HOW TO USE THIS BOOK

To access a topic, click on it in the Contents, which follow on the next page. On every page, there is an icon of a Blue-headed Vireo in the upper left corner. If you click on this icon, it will return you to the Contents. The entire document can be downloaded. The book is more than 2,400 pages long so it is recommended that one prints only those files that are of most interest. As can be seen in the Contents, the bulk of the book is devoted to accounts of the 145 passerine species that have nested in Ontario.

Literature Cited

Bookmarks are provided in the Literature Cited section. The bookmarks panel is closed in the online version but can be opened by clicking on the icon in the navigation toolbar. Once you have opened the bookmarks panel, ">Literature Cited" will be displayed. Click on > to reveal the letters of the alphabet. The list of references is 222 pages long, so bookmarks are provided for the first reference starting with each letter of the alphabet to reduce the amount of scrolling that may be required to find a reference. So, for example, if you are looking for an article authored by "Caffrey", you can click on the "C" bookmark to get close to the reference. In this example, the bookmark takes you to "Cabe".

I have provided hyperlinks to references that occur only online. Clicking on a hyperlink should take one directly to the paper that is cited. Over time, some of these may cease to function because of updates and other changes. This is most likely to occur in the *Birds of the World* species accounts. These accounts are constantly being updated and the references are changed with each revision. There are a few cases where a website has already been taken down. In these cases, I have not provided a hyperlink.

ACKNOWLEDGMENTS

Thanks to my wife, Anne, for her understanding and support throughout the process of writing this book. She typed the first draft of the species accounts and tolerated my working on this project when I probably should have been doing something else.

Ross James was instrumental to this project, and it would not have been completed without him. Initially, he encouraged me to work on this and helped decide on the format and content of the species accounts. He provided much of his extensive knowledge on the avifauna of Ontario to earlier versions of species accounts. There are few species accounts that do not reference his research. His superb illustrations and photographs greatly enhance the book. At one point, I considered abandoning the project, but his illustrations inspired me to continue. I am extremely grateful for everything he has contributed.

I am extremely grateful to Andy McLennan of Cartographics Mapping & Design Inc. for his never-ending patience in making edits to the maps. The maps underwent several design changes throughout the process and he cheerfully made all the necessary changes. In addition, he inserted the maps and illustrations into the species accounts and formatted the PDF files. His design expertise resulted in an excellent presentation of the species accounts. Caitlin Weeks prepared earlier black-and-white versions of some of the maps.

Cole McLennan designed the website. He provided me valuable information on design options and helped me select the preferred design.

Staff at the University of Guelph library annex were extremely helpful, getting publications out of storage and allowing me to photocopy them on site. Angela Davidson, in particular, was of great assistance. Without their help, I would not have been able to track down many of the older or more obscure references.

Several people took the time to talk to me and relate to me some of their personal experiences or provided unpublished data. Others went out of their way to provide published material that would otherwise have been difficult to track down. These include Peter Burke, Mike Cadman, Craig Campbell, Glenn Coady, Helen Dancey, Grant Egerdee, Matt Hallman, Neil Sandilands, Donald Sutherland, Doug Tozer, Allen Woodliffe, and Alan Wormington.

This work would not have been possible without the help of the hundreds of people who sent me reprints of their publications, and especially those who did all the research that is summarized in this book.

I am indebted to all those citizen scientists that conducted fieldwork for the programs that I used in summarizing status trends for species. These include the Breeding Bird Survey, Christmas Bird Count, Project FeederWatch, Marsh Monitoring Program, Forest Bird Monitoring Program, and Winter Bird-Population Study.

Although many have helped me throughout this process, all errors and omissions are mine.

INTRODUCTION

This book summarizes the life history requirements of 145 species of passerine birds that occur in Ontario. Two previous volumes (Sandilands 2005, 2010) covered the nonpasserine species.

Only species that are normally part of the ecology of the province or that have been confirmed breeding are included in the accounts. Vagrants and extremely rare species are not discussed because they are typically out of their normal range and habitat.

Through strict application of the breeding evidence rules for the Ontario Breeding Bird Atlas, 5 species that I have not included as breeding species are considered breeders by one or both of the atlases (Cadman et al. 1987, 2007). These are the Northern Wheatear, Sprague's Pipit, Worm-eating Warbler, Kentucky Warbler, and Summer Tanager. These species have not been confirmed as breeders in Ontario. Because these species do not occur regularly in the province during other seasons, I have not prepared species accounts for them. The Mountain Bluebird has nested in the province, but only in mixed pairs with the Eastern Bluebird. Because the Mountain Bluebird has not been confirmed nesting conspecifically in the province, no account is presented for it.

Three aspects of bird life histories are the focus in this book: habitat requirements, limiting factors, and status. Where applicable, each species is discussed during the breeding season, postfledging period, migration, and winter. A more detailed explanation of the format of the species accounts follows.

I have omitted many topics typically considered in life history accounts. These include description and identification information, vocalizations, behaviour, parasites other than the Brown-headed Cowbird, and predators. Occasionally, the latter three topics are discussed if they have a direct bearing on habitat use, are a limiting factor, or may affect the status of the species. Details of the materials used in the construction of the nest and its size have been omitted. This information is available in Peck and James (1987). No information is provided on hybrids or misdirected parenting among species except in cases where these pose a significant limiting factor or change the habitat or behaviour of the species involved.

The information in the species accounts is derived almost entirely from published data. The accounts also contain my unpublished personal observations and those of individuals who have provided me with some of their personal knowledge.

The order and nomenclature of the accounts follow the seventh edition of the American Ornithologists' Union (1998) *Check-list of North American Birds* and its supplements through to 2025 (Chesser et al. 2025a). Scientific names of species mentioned in the text are provided in the appendix. Bird species for which species accounts are presented are not included in the appendix.

Definitions of the extent of southern and northern Ontario are identical to those presented by James (1991), and are similar to the delineation used in the Ontario Breeding Bird Atlases (Cadman et al. 1987, 2007). The 47th parallel is used to distinguish between northern and southern portions of the province. Figures 1 and 2 show southern and northern Ontario respectively, along with

municipal boundaries and most localities mentioned in the text. Figure 3 indicates physiographic and forest regions of the province.

The species accounts deal with 4 biological seasons: breeding, postfledging, migration, and winter. Due to the different "biological clocks" of various species, these seasons are only loosely related to the human calendar. For example, February is winter for most species, but breeding season for the Great Horned Owl and spring migration for the Horned Lark.

For each species, approximate dates of major life history events are identified. In many cases, different dates are relevant to northern and southern portions of the province. Ranges of dates of occurrence are often presented along with periods of peak occurrence when they are available.

Winter species usually include only birds that normally occur in the months of January and February. December birds and those reported on Christmas Bird Counts are often late autumn migrants.

Not all species are present during all biological seasons. When a species is consistently absent in a season, or very rare and sporadic, this season is not mentioned in the species account. Breeding requirements are discussed for all species that have nested even only occasionally in the province. All species are present during the postfledging period, but no information is available for some species.

The following sections describe topics that are usually addressed during the 4 seasons. If no information is presented, it is because I could not find any. Although I have undoubtedly overlooked some publications, lack of discussion usually means that no information is available.

FORMAT OF THE SPECIES ACCOUNTS

Breeding Season

Under habitat requirements, 3 topics are discussed in all accounts: nesting habitat, a description of where the nest is likely to be situated, and the territory and/or home range size. Additional information that is presented includes natal philopatry and site fidelity of adults to territories. The information on nesting habitat is often quite detailed. Information is provided on a species' habitat requirements in each of the physiographic regions that it occurs in Ontario followed by details on habitat use in other areas. In addition to the general habitat, information may be provided on landscape-level habitat, microhabitats, differences in habitat at nests and the remainder of the territory, differences between occupied and unoccupied habitat, and comparison of habitat use with other species using the same habitat. For most species, a discussion in provided on where it nests within a habitat patch (on the edge, in the interior, or throughout), and whether it is area sensitive.

Under limiting factors, information is always provided on the time of key events in the nesting period, the annual reproductive effort, mating systems, and diet. Topics discussed about timing include how long it takes to build the nest, when nesting is usually initiated, the egg-laying interval, incubation period, and the nestling period. Factors considered under reproductive effort are number of broods raised, whether renesting occurs, and clutch size. Topics under mating systems include age at first breeding, breeding periodicity if breeding does not always occur every year, the mating strategy (monogamy or polygyny, extra-pair copulations, and intraspecific parasitism), and

mate fidelity within and between seasons. The discussion of diet emphasizes the breeding season. Diet in other seasons is occasionally included here if there are no significant differences among seasons, or if the entire diet can be summarized briefly. Besides a description of food items, information on food-size preferences may be presented, and it is noted whether feeding territories are defended. Feeding techniques and substrate are also described. Information on parasitism by the Brown-headed Cowbird is provided for all species that are hosts. This includes information on how the species responds to parasitism and how it is affected by parasitism.

The section on breeding season limiting factors is frequently the most extensive portion of a species account. In addition to the topics that are always addressed, habitat loss and fragmentation, human disturbance, environmental contaminants, effects of water-level fluctuations, forest management, water and air quality, nest-site availability, interspecific competition, mowing, prescribed burns, livestock grazing, climate change, and many other factors may be discussed. When no additional information is provided, it is because there is no evidence to suggest that adverse effects are occurring or because no information is available. Some minor effects that are not limiting factors, such as entrapment in spider webs or burdocks, are not presented.

For status, a historical perspective of changes since the late 19th century to the present is given. In some instances, the future status of species has been predicted. Occasionally, a distinction is made between status in the northern and southern portions of the province.

The status section is the weakest in the book, simply because status is dynamic and because it varies so much across the province. In addition, many bird species are not routinely monitored throughout the province by any survey program, and there is no reliable information on the status of many species. For status, I have identified differences in abundance over large geographic areas, such as in and south of the Canadian Shield, but I have seldom discussed differing abundance levels within smaller regions. There are numerous excellent publications on birds in different regions of the province and these should be consulted for more detailed information on local status.

The Ontario Breeding Bird Atlas program is an important analysis of breeding bird distribution and status in the province. Two atlases have been completed to date. Fieldwork for the first atlas was completed 1981-85 and results were summarized by Cadman et al. (1987). Fieldwork for the second atlas was conducted 2001-05 (Cadman et al. 2007). These are referred to the "first atlas" and the "second atlas" in this document.

The atlases use the term "probability of observation", and this information is provided throughout the species accounts. The probability of observation is the percentage of squares that a species could be expected to be found in during 20 hours of atlassing effort within the province and the 5 regions that were used in analyzing atlas data. For a full discussion of the methods of calculating changes in the probability of observation between atlases, Cadman et al. (2007) should be consulted. The information on changes in probability of observation of species reported by Cadman et al. (2007) is very useful. In many cases, a species was found in a similar number of squares during the second atlas as during the first, but is identified as significantly decreasing or increasing based on the statistical analysis of the probability of observation. In some cases, I have also provided information on the number of squares that the species was detected in during the 2 atlases. The

third atlas, currently underway 2021-25, will be a much better indicator of change in the probability of observation provided that the same methods for reporting when birds are observed are followed.

Breeding abundance is defined slightly differently than for migration and winter. During the breeding season, species maintain territories or home ranges that disperse birds throughout suitable habitat. For most species, territorial boundaries dissolve in other seasons, allowing concentrations of birds in preferred habitats.

Abundance is difficult to define and has been done in several ways historically. The most frequently used technique is based on how many breeding pairs could potentially be recorded daily. This definition works well for common and abundant species that are readily observed and use widespread habitats. Species that are difficult to detect, have large territories, or have specialized habitat requirements may not be adequately defined by these criteria.

Abundance of species can be greatly affected by the size of their territory and the availability of their preferred habitats. Some raptors have extremely large home ranges and would not be plentiful even if the entire province were suitable habitat. The Peregrine Falcon, in addition to having large area requirements, is limited by the availability of nest sites such as cliffs or skyscrapers. Thus, even under ideal conditions, it would not be a common species in the province.

Even species that do not have specialized habitat requirements are limited by the abundance of their general habitat needs. Southern Ontario species that nest in urban areas, pastures, or old fields are likely to be more common than those that require bogs, simply because the former habitats are much more common.

Among species inhabiting a particular vegetation type, there are usually generalists and specialists. This has been well documented for forests but also applies to wetlands and grasslands. In forest habitats, the generalists are edge species that occur around the periphery of woodlots, and they often use adjacent open habitats for foraging, displaying, or even nesting. When openings are created in forests, these species are able to exploit microhabitats within the woodlot. Specialists require specific microhabitats within the forest. Thus, within any given forest or any other habitat, generalist species are more abundant than specialists.

An attempt has been made to take all of the above factors into account when assigning a status designation to a species. When one or more factors affect abundance, this is usually stated under both limiting factors and status.

A reasonable estimate of abundance is whether the existing habitat is being used to its carrying capacity. A species could be considered common to abundant if all suitable habitat was defended in nesting territories. Although there are some obvious microhabitat preferences, Savannah, Grasshopper, and Henslow's sparrows occupy similar habitats, and may nest together in the same field. Based on their occupancy or use of available habitat within their normal geographic range, they would be classified as abundant, uncommon, and rare, respectively.

With all of the caveats mentioned above, I have used a combination of 2 techniques to define breeding abundance when actual numbers cannot be estimated: (1) amount of available habitat used, and (2) numbers of birds that could be observed in a single day.

The usage of available habitat is difficult to determine for many species because information on their requirements is deficient. For those species for which an appropriate judgment could be made, I used the following definitions:

Abundant — Essentially all suitable habitat is incorporated into a breeding territory or home range. It is certain that the species will be observed in suitable habitat.

Common — Almost all suitable habitat is incorporated into a breeding territory or home range. It is highly probable that the species will be observed in suitable habitat.

Uncommon — Less than 50% of suitable habitat is occupied. It is unlikely that the species will occur in any given area, but it can usually be found by searching several areas of suitable habitat.

Rare — Less than 10% of suitable habitat is occupied. It is highly unlikely that the species will occur in any given area. It is present in isolated portions over a wide geographic range of suitable habitat.

The numerical rating is identical to that used by James (1991). These definitions are based on the number of birds that could be observed during the breeding season away from the periphery of the normal range. The definitions assume that the observer is looking in appropriate habitat and concentrating on that species only.

The following 2 examples indicate how designations of abundance have been tempered. The Savannah Sparrow is considered abundant. In a long day, starting slightly before dawn and ending at nightfall, one could probably find 500 individuals of this species. Admittedly, it would not be easy and the observer might not achieve this, depending on the distance between suitable habitats and the amount of time consumed by walking. On the other hand, if one visited a single suitable habitat patch 500-1,000 ha in area, 500 birds could easily be recorded. The important factors are that whenever suitable habitat is visited, Savannah Sparrows will be present, and that suitable habitat is abundant.

The Lesser Yellowlegs was formerly considered common (James 1991; Sandilands 2010), which means numerically that one should have been able to see between 25 and 500 birds in a day. This species nests in the Hudson Bay Lowland and the northern Boreal Forest Region. The area is fairly inaccessible, but it is likely that 25 could have been observed with the aid of a helicopter. The fact that this species was a widespread breeder in the available habitat lends credence to the fact that it was common. Wherever one sets down in a helicopter in suitable habitat, there was a moderate probability of observing a Lesser Yellowlegs. Since then, this species has declined significantly and is no longer a common breeder.

Following are the numerical definitions of abundance:

Abundant — More than 500 can be seen in 1 day.

Common — Can always be found (well distributed). More than 25 a day is usual, but seldom more than 500.

Uncommon — Can usually be found but numbers seen are likely to be small (6-25 a day).

Rare Usually seen singly (seldom more than 5) and difficult to find on any particular outing (unless a specific location is known).

James (1991) presented definitions of frequency based on the rate of annual occurrence. Frequency generally has not been a concern, because I have focused on those species that are of regular or occasional occurrence in the province. Regular species are usually present every year, while occasional species occur most years and at least once a decade.

Vagrant species have been ignored in this work, except for species that have been documented breeding in the province. From a breeding perspective, the Black-necked Stilt could be considered a vagrant, yet it was included in Volume 2 because breeding has been confirmed. Similarly, I prepared an account in this volume for the Blue Grosbeak because 1 pair with a fledgling was observed, the only breeding record for the province.

Postfledging Period

The postfledging period begins when young leave the nest and lasts until autumn migration takes place. This is a critical period for birds. Young just out of the nest may be subject to high rates of mortality and this is an important time for building up fat reserves prior to migration. Adults may undergo a moult at this time with some species becoming flightless.

Although this is a critical period, limited information is available for the postfledging period. For some species, there is essentially no information. This topic was not dealt with in any detail in the volumes on nonpasserine birds. More research is being done during this period now due to the development of miniature radiotags.

A good understanding of a species' habitat and diet requirements during the postfledging period is essential. Some species may move to a different habitat type after the young leave the nest. A forest that appears to be ideal breeding habitat may be unoccupied if there is no suitable postfledging habitat nearby.

Movement patterns during the postfledging period vary considerably among species. For some species, the fledglings and adults may remain in or near the breeding territory until autumn migration, some remain near the territory until the young are independent and then move to nearby but different habitat, and others may disperse long distances prior to migration.

Topics that may be included in this section are habitat requirements of dependent and independent juveniles and the adults, movement patterns, foraging behaviour and diet, flocking behaviour, and associations with other species. Some species are highly gregarious and gather in large conspecific or multispecies roosts. In these cases, details are provided on the roosting habitat, site fidelity to roosts, and movement patterns among foraging areas and roosts.

Migration

In addition to habitat requirements, limiting factors, and status, migration timing is discussed for spring and autumn. For some species, general information on routes is provided, but only if there is something relevant to Ontario.

Approximate dates of migration are given for each species. Dates are provided for different areas of the province when they are available.

For most species, the discussion of habitat requirements during migration is brief. Many species do not have very specific needs during migration. Others are limited by their microhabitat requirements. In these instances, more detailed discussion is presented.

No limiting factors are apparent for some species during migration. For others, degradation and loss of habitat, diet, territoriality, collisions with human-made structures, climate change effects, and other factors may be discussed.

For status, the numerical definitions of abundance presented in the section on breeding season are used. In some cases, the number of birds observed during the peak of migration at different locations is provided. This information is usually generalized without giving exact numbers by site because these are likely to change with time.

Some species are year-round residents in the province. A few of these exhibit some southward movement in autumn and others disperse from breeding grounds to intermediate habitat prior to going to wintering areas. For resident species that do not remain within the home range all year, habitat requirements and limiting factors are discussed under the heading of autumn. Spring is not treated as a season for these species; most move directly from wintering areas to breeding habitat. The 2 crossbill species may nest almost any time in the province and make extensive movements between breeding areas. These movements are discussed under the heading of nonbreeding season.

Winter

The winter portion of the account for most species is brief. For a few species, the winter season is significant, with very particular habitat preferences. Limiting factors may include habitat availability, snow depth and other weather variables, and food. Winter status is defined numerically.

Mapping

A map is included for all species. For the breeding season, the normal breeding range is shown and extralimital or marginal breeding areas may be indicated. Normal wintering areas and extralimital or marginal wintering areas are depicted.

Extralimital habitat includes areas that are outside the species' normal range, where the species may not occur again or occurs infrequently. Some species establish small populations and these may be considered extralimital if they continue to be isolated from the main population.

Marginal habitat consists of part of the range that is regularly inhabited but at lower than normal density because habitat conditions are less than ideal. For instance, many open-country species nest sparingly in densely forested regions even though these areas may well be within the species' range. I have tried not to confuse low abundance of a species in an area and marginal habitat, but may not have succeeded in some cases. Marginal habitat is habitat that is less than ideal for a species; low abundance of a species may potentially occur in good as well as marginal habitat.

The range maps are general. A species may be locally absent in some areas where the range map indicates that it is present, and isolated records of a species may occur outside the indicated range. Distribution during the breeding season is fairly well known for most species. The winter range is not well defined for many species, including some very common birds. Christmas Bird Counts are typically completed before winter arrives and Project FeederWatch is the only program

that monitors birds over the winter. The northern extent of the winter range of many species has not been determined adequately.

FOREST-INTERIOR BREEDING BIRDS

I have learned much during the compilation of 312 species accounts. Possibly the most important fact is that the existence of obligate forest-interior birds appears to be a myth. I did not find a single forest-breeding species that always avoids edge. A possible exception is the Acadian Flycatcher, but there are few studies that explicitly examine where it nests in relation to forest edge.

The concept of forest-interior species was first introduced in 1981 (Whitcomb et al. 1981) based on point count results with no attempt to determine nest and territory locations relative to edge. Forest breeding birds were put into 1 of 4 categories based upon where they putatively nested in the forest (edge, interior-edge generalists, forest-interior specialists, and field-edge species). This classification system was widely adopted and is still used by some researchers.

After the original concept of forest-interior breeding birds was introduced, much research was undertaken to refine this information. Numerous field studies were undertaken to ascertain where species nested in relation to forest edge. This resulted in some species being moved into different categories, but some of the research appeared to confirm edge avoidance by some species. Much of this research used point counts or transects to detect where bird species occurred within the forest.

Villard (1998) was the first to question the concept of forest-interior birds. Further research has confirmed that individual species identified as forest-interior do not always avoid edge. One of the issues with the earlier fieldwork was that it was completed very early in the morning when birds are actively singing and defending their territories. At this time, birds with a territory bordering on edge sing away from the edge because the interior is the only location where they may have potential competitors. More recent studies using radiotracking techniques indicate that these same birds spend most of the remainder of the day near forest edge because food is usually more abundant there.

From the extensive information I reviewed, it is apparent that forest-breeding birds use 3 criteria to select where they nest in relation to edge. They select areas with the best habitat, the most abundant food supply, and where predators are least abundant. As an example, the Ovenbird is considered a forest-interior species by many authors (Burke and Nol 1998, 2000; Freemark and Collins 1992; Hann 1937), but in 1 Pennsylvania forest it completely avoided forest interior and could not be coaxed into the interior with broadcasts of its song. This was because of a high density of chipmunks in the forest interior, one of the main Ovenbird nest predators (Emmering et al. 2018). Another example is the Winter Wren which appears to prefer forest interior south of the Canadian Shield in Ontario, but commonly nests along edges of rivers, lakes, and wetlands in the Shield. The reason for this is that it prefers to nest where there are large logs and other downed timber, a resource that is most common in forest interior south of the Shield and common on edges in the Shield.

The term "forest-interior breeding bird" cannot be accurately applied to any Ontario bird species.

AREA-SENSITIVE BREEDING BIRDS

In most species accounts, I have discussed whether the species is area sensitive. I have considered area-sensitive species to be those species that require a habitat patch to be much larger than its territory size before inhabiting it. There are numerous examples of species with territory sizes of 1 ha or less that require habitat patches of 20 ha or larger. Birds inhabiting forests, grasslands, and marshes may be area sensitive.

Some authors consider species to be area sensitive if their density increases with increasing patch size. I have included these results in the species accounts, but do not consider this a true indication of area sensitivity. Many of these species inhabit patches that are not much larger than their territory size.

