumn migrants at Hillman Marsh were in a zone of grasses, sedges, and beggarticks between the shore and cattails. In southern Ontario, it usually inhabits marshes bordering large lakes and rivers, but not in deep-water marshes or dense stands of cattails. It tends to concentrate where grasses and sedges are knee to waist high and sometimes taller, and where the ground is moist to slightly wet. It is occasionally found in drier sites where lake levels have receded. It may occur in communities of bulrushes, sedges, cordgrass, reed canary grass, manna grass, and other similar grasses, and sometimes in a mix of cattails, beggarticks, or smartweeds (Pittaway 1997).

During autumn migration in Kansas, Nelson's and LeConte's sparrows often occupied stands of cordgrass in a matrix of shorter annual forbs and spikerushes. They often occurred in the same area at the same time, but rarely within 10 m of each other (Powell and Nyari 2007).

The Nelson's Sparrow is a rare migrant in Ontario, or at least rarely observed. It passes through southern Ontario regularly but is rarely seen because few people search the appropriate habitat at the right time. Eighteen were seen on 8 October at Hillman Marsh. Maxima seen in the Hamilton area were 10 on 28 September and 8 on 29 September. Maxima in the Kingston area were 6 on 1 October and 3 on 3 October, and the maximum count at Algonquin Park is 10 on 3 October (Curry 2006; James 1991; Pittaway 1997; Tozer 2012; Weir 2008).

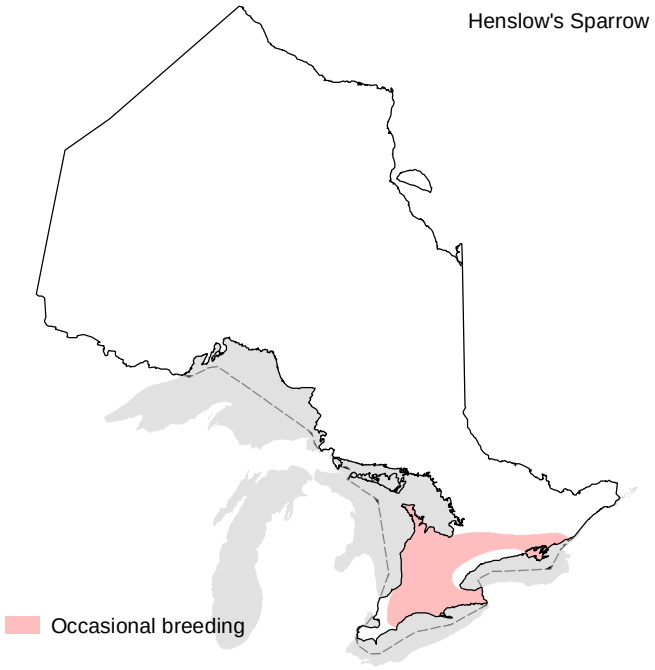
Henslow's Sparrow

Centronyx henslowii

BREEDING SEASON

Habitat Requirements

In Ontario, the Henslow's Sparrow has nested in hayfields, meadows, and pastures, all with characteristically tall growths of grasses, legumes, and forbs. Several nests were in wet or damp fields and 1 field contained scattered small shrubs (Peck and James 1987). It has nested in abandoned fields, ungrazed or lightly grazed pastures, fallow fields with a high clover and alfalfa content often mixed with timothy, grassy swales in open rolling farmland, wet meadows, infrequently mowed fields with a thick layer of thatch, and tallgrass prairie on Walpole Island (Austen et al. 1995; Pearce et al. 2010). In Haldimand County, it nested in a pasture containing many small tributaries lined with dogwoods. The site was dominated by tall grasses with even taller forbs (Speirs 1933). Many occupied sites contain tall common mullein stalks that are used as singing perches. Speirs and Orenstein (1967) reported it in Durham Region in an old field dominated by bluegrasses and other grasses, with asters and goldenrods and some encroachment by raspberries, dogwoods, and other shrubs; a hayfield on a hilly sandy moraine dominated by clover, timothy, and alfalfa with a good