Area sensitivity is complex and results from 1 area are not directly applicable to other areas. The amount of habitat that a given species requires depends on factors such as how common the species is in the general area, whether it is in the core or periphery of its range, and the amount of suitable habitat in the landscape. Where a species is rare or at the periphery of its range, it tends to inhabit the best and largest examples of its preferred habitat. It is unlikely to inhabit smaller patches even if the habitat is ideal. Where suitable habitat is rare or patchily distributed, a species may require large habitat patches. The same species may not exhibit any area sensitivity where its habitat is abundant. In Ontario, some birds may require forests a minimum of about 100 ha in Essex County where there is only 3% forest cover, may only need about 20 ha in Waterloo Region where there is 15% forest cover, and are unlikely to be area sensitive at all along the Niagara Escarpment where there is 80% forest cover.

The reason for area sensitivity in breeding birds may be related to the mating system. Many species engage in extra-pair copulations to enhance the genetic viability of the brood and to ensure fertility. Extra-pair copulations are best facilitated when a habitat patch is large enough to support several pairs of the species, especially in fragmented landscapes. In landscapes where the preferred habitat is common and patches are close together, birds may move among patches to seek extra-pair copulations and the nest patch does not have to be larger than a single territory.

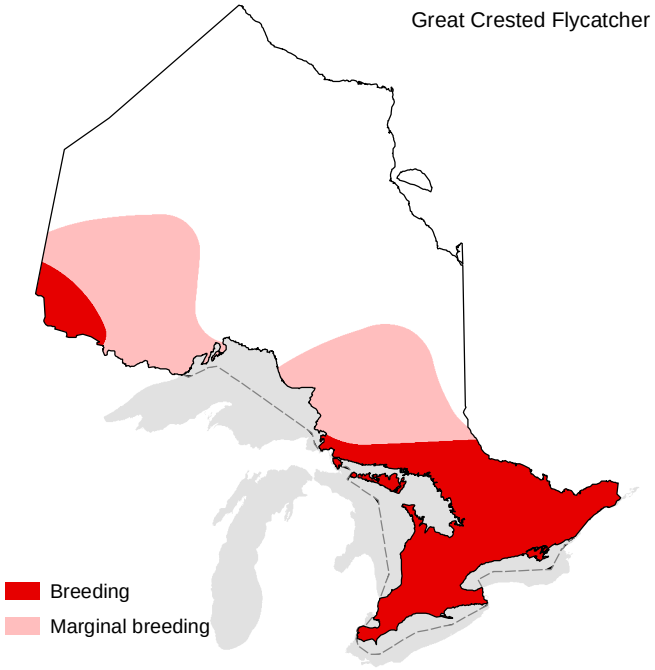
BREEDING SEASON

Habitat Requirements

In Ontario, the Great Crested Flycatcher breeds in upland and lowland mixed (13.2% of nests), deciduous (8.6%), and coniferous (1.1%) forests and in unspecified woodlands (13.8%); in agricultural fields and pastures (23.0%); in orchards (6.3%); in beaver ponds, marshes, and bogs with scattered trees (17.8%); in gardens, near cottages, and on golf courses and cemeteries (8.0%); in fencerows and along roads (6.9%); and on sand dunes (1.1%). It prefers dry habitats, but will nest in wetlands with dead trees that provide suitable nest sites (Peck and James 1987). Near Parry Sound, it was absent in pure jack pine forests, but present in semi-open jack pine associated with trembling aspen, white birch, sugar maple, and white pine (James 1979a). In Durham Region, it occurred on 9 of 11 plots surveyed. Highest densities were in a mature beech–sugar maple forest and a mature white



cedar–elm swamp with numerous dead elms and openings (Speirs and Orenstein 1975). There is a record of it nesting in a Toronto backyard (Iron and Pittaway 2001).

In other areas, the Great Crested Flycatcher nests mostly at edges of deciduous and mixed woods; many authors state it prefers wet habitats to dry areas. Presence of suitable nesting sites is probably more important than moisture regime. It tends to favour second-growth woodlots and those that have been selectively cut, and avoids extremes of closed-canopy forests or open savannahs. Breeding has been documented in urban areas and orchards, although it is uncommon in these habitats. In the early 1900s, it was a common breeder in Illinois orchards, but virtually absent in this habitat by the mid-1960s. Most authors agree that it is associated with edge and semi-open canopies, and is much less frequent in forest interior. It appears to have benefitted from forest fragmentation. In Maryland and the mid-Atlantic states, degree of forest isolation was a significant predictor of its presence. It requires forests mature enough to have snags of suitable size (approximately 30 cm diameter at breast height [DBH]) for providing a nesting cavity. In fragmented aspen forests in North Dakota, its abundance was negatively correlated with the number of trees 15-23 cm DBH. In the Appalachians, it was less likely to occur in old-growth forest than in the landscape as a whole. In Kansas, all territories contained woodland edges and fields with scattered groves of trees, but most activity was confined to woodlands. In New Jersey, there was no significant difference in its abundance in oak-pine forests and hardwood swamps (Back 1979; Bent 1942; Blake and Karr 1987; Capen 1979; Evans and Conner 1979; Faanes and Andrew 1983; Fitch 1958; Graber et al. 1974; Haney 1999; Kirk et al. 1996; Lynch 1987; Miller and Lanyon 2020; Mossman 1988; Mossman and Hoffman 1989; Mossman et al. 1991; Noon et al. 1979; Rail in Gauthier and Aubry 1996; Rich et al. 1994; Robbins 1979; Robbins et al. 1989; Samson 1979; Temple et al. 1979).

In southern Ontario, the probability of detection of the Great Crested Flycatcher was negatively correlated with the amount of forest cover 100 m or more from edge, woodlot size, the amount of forest cover within 2 km, and the amount of regional forest cover. All but the latter relationship were significant, although correlations with amount of core forest habitat and amount of forest within 2 km were significant only at the 0.10 level (Austen et al. 2001). Based on these results and the fact that it regularly occurs in small forest fragments, it can be concluded that the Great Crested Flycatcher is not area sensitive in Ontario. Forest size was a significant predictor of abundance in the mid-Atlantic states. Robbins et al. (1989) concluded that it required forests at least 10 ha in area, it occurred in forests as small as 0.8 ha. In Pennsylvania, there was no significant relationship between

its abundance and forest size or degree of habitat fragmentation in the landscape (Keller and Yahner 2007).

At the landscape level, the Great Crested Flycatcher preferred areas that were 59-75% forested in North Dakota and 82-100% forested in New York. There were no areas in North Dakota that had more than 75% forest cover (Cunningham and Johnson 2019). Brennan and Schell (2007) used Breeding Bird Survey (BBS) data from south-central states to determine its landscape-level preferences. It was most abundant in undisturbed areas with a high ratio of edge to interior. Population numbers were higher in densely wooded areas and lower in more sparsely wooded locations.

In a Connecticut woodlot over a 59-year period, there was a progressive shift to larger trees, a sparser shrub layer, and a less diverse tree canopy dominated more by oaks and maples, with a severe decline in the amount of hemlock. There was no significant change in the abundance of the Great Crested Flycatcher (Buchanan et al. 2016). In Pennsylvania, Rohnke and Yahner (2008) conducted bird surveys in a woodland 16 years apart. During this time, the density of tall shrubs increased, but density of short shrubs and overstorey and subcanopy trees declined. The Great Crested Flycatcher decreased by 56% as a result of these habitat changes.

Ontario nests were in dead or living deciduous or coniferous trees, snags, and stumps; in bird boxes, barrels, and gourds; and in fence posts, rails, and utility poles. Over 87% of nests in trees were in deciduous species, and 61.8% of tree nests were in dead or partially dead trees. DBH of 1 nest tree was 20 cm. Nests were in both natural cavities and abandoned woodpecker nests. Nests were 0.6-18.3 m from ground, with most 1.5-4.6 m up (Peck and James 1987). Fairfield and Fairfield (2004) reported a Toronto nest in a nest box.

Elsewhere, the Great Crested Flycatcher appears to prefer natural cavities to old woodpecker nests in deciduous trees, but readily uses cavities excavated by the Red-headed Woodpecker, Red-bellied Woodpecker, Northern Flicker, and Pileated Woodpecker, particularly in conifers. It prefers dead to living trees and deciduous trees to conifers. Nests have been reported in oaks, willows, cottonwood, black locust, ashes, maples, birches, pines, beech, white cedar, tulip tree, pear, elms, apple, sycamore, common hackberry, and red cedar. Nest boxes of a variety of sizes are used, from screech-owl boxes and Purple Martin houses to those of bluebird size, with 5 cm the optimum cavity entrance diameter. Hanging or swinging nest boxes are preferred to fixed boxes. Other nest sites include hollow posts, old wooden pumps, stove pipes, and old tin cans and boxes. Nest heights of 0.6-23 m have been reported, with most 3-7 m up (Bancroft 1984, 1986a; Bent 1942; Engels 1949; Evans and Conner 1979; Gillespie 1924; Graber et al. 1974; Iron and Pittaway 2001; Miller and Lanyon 2020; Mousley 1934a; Rail in Gauthier and Aubry 1996; Stauffer and Best 1982; Taylor and Kerschner 1991; Twedt and Henne-Kerr 2001). In Florida pine habitats, nest density increased where nest boxes were provided, and numbers peaked during the first year after boxes were introduced. Once boxes were installed, some birds moved from the control areas to the nest-box areas, and the overall population increased. Suitable nest sites appeared to be limiting (Miller 2010). Medlin and Risch (2006) used artificial nests and added snake skins to some nests, and to the outside of some nest boxes as well as in those nests. Twenty percent of the control nest boxes were depredated whereas

no nests with snake skins were depredated. Snake skins appear to be effective in deterring mammals from preying on nests; this flycatcher frequently incorporates snake skins into its nest.

Territories are established shortly after arrival, and other Great Crested Flycatchers are vigorously excluded. Territories frequently overlap with those of Eastern Wood-Pewee, Acadian Flycatcher, Least Flycatcher, and Eastern Phoebe (Hespenheide 1971a; Johnston 1971; Peck and James 1987; Taylor and Kerschner 1991). The largest reported territory sizes were from the Kingston area. Until egg laying, 3 territories were 23.8, 38.5, and 15.9 ha. After egg laying, these pairs had territories of 24.6, 13.9, and 2.0 ha, respectively. The third pair made a second nesting attempt and had territory sizes of 9.6 and 3.1 ha before and after egg laying (MacDougall-Shackleton and Robertson 1995). In Quebec, Rail (in Gauthier and Aubry 1996) reported territory sizes of 0.2-3.2 ha, mostly 1.5-2.5 ha. Territories in sugar maple and hemlock stands averaged 1.2 and 1.9 ha, respectively. In 1 Illinois study area, territories were very closely spaced, with all available area claimed. Twenty-six territories were 0.24-1.86 ha (average 1.25 ha). Other territories were 0.6, 1.2, 4.5, and 5.7 ha (Graber et al. 1974). Other reported territory sizes are 1.6 and 3.2 ha in Maryland, and 2.9, 2.7, and 2.3 ha in Kansas (Fitch 1958; Miller and Lanyon 2020). In North Carolina, Engels (1949) found 2 nests in dead trees on a sand dune. Adults of both pairs foraged in an adjacent woodland 153 and 250 m from their nests.

Natal site fidelity appears to be low, although there are few data. None of 61 nestlings returned in subsequent years. Adults exhibit high site fidelity. In Illinois, 9.5% of adults returned 4 years later, probably most surviving birds. One pair nested in the same cavity as 9 years previously. There are numerous records of the same birds using the same nesting area or nest site for 3-5 years, and occasionally as long as 8 or 9 years. The same cavity is usually used for replacement nests, but occasionally a new cavity is used (Bancroft 1984, 1986a; Bent 1942; Graber et al. 1974; Miller and Lanyon 2020; Peck and James 1987; Rail in Gauthier and Aubry 1996; Robinson 1992; Taylor and Kerschner 1991).

Limiting Factors

Eggs have been found in Ontario nests from the third week of May until mid-July, with most present from the second to fourth weeks of June (Peck and James 1987). In Algonquin Park, adults have been observed inspecting potential nest cavities 18-25 May and nests with young occur from 29 June to 7 July (Tozer 2012).The female builds the nest in 2-10 days. Two to 11 days (mean 4.8 days in Florida) may elapse between nest completion and laying of the first egg. These intervals are shorter further north. Eggs are laid at the rate of 1 a day. Incubation usually begins with the laying of the last egg or occasionally the penultimate egg, or on the afternoon before the last egg is laid. The incubation period of 11 Ontario nests was 12-15 days, with eggs in 8 nests hatching in 13 or 14 days. Overall, the incubation period has been reported as 12-15 days. Fledging usually occurs at age 13-15 days, with longer reported fledging periods of 18-25 days being incorrect. Young can fly short distances when they are 9 days old if they are disturbed (Bent 1942; Fairfield and Fairfield 2004; Gillespie 1924; MacDougall-Shackleton and Robertson 1995; Miller and Lanyon 2020; Peck and James 1987, 1997; Taylor and Kerschner 1991).

One brood is raised a season, but renesting is common if a clutch is lost. Second clutches may be initiated 1-7 days after the first is lost, and replacement clutches typically have 1 or 2 fewer eggs than the first. Clutches of 1-7 eggs have been reported in Ontario with most containing 5 or 6 eggs;

the number of clutches containing 5 or 6 eggs was equal. Clutches of 1, 2, 3, and 7 eggs were rare. Elsewhere, clutches of 3-8 eggs have been reported, with 5 eggs most common. Six-egg clutches are common; larger clutches are rare (Bent 1942; Graber et al. 1974; MacDougall-Shackleton and Robertson 1995; Miller and Lanyon 2020; Peck and James 1997; Taylor and Kerschner 1991).

The age at first breeding is 1 year, and the mating system is monogamous. Because of the strong homing tendency, the male and female may reform their pair bond in subsequent years. Some pairs were together at least 3 years. Different mates may also be selected (Bent 1942; Miller and Lanyon 2020; Taylor and Kerschner 1991).

The Great Crested Flycatcher is a canopy species, feeding mostly at heights of 15-21 m, except in edge situations where it may feed near the ground. In Illinois, 72% of foraging occurred in the lower canopy (11-15 m) and upper canopy (above 16 m). It forages mostly from dead perches in the canopy and the outer periphery of trees on edges. It forages significantly higher than the Eastern Wood-Pewee, Least Flycatcher, Acadian Flycatcher, and Eastern Phoebe. In Virginia, food items overlapped 28% with the Least Flycatcher and 25% with the Eastern Wood-Pewee, but the Great Crested Flycatcher selected significantly larger prey. It uses 3 main foraging techniques in equal frequency: sallying from a perch; hover gleaning from leaves, branches, and trunks; and dropping to the ground from a perch to capture prey. In Illinois, it changed foraging techniques depending upon whether it was in open-canopy forest (savannah) or closed-canopy forest. It flycatched significantly more in open habitat and sallied more often in closed-canopy forest. It hovered more frequently in closed-canopy forests and used gleaning and flushing as foraging techniques in open-canopy forest but not in closed-canopy forest (Bent 1942; Hartung and Brawn 2005; Johnston 1971; Miller and Lanyon 2020).

Young are fed mostly insects, including dragonflies, crickets, grasshoppers, spiders, beetles, katydids, stink bugs, flies, and adult and larval butterflies and moths. Fruit may also be brought to young including common elderberry, black cherry, raspberry, and white mulberry. A sample of 265 adult stomachs contained 93.7% animal matter and 6.3% plant material. Lepidopterans comprised 21.4% of the diet; 52 species of 12 families of beetles constituted 16.8%; grasshoppers, crickets, and katydids 15.6%; bugs 14.3%; bees and wasps 13.7%; dragonflies and other miscellaneous insects 4.1%; and spiders 4.0%. There were also traces of eggshells and lizard bones. Fruits eaten included those of mulberry, pokeweed, sassafras, spicebush, blackberry, raspberry, chokecherry, black cherry, Virginia creeper, wild grape, huckleberry, blueberry, and elderberry. Other adult foods include beetles (June, darkling, and lady beetles), cicadas, ants, mosquitoes, juneberries, damselflies, flies (blow, fruit, anthomyiid, and snipe flies), long-horned grasshoppers, and midges. On Pelee Island, 1 captured a Ruby-throated Hummingbird in mid-air and ate it. In Alabama, it fed on maggots in mammal road kills. Insects consumed are 3-40 mm in size, mostly those longer than 10 mm. It has also been documented consuming an Eastern Whip-poor-will egg (Bent 1942; Cink et al. 2020; Gillespie 1924; Graber et al. 1974; Hespenheide 1971b; Holt 1918; Johnston 1971; Miller and Lanyon 2020; Mousley 1934a; Nelson 1997; Sargent and Sargent 1996; Taylor and Kerschner 1991).

The Great Crested Flycatcher is an infrequent host of the Brown-headed Cowbird. Six of 227 Ontario nests (2.6%) were parasitized. Rare records of parasitism have been documented in Illinois,

New York, Massachusetts, Michigan, and Maryland. There is 1 record of a clutch containing a starling egg (Bent 1942; Graber et al. 1974; Miller and Lanyon 2020; Peck and James 1997).

Although the Great Crested Flycatcher initially benefitted from forest fragmentation, habitat loss and alteration may affect populations. Some remnant forests in southern Ontario are being completely removed resulting in direct habitat loss. Forestry practices that cull dead and dying trees and snags may reduce or eliminate nest sites. Total clear-cuts eliminate habitat, but clear-cuts that retain snags and copses of trees may enhance habitat. Aerial spraying of pesticides may be detrimental directly or indirectly through loss of prey (Miller and Lanyon 2020; Stribling et al. 1990). In the Carolinian Forest Region of Ontario, it was more abundant in heavy, diameter-limit cuts than in forests with no recent history of harvesting (Holmes et al. 2004). In Illinois, Robinson and Robinson (1999) clear-cut openings of 0.02-0.4 ha in contiguous forest. There was no difference in its abundance in uncut and cut forest.

Abundance of the Great Crested Flycatcher appears to be unaffected by urban and suburban development. It inhabits a variety of anthropogenic habitats including old orchards, wooded pastures, parks, and other urban areas with numerous large shade trees (Miller and Lanyon 2020). It is absent in recent developments where there are no mature trees. In urban woodlots in Chicago, it decreased as the proportion of buckthorn trees in plots increased (Schneider and Miller 2014).

The Great Crested Flycatcher is positively associated with roadsides and is vulnerable to collisions with vehicles (Miller and Lanyon 2020).

In New Jersey and Pennsylvania over a 15-year period, hemlock declined from representing 56% of the total basal area to 46% due to the hemlock woolly adelgid; the amount of deciduous understorey increased. The Great Crested Flycatcher responded positively to hemlock decline and increased (Toenies et al. 2018).

The Great Crested Flycatcher competes for nest sites with many other cavity-nesting species. These include the Red-headed Woodpecker, Red-bellied Woodpecker, Tree Swallow, Northern House Wren, Eastern Bluebird, European Starling, and red squirrel. In Iowa, this flycatcher chose nest sites similar to the 2 woodpecker species and starling, but nested more in dead limbs of live trees than the other species. In the mid-19th century, it commonly nested in crevices around dwellings and outbuildings, but was ousted from these habitats by the starling and House Sparrow. Woodpeckers and the starling are dominant to the Great Crested Flycatcher, but it may dominate the Tree Swallow (Bent 1942; Graber et al. 1974; Miller and Lanyon 2020; Rendell and Robertson 1991; Stauffer and Best 1982). Breeding success in nest boxes is highest in new boxes and declines with time; predators learn to exploit nest boxes (Miller 2002).

In North Carolina pine-oak forests, the Great Crested Flycatcher exhibited no response to fire (Rose and Simons 2016).

DesGranges and Morneau (2010) considered the Great Crested Flycatcher sensitive to climate change in Quebec. Its distribution was correlated predominantly with the mean annual number of degree-days 10°C or more in May, June, and July.

Status

The Great Crested Flycatcher is probably more common in Ontario now than in presettlement days. It was apparently absent in the Kingston area in the 1850s, but was the fourth-most abundant flycatcher during the first atlas. It was more frequent on the Canadian Shield where snags are more abundant (Weir 2008). McIlwraith (1894) considered it a regular breeder in the south and Baillie and Harrington (1937) considered it common north to southern Algoma District and Lake Nipissing. The first atlas confirmed that it nested throughout southern Ontario and the Shield portion of the Great Lakes–St. Lawrence Forest Region. It was almost entirely absent in the Boreal Forest Region except for isolated records in the extreme south of this forest community. It was most abundant along the southern edge of the Shield (Bennett in Cadman et al. 1987). James (1991) considered it a common breeder in the south and uncommon to locally rare north to Red Lake and Timmins.

The second atlas indicated that the range of the Great Crested Flycatcher had remained the same since the first atlas. Its probability of observation declined significantly between atlases. Significant declines occurred in the Great Lakes–St. Lawrence Forest Region both south of and in the Shield. South of the Shield, it was seen in almost every square. Most of the decline occurred in the Algonquin Highland, possibly a result of forest maturation. It was most abundant in a broad band along the southern edge of the Shield. It was less abundant in the more northerly, heavily forested portions of the Shield and the intense agricultural areas in the extreme southwest (McLaren in Cadman et al. 2007).

Long-term (1970-2021) population trends determined by the BBS indicate annual declines of 0.753% in Canada and 0.567% in Ontario. The short-term (2011-2021) trends were annual increases of 0.309% in Canada and 0.459% in Ontario. All estimates were highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

After fledging, the family remains together near the nest site for about 3 weeks (Miller and Lanyon 2020).

Akresh et al. (2009) netted birds during the postbreeding season in Michigan upland and riparian forests. Only 2 juveniles were captured, both in riparian habitat. Upland and riparian forests had a similar canopy composition, but riparian forests had a much denser shrub and sapling layer than upland forests.

MIGRATION

Migration is partially nocturnal, but may also occur during day, and the Great Crested Flycatcher travels singly during migration (Miller and Lanyon 2020). It arrives in Ontario in early May, or occasionally late April, with individuals continuing to arrive throughout May, peaking around mid-May. Males arrive on territories 7-12 days before females. Most birds have left the province by mid-September, but typically a few are present until the end of the month. Occasionally, stragglers occur until late October (James 1991; Miller and Lanyon 2020).

While migrating, the Great Crested Flycatcher uses a broader range of wooded habitats than during the breeding season, including shrubby clearings and second growth (Graber et al. 1974; Miller and Lanyon 2020). During spring migration in Wisconsin and Minnesota, it was significantly more abundant in mature floodplain forests than in mature upland forests (Kirsch et al. 2013).

The Great Crested Flycatcher frequently collides with television towers in Florida and probably elsewhere, and may be vulnerable to striking any tall structure during migration (Miller and Lanyon 2020).

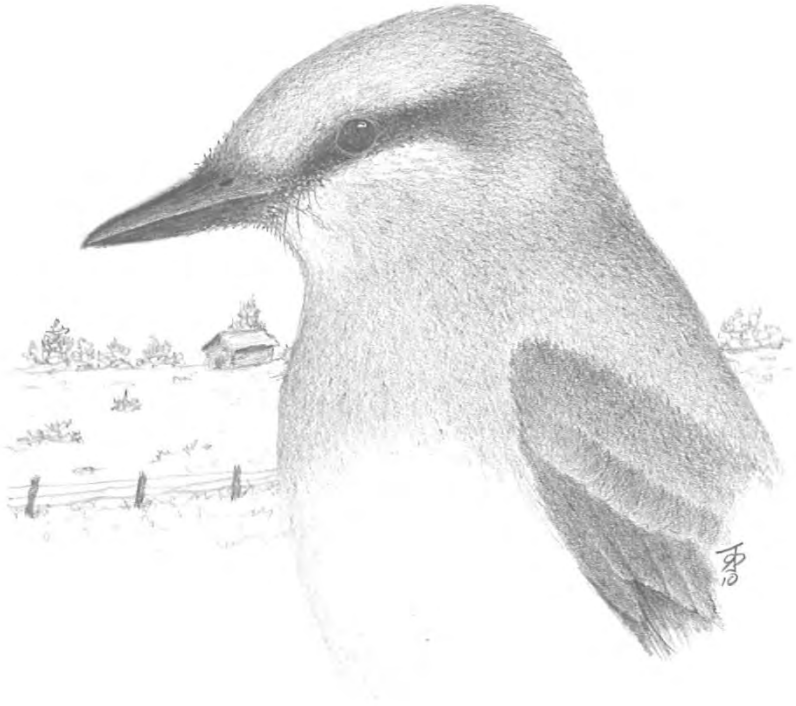
In New York, Zelt et al. (2017) compared spring arrival dates, autumn departure dates, and the length of the breeding season for 1888-1939 and 1967-2012. There was little climate change during the first period but significant warming occurred during the second period. The spring arrival date of the Great Crested Flycatcher was significantly earlier during the second period but there were no significant differences in its autumn departure dates or length of the breeding season.

The Great Crested Flycatcher is a common migrant that occasionally wanders as far north as Moosonee (James 1991).

At Long Point Bird Observatory, the Great Crested Flycatcher decreased during the late 1960s and early 1970s, increased in the early to mid-1980s, decreased in the late l980s, and increased in the 1990s, with no significant overall trend (Badzinski 2000; Hussell et al. 1992).

Western Kingbird

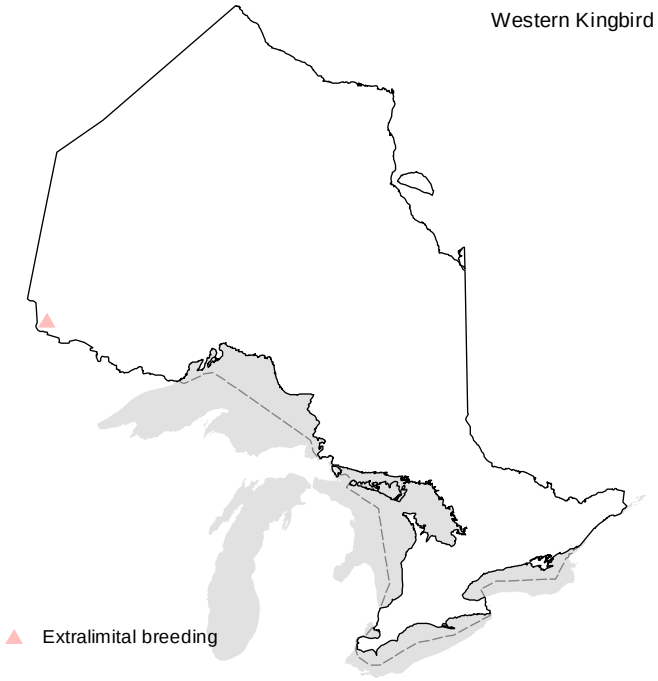
Tyrannus verticalis



BREEDING SEASON

Habitat Requirements

The Western Kingbird nests in open, grassy habitats with scattered trees, hydro poles, or fence posts. Where trees are scarce, it frequently associates with humans, nesting around farmsteads, dwellings, and in shade trees in villages and towns. One Ontario nest was in a farmyard near buildings and another was in a residential area of a small town. In natural habitats, it prefers grassy areas with scattered trees or groves of trees. In Nebraska, it selected sites with fewer but larger trees, resulting in an open canopy with taller ground cover and more shrubs. In addition to savannah-like habitats, it nests in grasslands, deserts, pastures, open riparian strips and patches, shelterbelts around farms, and urban areas. Frequently used habitats in British Columbia include cultivated farmland, orchards, vineyards, and rural and suburban areas. It was extremely adaptable



there, with breeding occurring in 40 habitat types. Over half of nests were associated with roadsides, gardens, and open hillsides. In Texas, it frequently nested at power substations where there were open expanses of grass for foraging and human-made structures for nest sites. Where it overlaps with the Eastern Kingbird, the Western Kingbird selects drier, more open areas with taller trees (Bent 1942; Bergin 1992a; Blancher and Robertson 1984a, 1987; Campbell et al. 1997; Gamble and Bergin 2020; Honig 1992; MacKenzie and Sealy 1981; Peck and James 1997; Rumble and Gobeille 1998; Semenchuk 1992; Smith 1996). In California, the Western Kingbird was significantly more abundant in oak savannahs with grass cover than in oak savannahs with shrub cover, montane hardwoods, and oak woodlands (Wood et al. 2013).

Brennan and Schnell (2007) used Breeding Bird Survey (BBS) data from south-central states to analyze landscape-level habitat requirements of the Western Kingbird. It was strongly associated with edge and was more abundant in areas that were predominantly open. Trees, shrubs, or tall human-made structures are an essential component of its habitat, even though areas that are selected are predominantly open in nature. It is frequently found where 2 or more habitats converge. Human presence is important in many open habitats where shade trees and other structures (power lines and poles) provide perches and potential nest sites (Gamble and Bergin 2020).

The first 3 nests documented in the province were in trees. Nest heights were 3, 6, and 10 m and they were in willow, Manitoba maple, and bur oak. Two were in large forks near the trunk and the other was on a lateral branch (Carpentier 1989; Peck and James 1997). A nest in Rainy River District in 2001 was on a radio tower (Carpentier in Cadman et al. 2007).

Throughout its range, the Western Kingbird prefers to nest in trees. In Manitoba, it preferred green ash and peach-leaved willow for nesting, but selected only the largest trees. Trees with a diameter at breast height (DBH) greater than 30 cm represented 4.6% of available trees but supported 82% of nests. Nests were in taller trees with a larger DBH and higher up than Eastern Kingbird nests. In British Columbia, a wide variety of dead and living coniferous and deciduous trees and shrubs was used for nesting, but 84% of nests were on power poles. Additional trees species it has nested in include elms, sycamore, oaks, hackberry, cottonwood, junipers, apple, locusts, aspens, alders, and rarely pine. It typically nests in the top third of trees, well within the canopy, and usually on a horizontal branch, although nests may be in crotches of upwards-slanting branches. Because trees larger than average are selected, many nest trees are used more than once. Nests from the

previous breeding season may be reused, and it has also used old Northern Flicker, American Robin, and oriole nests. Heights of nests from ground range from 0 to 45 m, with most 3.8-17 m up. Nests are frequently on human-made structures, particularly power poles, fence posts, and buildings. It has nested in a lampshade suspended from a ceiling in an abandoned house, on windmills, in an old woodpecker cavity, on metal girders, in open wooden boxes, on rocky cliffs, on top of hollow stumps, in eavestroughs of houses, on a ledge over a kitchen door that had considerable human use, and on bridges (Bent 1942; Bergin 1992a, 1992b, 1997; Blancher and Robertson 1984a; Campbell et al. 1997; Gamble and Bergin 2020; Honig 1992; Koonz 1982; MacKenzie and Sealy 1981; Ohlendorf 1974; Pinkowski 1982; Whedon 1938).

Shortly after arrival, the male defends a loosely defined territory. After pairing, both sexes defend the territory, but territory size and amount of patrolling decrease after pairing. By mid-incubation, only the nest tree and nest are defended, but this is done very aggressively. Even early in the breeding season, feeding areas are not defended. Some authors state that it is aggressive toward Eastern Kingbirds, but they were tolerated in a Manitoba study area. No information on territory or home range size is available. Occasionally, 2 or 3 pairs nest together with nests separated by as little as 12 m. Rarely, there may be 2 or more nests in a single tree (Bent 1942; Bergin 1992a; Gamble and Bergin 2020; Honig 1992; MacKenzie and Sealy 1981; Ohlendorf 1974).

No information on natal philopatry is available. Some successful breeders have been documented returning in subsequent years, but there are few data. In Oklahoma, geolocators were attached to 40 adults, and 25 of these were recovered the next year for a return rate of 62.5% (Bergin 1997; Gamble and Bergin 2020; Jahn et al. 2013).

Limiting Factors

Clutches have been found in Ontario nests in the first 2 weeks of June (Carpentier 1989; Peck and James 1997). Western Kingbird clutches could conceivably be present in Ontario from mid-May until late July, but most likely throughout June (Peck and James 1987). In Manitoba, the nesting chronology of the Western and Eastern kingbirds highly overlapped, with the Western Kingbird establishing territories slightly earlier (MacKenzie and Sealy 1981). Nest construction takes 4-8 days, and 4 or 5 days may elapse after nest completion before the first egg is laid. Eggs are laid at the rate of 1 a day. Incubation takes 12-20 days; incubation is initiated after the last egg is laid. In the southern portion of the range, the average incubation period was 14 days, but all British Columbia clutches had incubation periods of 18-20 days. Eggs hatch over a 2-day period and nest departure may be spread over several days. Fledging occurs at age 13-19 days, averaging 16 days in the south, but 16-19 days in British Columbia (Bent 1942; Blancher and Robertson 1987; Campbell et al. 1997; Gamble and Bergin 2020).

Usually 1 brood is raised in a season, but double brooding has been confirmed in Arizona, Mexico, and California; there is evidence to suggest that it occurs in British Columbia. Clutches of 2-7 eggs have been reported, normally 3-5 eggs, with 4 eggs most frequent. Clutch size declines with advancement of the breeding season and decreasing insect abundance. Some of the smallest clutches were laid in old oriole nests or other sites where there was not enough room for more eggs (Bent 1942; Bergin 1992b; Blancher and Robertson 1987; Campbell et al. 1997; Gamble and Bergin 2020).

The mating system is monogamous and age at first breeding is 1 year. Breeding typically occurs every year thereafter, but in Arizona, some pairs built nests but did not lay eggs due to a scarcity of insects. Lack of food is unlikely a limiting factor in Ontario (Blancher and Robertson 1987; Gamble and Bergin 2020).

Most foraging is by sallying from an exposed perch after flying insects. The Western Kingbird may also fly down to pick prey from the ground and glean insects from vegetation. It has been observed feeding opportunistically on tiger beetles congregated around a pond, capturing them in flight or flushing them into the open to capture them. It occasionally feeds nocturnally under lights. In Arizona, it fed at heights of 0-50 m, but almost half of foraging flights were at or below 1.5 m. In Kansas, most foraging occurred at heights of 1-2.4 m. At 2 sites in Arizona, 83.6% and 59.2% of prey were captured in the air, 3.6% and 11.2% were gleaned from vegetation, and 12.7% and 25.9% were picked from the ground. In Kansas, prey was gleaned from vegetation more frequently than from the air or ground (Blancher and Robertson 1984a, 1987; Gamble and Bergin 2020; Honig 1992; Schulz 1993).

Nestlings are fed crickets, dragonflies, butterflies, short-horned grasshoppers, bees, wasps, beetles, flying ants, spiders, robber flies and other flies, and bugs. An analysis of nestlings' feces revealed that they had consumed 48.2% grasshoppers and crickets, 18.5% flies, 12.5% beetles, and 11.3% bees, wasps, and ants. In Arizona, the average length of prey consumed by adults was 8-10 mm; the diet consists of 90-99% insects. In Manitoba, it ate mostly midges. Bees, wasps, ants, beetles, grasshoppers and crickets, bugs, flies, and spiders are important in the diet. Other animal foods include millipedes, cicadas, caterpillars, moths, dragonflies, and treefrogs. It occasionally eats fruits of elderberries, hawthorns, and mulberries. In California, the most important items in the diet were bees and wasps (31.4%), grasshoppers and crickets (27.8%), and beetles (17.0%). Forty-eight adults from Texas had consumed 35.7% grasshoppers and crickets, 26.7% beetles, 16.9% bees, wasps, and ants, and 10.0% bugs. At 2 sites in Kansas, beetles (29.5% and 88.2%), hymenopterans (45.9% and 2.9%), and grasshoppers and crickets (8.2% and 3.9%) were most important in the diet (Beal and McAtee 1912; Bent 1942; Blancher and Robertson 1984a; Gamble and Bergin 2020; MacKenzie and Sealy 1981; Ohlendorf 1974). In Texas, a pair feeding near a honey bee colony consumed 149 drone bees and 0 worker bees. They were capable of distinguishing them in flight. Worker bees are distasteful and have stingers; drone bees are palatable and lack stingers (Schmidt and Klotz 2023).

No parasitism of Western Kingbird nests by the Brown-headed Cowbird has been documented in Ontario. Parasitism of this kingbird is rare and it is a known cowbird egg and nestling ejector. Kingbirds defend their nests vigorously against cowbirds (Gamble and Bergin 2020).

DDE was evident in samples collected from eggs, nestlings, and adults in Texas. Despite high concentrations of DDE in eggs, there was no effect upon eggshell thickness or nesting success (Gamble and Bergin 2020).

Status

Four nests have been confirmed in Ontario, all in western Rainy River District. The first nest was found on 9 June 1987, with 1 nest each in 1988, 1989, and 2001. A nest was reported from Kent County in 1943, but photographs and descriptions were inadequate to positively confirm it as a Western

Kingbird nest (Carpentier 1989; Carpentier in Cadman et al. 2007; Peck and James 1987, 1997). In Ontario, the Western Kingbird is a rare and irregular breeder in the Rainy River area. It is likely that it is absent as a breeding species most years, with maximum populations of 1 or 2 pairs annually (Carpentier in Cadman et al. 2007).

Overall, the Western Kingbird has increased significantly and greatly expanded its range. Range expansion was facilitated by tree planting and erection of human-made structures, particularly on the prairies where trees were rare or absent. In Saskatchewan, it usually arrived in a given location 20-30 years after shelterbelts were planted. It is a recent arrival in Manitoba, first occurring around the 1920s. In British Columbia, its range expanded when residential areas and orchards replaced natural open areas, and it also expanded along highway corridors and farm clearings. It has also increased in traditional breeding areas due to proliferation of human-made structures suitable for nesting and perching (Bent 1942; Campbell et al. 1997; Gamble and Bergin 2020; MacKenzie and Sealy 1981; Ohlendorf 1974; Smith 1996). BBS data for Canada indicate an annual increase of 0.113% 1970-2021 and a decrease of 3.07% 2011-21. All results were highly reliable. Due to its rarity in Ontario, there are no BBS data (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Young are dependent on adults for 2 or 3 weeks after fledging (Gamble and Bergin 2020).

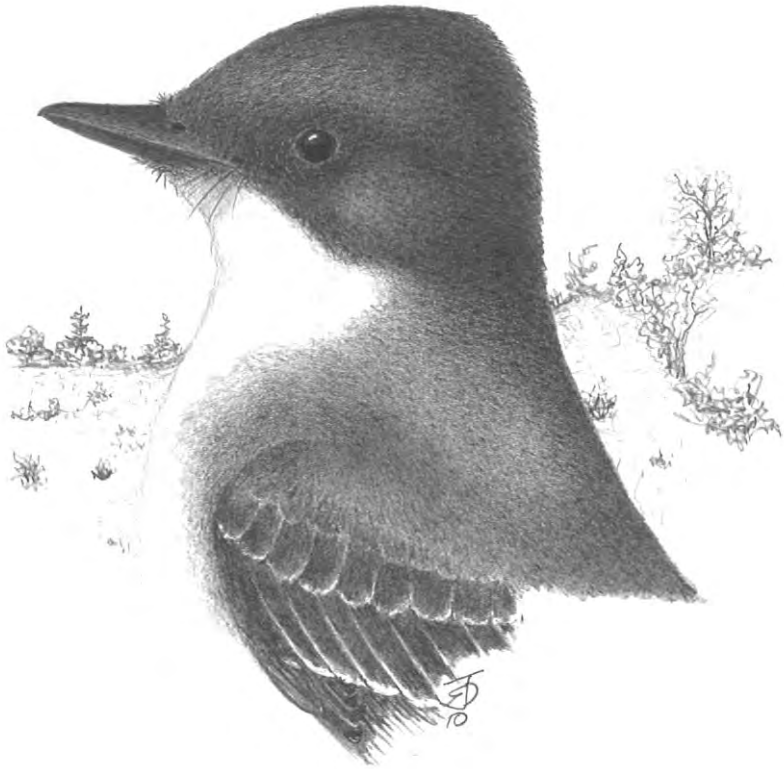
MIGRATION

The Western Kingbird is typically a diurnal migrant, but has also been observed migrating in late evening and early morning. It migrates singly or occasionally in small flocks, but flocks are more likely to occur in the southern states and further south (Gamble and Bergin 2020). Adults undertake a moult migration in the main portion of their range. Most adults leave the breeding grounds before moulting and fly to Mexico and the southeastern states for the moult. Moult migration of adults may begin in mid-July and continue until mid-October. Juveniles remain on the breeding grounds throughout the breeding season and moult after autumn migration (Barry et al. 2009; Gamble and Bergin 2020).

The Western Kingbird is an irregular, rare migrant in Ontario, more of a vagrant than a true migrant. It now occurs annually in the province and may become more regular as a migrant. In spring, males arrive before females. Normally, it appears late in May but occasionally in mid-May. Autumn migration begins in early August and continues until mid-September, with the peak in late August. It has been observed in the province as late as mid-November. During migration, it frequents habitats similar to those used during the breeding season (Gamble and Bergin 2020; James 1991).

Eastern Kingbird

Tyrannus tyrannus



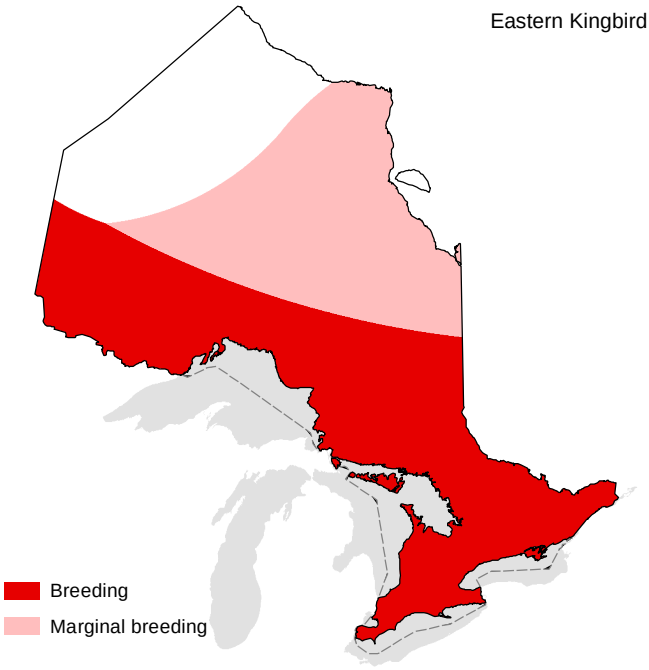
BREEDING SEASON

Habitat Requirements

The Eastern Kingbird nests in a variety of open habitats in Ontario. These include shrubby meadows and pastures, orchards, fencerows, and golf courses (46.7% of nests); beaver ponds, bogs, and marshes with standing trees or snags, and shorelines (27.5%); forest edges and openings (10.3%); treed sand dunes (9.0%); parks, cottage areas, and residential areas (6.4%); and tundra (0.1%). Fifty-two percent of nests were in dry habitats, 18% were in wet areas, and 30% were over water (Peck and James 1987).

Near Cape Henrietta in the Tundra Region, the Eastern Kingbird nested on tundra in willow shrubs bordering a pond (James and Peck 1995b). Near Gogama in the Great Lakes–St. Lawrence Forest Region in the Canadian Shield, it was rare in stands dominated by jack pine, occurring where

there were scattered large trees adjacent to very young regeneration with open areas suitable for foraging (James and Peck 1995a). In Algonquin Park, it inhabited bogs with dead stubs and was absent in upland forested habitats (Martin 1960). At Lake Opinicon near Kingston in the Great Lakes–St. Lawrence Forest Region south of the Shield, it showed distinct habitat preferences. Islands were much preferred to mainland areas although the habitat was virtually identical, and small islands were preferred to large islands (Blancher and Robertson 1985a).



In heavily forested areas, the Eastern Kingbird is restricted to natural openings such as swamps, marshes, edges of lakes and rivers, beaver ponds with dead trees and shrubs, bogs and fens with scattered trees or snags, savannahs and alvars or other barrens, sparsely treed sand dunes, and natural disturbances due to forest fire and windthrow. Clear-cuts with residual trees and snags provide good breeding habitat. In natural habitats, it prefers wetlands and often nests over water or in trees and stumps surrounded by water. In human-altered landscapes, it prefers uplands. In British Columbia in altered habitats, 57% of nests were associated with anthropogenic habitats, 37% with woodlands and grasslands, and 6% with wetlands; in natural areas, 48% of nests were in wetlands. Forty-one percent of British Columbia and 50% of Montana nests were close to water. In Michigan, it was common to abundant in a burned forest of jack pine and Hill's oak, but absent in the residual forest of similar species composition. In Kansas, it was common in a heavily grazed pasture, but quickly abandoned it when grazing ceased and grass height increased. In Illinois, it was most abundant in savannahs, followed by marshes, grazed grass, grass mowed for hay, water, shrubs, low-density developments, idle grass, developed open spaces, upland forests, floodplain forests, and soybeans. In agricultural landscapes, it is associated mostly with woodland edges, shrubby meadows, orchards, pastures, shelterbelts, roadsides, hedgerows, riparian strips, airports, city parks, sewage lagoons, and golf courses. In Michigan, it was strongly associated with grassy meadows with coniferous snags rather than meadows with deciduous trees and snags. In North Dakota, its abundance was correlated with the number of ponds available, so it may be adversely affected by drought. In North Dakota mixed-grass prairies, it was significantly more abundant in plots with 30-80% shrub coverage than in plots with 10% or less shrub coverage (Arnold and Higgins 1986; Campbell et al. 1997; Davis 1941, 1955; Fitch 1958; Graber and Graber 1963; Graber et al. 1974; Hamas 1983; Johnson and Igl 2001; MacKenzie and Sealy 1981; Mossman 1988; Mossman et al. 1991; Murphy and Pyle 2020; Niemuth et al. 2008; Riffell et al. 2001; Roy and Choiniere in Gauthier and Aubry 1996; Tyler in Bent 1942; Walk et al. 2011).