deal of mullein and other forbs; a very hilly hayfield; and an area of mixed farmland consisting of hay, corn, and oats. It appeared to prefer old fields and hayfields with clover and alfalfa. In Simcoe County, it nested in moist weedy fields and sometimes in clover fields or wet meadows bordering marshes. It formerly nested in Holland Marsh before it was cleared and drained for market gardening (Devitt 1967). In Wellington County, it nested in a 160-ha abandoned pasture dominated by grasses 30 cm or taller, including timothy, quack grass, and orchard grass, with some areas of reed canary grass and scattered common mullein (personal observation). Near Brockville, it nested in an old hayfield that consisted of 90% orchard grass and 10% shrubs and forbs. The grasses were 0.5-1 m tall and the shrubs were less than 0.5 m tall, but the field was becoming invaded with shrubs. The thatch layer was 7-10 cm high and trees less than 10 m tall bordered the field on 3 sides. There was a marsh on the fourth side (Austen and Cadman 1993). The site that was occupied at Luther Marsh in Dufferin County (Brewer 1977) was dominated by smooth brome. Some historical Ontario locations contained or were adjacent to low-lying areas that were seasonally flooded during spring. Canada bluejoint and reed canary grass were common in these areas. Wet areas may contain the most stable vegetation communities and be less likely to be invaded by shrubs (Pearce et al. 2010). Reed canary grass forms dense monotypic stands that typically preclude establishment by other species. Although it is often stated that it occurs in wet low-lying areas, it also inhabits dry areas, including hilltops (Knapton 1984a).

Optimal Ontario habitat includes a high percentage of grasses, moderate to high density of grasses, a thick mat of ground cover from previous years' vegetation, dense vegetation at least 0.5 m tall, no current disturbance due to grazing, and low coverage by shrubs. Intermediate moisture regimes or low-lying areas are considered essential by some authors, but this is not the case. The Henslow's Sparrow avoids fields that are frequently mowed, cultivated or grazed, and recently burned grasslands. Sites that meet all or most of its habitat requirements are becoming increasingly scarce in Ontario (Austen et al. 1995; Heagy 2011; Knapton 1984a; Kraus 2015; Pearce et al. 2010).

Knapton (1984a) described the habitat at 5 occupied Ontario sites. The Aberfoyle site consisted of 70% grass cover with a high density of grass, 51 cm mean height of dense vegetation (range 48-54 cm), maximum height of grasses and forbs 88 cm and 116 cm, and high litter density. The Hockley Valley site consisted of 50% grass cover with a high density of grass cover, 82 cm mean height of dense vegetation (range 56-104 cm), maximum height of grasses and forbs 100 cm and 146 cm, and moderate litter density. The Rockton site consisted of 50% grass cover with a moderate density of grass cover, 30 cm mean height of dense vegetation (range 26-34 cm), maximum height of grasses

and forbs 80 cm and 100 cm, and moderate litter density. The Tiny Marsh west site consisted of 40% grass cover with a moderate density of grass cover, 29 cm mean height of dense vegetation (range 25-31 cm), maximum height of grasses and forbs 54 cm and 76 cm, and moderate litter density. The Tiny Marsh east site consisted of 60% grass cover with a high density of grass cover, 42 cm mean height of dense vegetation (range 25-48 cm), maximum height of grasses and forbs 76 cm and 102 cm, and high litter density. Both the Rockton and Hockley Valley sites lacked one or more of the optimum habitat requirements. Sites in Ontario and New York had 50-80% grass coverage, often with vetches, bird's-foot trefoil, and strawberries; dense vegetation 30-80 cm tall; grass and forb height 89-115 cm; and woody vegetation (willow, dogwood, or staghorn sumac) 76-183 cm tall.

Some studies examined landscape features that may affect occupancy of grasslands by the Henslow's Sparrow. Murray et al. (2008) used Breeding Bird Survey (BBS) data in the Midwest. Its abundance was most closely related to the amount of grassland within 800 ha. Thogmartin et al. (2006) also analyzed BBS data and found that higher abundance occurred in grasslands surrounded by forest; it was positively associated with precipitation during warm months. The positive association with forests could be a result of the types of grasslands that occur within these landscapes. These grasslands tended to have greater topographical relief, less agricultural land, and more idle and Conservation Reserve Program (CRP) lands. In New York, Peterson (1983) measured the distance to the horizon in the 4 cardinal directions. The mean distances to the horizon of 4 occupied sites were 7.3-15.6 km (average 10.25 km), significantly greater than the mean of 3.3 km for unoccupied sites. All occupied sites were on or near hilltops with sweeping panoramic views to distances greater than 35 km in some cases. Sites in valleys with hills or treelines rising above the grassland were not occupied, and even a single treeline or forest edge at a short distance precluded occupancy. At 2 occupied sites, adjacent areas that differed only in the presence of a treeline were unoccupied. The requirement for a lack of treelines and long panoramic views does not appear to be the case in Ontario. The only known occupied site in 1992 and 1993 was a small field with trees bordering it on 3 sides (Austen and Cadman 1993). In Pennsylvania, the distance to the nearest grassland and the surrounding land cover were unrelated to occupancy probability. Forested landscapes did not appear to be effective barriers to dispersal and colonization, even when more than 80% of the landscape was unsuitable habitat (Hill and Diefenbach 2014). Many colonies in New England, New York, and Pennsylvania were in river valleys (Hyde 1939), contrary to Peterson's (1983) findings.