At the landscape level, the Eastern Kingbird preferred areas with 5-28% forest cover in North Dakota (Cunningham and Johnson 2019). In North Dakota 400-m landscapes with more than 30% tree cover, its probability of occurrence was 10% with 10% tree cover within 100 m, declining to 0% at 70% tree cover. In landscapes with less than 30% tree cover, its probability of occurrence was highest at 17% with 10% tree cover, declining to 10% at 40-70% tree cover (Cunningham and Johnson 2016).

In North Dakota aspen woodlands, abundance of the Eastern Kingbird was negatively associated with forest size. In aspen groves 1 ha in area, there was a 50% chance of detecting a kingbird. This probability declined quickly with forest size and was only 10% for 10-ha woodlands (Grant and Berkey 1999). In Michigan, its presence was positively associated with increasing size of wet meadows (Riffell et al. 2001).

In Ontario, 90% of nests were in trees, shrubs, or vines; 6% on standing stumps; 1.0% in roots of upturned stumps; 1.0% on fallen tree trunks and branches; 0.2% in a rotted-out woodpecker cavity; and 2% on human-made structures (hydro towers, the end of a small crane, on top of a steel culvert, on a sill, on a beam of a hydro transformer, on telephone-pole insulators, on a bridge, on a pole on a ski hill, and on a fence post). When nesting in trees or shrubs, living ones were much preferred (84% compared with 16% for dead). Most nests were on horizontal branches with a few on up-slanting or almost vertical branches. Most were in crotches or forks away from the trunk, but they were occasionally at the trunk. Distances of nests from the trunk were 0.6-4.6 m, mostly 1.2-2.4 m away. Deciduous trees, shrubs, and vines were preferred (81%) to conifers. Favoured nest trees were hawthorns (30.9% of nests), apple (26.2%), poplars (10.3%), white cedar (9.6%), pines (9.0%), elms (7.4%), and oaks (6.6%). Occasionally old nests were rebuilt or material from an old nest may be reused. Some nests were built on top of old American Robin and Cedar Waxwing nests. Nests were 0.3-21.3 m from the ground, with most 1.8-4.3 m up (Peck and James 1987). At Lake Opinicon, there were significant differences between lakeshore and upland nests. Lakeshore nests were at a mean height of 2.80 m compared with 7.75 m for upland nests. This was unrelated to the height of available trees. Over 61% of lakeshore nests were in the lower half of the tree, which is atypical, compared with 5.7% for upland nests. Over 90% of lakeshore nests were built over water, at an average distance of 3.45 m from shore. More lakeshore nests were in white cedar than expected based on availability. This species has low branches extending over water; most other species do not. Most upland nests were in elm, hawthorn, and apple (Blancher and Robertson 1985a).

Most nests elsewhere are in woody vegetation, but human-made structures are also used. These include eavestroughs on houses, hydro towers, on culverts, in nest boxes, in gourds hung up for Purple Martins, street lights, a rain gauge, utility poles, posts, pilings, abandoned cars, buildings, and water towers. In British Columbia, the Eastern Kingbird also nested on cliffs and banks. In Illinois, it showed a preference for placing its nests in tree branches overhanging water. In upland habitat, it prefers living trees and shrubs for nesting, but in wetlands selects dead vegetation, including stumps. Nests at the tops of stumps or snags are often recessed so that the nest is almost in a cavity. In 1 burn, most nests were in cupped depressions formed by embers burning into the heartwood. In dead wood, it prefers sites where the nest is in a bit of a cavity, but it also nests in dead branches. In trees, most nests are on horizontal or diagonal branches approximately 60% of the distance from

the trunk to the canopy edge. Nest tree preference varies geographically, but overall deciduous trees are greatly preferred. In Manitoba, green ash and peach-leaved willow were actively selected. These same tree species were available in New York and Kansas, but seldom used. Hawthorn and apple are preferred nest trees and are actively selected for nest sites. Other species it has nested in that occur in Ontario include white pine, blue beech, willow, white ash, alder, oak, juniper, locust, Manitoba maple, cherry, rose, mulberry, elm, Norway spruce, cottonwood, aspen, white cedar, sycamore, jack pine, and birch. Overall, nests were 0-33 m from ground, with most 1.5-7 m up. It appears to prefer to nest about 2 m above the surrounding vegetation. As in Ontario, it has nested in old robin, Cedar Waxwing, and oriole nests (Campbell et al. 1997; Davis 1941, 1955; Graber et al. 1974; Hamas 1983; MacKenzie and Sealy 1981; Mayfield 1952; Mousley 1916a; Murphy 1983a; Murphy and Pyle 2020; Murphy et al. 1997; Roy and Choiniere in Gauthier and Aubry 1996; Sprunt 1946; Tyler in Bent 1942; Walk et al. 2011). In Oregon, 35 of 341 nesting attempts (10.3%) were in old nests of Eastern Kingbird and other species, with 8-14% of old nests reused annually. American Robin nests were used most frequently (49% of reused nests) followed by Eastern Kingbird (31%), Brewer's Blackbird (14.3%), and oriole (5.7%) nests. There appeared to be no benefit in reusing nests as there were no differences in egg-laying dates, clutch size, reproductive success, or age of females reusing nests or building their own entirely (Redmond et al. 2007). In Oregon, kingbirds readily used artificial nests built of a mix of mud and grass over a wire frame; these closely resembled robin nests (Cancellieri and Murphy 2014).

The Eastern Kingbird is fiercely territorial, driving away conspecifics and potential predators. Early in the breeding season, a large, ill-defined territory is defended. Once a nest site is selected, it becomes the centre of the territory. Both adults are involved in defence, but the male is at least twice as aggressive as the female. Initially, the territory may be quite large, but shrinks with time until only a radius of about 10 m (0.03 ha) around the nest is defended by mid-incubation then it increases again. Four territories in South Carolina during the nesting period were 5.7, 6.5, 7.3, and 14.2 ha. In Georgia, 1 pair had a territory of 5.7 ha during nest building and incubation, but it shrank to 3.8 ha during the nestling stage. One pair near Guelph foraged as far as 180 m from the nest, suggesting a home range size of about 10 ha. Despite the fierceness of territorial disputes, nests have been found very close together in Ontario. Twice 2 active nests have been found in the same tree and 2 nests were separated by only 0.9 m. Any animal that is perceived as a potential predator is vigorously attacked and often chased for great distances. It is particularly aggressive towards humans, cats, squirrels, chipmunks, and almost all birds its size and larger. Even when not chasing predators, it frequently flies out of the territory. Consequently, the home range is much larger, but there is no information on its size (Blancher and Robertson 1985a; Davis 1941; Dyer 1974; Graber et al. 1974; James 1999a; Murphy and Pyle 2020; Odum and Kuenzler 1985; Peck and James 1987; Redmond et al. 2009; Roy and Choiniere in Gauthier and Aubry 1996; Tyler in Bent 1942).

Natal philopatry is low. At Lake Opinicon, 4 of 259 fledglings (1.5%) returned to breed. The average distance between the natal site and the first breeding area was 2.85 km for those that returned (Blancher and Robertson 1985b). Two of 62 young (3.2%) returned to nest in British Columbia (Campbell et al. 1997) and 8 of 428 (1.9%) returned in New York (Murphy and Pyle 2020). A study in New York revealed a natal return rate of 3-4% (Murphy 2007). In Oregon, 22.4% of nestlings

were observed in a subsequent year. Male nestlings tended to return at a higher rate (25.6%) than females (18.7%), but the difference was not significant. Many returning yearlings were prevented from acquiring a territory as a result of competition with adults; these birds were nonterritorial. The high return rate in Oregon was probably because habitat was restricted to areas within 200 m of aquatic habitats, with the remainder of the area being desert (Redmond and Murphy 2012).

Breeding site fidelity by adults is high. At Lake Opinicon, 43% of adults returned to breed in subsequent years, but they were less likely to return the year after banding (36%) than in later years (50%). Males returned to the same territory 33% of the time compared with 11% for females. Average dispersal distances were 0.04 km for returning males and 0.58 km for females. The same territories are frequently used, especially if breeding was successful the previous year. Of territories that fledged at least 1 young the previous year, 75% were reoccupied compared with 51% for unsuccessful territories (Blancher and Robertson 1985b). In New York, males reused their former breeding territories 92.7% of the time compared with 72.5% for females. In Oregon, 65.2% of adult males and 65.5% of adult females returned the year after they were banded. Geolocators were attached to adults in Nebraska and Oklahoma and 8 of 10 (80%) Nebraska birds returned and 2 of 2 (100%) Oklahoma birds returned. There are numerous examples of the same nest site being used year after year, with the old nest occasionally being repaired and reused several times. If a nest is unsuccessful, use of the site may be skipped for a year (Fairfield 2000; Hamas 1983; Mousley 1916a; Murphy and Pyle 2020; Peck and James 1987; Redmond and Murphy 2012).

Limiting Factors

Eggs have been found in Ontario nests from mid-May until the first week of August, with most present in the last 3 weeks of June. At 1 nest at Cape Henrietta Maria, egg laying was not initiated until the second week of July, suggesting that extreme northern nests may be about a month behind those in the south (James and Peck 1995b; Peck and James 1987, 1997). In Algonquin Park, nests are under construction from mid-May to early July, eggs occur from late May to late July, nestlings are present from mid-June to late July, and fledglings have been observed from early July to late August (Tozer 2012). At Lake Opinicon, eggs were laid significantly earlier at lakeshore than upland sites. The water ameliorated ambient temperatures, resulting in warmer spring temperatures near the lake (Blancher and Robertson 1985a)

The female selects the nest site and builds the nest in 7-14 days, with inclement weather increasing nest construction time. Replacement nests may be built more quickly. One Ontario nest was completed 3 weeks before egg laying commenced. In other areas, the time between nest completion and egg laying ranged from 1 to 20 days (average 6 days). Eggs are typically laid at the rate of 1 a day, but occasionally a day is skipped between the penultimate and last eggs. Incubation starts with laying of the penultimate egg. The incubation period of Ontario clutches was 12-18 days, with most eggs hatching in 13-15 days; the 18-day incubation period was considered a delay in initiation of incubation rather than a true incubation period. Elsewhere, the incubation period has been reported as 14-17 days. The incubation period may increase with latitude due to effects of ambient temperatures. Incubation periods determined by the same researcher were significantly shorter in Kansas than in New York. Hatching is asychronous in most 3-egg clutches and all larger clutches. Fledging occurs at age 13-19 days, mostly 16-17 days. The fledging period is strongly

correlated with brood size, with longest fledging periods in broods of 4 or 5 young (Campbell et al. 1997; Davis 1941; Graber et al. 1974; Morehouse and Brewer 1968; Murphy 1983a, 1983b; Murphy and Pyle 2020; Peck and James 1987).

Most authors state that the Eastern Kingbird is single brooded (Davis 1941; Murphy 1983a; Murphy and Pyle 2020). Blancher and Robertson (1982, 1984b) presented compelling evidence for a second brood at Lake Opinicon, although it was not totally conclusive that the same pair was involved (Peck 1984). Renesting occurs, with the likelihood of renesting declining with the season. In Kansas and New York, 88.9% of nests that failed during nest construction were replaced, 30.4% of those that failed during incubation were replaced, and 6.7% of nests with nestlings that failed were replaced (Murphy 1983a). Clutches of 1-6 eggs have been reported in Ontario, with most containing 3 or 4 eggs. Clutch size diminishes with season. At Lake Opinicon, most late-May nests contained 4 eggs; most clutches laid from late May onward contained 3 eggs. Replacement clutches were significantly smaller than those of first nests (3.13 eggs compared with 3.74 eggs; Blancher and Robertson 1985a, 1985b). Murphy (1986a) observed a similar decline in clutch with season in Kansas. Elsewhere, clutches of 2-6 eggs have been reported, with 5- and 6-egg clutches rare. Most clutches contain 3 or 4 eggs. Clutch sizes vary by latitude and longitude, with larger clutch sizes in the west and north (typically 4) compared with 3 eggs in the south and east (Campbell et al. 1997; Graber et al. 1974; Murphy 1983a, 1986a, 2000; Murphy and Pyle 2020; Tyler in Bent 1942).

The age at first breeding is 1 year, but it is uncertain what proportion of yearlings breed. Some may not be able to establish territories and adults that die are readily replaced by floaters. Once breeding has been initiated, it continues every year thereafter. The mating system is monogamous. If both birds of a former pair return, about 85% of them remate. At Long Point, 1 pair mated for 5 years. Extra-pair copulations are common. About 60% of nests contain extra-pair young and 50% of nestlings are extra-pair. Some intraspecific parasitism may occur, but the extent of this is unknown (Fairfield 2000; Hayes and Robertson 1989; Murphy and Pyle 2020).

At Lake Opinicon, aerial hawking was the most common foraging technique, and hover-searching frequently occurred. Rarely, the Eastern Kingbird flew from a perch to the ground to capture prey or sallied and gleaned from leaves (Blancher and Robertson 1985a). Most foraging is by sitting and waiting, then attacking aerial prey. Hover-gleaning and attacking prey on the ground are seldom-used foraging techniques. During rain or emergence of aquatic invertebrates, it may glean caterpillars from underneath leaves and from the surface of water bodies. During major insect emergences, it may hover and make multiple captures during a single flight. Most foraging flights are from a perch 1-4 m tall, for an average distance of 1.3 m (range 0.5-9.0 m). In Kansas, perch height averaged 1.3 m (range 0.3-9.1 m) and the average sally distance was 2.9 m (range 0.9-7.6 m). Commonly used perches are fences and fence posts, power lines, shrubs, trees, and herbaceous plants. Occasionally, it forages on the ground, particularly in plowed fields. Near Guelph, foraging occurred as far as 180 m from the nest. Most (46.0%) foraging occurred 90-150 m from the nest, 16.6% of time was spent foraging within 60 m of the nest, 10.0% beyond 180 m, and the remaining 27.4% of time was spent foraging 150-180 m from the nest. In Oregon, there were no differences in the foraging techniques of the sexes: 88.3% aerial hawking, 8.7% outward strikes, 17% perch-to-ground sallies, and 1.3% hover-gleans. During inclement weather, it moved into the canopy of tall

deciduous trees to capture insects by upward-striking and hover-gleaning (Dyer 1974; Graber et al. 1974; Murphy 1987; Murphy and Pyle 2020).

Both adults feed the young, with the female doing most of the deliveries. Nests in Ontario that lost the male all failed to fledge the entire brood. Only 23% of young fledged from nests without a male compared with 57% of nests with both adults. Young are fed mostly insects, predominantly beetles, grasshoppers, flies, butterflies, moths, bees and wasps, dragonflies and damselflies, and rarely small frogs. Young may also be fed fruits of mulberries, cherries, dewberries, common elderberry, nightshade, juneberries, currants, and raspberries. Adults feed mostly on flying insects, although some fruit is consumed later in the breeding season. These include cherries, sassafras, red-osier dogwood, wild grapes, and fruits that are commonly fed to young. Over 85% of the diet consists of insects: 32% hymenopterans, 25% beetles, 12% orthopterans, and 4% bugs. Typically, this kingbird feeds on large adult insects such as beetles, butterflies and moths, grasshoppers, leafhoppers, and cicadas and other bugs. Beetles consumed ranged in size from 3 to 20 mm, including June and click beetles and weevils. Hymenopterans consumed include wasps, bees, and ants. Other prey items include robber flies and geometer moth caterpillars. In Kansas, the diet at 2 sites included 49% and 58% beetles, 32% and 22% hymenopterans, 10% and 2% flies, and 0% and 11% lepidopterans. In Manitoba, midges comprised most of the food. It also eats spiders and rarely dives into water for aquatic insects and small fish. It has been observed eating treefrogs (Beal 1897a; Campbell et al. 1997; Chandler 1996; Davis 1941; Graber et al. 1974; Hayes and Robertson 1989; Hespenheide 1971b; Holt 1918; MacKenzie and Sealy 1981; McIlwraith 1894; Morehouse and Brewer 1968; Morton 1971; Murphy 1986a; Murphy and Pyle 2020; Tyler in Bent 1942).

The Eastern Kingbird is a rare host of the Brown-headed Cowbird. It is an egg rejecter, so parasitism rates are probably higher than observed. Cowbirds may also eject or damage kingbird eggs. In Ontario, 12 of 1,066 nests (1.1%) were parasitized. Other reported parasitism rates are 1 of 402 nests (0.2%) at Delta Marsh; 0 of 213 nests in British Columbia, although adults were observed feeding a young cowbird; 4% in western New York; 0 of 450 nests in central New York; 2 of 119 nests (1.7%) in the Dakotas, Minnesota, and Montana; and 13% in eastern Kansas. Parasitism usually does not affect the growth rate of kingbird nestlings, and occasionally kingbirds and cowbirds are fledged from the same nest (Campbell et al. 1997; Graber et al. 1974; Igl and Johnson 2007; Murphy 1986b; Murphy and Pyle 2020; Peck and James 1997; Rothstein 1975; Tyler in Bent 1942).

Habitat loss and degradation may limit the amount of suitable breeding areas. There have been large losses of pastures and orchards in southern Ontario and throughout the Eastern Kingbird's range. The decline in numbers of small farms and removal of hedgerows are negative factors. Through natural succession, many old fields have reverted to forest, making them unsuitable habitat. In Illinois, densities in favoured habitats were similar in the 1950s to the early 1900s, although there were less of these habitats. Densities were much lower in the later period in marginal habitats and some formerly used habitats, such as urban areas, were no longer used (Graber and Graber 1963; Graber et al. 1974; Murphy and Pyle 2020; Roy and Choiniere in Gauthier and Aubry 1996).

Nest location and breeding success are strongly correlated. Predation is the greatest cause of nest failure, and the more water there is near the nest, the greater the success rate. At Lake Opinicon, nesting success was greatest on stumps surrounded by water, followed by nests on large islands,

small islands, and the mainland. Breeding success in a given territory is strongly related to breeding success the previous year. Pairs nesting in previously successful territories were twice as likely to be successful as those nesting in previously unsuccessful territories. Previously successful birds that nested at the same site were 81% successful compared with 57% for birds that selected a different site. Previously unsuccessful birds were only 18% successful if they nested at the same site compared with 34% for those selecting a new site (Campbell et al. 1987; Blancher and Robertson 1985a, 1985b). In Oregon, natural and artificial nests were equally likely to fledge young. Differences in nest-site characteristic between failed and successful nests were similar for natural and artificial nests. The angle of the supporting branch was about 2.35 times steeper for successful nests for both types of nests, but the difference was significant only for natural nests (51.2° for successful nests compared with 21.8° for failed nests). Although not significant, successful nests of both types tended to be higher. Successful nests tended to be on more vertical branches and placed higher and closer to the top of the tree and closer to the centre of the tree than failed nests (Cancellieri and Murphy 2014).

In Saskatchewan, fire appeared to have no effect on the Eastern Kingbird. Its abundance was similar in burned and unburned areas (Pylypec 1991).

Weather may greatly affect nesting success. Cool and/or wet springs may delay nest initiation by as long as 2 weeks. Food is scarce under these conditions and adults often cannot find enough food to adequately feed young. Starvation of nestlings is common, particularly in larger broods. Nestlings exposed directly to intense sunlight may also die (Murphy 1983a, 1983b, 1983c, 1986a, 1986c; Murphy and Pyle 2020). Gorzo et al. (2016) used Breeding Bird Survey (BBS) data to analyze the response of the Eastern Kingbird to large-scale weather extremes in South and North Dakota, Montana, and Wyoming. Its abundance was significantly associated with weather. It responded negatively to both within-year precipitation and precipitation in the previous year.

The Eastern Kingbird frequently nests in orchards where pesticide use is common. Pesticides are a potential source of egg and nestling mortality, but this needs further study. Pesticides are also used along roads, railways, and hydro corridors, all habitats that may be used for nesting (Graber and Graber 1963; Murphy and Pyle 2020).

This flycatcher frequently collides with vehicles because it commonly forages and nests adjacent to roads (Murphy and Pyle 2020)

Status

The Eastern Kingbird has always been a common breeding species in Ontario, at least since European settlement. McIlwraith (1894) called it one of the most familiar birds in rural areas. Baillie and Harrington (1937) considered it common in the south and occurring north to James Bay and southern Thunder Bay and Temiskaming districts, and west to Lake of the Woods. In the Kingston area, it was common in the 1850s and 1900-10, and was the most common breeding flycatcher during the first atlas (Weir 2008). The first atlas confirmed that the Eastern Kingbird bred from the southern border of Ontario north through much of the Boreal Forest Region, except in the northwest. There were also scattered records along the Hudson and James bay coasts (Helleiner in

Cadman et al. 1987). James (1991) termed it common to locally abundant in the south, uncommon in the north to Red Lake and Moosonee, and rare north to Winisk and Cape Henrietta Maria.

The second atlas indicated a significant decline in the probability of observation of the Eastern Kingbird province-wide since the first atlas and in all regions except the Hudson Bay Lowland. Although declines south of the Canadian Shield were statistically significant, it was observed in virtually every square south of the Shield during both atlases. The greatest decline occurred in the Great Lakes–St. Lawrence Forest Region in the Shield, particularly in the Algonquin Highlands. This decline may be due in part to forest maturation and conversion of old-field habitats to forest. It was much more abundant south of the Shield than in it. Greatest abundance occurred from Lake Simcoe in a broad band east to the Brockville and Perth area, and in Bruce, Grey, and northern Wellington and Dufferin counties (Blancher in Cadman et al. 2007).

Long-term (1970-2021) population trends determined by the BBS indicate annual decreases in Canada of 0.929% and 1.94% in Ontario. The short-term (2011-2021) trends were an annual increase of 1.73% in Canada and an annual decrease in Ontario of 2.145%. All estimates were highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

It is several days after fledging before young can fly strongly. Although young may start to capture their own food the second week after fledging, they remain highly dependent on the parents for 5 weeks after fledging (Murphy and Pyle 2020).

MIGRATION

Migration occurs both diurnally and nocturnally. Most authors concluded that the Eastern Kingbird migrates mostly in flocks during the day, but some nocturnal migration occurs as evidenced by casualties at chimneys and towers. During autumn migration, birds stage during the day along the southern shores of Amherst Island, Wolfe Island, and Prince Edward Point, then cross Lake Ontario at night. Habitat used during migration is similar to breeding habitat (Campbell et al. 1997; Graber et al. 1974; Murphy and Pyle 2020; Tyler in Bent 1942; Weir 2008).

The Eastern Kingbird arrives in the province in the first week of May, rarely in early April. Spring migration may continue until June, with the peak in the second week of May. Males arrive about 5 days earlier than females, and older birds of both sexes arrive about a week before younger birds. Autumn migration may begin in mid-June and continue until mid-September, with rare stragglers to mid-October (Cooper et al. 2009; James 1991; Keast 1990; Murphy and Pyle 2020).

The Eastern Kingbird is common during migration and may be locally abundant in autumn when larger flocks may occur. Taverner and Swales saw hundreds at Point Pelee 24-27 August 1907, with occasionally 15-20 in a single tree. In the latter half of August, flocks of 150-400 may be observed in the Kingston and Presqu'ile areas (James 1991; LaForest 1993; Tyler in Bent 1942; Weir 2008).

Olive-sided Flycatcher

Contopus cooperi

BREEDING SEASON

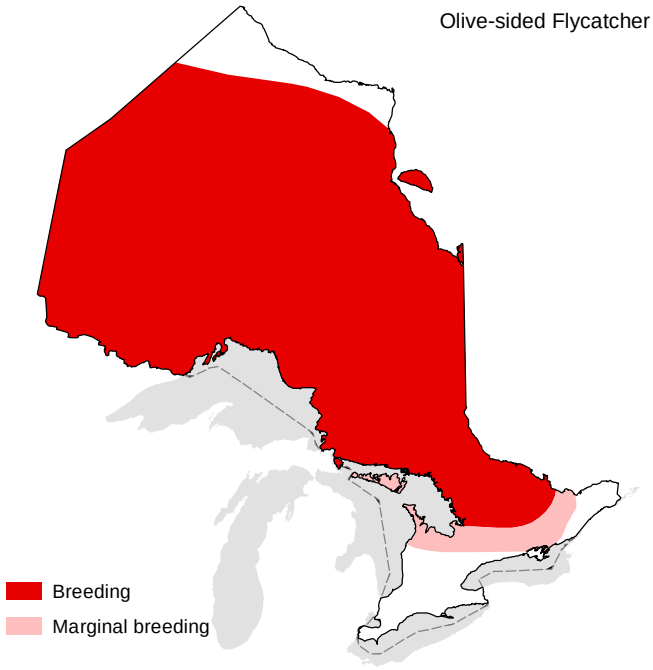
Habitat Requirements

The Olive-sided Flycatcher nests in coniferous and mixed forests, usually in wetlands, but occasionally in upland habitat. Ontario nesting habitats include black spruce bogs and burns, jack pine stands and burns, mixed woods, and treed margins of beaver ponds and cattail marshes (Peck and James 1987).

In the Boreal Forest Region, the Olive-sided Flycatcher is characteristic of burns and clear-cuts as long as there are standing snags and stubs, but it also occurs in swamps and floodplain forests. Near Pickle Lake, it bred in small numbers at edges of bogs, in burned areas, and in clear-cuts (Erskine 1977; James 1980; McLaren and McLaren 1981).

In the Great Lakes–St. Lawrence Forest Region in the Canadian Shield, the Olive-sided Flycatcher preferred very open treed swamps and regularly foraged from and nested in jack pines adjacent to

riparian areas (James and Peck 1995a). In Quetico Park, it occurred in low-density coniferous forests with an understorey and in mixed forest and mixed scrub. It was rare in coniferous forests without an understorey and in heath areas. Following forest fires, it was most common the first 3 years after fire. It was absent in intermediate-aged and old-growth stands, and uncommon in mature stands (Apfelbaum and Haney 1985). In Algonquin Park, it occurred commonly in drowned lands with tall dead trees, in spruce and tamarack swamps, in pine forests, and near beaver ponds (MacLulich 1938; Tozer 2012).



In Durham Region in the Great Lakes–St. Lawrence Forest Region south of the Shield, the Olive-sided Flycatcher nested in a spruce bog with some white spruce and tamarack surrounding an open area dominated by leatherleaf. Speirs and Orenstein (1975) considered it a mid-successional species associated with conifers.

Outside Ontario, the Olive-sided Flycatcher has been documented nesting primarily in sparsely treed bogs, burns and clear-cuts with residual trees or on edges of these habitats, at edges of beaver ponds, along forested shorelines with standing dead trees, at ecotones between riparian habitat and coniferous forest, in mixed forests, and in wetland shrubby areas. Although typically associated with coniferous and mixed stands, it rarely occurs in deciduous stands. It usually occurs in very young and young stands, frequently in areas that are nutrient poor, and most often near water. Areas near water may have a greater density of insects. In California, it nested in mature open forests. Tall perches and open habitats for foraging are important habitat components. In Alaska, males perched and sang from the tops of coniferous trees, predominantly white spruce. More than 80% of perch trees had dead tops or were completely dead. Perches were prominent trees averaging 1.4 times taller than the forest canopy. Mean height of perches was 17.8 m (Altman and Sallabanks 2020; Bent 1942; Campbell et al. 1997; Capen 1979; Dawson 1979; Hack et al. 2024; Kirk et al. 1996; Niemi and Pfannmuller 1979; Noon et al. 1979; Séguin in Gauthier and Aubry 1996; Temple et al. 1979; Walkinshaw and Henry 1957a; Wright 1997).

At the landscape level, the Olive-sided Flycatcher is significantly more abundant in areas with clear-cuts than those without clear-cuts, and in fragmented landscapes than extensively forested areas (Altman and Sallabanks 2020). Baker et al. (2016a) reported that highest Canadian densities occur in mature conifer stands within patchy landscapes influenced by natural disturbances such as fires. Wetlands have a positive influence on its abundance at the landscape level, but a negative effect at the local level. In Minnesota, it was associated with lowland conifer communities

embedded within landscapes containing a high proportion of non-forest (Zlonis et al. 2017). In Nova Scotia, its presence was positively correlated with canopy height and valleys and negatively correlated with canopy height heterogeneity, distance to a coniferous stand, and distance to a stand with dead material. Canopy height was the most important factor (Bale et al. 2020).

In 2 study areas in Montana, the Olive-sided Flycatcher selected territories on steeper slopes than were randomly available. Ground slope was 33.8° and 15.5° at territories in the study areas compared with 15.9° and 7.2° at random sites, respectively (Robertson and Hutto 2007).

Ralston et al. (2019) surveyed 20 sites in boreal forest habitat in New York, Vermont, Maine, Nova Scotia, and Newfoundland for the Olive-sided Flycatcher. The Olive-sided Flycatcher occurred at only 3 locations indicating specialized habitat requirements. Its presence was positively correlated with black spruce, tamarack, and mean temperature. It was restricted to lower-elevation sites with higher temperatures, predominantly in black spruce–tamarack swamps.

Westwood et al. (2009) modelled Olive-sided Flycatcher habitat in Nova Scotia and New Brunswick. Its population density was highest in stands dominated by spruce species (excluding white spruce), black spruce, and balsam fir. It was least abundant in stands dominated by pines and deciduous species. For all tree cover types except alder, density increased with the amount of forest that had a depth to water table of 1 m or less, with the proportion of the area within 250 and 1,000 m classified as wet, and with lower mean canopy cover and mean stand height. Population density increased with landscape complexity and connectivity. Density decreased with the presence of roads. Areas within national parks had a slightly higher population density than areas outside parks.

In Alaska, vegetation at perches, nests, and random areas was similar. There was almost complete coverage by vegetation less than 50 cm tall dominated by mosses, lichens, and dwarf shrubs. Dwarf birches and Labrador tea were the most abundant shrubs with spruce saplings and willows also common. Spruce dominated the trees taller than 1.4 m with a diameter at breast height (DBH) of less than 8 cm, with alder and tamarack common. Spruce also dominated the larger trees, although there were few larger than 23 cm DBH (Wright 1997). In Montana, there were no differences in the height of perches selected by flycatchers in burned (16.7 m) or selectively harvested (18.3 m) stands for singing males, or for foraging males (15.2 m compared with 14.7 m) and females (8.7 m compared with 9.5 m). Females selected perches that were an average of 55% shorter than those selected by foraging males, and 115% shorter than those used by singing males. The probability of a bird selecting a live tree for a perch was significantly higher in selectively harvested (64%) than burned (17%) forests. Females preferred perches that were significantly shorter than available trees. Male perch height was similar to that of available trees. Both sexes strongly selected standing dead and dead-topped trees as perches in selectively harvested stands but not in burned stands. Tree species preferred for perching included fir, larch, and white birch (Robertson 2012).

Ontario nests were on horizontal branches of conifers, mostly black and white spruce, but also jack pine and balsam fir. One nest tree in a burned area was dead. Most nests were 0.3-2.5 m from the trunk of the tree; 2 nests were at the end of a branch and 1 was against the trunk. Nests were 4-

15 m from ground, with most 7-10 m up. Most nests were well concealed in foliage, but 1 was conspicuous (Peck and James 1987).

All reported nests were on horizontal limbs (usually the bottom limb), and most were distant from the trunk. In Alaska, nests were an average of 16.7 cm from the trunk atop live branches averaging 50.4 cm long. In Oregon, nests were 91.4-106.7 cm from tree trunks on branches 137.1-167.6 cm long. More than 90% of nests are in conifers, with other coniferous nest trees including red cedar, tamarack, pitch pine, and hemlock. All nests reported in an Alaskan study were in live conifers. Nest trees were significantly shorter than perches and the surrounding canopy. Deciduous trees that have been used for nesting are apple, sycamore, cottonwood, elm, locust, oaks, alder, willow, and trembling aspen. Extremes in nest heights reported are 1.5-60 m, with most 6-12 m from ground. Mean height of 19 Alaska nests was 6.4 m (range 3-12 m); mean nest height in Montana was 12.1 m (Altman and Sallabanks 2020; Bent 1942; Campbell et al. 1997; Robertson and Hutto 2007; Séguin in Gauthier and Aubry 1996; Walkinshaw and Henry 1957a; Wright 1997).

The Olive-sided Flycatcher is fiercely territorial, and may attack other bird species such as hawks, crows, and Scarlet Tanagers (Bent 1942). Limited information on territory size is available. Most estimates are 10-20 ha, but territories as large as 25, 40, and 45 ha have been reported. Average size of 16 territories in Alaska was 18.4 ha (range 10.8-26.4 ha). Territories in Alaska were long and narrow and were often along a watercourse or drainage. The average length of territories was 625 m (range 360-1,120 m). Territories may not be contiguous and are frequently separated by unsuitable habitat. When territories abut, it is usually on 1 side only. The closest nests are 200 m apart (Altman and Sallabanks 2020; Wright 1997).

Although there are few banding recoveries for the Olive-sided Flycatcher, data indicate strong breeding-site fidelity. Birds have been captured 5 and 6 years later in the same location in California, 2 birds in California returned the subsequent 2 breeding seasons, and 5 of 9 Alaska birds returned to the same territory. Reuse of nests has not been reported outside Ontario, but subsequent nests have been found in the same tree as close as 1 m to the old one. In Alaska, nests on regularly used territories were an average of 271 m from the previous year's nest with a range of 45-625 m (Altman and Sallabanks 2020; Wright 1997). A nest found in 1998 in Sudbury District was used again in 1999 (Peck 2000).

Limiting Factors

Eggs have been reported in Ontario nests throughout June (Peck and James 1987). In Algonquin Park, nests are under construction from early to mid-June, eggs are present from mid- to late June, nests contain young from early to mid-July, and recently fledged young have been documented from late July to late August (Tozer 2012). In Alaska, timing of territory establishment was irregular. Some birds apparently on territory in late May and early June were not detected again, and some territories were not established until late June or early July. Of 23 males, 6 (26%) were found only once or twice and did not maintain a territory throughout the season (Wright 1997).

Nests are typically built in 5-7 days, although 1 took 10 days to complete. The egg-laying interval is 1 day and the incubation period is 14-19 days, with most eggs taking 15-17 days to hatch. Young may leave the nest when they are 15-17 days old if disturbed, but the normal fledging period is 19-

23 days (Altman and Sallabanks 2020; Bent 1942; Campbell et al. 1997; Pearce and Kirk 2007; Séguin in Gauthier and Aubry 1996; Walkinshaw and Henry 1957a; Westwood and Stehelin 2018; Wright 1997).

A single brood is raised annually; there is no evidence of second broods. Renesting may occur once or even twice if a clutch is lost. In this event, a new nest is built. In Alaska, all but 1 pair renested within 225 m of the first nest and the other was 600 m distant. The mean distance of replacement nests from the first nest was 144 m and the closest was 25 m. The replacement clutch is laid in 3 weeks or less (10-12 days in Alaska). Ontario clutches contained 2-4 eggs, mostly 3 eggs. The Olive-sided Flycatcher almost always lays 3 eggs with 4-egg clutches scarce and 2-egg clutches rare. In Alaska, 10 first clutches all contained 4 eggs. One Michigan nest contained 6 eggs and 5 young were fledged from this nest. It is unknown if these eggs were produced by 1 or 2 females. Two-egg clutches are usually replacement nests. In Alaska, 2 of 3 replacement clutches contained 3 eggs and the other contained 4 eggs (Altman and Sallabanks 2020; Bent 1942; Séguin in Gauthier and Aubry 1996; Walkinshaw and Henry 1957a; Wright 1997).

The nesting system is monogamous although there is 1 instance of suspected polygyny in Alaska and 1 in Oregon. There are 2 records of the same pair remaining together in consecutive years. The age at first breeding is 1 year, but many birds may not breed or attract a mate (Altman and Sallabanks 2020; Wright 1997).

The Olive-sided Flycatcher hunts from an open perch, usually the top of a tree or snag. It preys exclusively on flying invertebrates. In windy or cool, inclement weather, both sexes forage from lower perches less than 15 m from the ground such as shrubs, saplings, and exposed branches of slash piles and root wads. Most flights under these circumstances are directed downward toward the ground. In Alaska, 2 females foraged from low snags or broken saplings 1-3 m tall, occasionally disappearing for as long as 15 seconds into low (0.5 m or less) flowering vegetation. These females also hovered over or flew directly over the top of low vegetation. These perches were directly adjacent to sunlit patches of flowering shrubs and forbs that supported bumble bees, yellowjackets, and moths. Near-ground foraging had not been previously reported, but was frequent, representing 70% of 27 foraging attempts. Unlike most other flycatchers, it rarely takes invertebrates from foliage and usually does not eat prey that does not fly. It does not eat caterpillars, millipedes, or other non-aerial invertebrates often eaten by other flycatchers, but occasionally eats spiders. Honey bees and flying ants constitute more than 80% of the breeding season diet; almost all birds sampled had eaten these hymenopterans and more than 40% had fed on them exclusively. Other invertebrates eaten, in order of decreasing abundance, were beetles, moths, grasshoppers, true bugs, dragonflies, and flies. Animal food was 99.95% of the diet, with the remainder being fruit pulp and spruce foliage (Altman and Sallabanks 2020; Bent 1942; Hagelin et al. 2015; Séguin in Gauthier and Aubry 1996). In New Brunswick, the Olive-sided Flycatcher exhibited no response to increasing numbers of spruce budworms (Morris et al. 1958).

Brown-headed Cowbirds have not been documented parasitizing the Olive-sided Flycatcher in Ontario, and it is a very rare cowbird host. Campbell et al. (1997) reported 1 incident of parasitism in British Columbia, apparently only the fourth record in North America. Altman and Sallabanks (2020) reported no additional observations of parasitism.

It has been estimated that 17% of this flycatcher's habitat in the Boreal Forest Region of Canada has been disturbed by anthropogenic activities. Depending on how it is done, clear-cutting may be detrimental or beneficial. Clear-cutting that removes snags adjacent to small clearings or in small wetlands may decrease habitat quality. Overall, clear-cutting is usually beneficial because it creates forest edges and openings suitable for foraging. Clear-cuts that leave isolated trees and snags may be beneficial provided they are close to suitable breeding habitat and do not remove existing breeding areas. It has been suggested that the Olive-sided Flycatcher is dependent on fire, and clear-cuts may be ecological traps where birds have limited reproductive success (Altman and Sallabanks 2020; Baker et al. 2016a; Séguin in Gauthier and Aubry 1996). In the Canadian Shield of Ontario, it was significantly less abundant in early successional clear-cuts than in early successional burns, but there was no difference in its abundance in mid-successional clear-cuts and burns. It was significantly more abundant in early successional than mature stands, but equally abundant in mid-successional and mature stands (Zimmerling et al. 2017). In Montana, its reproductive success was lower in harvested forests than in burned forests. This may be due to higher densities of predators in clear-cuts. There may also be increased abundance of aerial insects in clear-cuts, thus attracting Olive-sided Flycatchers into an ecological trap (Robertson and Hutto 2007). Snag retention in clear-cuts is an important habitat consideration (Robertson 2012). In Newfoundland, Whitaker and Montevecchi (1999) studied its distribution in relation to riparian edges and buffer strips retained around watercourses and water bodies where clear-cutting occurred. In unharvested balsam fir stands, it occurred only within a 30-m riparian band and was absent in forest interior. In clear-cut areas, it was present in the riparian buffers but absent in the clear-cuts. These authors categorized it as an open-edge species. Pearce and Kirk (2007) concluded that the continued decline of the Olive-sided Flycatcher throughout its range despite continued addition of early successional habitat through forest harvesting suggests that forest management practices may be a significant factor in population declines.

The Olive-sided Flycatcher may be vulnerable to acid precipitation which has the potential to reduce insect prey and may also release mercury into the environment (Baker et al. 2016a).

Reduced availability of insect prey has been raised as a potential threat. Many insects are declining and have shrinking ranges. There is also the potential for mismatch of timing of flycatcher breeding activities and insect emergence (Baker et al. 2016a).

In California, the presence of the Olive-sided Flycatcher was related to presence of early successional habitats and fire. Meehan and George (2003) found that fire had negative impacts on reproduction, perhaps related to reduced food availability in recently burned areas. Another California study concluded that low- to moderate-severity fires could be beneficial by burning small trees and leaving older trees unscathed, resulting in the open forest dominated by large trees that it preferred (Hack et al. 2024). In most areas, it is more abundant in burned than unburned forest (Altman and Sallabanks 2020). In Oregon, it responded positively to fire and its abundance increased with increasing severity of the burn. It showed a positive response beginning in year 4 after the fire (Stephens et al. 2015). Fire suppression may be a threat in Canada because 97% of fires are suppressed before they reach 200 ha in size (Baker et al. 2016a).

Deforestation of wintering habitat has been identified as a limiting factor to the Olive-sided Flycatcher (Baker et al. 2016a).

Price (2004) predicted that the Olive-sided Flycatcher could disappear as a breeding species in southern Ontario if the average summer temperature increased by 2°C.

Status

McIlwraith (1894) considered the Olive-sided Flycatcher rare in Ontario and not very abundant anywhere; he had only 1 record of a migrant. Most of his observations were made in the Hamilton area and there were few observers within its main breeding range, so his comments may not be representative of its status at that time. Baillie and Harrington (1937) termed it not uncommon from latitude 44° N to James Bay and west to Thunder Bay. Although they had no direct evidence, they assumed it nested to the western boundary of the province. MacLulich (1938) considered it common at Algonquin Park. The first atlas confirmed that it bred throughout the Canadian Shield and Boreal Forest Region north to latitude 56°N along the Severn River. Its distribution in the Hudson Bay Lowland was sporadic and concentrated mostly in the northwest. There were scattered records in the south from the Bruce Peninsula, Manitoulin Island, and in the Frontenac Axis (Shekey in Cadman et al. 1987). James (1991) considered it an uncommon breeder in forested areas of the province south to Lake Simcoe and Brockville.

There was no significant change in the breeding distribution of the Olive-sided Flycatcher between the 2 atlases. It breeds in low density throughout the Canadian Shield and Hudson Bay Lowland, except for the strip of tundra along the Hudson Bay coast. It is rare south of the Shield where habitat is marginal. There was no significant difference in its probability of observation province-wide, but there were significant declines south of the Shield and in the southern Shield (Cheskey in Cadman et al. 2007).

Breeding Bird Survey (BBS) data for 1970-2021 indicated declines of 1.85% per year in Canada and 1.67% in Ontario. During 2011-21, the rate of decline was 2.05% annually in Canada and 0.52% in Ontario. All estimates were highly reliable (A.C. Smith et al. 2023). BBS results are biased toward southern populations of birds because surveys are conducted from roadsides (Westwood and Stehelin 2018); only a small proportion of the Olive-sided Flycatcher's range is sampled. The Committee on the Status of Endangered Wildlife in Canada originally designated the Olive-sided Flycatcher threatened in Canada, but later downgraded its status to special concern based on revised population estimates. It is listed as special concern in Ontario.

The short-term objective of the recovery strategy for the Olive-sided Flycatcher is to halt its national decline by 2025 while ensuring that the population does not decrease by more than 10% over this time. The long-term objective after 2025 is to ensure a positive 10-year population trend for it and to maintain its current distribution (Baker et al. 2016a).

POSTFLEDGING PERIOD

After fledging, young remain close to the nest for several days and depend on the adults for food for their first week. Fledglings remain on the territory for as long as 17 days after fledging, and the family may remain together until autumn migration (Altman and Sallabanks 2020).

MIGRATION

The Olive-sided Flycatcher has the longest migration route of any North American flycatcher, and arrives later in spring and departs earlier in autumn than most other flycatchers. It usually arrives in mid-May or later, with earliest arrivals in very late April. Normally, it lingers in the south until early June, but is often seen as late as mid-June. In autumn, it is an early migrant, appearing in the south in mid-August. Most leave the province by early September, but stragglers may persist until early October (James 1991; Westwood and Stehelin 2018).

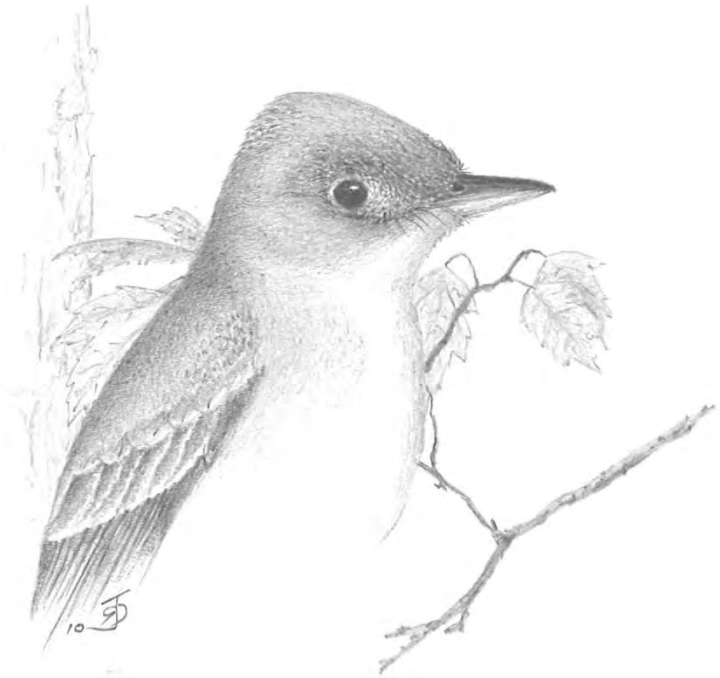
The Olive-sided Flycatcher may occur in a variety of habitats during migration, but it prefers edges and open areas with suitable perches. It is most frequent at edges of mature coniferous and mixed forests, especially if they are adjacent to water, but it also occurs along edges of deciduous woodlands, particularly swamps and floodplains. Edge habitats it may use during migration include ponds, sloughs, lakes, wetlands, blowdowns, rivers, burns, clear-cuts, utility corridors, and highways. Tall trees with dead tops or other open perches are essential (Campbell et al. 1997).