The optimal habitat conditions identified for Ontario are the same for the Henslow's Sparrow throughout its range. Inhabited areas are typically dominated by grasses 0.5 m or more in height, the grass layer is very dense, and there is a deep thatch or litter layer from previous years' vegetation. In Pennsylvania, it was most likely to occupy fields with a larger grass component and low coverage by forbs (Hill and Diefenbach 2014). In North Carolina where pine trees had been planted, occupied areas had a dense ground cover of grasses, sedges, and ferns (Lynch and LeGrand 1985). In Iowa, occupied fields were dominated by smooth brome 45-85 cm tall, 5-20% of the area was covered with forbs, and there were dense standing dead grass stems from the previous year (Melde and Koford 1996). In Kentucky, it occurred in fields of orchard grass with some forbs such as wild carrot. In Missouri, numbers increased markedly as grass heights exceeded 15 cm in prairies (Knapton 1984a). In Pennsylvania, habitat at nests consisted of 2% bare ground, 22% forbs, 66% grasses, and

1% shrubs. The thatch layer was 4 cm deep, grasses were 57 cm tall, and forbs were 32 cm tall (Hill and Diefenbach 2013). In Michigan, habitat consisted of vegetation dominated by nonwoody vegetation, particularly grasses and sedges, that was dense or at least had dense patches, and presence of litter (Robins 1971a). In New York, all occupied sites were heavily dominated by grasses and most contained sedges. Subdominant herbaceous species composition had little importance in habitat selection and herbaceous species may not be required; 1 site was pure timothy (Peterson 1983). In Kansas, forb coverage was not important when selecting territories (Zimmerman 1988). In Illinois, important habitat characteristics included litter density and depth, standing dead residual vegetation, and vegetation height and density. Occupied areas were dominated by sedges, dropseeds, cordgrass, meadow fescue, and bluegrass. Occupied areas had a greater vegetation density between 0 and 25 cm and a higher percentage of standing dead residual vegetation than unoccupied areas (Herkert 1994a, 1994b). At a military base in Kansas, vegetative characteristics that were consistently associated with occupied sites included high litter coverage and dense homogenous vegetation. In spring, it used sites that had retained higher cover by standing dead vegetation and deeper litter; those differences disappeared by summer (Cully and Michaels 2000). At reclaimed mines in Indiana, its presence was positively associated with percent coverage by grasses, grass species diversity, percent coverage by smooth brome, and percent coverage by broomsedge. It was marginally associated with vegetation height and negatively associated with forb species diversity (Bajema et al. 2001). In Wisconsin, occupied areas had lower coverage and density of forbs, significantly taller forbs, higher vertical vegetation density and mean effective height with a lower proportion of vegetation occurring in the 0-10 cm layer, considerably less coverage by lawn-like vegetation, and deeper, more compact, and more extensively distributed litter than unoccupied areas (Wiens 1969). In Wisconsin, its abundance was positively correlated with maximum vegetation height and density and percent coverage by standing residual vegetation. It was negatively correlated with bare ground (Swanson 1996). In western shrubsteppe vegetation, it was positively correlated with litter depth (Rotenberry and Wiens 1980). In Quebec, it nested in a wet meadow of sedges and grasses. Another site was in the upper part of a gently sloping field with dense smooth brome and timothy 1.2-1.5 m tall (Bannon in Gauthier and Aubry 1996). The vegetation that the Henslow's Sparrow inhabits may be rather irregular in height and density or uniform, but the ground cover is usually quite dense and at least 30-60 cm tall (Graber in Austin 1968). There is no difference in its rates of occupancy or nest survival in native and planted grasslands, and the species of grass that are present do not appear to be important. It has been documented breeding in little bluestem, smooth brome, paspalum, Kentucky bluegrass, tall ryegrass, cordgrass, wiregrass, broomsedge, perennial rye grass, orchard grass, redtop, timothy, big bluestem, switch grass, reed canary grass, Canada bluejoint, Indian grass, sweet grass, beach grass, and muhly grass (Arnold and Garza 1998; Ells 1995a; Graves et al. 2010; Herkert 1994b; Hill and Diefenbach 2013; Hyde 1939; Jaster et al. 2013; Schulenberg et al. 1994; Skipper 1998; Winter 1999).