The Olive-sided Flycatcher is at moderate risk for striking buildings during migration (Loss et al. 2014).

During migration, the Olive-sided Flycatcher is rare to uncommon, and tends to be more common in autumn (James 1991; Weir 2008).

Eastern Wood-Pewee

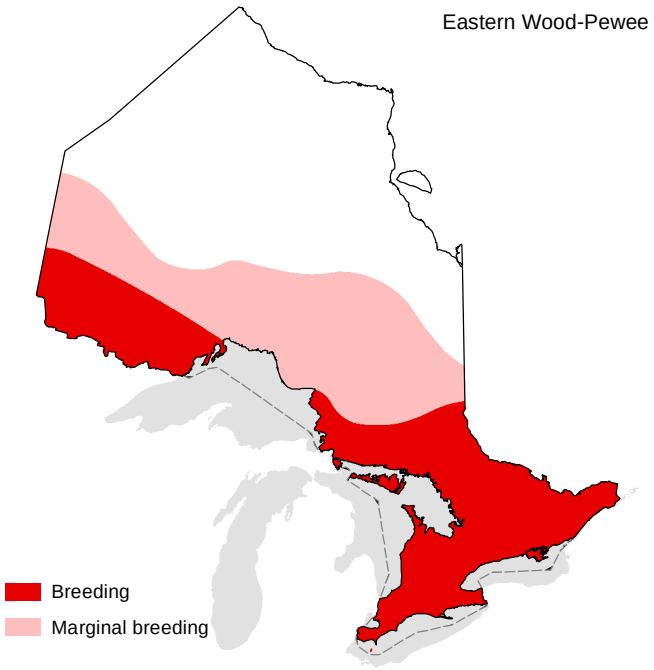
Contopus virens



BREEDING SEASON

Habitat Requirements

In Ontario, the Eastern Wood-Pewee breeds most frequently in deciduous woodlands, occasionally in mixed-wood forests, and rarely in coniferous stands. It may occasionally nest in more open habitats such as orchards, hedgerows, shrublands, residential gardens, parks, and campgrounds. It has a definite preference for open areas near the nest such as forest edges and clearings, roads, and water. Upland sites are greatly preferred over wet areas (Peck and James 1987). In eastern Ontario, it settled in pine plantations and deciduous forests nearly simultaneously and at similar densities, suggesting no preference for either stand type (Falconer and Nol 2020). McIlwraith (1894) stated that it frequently nested in orchards, but this habitat is seldom used now. It continues to nest in urban woodlands (Weir 2008).



Kirk et al. (2012) documented the Eastern Wood-Pewee in mature and old-growth white pine stands in the Great Lakes–St. Lawrence Forest Region in the Canadian Shield of Ontario. It was more common in mature than old-growth stands. In burned forests in Quetico Park, it occurred only in stands that had been burned 1-23 years previously. It was absent in intermediate-aged stands (67-73 years), mature stands (112-176 years), and old stands (367-370 years; Apfelbaum and Haney 1984). In Parry Sound District, it avoided pure jack pine stands. It was present in a jack pine stand with 50% canopy closure, with trembling aspen, white birch, and white pine codominating in the canopy. In an open jack pine stand with 25% canopy closure and several other deciduous and coniferous canopy species, it was present at half the density of the more closed-canopy habitat (James 1979a).

In eastern Ontario in the Great Lakes–St. Lawrence Forest Region south of the Shield, territories had lower basal area, tree species diversity, and fewer pines than unoccupied areas. Wood-pewees selected for fewer trees and more openness in the forest, which would favour aerial foraging (Savignac 2012a). In Durham Region, Speirs and Orenstein (1975) found it on 9 of 11 of their plots. Highest densities occurred in mature beech-maple woodlands, followed by mature maple-oak forest, a relict farm woodlot of mature maple-beech sloping down to a coniferous riparian forest, and an upland mature white cedar–elm forest. It occurred mostly in late-successional stands, but also in subclimax forests.

Although the Eastern Wood-Pewee may occur in almost every forested habitat outside Ontario, it is most common in deciduous woods, less frequent in mixed woods (depending on canopy species composition), and rare to absent in pure conifers. It has nested in maple-beech, cedar-aspen, balsam fir–spruce-poplar, hemlock–yellow birch, poplar-birch, maple, ash-basswood, pitch pine, and mixed pine-spruce stands. In Ohio, dry ridge tops forested with oaks were preferred nesting habitat and it was equally abundant in uncut forest and shelterwood cuts. In Illinois, it was most abundant in savannahs, followed by upland forests, floodplain forests, and developed open space with mature trees. Most studies concluded that it requires intermediate-aged to mature stands. It may be present in immature stands, but in low numbers. In bottomland forests in South Carolina, it occurred only in late-successional stands. In New Hampshire and Maine, it was significantly more abundant in large sawtimber stands (with average tree diameter at breast height [DBH] greater than 60 cm) than in smaller size classes of stands. It was positively correlated with the number of dead trees larger than 10 cm DBH and taller than 5 m, the total foliage volume of coniferous trees larger

than 10 cm, the total foliage volume of deciduous trees 2-10 cm DBH, and the total foliage volume of both coniferous and deciduous trees less than 2 cm DBH. It was negatively correlated with percent ground cover. It was associated with openings such as forest edges and breaks in the canopy. In Minnesota, it inhabited a clear-cut with dead snags and few live residual trees. Although it occurs in swamps and moist habitats, it seems to prefer upland areas. It may be considered an edge species that prefers a tall, broken canopy. Many authors described individual home ranges as being very heterogeneous and difficult to characterize. Its habitat requirements do not overlap significantly with those of the Least and Acadian flycatchers, but there is a macrohabitat overlap with the Great Crested Flycatcher (Adams et al. 1988; Back 1979; Beals 1960; Buffington et al. 1977; Capen 1979; DeGraaf and Chadwick 1987; DeGraaf et al. 1998; DesGranges et al. 1987; Erskine 1977; Fitch 1958; Freemark and Collins 1992; Graber et al. 1974; Hespenheide 1971a; Hoffman 1989a; Johnston 1971; Keller and Yahner 2007; Limoges in Gauthier and Aubry 1996; Lindell et al. 2007; Lynch 1987; Mossman 1988; Mossman and Hoffman 1989; Newell et al. 2013; Niemi and Hanowski 1984a; Niemi and Pfannmuller 1979; Niemi et al. 1995; Samson 1979; Temple et al. 1979; Thompson and Capen 1988; Tyler in Bent 1942; Walk et al. 2011; Watt et al. 2020).

At the landscape level in southern Ontario, abundance of the Eastern Wood-Pewee was negatively correlated with the amount of forest cover 100 m or more from edge, woodlot size, the amount of forest cover within 2 km, and the amount of regional forest cover. All relationships except the last one were significant (Austen et al. 2001). In North Dakota 400-m landscapes with less than 30% tree cover, its probability of occurrence increased linearly as tree cover within 100 m increased from 20% to 70%. In landscapes with more than 30% tree cover, its probability of occurrence increased as tree cover increased from 20% to 50%, then levelled off and declined as tree coverage increased to 90-100%. The probability of occurrence at 70% tree cover was greater in open than in wooded landscapes (Cunningham and Johnson 2016). In North Dakota, it preferred landscapes that were 59-75% forested; no areas had more than 75% forest cover there. In New York, it selected landscapes that were 81-100% forested (Cunningham and Johnson 2019). In Missouri, its density was negatively affected by forest cover within 10 km and by increasing sapling density at the point. Density peaked at high levels of canopy cover and low levels of forest cover in the landscape. It may be best adapted to open wooded habitats at the landscape scale (Watt et al. 2020). Using Breeding Bird Survey (BBS) data for the south-central states, Brennan and Schnell (2007) determined that the Eastern Wood-Pewee appeared to be most abundant in relatively undisturbed areas with high edge-to-interior ratios. Populations tended to be higher in densely wooded areas and lower in more sparsely wooded locations. Grundel and Pavlovic (2007a) reported similar results from Indiana. The Eastern Wood-Pewee was significantly more abundant in forested areas with more than 90% crown closure than any other habitats. There were no significant differences in its abundance in savannahs, woodlands with 50-90% canopy closure, and shrub habitat, where it was significantly more abundant than in open areas with less than 20% canopy closure. Grundel and Pavlovic (2007b) reported highest densities of wood-pewees at tree densities of 375-500 per ha, with numbers declining with lower or higher tree densities.

In Muskosa District and Haliburton County, the Eastern Wood-Pewee was associated with higher tree canopy volume and tree density, characteristic of the periphery of a clearing. It was typically found in forest edges of cottage clearings regardless of the size of the lot (Clarke et al. 1983).

In a Connecticut woodlot over a 59-year period, there was a progressive shift to larger trees, a sparser shrub layer, and a less diverse tree canopy dominated more by oaks and maples with a severe decline in hemlock. There was no change in the abundance of the wood-pewee despite the authors' expectations that it would increase in response to declines in hemlock (Buchanan et al. 2016).

The Eastern Wood-Pewee is not an area-sensitive species; it nests in forest edges and suburban habitats. In Illinois, it nested in forest patches as small as 1.8 ha and in Iowa it nested in riparian corridors as narrow as 20 m (Watt et al. 2020). In the mid-Atlantic states, its probability of detection was similar for forests 0.3-3,200 ha in area, but it preferred woodlands larger than 2-4 ha (Robbins 1979; Robbins et al. 1989). In Pennsylvania, abundance of the wood-pewee was positively associated with forest size. In southern Ontario, it occasionally nests along gravel roads with mature trees on either side that form a canopy over the road (personal observation). In North Dakota, its abundance was positively associated with forest size and the number of trees larger than 23.1 cm DBH. Probability of observation in aspen groves of different sizes was approximately 13% in 1-ha woodlots, 85% in 10-ha woodlots, and 100% in 70-ha and larger forests (Grant and Berkey 1999).

Except for 1 nest in a shrub, all Ontario nests were in trees. Ninety-three percent of nests were in deciduous trees, most of which were alive, although the limbs that nests were on were often dead. Tree species most frequently selected for nesting were elm, oak, maple, birch, and apple, and many nest trees were large and mature. Most nests were well out from the trunk on a horizontal limb, either at natural forks or forks created by the intersection of limbs or saddled on the upper surface of a limb. Diameters of limbs with nests ranged from 3.8 to 5 cm, and the distance of the nest from the trunk ranged from 0.6 to 6 m, with most 1.5-3 m from the trunk. Height from ground ranged from 1.8 to 21 m, with most 4.5-9 m up (Peck and James 1987).

Nest placement is similar in other areas. Other tree species that it has nested in include willow, black walnut, pear, flowering dogwood, and sycamore. In Missouri, nests were 2.5-26.6 m from the ground (mean 18 m). Manitoba nests averaged 7.0 m from the ground. Nests tend to be placed higher than those of the Least Flycatcher. The wood-pewee has been observed robbing materials from Ruby-throated Hummingbird and tanager nests to construct its own nest. Nest materials may be taken from within-season failed or successful nests and used to build a new nest. Nests may be reused for second broods but failed nests are not used for replacement clutches (Graber et al. 1974; Johnston 1971; Kendrick et al. 2013, 2014; Limoges in Gauthier and Aubry 1996; McIlwraith 1894; Trail 1987; Tyler in Bent 1942; Underwood et al. 2004; Watt et al. 2020).

The wood-pewee is a fierce defender of its territory, expelling other wood-pewees as well as Mourning Doves, phoebes, Blue Jays, bluebirds, Field Sparrows, grackles, and gray squirrels. Least Flycatchers and Great Crested Flycatchers are tolerated. Territory sizes of 0.4-7.7 ha have been reported, but larger estimates may have been home ranges rather than territories. In eastern Ontario, territories averaged 1.70 ha in deciduous forests, 1.83 ha in pine plantations, and 1.76 ha overall

(Falconer and Nol 2020). In Quebec, territories were 0.4-1.3 ha and home ranges were 4 ha or larger. Territories averaged 0.71 ha in sugar maple stands and 0.46 ha in hemlock stands. Quebec territory sizes are similar to those reported from Illinois and Kansas (Fitch 1958; Graber et al. 1974; Johnston 1971; Limoges in Gauthier and Aubry 1996; Watt et al. 2020). Near Quebec City territories were randomly distributed through forests with no evidence of clumping or colonialism (Bourque and Desrochers 2006).

No information is available on natal philopatry but no males returned as yearlings in Ohio (Watt et al. 2020). Limited evidence suggests that adults have a moderate to high homing rate to nesting areas. In Illinois, 22.2% of birds were recaptured the next year. In Ohio, 100% of breeding adults returned the following year (Newell et al. 2013). In northern Ohio, 29-57% of males returned over a 3-year period (Watt et al. 2020). Tyler (in Bent 1942) stated that females returned year after year to the same group of trees and often built a nest on the same branch. In 1 instance, there was a nest in the same fork of a tree for 35 years. There are 2 breeding season recoveries of banded adults. One was recaptured at the same banding station in Quebec almost exactly a year after it was banded there, suggesting breeding-site fidelity. The other was banded during the breeding season in Michigan and recovered 2 years later in Quebec, indicating movement between nesting seasons (Brewer et al. 2018).

Limiting Factors

Eggs have been found in Ontario nests throughout June and July until mid-August, with most clutches present in the last half of June and the first week of July (Peck and James 1987). In Algonquin Park, nests are under construction in early June, eggs are present from mid-June to early July, nestlings are present from early to mid-July, and fledglings have been observed from late July until early September (Tozer 2012).

The pair bond is established shortly after the birds arrive. The pair travels around the territory together, checking several sites before starting to build the nest. Nest construction takes about 6 days (range 4-10 days). Eggs are laid on consecutive days. The incubation period appears to be 12-14 days. It may be longer than this because the mean incubation period in Missouri was 14.1 days. Young fledge at age 16-18 days. In Missouri, the mean length of the nesting cycle from the initiation of a clutch until fledging was 35.5 days, including 14.1 days for incubation and 15.4 days for the nestling period; mean nesting period in Ohio was 17.2 days (Kendrick et al. 2014; Limoges in Gauthier and Aubry 1996; Newell et al. 2013; Tyler in Bent 1942; Watt et al. 2020).

Breeding activity extends into August or even September in some areas, so it is likely that more than 1 brood is raised (Watt et al. 2020). In eastern Ontario, 16.9% of pairs were suspected of double-brooding (Falconer and Nol 2020). Newell et al. (2013) confirmed double-brooding in Ohio when a female reshaped a nest in which she had fledged 3 young 10 days previously. A total of 5 young were fledged by this pair in this nest. There was another apparent case of a double brood and 6-12% of pairs may have raised 2 broods. In Missouri, Kendrick et al. (2014) reported that 19 of 92 pairs (20.6%) that successfully raised a first brood attempted a second brood, but only 3 (15.8%) were successful. An average of 9.4 days elapsed between a successful nest and the first egg of the second clutch. Nine pairs reused their nest for a second brood but none were successful. Mean distance between subsequent nests was 42.7 m (range 23.5-72.6 m). Curry (2006) reported a 1961 nest from

Speyside that contained half-grown young on 3 July and 2 young later on 19 August, suggesting that 2 broods were raised in this nest. Newell et al. (2013) confirmed that renesting occurs if a clutch is lost. In Missouri, 53 pairs attempted a second nest after failure and 5 attempted a third nest with an average of 8.15 days between nest failure and the first egg in a replacement clutch. One pair made 3 unsuccessful attempts to raise a second brood, thus making 4 nesting attempts (Kendrick et al. 2014). One to 4 eggs have been reported in Ontario nests, with over 60% of clutches containing 3 eggs (Peck and James 1987). The normal clutch size is 2-4 eggs, with 3 eggs typical. Four-egg clutches are rare and a 5-egg clutch was reported in Illinois. Clutch size declined with time in Missouri (Graber et al. 1974; Kendrick et al. 2013; McIlwraith 1894; Tyler in Bent 1942; Watt et al. 2020).

The age at first breeding is undocumented. It is likely that second-year birds breed because yearlings with brood patches have been captured. The mating system is typically monogamous (Watt et al. 2020) but Newell et al. (2013) confirmed polygyny in Ohio. One male was mated polygynously in 2 consecutive years and 5 other cases of polygyny were observed. The 6 males were each seen with 2 different females that had nests an average of 110 m apart. Over a 2-year period, at least 6.3% and 21.7% of males were polygynous. Polygynous males had nests on xeric ridges in areas of greater basal area of oaks, and this was preferred habitat. Eleven percent of 53 eastern Ontario males were polygynous (Savignac 2012a).

The wood-pewee forages in the lower edge of the forest canopy, or just below it. In 1 study area, foraging height ranged from 8 to 14 m (mean 11 m), higher than the average foraging height of Least Flycatchers and lower than that of Great Crested Flycatchers. While foraging, the wood-pewee perches more in dead trees or on dead limbs and twigs than other flycatchers. Over 90% of food is obtained by sallying from a perch a distance of less than 1 m to more than 30 m (average 5.2 m) to catch flying insects. It may use the same foraging sites and perches for an entire season. The remainder of food is obtained by gleaning insects from foliage or from the ground. During periods of emergence of aquatic insects, these may be captured near the surface of the water (Graber et al. 1974; Johnston 1971; Keast et al. 1995; Limoges in Gauthier and Aubry 1996; Watt et al. 2020). In Illinois in open-canopy habitat, it foraged in tree species according to their availability. In closed-canopy forest, it foraged in black oak and white oak more than expected and less than expected in sugar maple and red elm based on tree availability. It also foraged more than expected in black locust and hackberry. In open-canopy habitat, the shrub layer (0-5 m from the ground) and subcanopy (6-10 m) were the preferred foraging strata, accounting for 68% of foraging activities; 27% of foraging activity occurred at 11-15 m and 5% at heights of 16 m or more. In closed-canopy habitat, the wood-pewee showed an aversion to foraging in the shrub layer, with only 14% of foraging activity there compared with 36% in open-canopy areas. The subcanopy level was preferred for foraging in closed-canopy forests (37% of activity), with 22% of foraging at heights of 11-15 m and 27% higher than 16 m. It obtained prey by flycatching significantly more often in open-canopy habitat and sallying more often in closed-canopy forest (Hartung and Brawn 2005).

Almost all the diet is comprised of flying insects, although approximately 1% of the food is vegetable matter. The wood-pewee preys on insects 5-30 mm in length, with most food items 10-14 mm long, intermediate in size between the Least Flycatcher and Great Crested Flycatcher. Diet overlap with the Least Flycatcher and Great Crested Flycatcher is 46% and 25% respectively. Most

food brought to nestlings is minute, although occasionally larger items may be brought such as cabbage white butterflies, damselflies, and crane flies. Dominant food items include flies, bugs, moths, butterflies, hymenopterans, beetles, grasshoppers, stoneflies, and mayflies. Young nestlings in 1 nest had consumed 52.5% grasshoppers, 32.5% bugs, and 15% spiders. Another brood had eaten 66% orthopterans, 12.5% flies, 17.5% caterpillars, and 4% spiders. Important insects in adults' diet include flies (house, blow, dance, root-maggot, snipe, and flower flies), beetles (leaf, ground, and long-horned beetles), moths, ichneumonid wasps, ants, leaf bugs, and treehoppers. It also eats spiders and millipedes in small numbers. Vegetable matter eaten includes fruits of elderberries, raspberries, dogwoods, pokeweed, blueberries, poison ivy, and panic grasses. There is a report of it capturing trout fry in a pond. Feeding habits and diet are similar during migration (Graber et al. 1974; Johnston 1971; Kendrick et al. 2014; Tyler in Bent 1942; Watt et al. 2020).

The Eastern Wood-Pewee is vulnerable to Brown-headed Cowbird parasitism and frequently only cowbirds are fledged from parasitized nests (Tyler in Bent 1942; Watt et al. 2020). The rate of parasitism is low throughout its range at 5.4% (Underwood et al. 2004). In Ontario, 5.5% of 165 nests were parasitized (Peck and James 1997) and 1 of 202 eastern Ontario nests (0.5%) was parasitized (Falconer and Nol 2020). In Missouri, 4 of 310 nests (1.3%) and 0 of 133 nests were parasitized (Kendrick et al. 2013; Roach et al. 2018). In Manitoba, Underwood et al. (2004) monitored 20 wood-pewee nests and added real or artificial cowbird eggs to 12 nests. None of the nests were parasitized naturally by cowbirds, and all parasitic eggs were accepted. The low frequency of wood-pewee parasitism may be to high placement of nests and breeding season asynchrony. Average wood-pewee nest height was 7.0 m. In the same area, Yellow Warblers were a common host of the cowbird, but nests higher than 5 m from the ground were rarely parasitized. The average date of wood-pewee clutch initiation was 23 June whereas the average last date of egg laying by cowbirds was 25 June. Wood-pewees are highly aggressive toward cowbirds and this may deter parasitism (Watt et al. 2020).

The wood-pewee is not considered vulnerable to forest fragmentation because it breeds in small remnant woodlots. In West Virginia, Farwell et al. (2019) examined its response to shale gas infrastructure, which consisted of well pads, access roads, and pipelines. It increased in abundance near all facilities. The forest gaps created by infrastructure provided additional habitat for it. In fragmented Illinois forests, the ratio of hatching-year to after-hatching-year birds was 0.2 indicating poor reproductive success (Robinson 1992; Watt et al. 2020). In New Jersey, Rich et al. (1994) examined the effects of different widths and types of fragmenting corridors on the wood-pewee. It was significantly more abundant adjacent to unpaved roads creating an opening 8 m wide than adjacent to 23-m wide power-line corridors. In South Dakota, it was significantly more abundant in large contiguous riparian forests than in small, isolated woodlots (Gentry et al. 2006).

The wood-pewee is unaffected by forest harvesting, or increases. A review of 42 studies on the effects of partial harvesting of forests found no significant effects on the wood-pewee (Vanderwel et al. 2007). Holmes and Pitt (2007) examined the effects of selection harvesting near Sault Ste. Marie in northern hardwood stands. It increased after stands were harvested. In Algonquin Park, Jobes et al. (2004) and Tozer et al. (2010) found no difference in abundance of wood-pewees in areas subjected to varying intensities of group-selection forest harvesting (0.5 and 4 gaps per ha). In

Illinois, Robinson and Robinson (1999) created openings of 0.02-0.4 ha within a 2,000-ha forest. The wood-pewee was significantly more abundant in recently cut ravines than in uncut ravines, but was not affected by logging on ridges. In Minnesota, it exhibited a modest increase following timber harvest (Hanowski et al. 2002). Forestry practices that convert woodlands to areas dominated by poplars are detrimental because this habitat is seldom used. Removal of old large trees, dying trees, and snags has a negative effect due to loss of foraging and nesting habitat (Niemi et al. 1995; Pashley and Barrow 1992). In Missouri, daily nest survival rate was negatively correlated with mean canopy cover within 150 m of the nest. A more open canopy may provide an ideal mix of perching sites and open spaces to maximize foraging efficiency (Roach et al. 2018).