Some studies reported that the Henslow's Sparrow is intolerant of any woody vegetation within its territory; others concluded that short shrubs may be widely scattered throughout the territory. It is universally agreed that invasion of grasslands by tall shrubs and saplings render habitat unsuitable. In New York, it occurred in fields with no woody vegetation at 1 site. At another site, shrub coverage was less than 1% and the density of shrubs with an average height of 0.5 m was less than 10 per 250

m^2. In Kansas, densities of trees taller than 4 m were significantly lower in territories (0.54 per ha) than in random sites (6.67 per ha). In Ohio, grasslands used for nesting included scattered shrubs that provided singing perches. In Missouri, territories contained no shrubs with a diameter at breast height greater than 2.5 cm and few or no smaller woody stems (range 0-1.00 per ha). Males avoided areas with woody vegetation taller than 1 m. In Illinois, occupied areas had no or very sparse coverage by shrubs. In Kansas and Ohio, its abundance was negatively correlated with woody vegetation. Daily nest survival was negatively correlated with the amount of woody vegetation surrounding the nest. In Indiana, nest survival increased with increasingly open habitat. At a Pennsylvania reclaimed mine site, all standing woody vegetation was pulverized to a maximum height of 0.3 m and spring sprouts were sprayed with herbicide. There was no difference in nest survival between control and treatment areas, suggesting that woody vegetation did not affect survival. In Massachusetts, it nested in wet meadows grown up in steeplebush and in fields invaded by hazel and blackberries. It may nest in young plantations where the conifers have not yet overtopped the grasses. In New York, woody vegetation at occupied sites was either nonexistent or limited to a very few widely scattered low hawthorns, dogwoods, or raspberries that comprised less than 2% coverage. Almost any woody vegetation appeared to decrease suitability. In Texas, the amount of woody vegetation on 4 transects through territories was 3.4%, 12.1%, 14.3%, and 6.8%. At 1 Kansas site, it used open grassland with few trees. Presence of low woody vegetation did not reduce usage of areas, but shrubs were scattered in distribution. In Indiana, sites with more than 50% shrub coverage were avoided (Arnold and Garza 1998; Crimmins et al. 2016; Cully and Michaels 2000; Galligan et al. 2006; Graves et al. 2010; Herkert 1994b; Hill and Diefenbach 2013; Hyde 1939; Pearce et al. 2010; Peterson 1983; Pruitt 1996; Smith and Smith 1992).

Many studies concluded that the Henslow's Sparrow prefers moist low-lying areas, but it has nested in a wide range of moisture regimes. Vegetation characteristics are much more important in habitat selection and moisture regime may either be a secondary characteristic or not important at all. The apparent preponderance of wet habitats may be because these areas are less likely to be cut for hay, burned, or converted to other land uses than drier sites. In New York, it often nested on hilltops with a variety of moisture regimes. In Texas, it nested in a 105-ha field divided by a drainage canal. The western part of the field was higher and drier than the eastern part, and all Henslow's Sparrows nested in the western part. In Michigan, it appeared to prefer an intermediate moisture regime. In Kansas, it nested near the crest of a hill. In another New York study area, it occurred in a variety of moisture regimes from dry and well-drained to 30% seasonally or continually moist with numerous clumps of sedges and grasses. In prairies in Kansas, it was significantly more abundant in sites with deep silty clay loam than shallower soils. The clay soils supported a greater above-ground biomass of grasses. It tends to occupy flatter slopes of fields with a maximum slope of 7° (Arnold and Garza 1998; Herkert et al. 2020b; Hyde 1939; Peterson 1983; Pruitt 1996; Robins 1971a; Smith and Smith 1992; Zimmerman 1988).

Several studies compared habitat at the nest with the remainder of the territory or habitat within the territory to unoccupied areas. In Minnesota, both the depth of the litter layer and the distance from the ground to the bottom of the litter layer were greater in occupied than unoccupied sites (Pruitt 1996). In Ohio, Graves et al. (2010) found no significant differences in habitat variables between occupied and unoccupied sites on reclaimed surface mines. In Kansas, the amount of

standing dead vegetation was greater in territories than in unoccupied sites. Grass coverage within and outside territories, respectively, was 83.3% and 70.0% and 78.6% and 79.2% over 2 years. There was significantly less woody cover within (0.7% and 0.8% over 2 years) than outside (1.8% and 2.7%) territories. Grass height was significantly higher within (23.7-73.3 cm) than outside (31.2-50.7 cm) territories on all soil types. There was no significant difference in forb coverage within (12.0% and 14.4%) and outside (12.6% and 15.0%) territories. The Henslow's Sparrow's association with standing dead vegetation may be because it helps protect nests from predation, parasitism, and microclimate extremes. Dead vegetation and the litter associated with it may inhibit growth of new vegetation, providing a more open substrate (Zimmerman 1988). In Illinois, occupied areas had taller vegetation than unoccupied areas (27.5 cm compared with 19.8 cm for grasses and 47.2 cm compared with 30.1 cm for all vegetation). In occupied areas, vegetation was denser, particularly within 25 cm of the ground, and there was a higher proportion of dead plant material (45.0% compared with 13.6%) than in unoccupied areas (Herkert 1994b). At another Kansas site, mean vegetative cover and density, litter cover, and structural heterogeneity were higher at occupied sites in spring than at survey points. By summer, there were no significant differences between occupied and unoccupied sites (Cully and Michaels 2000). In Indiana, there were significant differences in habitat parameters for occupied and unoccupied sites, respectively: 5.4 cm and 3.8 cm litter depth; 79.1% and 70.9% litter coverage; 68.1% and 57.5% grass coverage; 15.8% and 7.5% coverage by smooth brome; 4.1% and 0.6% coverage by broomsedge, and 2.0 and 1.7 grass species diversity (Bajema et al. 2001). In Wisconsin, territories contained no fence posts, fence lines, wire bales or tangles, or trees. It is possible that suitable habitat simply did not contain these features rather than them being actively avoided. The percent coverage by vegetation in occupied and unoccupied areas, respectively, was 97% and 97% grass cover, 86% and 64% very narrow-leaved grass cover, 36% and 58% narrow-leaved grass cover, 20% and 31% forb cover, and 1% and 3% bare ground (Wiens 1969). In Missouri, coverage by grasses and standing dead vegetation was greater within than outside territories (Swanson 1996).

Other studies examined microhabitat characteristics within territories. In Kansas, vegetation at nest sites consisted of little bluestem, sedges, forbs, and a few shrubs. Cover within the 1 m^2 around nests consisted of 10% standing dead little bluestem, 10% alive little bluestem, 25% sedges, 20% forbs (blazing-star and hemp dogbane), and 5% bare ground; litter depth was less than 2 cm. Spaces around grass clumps may enable birds to disperse quickly through the grasses once the young fledge (Schulenberg et al. 1994). On Ohio surface mines, areas within 100 m of the nest averaged 2.3% woody vegetation coverage and there were 2.7 woody patches within a 100-m radius (Graves et al. 2010). In Missouri, 82% of nests were among layers of thick litter. There were no differences in any habitat variables between successful and unsuccessful nest sites. Habitats at successful and unsuccessful nests, respectively, were 3.3 cm and 3.7 cm litter depth, 43.0 cm and 40.7 cm vegetation height, 27.1% and 33.1% litter cover, 51.4% and 49.4% grass cover, 19.1% and 16.2% forb cover, 1.8% and 1.1% woody cover, 0.6% and 0.2% bare soil, 89.6% and 91.7% cover at the nest, and 7.0 cm and 7.9 cm nest height (Winter 1999). Wisconsin territories had less than 2% woody cover, 74% herbaceous cover (which probably included grasses), 24% litter cover, less than 2% bare ground, and 88 cm maximum vegetation height (Swanson 1996).

Although singing perches are a common component of Henslow's Sparrow territories, they may not be essential. It occasionally nests in uniform grass communities where there are no perches. In these cases, it sings from below the grass canopy (Peterson 1983). In Missouri, it was very selective and sang predominantly from woody vegetation less than 1 m tall. In Minnesota and Michigan, males returning in early spring sang while perched on last year's standing dead vegetation (Pruitt 1996; Robins 1971a). In North Carolina, it was never observed singing from a fence or exposed snag, but sang mostly from the tops of pine and deciduous saplings that had not yet overtopped the dense ground vegetation. One sang from a bare pine branch 4.6 m above ground, but such behaviour was rare. Most perched or sang in the middle of a sapling or by clinging to the stalk of a herbaceous plant (Lynch and LeGrand 1985). In Michigan, it sang from just below the top of the vegetative cover. Invading woody plants and grid stakes provided perches above this level, but were used infrequently (Robins 1971a). Another Michigan study determined that it used elderberries and other shrubs, but especially dead mullein stalks, as perches (Hyde 1939). In Wisconsin, perchs consisted of 3.3% grasses, 59.7% heavy-stemmed forbs, and 37.0% medium-stemmed forbs (Wiens 1969).