Although the wood-pewee nested in similar densities in pine plantations and deciduous forests in eastern Ontario, nesting success was lower in plantations due to higher abundance of predatory red squirrels and Blue Jays. In plantations, nest survival was higher where trees were more dispersed. Nests further from tree trunks had better survival in deciduous stands (Falconer and Nol. 2020).

In forests sprayed for gypsy moth control, the Eastern Wood-Pewee had reduced stores of subcutaneous fat, probably due to reduced populations of insect prey. The diet of those on sprayed and unsprayed plots differed significantly, with flies and bugs being more important in the diet on sprayed plots (Sample et al. 1993).

In North Carolina, abundance of the wood-pewee was negatively correlated with the number of houses and buildings within 200 m of the centre of the habitat patch (Lumpkin and Pearson 2013). In urban forests of Chicago, it had strong negative associations with distance to edge and amount of urban cover. It exhibited a strong positive response to increases in oak trees and a negative association with nonnative honeysuckles (Schneider and Miller 2014). Other studies have observed lower densities of the wood-pewee in sites heavily invaded by honeysuckle than in sites with native shrub understories.

Browsing by white-tailed deer may have contributed to the decline of the Eastern Wood-Pewee. In the northeastern states, it was not found breeding on plots with more than 8 deer per km^2. Heavy browsing results in fewer trees in the subcanopy, the area where it typically forages (Niemi et al. 1995; Watt et al. 2020). Nonetheless, the wood-pewee persisted at Rondeau when deer populations were as high as 55 per km^2 (Savignac 2012a).

In Quebec, declines of sugar maple forests affected wood-pewee breeding densities. In stands affected by die-back, densities were 27% lower than in healthy stands. Die-back of the canopy had adverse effects on birds inhabiting the upper canopy; species preferring the shrub layer increased (DesGranges et al. 1987).

In Pennsylvania, Rohnke and Yahner (2008) examined the same woodland twice 16 years apart. During this time, overstorey and subcanopy tree density decreased as did short shrubs, but tall shrub density increased. The Eastern Wood-Pewee declined by 90% apparently due to changes in forest structure. Habitat quality for it may decline as second-growth forests mature, and large tracts of homogeneous deciduous forest with few canopy gaps are of lesser quality (Ahlering and Faaborg 2006).

In New Jersey and Pennsylvania, hemlock declined from 56% of the total basal area to 46% due to the hemlock woolly adelgid; the amount of deciduous understorey increased. The wood-pewee responded favourably to hemlock decline and increased (Toenies et al. 2018).

In Georgia, the Eastern Wood-Pewee increased relative to fire severity. More severe fires suppressed the understorey and created more open-canopy conditions, resulting in higher insect abundance and improved foraging habitat (Klaus et al. 2010). In North Carolina pine-oak forests, it also responded favourably to fire. It occurred more frequently immediately following fire, regardless of its severity and declined with time since fire. Peak occupancy occurred at sites where there had been a severe burn in the past 0-5 years (Rose and Simons 2016). Fire suppression may be a limiting factor for the wood-pewee.

Status

The Eastern Wood-Pewee has always been a common breeding species in Ontario, and it presumably was more abundant before extensive forest clearing took place. McIlwraith (1894) stated that it was distributed throughout the province and Baillie and Harrington (1937) considered it a fairly common breeder north to southern Thunder Bay and southern Sudbury districts. They noted that there were breeding season records further north from Spanish River, Lake of the Woods, and Temagami. During the first atlas, it was common in most of Ontario south of the French and Mattawa rivers (Rising in Cadman et al. 1987). James (1991) considered it common in the south, becoming locally uncommon in the north to Woodland Caribou Provincial Park and Cochrane.

The second atlas indicated that the province-wide probability of observation of the Eastern Wood-Pewee had not changed significantly since the first atlas. Significant declines occurred in the Great Lakes–St. Lawrence Forest Region both in and south of the Canadian Shield, with a significant increase in the Boreal Forest Region. It was most abundant south of the Shield where it occurred in almost every square and its probability of observation was over 80%. Highest densities occurred in a broad band along the southern edge of the Shield, on the Bruce Peninsula, in a band from Toronto to Wellington County and down to Long Point, and in a few smaller areas south of the Shield (McLaren in Cadman et al. 2007).

Although there has been no historical change in the Eastern Wood-Pewee's North American breeding distribution (Watt et al. 2020), BBS data indicate a significant continental decline. An exception is in Illinois where its population has remained stable since the early 1900s despite substantial changes to the structure and composition of forests due to widespread logging in the 1800s and early 1900s, exposure to pesticides, and reductions in wintering habitat (Walk et al. 2011). Over the long-term (1970-2021), trends determined by the BBS were annual decreases of 2.17% in Canada and 1.61% in Ontario. The short-term trends (2011-21) were increases of 0.911% annually in Canada and 0.902% in Ontario. The reliability of all results was high (A.C. Smith et al. 2023).

The Eastern Wood-Pewee has been designated special concern nationally and provincially.

POSTFLEDGING PERIOD

Fledglings can fly when they leave the nest, but those younger than 18 days old often remain lower in shrubs. They follow the adults around begging for food for 3-4 weeks after fledging (Watt et al. 2020).

In Ohio, juvenile and adult Eastern Wood-Pewees moved to densely regenerating clear-cuts during the post-breeding period. Early successional habitats may be important shortly after breeding because they provide dense cover and abundant food resources (Vitz and Rodewald 2006, 2007). In Michigan, Akresh et al. (2009) captured 100% of juvenile wood-pewees in riparian versus upland habitat. Riparian habitat was dominated by trembling aspen with an understorey of alder and honeysuckle. Upland habitat was even-aged trembling and large-toothed aspen. In Minnesota, Streby et al. (2011b) did not capture any wood-pewees in regenerating clear-cuts during the breeding season, but caught 2 fledglings and 10 adults during the postbreeding season. In Missouri, Porneluzi et al. (2014) netted birds during the postfledging period in an oak-pine-hickory forest 2-15 years after it was clear-cut. There was no significant trend over time in abundance of the wood-pewee during the study.

MIGRATION

The Eastern Wood-Pewee is known to migrate at night due to kills at television towers, but it is unknown if migration also occurs during the day. It has been observed in morning flights in New Jersey suggesting that some diurnal migration occurs (Graber et al. 1974; Watt et al. 2020).

First arrivals usually occur in Ontario around mid-May, although the peak of migration is around the end of May. Autumn migration is predominantly in August, but birds may start to move southward in July. Adults migrate first, and it is regularly seen in small numbers until mid-October (James 1991; Watt et al. 2020).

During migration, the wood-pewee may be found in a variety of habitats where there are trees and shrubs. These include forest edges, early successional clearings, deciduous and mixed woodlands (Watt et al. 2020), hedgerows, and rural and suburban lots. During autumn migration in Pennsylvania, mean abundance was not significantly different in forest interior, forest-agricultural edge, or suburban habitat, but mean abundance in these habitats was significantly higher than in pole-stage forest and shrub-sapling-stage forest (Rodewald and Brittingham 2004). During spring migration in Pennsylvania, it was more abundant in larger forests but no relationship between its abundance and forest size was evident in autumn (Keller and Yahner 2007).

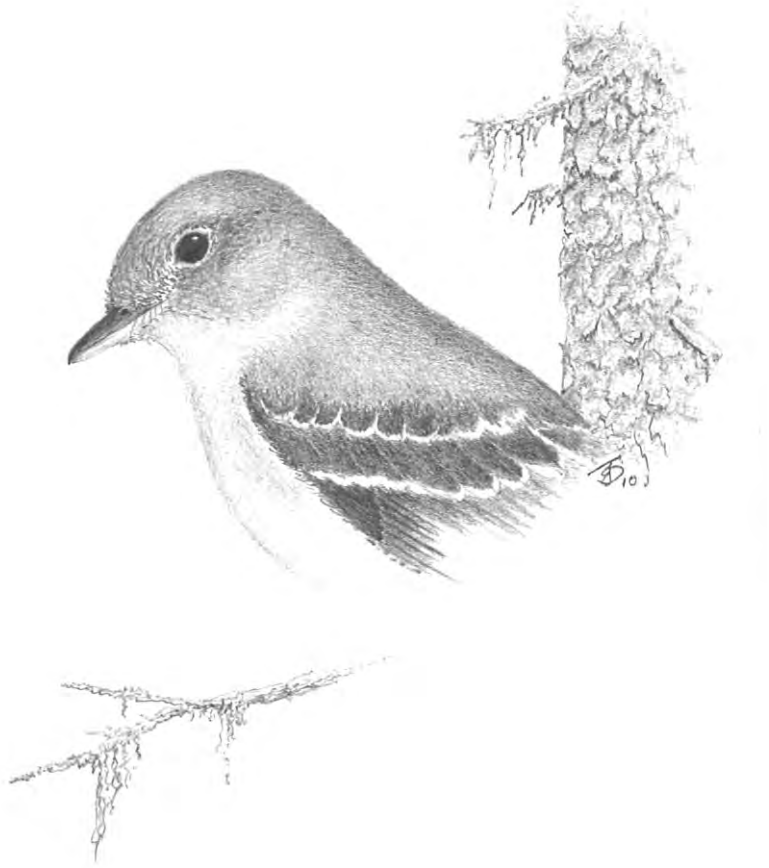
In New York, Zelt et al. (2017) compared spring arrival dates, autumn departure dates, and length of the breeding season for 1888-1939 and 1967-2012. There was little climate change during the first period but significant warming during the second period. Autumn departure was significantly earlier during the second period for the Eastern Wood-Pewee, but there were no differences in spring arrival dates or length of the breeding season.

Collisions with communication towers and other tall structures are a minor source of mortality during migration (Watt et al. 2020).

The Eastern Wood-Pewee is usually solitary during migration, but is common during both spring and autumn migration (James 1991). Banding results from the Long Point Bird Observatory since 1960 show significant increases in both spring (1.5% per year) and autumn (1.8% per year). It declined in the late 1960s, increased during the 1970s and 1980s, and numbers levelled off in the 1990s (Anonymous 2012a; Badzinski 2000; Hussell et al. 1992).

Yellow-bellied Flycatcher

Empidonax flaviventris



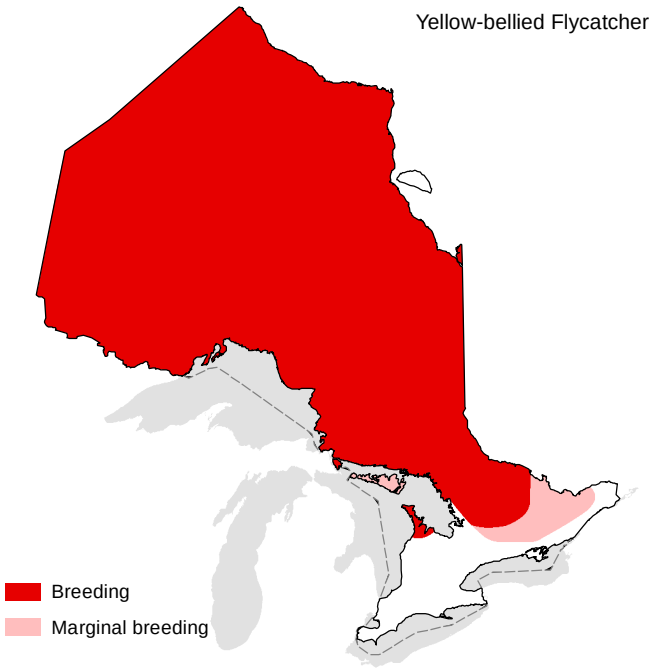
BREEDING SEASON

Habitat Requirements

The Yellow-bellied Flycatcher nests in 2 distinct habitat types: coniferous forests and forested cliffs or steep, rocky slopes. In Ontario, it nests most frequently in bogs and fens dominated by black spruce, and also damp to wet forests of tamarack, white cedar, and balsam fir (Peck and James 1987).

In the Hudson Bay Lowland, the Yellow-bellied Flycatcher occurs wherever there are large forested areas, nesting mostly in spruce-tamarack fens (Wilson and McRae 1993).

In the Boreal Forest Region of Ontario, abundance of the Yellow-bellied Flycatcher was significantly correlated with forest stand age at the local level of 50 ha and the amount of edge and intact mature and old forest at a landscape scale of 5,000 ha. It was associated with older, closed, coniferous forests within a mature forest matrix (Rempel 2007). Near Pickle Lake, it occurred mostly in spruce forests but also in dense jack pine regeneration (James 1980). North of Lake Nipigon, it nested solely within alder swamps (Kendeigh 1947). Near Hearst, it nested in uncut upland mixed



and lowland coniferous stands and in clear-cuts 11-24 years old (Welsh and Fillman 1980). Near White River, it was more abundant in clear-cuts 18-20 years old than in clear-cuts 3-15 and 23-25 years old and in mature forests, but not significantly (Venier and Pearce 2005). In the Clay Belt, it was most abundant in wet stands that were nutrient poor. It was associated with mid-succession forests (Welsh 1993; Welsh and Lougheed 1996).

In the Great Lakes–St. Lawrence Forest Region near Gogama, the Yellow-bellied Flycatcher was characteristic of jack pine stands and was rare to absent when deciduous trees exceeded 10% of cover. The pines in inhabited areas were often only 6-8 m tall, but canopy coverage was always greater than 75% and tree cover was often very dense. In young pine stands, shrubs were almost absent in breeding areas, but shrubs covered as much as 50% of the ground in areas where trees were taller. Sheep laurel and blueberries were the dominant shrubs. Maximum densities occurred in young stands where tree branches were near the ground (James and Peck 1995a). It also occurs in mature and old-growth white pine stands in the Great Lakes–St. Lawrence Forest Region in the Canadian Shield (Kirk et al. 2012). In Algonquin Park, it nests in dense coniferous forests that are a mix of red and white pine, hemlock, white cedar, and balsam fir, as well as in bogs. Dry mixed-wood forests are occasionally used for nesting. The other main breeding habitat includes forested cliffs and talus slopes. These consist of steep, rocky slopes and cliffs as tall as 100 m, and it also nests sparingly in similar habitat along the Niagara Escarpment. In nesting areas, the vegetation is structurally diverse with canopy trees, a sapling and shrub layer (often of wild raisin, grey alder, and mountain holly), and the ground is usually carpeted with mosses or lichens. The understorey is often quite dense (Brunton and Crins 1975; Crins in Cadman et al. 2007; Peck and James 1987; Prescott in Cadman et al. 1987; Tozer 2012).

Throughout its range, the Yellow-bellied Flycatcher occurs predominantly in coniferous forests. In the eastern Boreal Forest Region, it is typical of spruce forests and is more common in young stands (Erskine 1977). In Quebec, it occurs mainly in stands of intolerant hardwoods and jack pine, and is uncommon or even absent in spruce stands and peatlands (Limoges in Gauthier and Aubry 1996). Nonetheless, it nested in young and mature black spruce forests in Quebec and in clear-cuts where saplings were 2-5 m tall. It was absent in younger clear-cuts and recent burns. It was equally abundant in all habitats that it occupied (Imbeau et al. 1999). This flycatcher also prefers cool mountainsides and wet mixed woods with an understorey of mosses strewn with boulders and logs. In subalpine areas of New Hampshire, it occurred midslope where there was no surface water or

some wet depressions present. Average canopy height where it occurred was 9.0 m, canopy closure was 65%, and mean diameter at breast height of trees was 10 cm (Sabo 1980). There are some geographical variations in its habitat preferences. Most authors stated that it is associated with dense, young coniferous or mixed stands, but others found it more often in mature or open stands. It is usually found in mesic sites that are nutrient poor. A study of populations in mixed-wood stands found that it was associated with increasing abundance of spruce or balsam fir. In another area, it occurred only in hemlock–yellow birch forests (Beals 1960; Bent 1942; Campbell et al. 1997; Dawson 1979; DeGraaf and Chadwick 1987; Gross and Lowther 2020; Kirk et al. 1996; McLaren and McLaren 1981; Niemi and Pfannmuller 1979; Smith 1957; Temple et al. 1979; Thompson et al. 1999; Walkinshaw and Henry 1957b).

Ralston et al. (2019) surveyed for the Yellow-bellied Flycatcher in boreal forest habitat at 20 locations in New York, Vermont, Maine, Nova Scotia, and Newfoundland. It was observed at 19 of the 20 sites indicating that it had broad habitat preferences and an ability to use multiple boreal forest habitats.

In Newfoundland balsam fir stands, Whitaker and Montevecchi (1997, 1999) considered the Yellow-bellied Flycatcher a forest-interior specialist. It was significantly more abundant in forest interior than in riparian forest edges, but there was no significant difference in its abundance in forest interior and nonriparian forest edges. There was also no difference in its abundance in riparian areas of extensive forests and in 20-50-m wide riparian strips retained adjacent to clear-cuts. In balsam fir–white cedar forests in eastern Quebec, there was no significant difference in its density in riparian and nonriparian stands (LaRue et al. 1995). In Minnesota, its abundance was positively correlated with lowland conifers, black spruce, and tamarack. Forty-five percent of the variation in its abundance was related to nutrient-poor stands of black spruce, tamarack, and white cedar; 28% with patch richness within 500 m; 14% with increasing stand age; and 11% with stand area. The Yellow-bellied Flycatcher was the most abundant boreal species and was found in most stands and point locations. It appeared to breed in most lowland coniferous forests. It preferentially selected nutrient-poor stands surrounded by a variety of forest types. The models for it were not significant, suggesting that it was a generalist species (Zlonis et al. 2017).

All Ontario nests were on the ground, usually in mosses but occasionally in grasses or leaves. Hummocks in moss and moss-covered logs were frequently selected for nest sites (Brunton and Crins 1975; Peck and James 1987).

Ontario nests are typical of those reported throughout the Yellow-bellied Flycatcher's range. The centre of the nesting territory is usually heavily vegetated with mosses, forbs, sedges, ferns, shrubs, and small trees. The nest site is characteristically cool, moist, and shady. Nests are usually on the ground in mosses, but occasionally in mud or cavities in upturned roots of fallen trees. Some nests were under roots of standing trees or stumps, and on cliffs near watercourses. The nest is usually extremely well hidden and invisible from directly above and embedded in moss or at the base of a fern under dead stems from the previous year (Bent 1942; Gross and Lowther 2020; Walkinshaw and Henry 1957b).

Little information on territory size is available. Limoges (in Gauthier and Aubry 1996) reported that the territory size of a single pair near Black Sturgeon Lake in Ontario was 1.01 ha in an alder swamp. In Pennsylvania, territories were 0.7-1.0 ha (Gross and Lowther 2020). In subalpine areas of New Hampshire, territories averaged 1.8 ha (Sabo 1980). In Alaska, singing males were at least 100 m apart (Gross and Lowther 2020).

No information is available on natal philopatry or breeding site fidelity by adults.

Limiting Factors

Eggs have been found in Ontario nests from the second week of June until the third week of July, but most clutches are present during the last third of June (Peck and James 1987, 1997). In Algonquin Park, clutches usually occur in the last half of June and young hatch in the first half of July (Brunton and Crins 1975). Eggs are laid at 1-day intervals, and incubation presumably begins with the laying of the last egg. The incubation periods of 2 Ontario nests were at least 13 days and 15 days. Elsewhere the incubation period has been determined to be 15 days and young fledge when they are 13-15 days old (Gross and Lowther 2020; Peck and James 1987, 1997; Walkinshaw and Henry 1957b).

Usually only 1 brood is raised annually, but some pairs in the Appalachians are double brooded. Egg dates in Wisconsin suggest that double-brooding may occur there. The male tends to the first brood while the female builds another nest for the second brood in a new location within the territory. The original nest may be used for the second brood. It is unknown if renesting occurs after a clutch is lost. Clutches of 4 and 5 eggs have been reported in Ontario, with most containing 4 eggs. Elsewhere, most clutches contain 4 eggs, with 3-and 5-egg clutches uncommon to rare respectively. In second clutches in Pennsylvania, 5 contained 3 eggs and 2 contained 4 eggs (Bent 1942; Brunton and Crins 1975; Campbell et al. 1997; Gross and Lowther 2020; McIlwraith 1894; Walkinshaw and Henry 1957b).

The age at first breeding is 1 year, and the mating system is seasonally monogamous. In Pennsylvania, unmated males defended territories adjacent to mated males, providing the potential for extra-pair mating (Gross and Lowther 2020).

The Yellow-bellied Flycatcher obtains most food by sallying from a perch to catch flying insects, but also gleans invertebrates from vegetation. It forages predominantly in the understorey, particularly in low, dense conifers and shrubs. In Ontario, 72% of foraging occurred in deciduous trees and 28% in conifers (Greenberg et al. 1999). In New Hampshire, 42% of foraging was on coniferous foliage and 56.8% was on deciduous foliage. Foraging heights were 1.1% at 0.1-2 m, 47.5% at 2-5 m, 42.4% at 5-8 m, and 8.9% above 8 m (Sabo 1980).

Kendeigh (1947) analyzed the stomach contents of 2 birds north of Lake Nipigon. By frequency, the diet consisted of 25.8% spiders, 24.7% beetles (including click and leaf beetles), 23.7% lepidopterans, 12.1% dance flies, 6.3% stink bugs, 6.3% ants, and 1.1% lepidopterans. An examination of 103 stomachs revealed that 97% of the diet consisted of animal material and the remainder was vegetable matter. The diet consisted of 46.3% hymenopterans (including 13.4% ants), 16.5% beetles, 14.9% flies (house, crane, and horse flies), 8.5% spiders, and adult and larval moths. Vegetation that the Yellow-bellied Flycatcher ate included mountain-ash berries, poison ivy berries, cedar foliage,

and general vegetation rubbish. In the breeding season, it eats midges, stoneflies, crane flies, beetles, small caterpillars, spruce budworm larvae, and mosquitoes (Bent 1942; Crawford and Jennings 1989; Graber et al. 1974; Gross and Lowther 2020). Near Manitouwadge, abundance of the Yellow-bellied Flycatcher was not correlated with spruce budworm abundance (Venier et al. 2009). Similar results were found in New Brunswick (Morris et al. 1958). Mitchell (1952) analyzed the contents of 10 stomachs in 2 years during a spruce budworm outbreak in Maine. By volume, they contained 0% and 10% budworm larvae and pupae.

The Yellow-bellied Flycatcher is not very vulnerable to cowbird parasitism and few parasitized nests have been reported. Of 18 Ontario nests and 6 Michigan nests, none were parasitized (Peck and James 1997; Walkinshaw 1961). Campbell et al. (1997) reported that 2 British Columbia nests were not parasitized and that only 3 parasitized nests had been documented in North America. The habitat and range of the Yellow-bellied Flycatcher and Brown-headed Cowbird do not overlap much.

Conversion of coniferous forests to intolerant hardwoods may reduce habitat quality for the Yellow-bellied Flycatcher. Its primary habitats, coniferous swamps and talus slopes, are typically protected from forestry and development activities. Forest fragmentation may result in drying and loss of mosses that nests are associated with (Gross and Lowther 2020). Vanderwel et al. (2009) reviewed studies on the effects of partial harvesting of forest. There was no evidence of change in its abundance when 30%, 50%, or 70% of trees were removed. In the Canadian Shield of Ontario, there was no difference in its abundance in early successional clear-cuts and burns, but it was significantly more abundant in mid-successional clear-cuts than in mid-successional burns. It was equally abundant in early successional, mid-successional, and mature stands (Zimmerling et al. 2017). In Newfoundland, it occurred in 49% of cut forests and 38% of natural forests. Its presence was unaffected by the amount of forest cover in the landscape (Taylor and Krawchuk 2005). Whitaker et al. (2008) netted 59% of birds in cut forests and 41% in natural forests. In Minnesota, where it was the most abundant species, Zlonis et al. (2017) did not find it in clear-cuts and concluded that it would be negatively affected by extensive logging.

On Anticosti Island, the Yellow-bellied Flycatcher was able to use the ground layer of vegetation in a recently harvested clear-cut despite high densities of white-tailed deer. Browsing by deer reduced the amount of deciduous cover, especially white birch, but spruce was unaffected. It preferred coniferous cover (Cardinal et al. 2012).

In Alberta, there were no significant differences in the abundance of the Yellow-bellied Flycatcher at seismic lines, pipelines, or well pads than in forest interior adjacent to these features (Bayne et al. 2016).

Burris and Haney (2005) studied the impact of blowdown of spruce-fir forests in Minnesota. Blowdown resulted in a significant decline in canopy cover and an increase in the shrub layer. Significantly more Yellow-bellied Flycatchers occurred in the blowdown than in control plots. Its presence was correlated with shrub cover, and possibly coarse woody debris.

Price (2004) predicted that the Yellow-bellied Flycatcher would disappear as a breeding species in southern Ontario if the average summer temperature increased by 2°C. In the Boreal Forest Region

of Quebec and Labrador, its abundance was associated with cooler breeding season temperatures and relatively lower amounts of breeding season precipitation. Warming trends might adversely affect it (DesGranges and LeBlanc 2012).

Status

McIlwraith (1894) had records of the Yellow-bellied Flycatcher only during migration, but correctly presumed that it bred in the province. He considered it scarce everywhere. Baillie and Harrington (1937) stated that it was a summer resident from northern Wellington County north to the trans-Canada railway and west to Lake of the Woods. The southeastern breeding limit was Mer Bleue and there was 1 historical breeding record from Amherst Island. At that time, breeding had been confirmed from Wellington and Bruce counties and Parry Sound and Muskoka districts. Smith (1957) found it well distributed in the Clay Belt, and Brunton and Crins (1975) stated that it was more common in Algonquin Park than previously thought. Near Pickle Lake, it was second highest in breeding density to the Ruby-crowned Kinglet (James 1980). During the first atlas, it was fairly common within its breeding range, and more abundant in the north. It ranged sparingly throughout the Canadian Shield to the northern extent of the province, with scattered records from the Bruce Peninsula and Manitoulin Island (Prescott in Cadman et al. 1987). No evidence of breeding was found in Wellington and there was only 1 record from Grey during the first atlas. Peck and James (1997) reported a nest from Grey, which was the most southerly recent record. James (1991) termed the Yellow-bellied Flycatcher uncommon in the north and rare in the south to southern Georgian Bay and Brockville.

The second atlas indicated that the Yellow-bellied Flycatcher was somewhat more widespread than documented during the first atlas, and its probability of observation more than doubled province-wide. Significant increases in its probability of observation occurred in the Canadian Shield and Hudson Bay Lowland. Greatest abundance was in the northern Shield, particularly in a wide band north of Sault Ste. Marie and New Liskeard and south of a line from Moosonee to Red Lake (Crins in Cadman et al. 2007).

Long-term (1970-2021) population trends determined by Breeding Bird Survey (BBS) results indicated annual increases of 2.23% in Canada and 2.38% in Ontario. Short-term (2011-21) trends were annual increases of 7.67% in Canada and 0.855% in Ontario. Reliability of the data was medium for long-term trends and low for short-term trends (A.C. Smith et al. 2023). Gross and Lowther (2020) stated that the Yellow-bellied Flycatcher was notoriously overlooked on the BBS and concluded that its abundance was underestimated.

POSTFLEDGING PERIOD

In Minnesota, Streby et al. (2011b) captured 4 Yellow-bellied Flycatchers during the breeding season in regenerating clear-cuts. They caught 6 fledglings and 25 adults during the postbreeding period. Major and Desrochers (2012) also captured Yellow-bellied Flycatchers in clear-cuts during the postfledging period in Quebec.

MIGRATION

The Yellow-bellied Flycatcher is a late spring migrant. At Long Point, few are observed before 24 May. Usually migration is over there by 10 June, but stragglers have occurred until 15 June. Ninety

percent of birds occurred in the 19-day period of 22 May to 9 June. Males migrated earlier in spring than females, and second-year birds probably migrated later than older birds. Twenty-two percent of males occurred prior to 21 May, the earliest date for a female. It is an early autumn migrant that probably spends no more than 66 days on the breeding grounds. At Long Point, the earliest adult arrived on 18 July and the latest was 31 August. Most adults occurred in a 33-day period from 25 July to 26 August, with 8 August the median date. Juveniles arrived in the second or third week of August. Most juveniles passed through in the 28-day period of 18 August to 15 September. There was no apparent differential timing by sexes (Hussell 1982a). In eastern North America, peak numbers of autumn migrating adults occur in mid-August. Juveniles migrate approximately 24 days later, with peaks in late August and early September (Hussell 1982b). Bent (1942) stated that it left the breeding grounds in the last half of August. He reported that migration at Point Pelee started in mid-August and continued well into September.

During migration, the Yellow-bellied Flycatcher occurs in swamp thickets along streams, on borders of swamps and ponds, in flooded willow swamps, in birch stands near beaver ponds, at edges of open trembling aspen stands, and in second-growth deciduous stands. It may also frequent edges of black spruce muskegs, mature spruce–trembling aspen–white birch stands, young to intermediate-aged trembling aspen stands, and hedgerows (Bent 1942; Campbell et al. 1997; Gross and Lowther 2020).

Because it is a nocturnal migrant, the Yellow-bellied Flycatcher is prone to being killed at television towers and other tall obstructions (Graber et al. 1974; Weir 2008).

In Pennsylvania, an infestation of the viburnum leaf beetle resulted in an almost complete loss of southern arrowwood, which previously was the third most abundant shrub species. The number of spring migrating Yellow-bellied Flycatchers decreased significantly after the loss of the arrowwood (Smith and Hatch 2017).

The Yellow-bellied Flycatcher is an uncommon migrant that is more frequent in autumn (Hussell 1982a; James 1991).

Early migration monitoring data at Long Point suggested a significant decline in the 1960s, a major increase in the 1970s, and a small decline in the 1980s. Based on these data, the population would be 22% of when banding was initiated (Hussell 1991a; Hussell et al. 1992). Badzinski (2000) analyzed trends at Long Point during migration and stated that spring numbers have been stable since 1960 but autumn numbers have declined significantly by 2% per annum. She concluded that Long Point might be sampling 2 separate populations that followed different spring and autumn routes.

Acadian Flycatcher

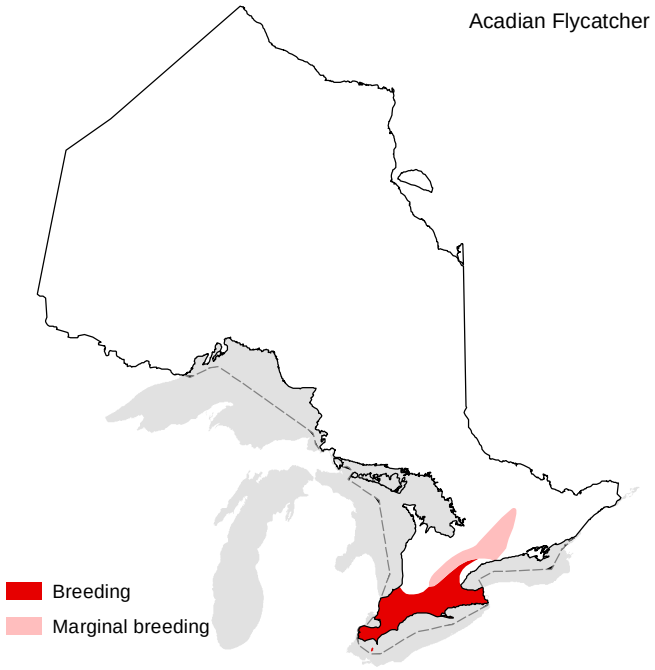
Empidonax virescens

BREEDING SEASON

Habitat Requirements

The Acadian Flycatcher breeds in mature deciduous forests, predominantly in maple-beech woodlands. One Ontario nest was in a wooded sand dune and another was in a heronry (Peck and James 1987). In Ontario, its primary habitat requirements are large, mature, deciduous forests with a closed canopy, limited woody growth in the understorey, and a watercourse or pools of water. In Elgin County, it breeds in heavily wooded ravines near Lake Erie and in larger upland forests. Ravines appear to be preferred in Ontario, possibly because they are less likely to be logged and have undisturbed older-growth features (Heagy 2010; Lancaster et al. 2004).

Forest composition and structure are very important habitat components in Ontario. The first Ontario nest was found in a mature, extensive black ash forest. The Acadian Flycatcher also nests in



mature red and silver maple swamps, but appears to prefer sugar maple–beech forests and black maple forests if water is present. Wooded ravines are favoured habitat. Almost invariably, canopy trees are tall and the canopy is completely or almost closed. Uneven-aged stands may be preferred. The understorey is very open with very few saplings, few if any shrubs, and the ground is virtually devoid of vegetation in prime habitat (Bisson et al. 2000; Martin et al. 1999; McCracken 1999a; Page and Cadman 1994a; Snyder 1953; Wormington 1977).

Elsewhere, the Acadian Flycatcher has been considered associated with old-growth and mature forests, and typically occurs in pure deciduous stands or deciduous stands with limited numbers of conifers. Preferred habitats in Illinois were floodplain forests and steep ravines in upland forests (Walk et al. 2011). In New Jersey, it was significantly more abundant in hardwood swamps than in oak-pine forests (Rich et al. 1994). In South Carolina, it was found only in mature bottomland deciduous forests and was absent in mid- and early succession bottomland forests. In Wisconsin, it breeds in many old coniferous plantations. Plantations used were mature, had closed gaps in pre-existing oak forests, had undergone 1 or more commercial thinnings, and had developed deciduous understories. Most authors state that it is found where there are limited numbers of saplings or shrubs, but in the mid-Atlantic states and Ohio, it was positively associated with foliage density 0.3-1 m tall. In Ohio, territories contained 50% greater arthropod biomass and 250% lower understorey vegetation density than unoccupied areas, but distribution within stands did not appear to be related to any other vegetation features. Forest types it has nested in elsewhere include hemlock, sugar maple–beech, mixed pine-maple, black gum swamps, pine stands heavily undergrown with hardwoods, upland oak with mixed hardwoods, oak-maple-poplar, beech-maple-hemlock, riparian cottonwood–sugar maple–Manitoba maple, beech–yellow birch–oak-maple, maple-ash-basswood, and oak-hickory (Allen et al. 2009; Bakermans and Rodewald 2006; Bielefeldt and Rosenfield 1994; Buffington et al. 1997; Bushman and Therres 1988; Christy in Bent 1942; Gates and Giffen 1991; Haney 1999; Hespenheide 1971a; Mossman 1988; Mossman and Hoffman 1989; Mumford 1964; Newman 1958; Noon et al. 1979; Robbins et al. 1989; Temple et al. 1979; Walkinshaw 1966a).

Benzinger (1994) concluded that the Acadian Flycatcher was associated with hemlock in New Jersey. In Pennsylvania and New Jersey, it was closely associated with hemlock. Ninety percent of all nests were in hemlock and this tree species was used for nesting more than expected. Use of hemlock for nesting ranged from 66.7 to 100% (Allen et al. 2009). In New Jersey and Pennsylvania

over a 15-year period, hemlock declined from constituting 56% of the total basal area to 46% due to the hemlock woolly adelgid; the amount of deciduous understorey increased due to creation of gaps in the canopy. The Acadian Flycatcher was adversely affected by the hemlock decline and its population decreased more than any other species (Toenies et al. 2018).

Presence of water appears to be an essential habitat component, and most nests are over pools of water or streams. Forested streams of almost any size may be used including small spring branches well up into wooded hills. Territories are often linear along watercourses. Preferred watercourses usually have steep ravines with closed-canopy forest. Complete breeding failure in Haldimand County in 1998 was attributed to drought that resulted in woodland pools drying up. Territorial males failed to attract mates, presumably because the habitat lacked the necessary open pools of standing water. This suggests that water is critical habitat. In Ohio and Illinois, however, successful nesting was reported in woodlands without water (Chapa-Vargas and Robinson 2007; Christy in Bent 1942; Graber et al. 1974; Martin et al. 1999; McCracken 1999a; Mossman 1988; Mumford 1964; Page and Cadman 1994a; Robinson 1992).

In Ohio, the Acadian Flycatcher occurred only in forests that were at least 85 m wide (Bakermans and Rodewald 2006). In Illinois, it nested in riparian forests 80-3,170 m wide (no narrower woodlands were studied). Distribution of 359 nests indicated that it rarely nested near anthropogenic edges. A larger number of nests than expected occurred within the first 5 m and 50 m from forest-creek edges but frequencies of nests near a beaver pond and backwater swamps were somewhat less than expected. Narrow floodplain corridors did not create an ecological trap because birds experienced higher than normal nesting success (Chapa-Vargas and Robinson 2007). In Ontario, it often nests in forested ravines and riparian corridors that may be as narrow 200 m in width (Heagy 2010). In Georgia, the Acadian Flycatcher was equally abundant in narrow, medium, and wide corridors, but the narrow corridors in that area were fairly wide, ranging from 36 m to 330 m. It was less likely to be found in wider corridors (480-2,088 m), but the differences were not significant (Hodges and Krementz 1996). Lindell et al. (2007) reviewed studies that determined presence and abundance of the Acadian Flycatcher in relation to edge and concluded that it avoided forest edges. In Tennessee, Kroodsma (1984) examined its distribution in relation to an edge created by a hydro corridor. It appeared to be negatively affected by the presence of edge, with populations significantly denser in forest interior. Birds were detected as close as 40 m to edge. Rich et al. (1994) found that it was more abundant on forest-interior point counts than on edge counts in New Jersey, but had insufficient data to test this statistically. Successful nests in Ohio were significantly further from forest edge (90.1 m) than unsuccessful nests (64.0 m; Bakermans and Rodewald 2006).

The Acadian Flycatcher is area sensitive and requires woodlands much larger than its territory size. Although it may occasionally occur in smaller woodlots (1-5 ha), forests 30-36 ha appear to be the minimum size to support a population. In other regions, it has been estimated that 30-50 ha and 38-120 ha are required for a viable population. In Ontario, 92% of forests supporting this species are larger than 25 ha and 56% of patches are larger than 100%. Of the 14 most productive breeding sites in Ontario, 11 are in areas with more than 30% forest cover within 1 km (Austen et al. 1994; Bushman and Therres 1988; Friesen et al. 2012; Page and Cadman 1994a; Robbins 1979). The abundance of the Acadian Flycatcher was correlated with larger forests in Pennsylvania (Keller and Yahner 2007).

Nests are in live deciduous trees or shrubs, almost always in the terminal fork of a horizontal or down-sloping limb. Nests frequently hang over a stream or pool. An open space below the nest is important because adults require space to fly, hover, and manoeuvre close to the nest. Ontario nests were in beech (a favoured species), sugar maple, hemlock, yellow birch, flowering dogwood, and hawthorn. Elsewhere, it has nested in hophornbeam, blue beech, red elm, willow, hemlock, shagbark hickory, white oak, white elm, basswood, elderberry, hazelnut, witch-hazel, flowering dogwood, black oak, and red maple. In many areas, hemlock is the preferred nest tree. In each woodlot, 1 species of tree or shrub appears to be favoured for nesting, although the structure of the vegetation may be more important than the species (Allen et al. 2009; Bisson et al. 2000; Bushman and Therres 1988; Christy in Bent 1942; Graber et al. 1974; Martin in Cadman et al. 2007; Martin et al. 1999; McLaren 1974; Mumford 1964; Newman 1958; Peck and James 1987; Schumacher 1995; Snyder 1953; Walkinshaw 1966a). Ontario nests were 0.5-3.5 m from a trunk and 2-9 m from the ground, with most 3-6 m up (Bisson et al. 2000; Peck and James 1987). Overall, nest heights of 1-16.7 m have been reported, with an average height of approximately 4 m. In Pennsylvania and New Jersey, average height of nests, which were mostly in hemlock, was 5.8 m and 6.2 m with an overall average of 6.0 m (Allen et al. 2009; Christy in Bent 1942; Graber et al. 1974; Mumford 1964; Walkinshaw 1966a; Wilson and Cooper 1998a). Often nest material is scavenged from old nests, and occasionally old nests are repaired and used again (Christy in Bent 1942; Peck and James 1987). There is a record of it using an old vireo nest (Allen et al. 2020).

In addition to Acadian Flycatchers, other species may be expelled from the territory including Downy Woodpecker, Eastern Wood-Pewee, Least Flycatcher, Ovenbird, Cerulean Warbler, Scarlet Tanager, vireos, chipmunks, and squirrels. Territories seldom border each other, and the female defends a small area (approximately 120 m^2) around the nest. Males defend a larger territory. In southern Ontario, mean distance between territories was 500 m. Over 2 years, territories averaged 2.7 ha (range 0.76-4.09 ha) and 1.94 ha (range 0.94-3.09 ha). In Illinois, 4 territories were 0.7-1.7 ha (average 1.1 ha). In Pennsylvania, males had territories that averaged 1.0 ha. One Michigan study reported that 13 territories averaged 1.0 ha (range 0.5-1.6 ha). Another Michigan study documented the size of 80 territories. The average size was 1.2 ha (range 0.7-1.7 ha). Fifteen Indiana territories averaged 1.6 ha (range 0.8-2.8 ha). This study was undertaken during a drought year and territories are larger in dry years or in dry sites due to a lower density of insects on leaves (Allen et al. 2020; Christy in Bent 1942; Evans et al. 2009; Graber et al. 1974; Heagy 2010; Mumford 1964; Walkinshaw 1966a).

Natal philopatry rates appear to be very low. In Michigan, 103 nestlings were banded and 0 returned to nest (Walkinshaw 1966a). In Indiana, 1 of 218 (0.5%) hatch-year birds returned (Allen et al. 2020).

Adult site fidelity is high. Almost all adults returned to the same or adjacent territory in Michigan. Males apparently maintain the same territory for their lifetime. Territories usually remain the same but expand if a previous neighbour does not return. Of 31 males that returned in Indiana, 28 returned to the same territory and the other 3 settled within 750 m of the original territory. The average return rate in Ohio was 46% for males and 32% for females. Only 1 male and 1 female changed territories between seasons and no birds shifted territories within seasons. In Ontario,

occupancy of breeding areas is often intermittent, possibly due to the low population (Allen et al. 2020; Heagy 2010; Mumford 1964; Shustack and Rodewald 2010; Walkinshaw 1966a).

Limiting Factors

Males establish territories as soon as they arrive. The shortest interval recorded between males' arrival and completion of nest construction is 11 days. Females begin building the nest 3-11 days after they arrive. Nest building typically takes 1-7 days, but occasionally as long as 2 weeks. Egg laying begins within 1-2 days of nest completion, and eggs are laid daily. Eggs have been found in Ontario from 10 June until the end of July, with most present from mid-June until the end of the first week of July. Incubation may start with laying of the penultimate egg. The incubation period is 13-15 days, with most eggs taking 14 days to hatch; clutches usually hatch within a single day. The nestling period is 12-18 days, but young may leave the nest at age 8-11 days if disturbed. In Michigan, the mean nestling period was 13.9 days (range 13-15 days). In Ontario, fledging may occur as late as mid-August. In Indiana, young did not fledge from 1 nest until the first week of September (Allen et al. 2020; Christy in Bent 1942; Fields 1990; Graber et al. 1974; McLaren 1974; Mumford 1964; Newman 1958; Page and Cadman 1994a; Peck and James 1997; Walkinshaw 1961, 1966a; Wilson and Cooper 1998b).

Two broods may occasionally be raised, particularly in the south, but double-brooding also occurs commonly in Michigan. Evans et al. (2009) confirmed 2 cases of double broods in Ontario. Double broods were common in Pennsylvania with 21.8% and 42% of females attempting 2 broods in 2 years. The potential for 2 broods may be related to habitat. In large forests, second broods may be attempted (13.6% in Indiana), but in edge forests adjacent to agricultural lands, only 2.5% attempted second broods. The time required to fledge 2 broods was 76 days in Michigan, with the length of time between fledging the first brood to laying of the first egg in the second clutch ranging from 4 to 10 days. A new nest is built for a second brood, usually within 40 m of the previous nest. One female had 7 nests over 3 years within an area of 0.14 ha; 1 had 10 nests in 3 years within 0.13 ha; 1 had 3 nests 1 year within 0.04 ha; and another had 3 nests 1 year within 0.07 ha. Renesting is common if a clutch is lost, and as many as 4 renesting attempts may be made. Clutches of 1-4 eggs have been reported in Ontario, with 3 eggs most common. Throughout the Acadian Flycatcher's range, clutches of 1-5 eggs have been documented, with 1-egg and 5-egg clutches very rare. The most frequent clutch size is 3 eggs. Early nests may have larger clutches, and clutch sizes tend to increase northward (Allen et al. 2020; Baillie and Harrington 1937; Christy in Bent 1942; Graber et al. 1974; McLaren 1974; Mumford 1964; Page and Cadman 1994a; Peck and James 1997; Walkinshaw 1961; 1966a; Wilson and Cooper 1998b).

The age at first breeding is 1 year, but 10% or more of territorial males may not attract a mate. The mating system is typically monogamous. The same pair stays together for renesting attempts and second broods. Two cases of bigamy were documented in Michigan. One male had 2 mates and fed young in both nests. Another had 2 mates in territories 578 m apart with 1 or 2 other Acadian Flycatcher territories in between. Polygyny has also been confirmed in Ontario, Indiana, and Pennsylvania. Ontario polygyny rates of 18.8% and 24.1% have been reported (Allen et al. 2020; Heagy 2010; Mumford 1964; Page and Cadman 1994a; Walkinshaw 1966a). Polygyny may be more prevalent than realized due to the difficulty of confirming the presence of more than 1 mate. Many

birds mate for life, but some occasionally select a different mate in subsequent years. Four of 29 southern Ontario nestlings (14%) were the result of extra-pair fertilizations and 3 of 12 pairs (25%) had extra-pair young. No extra-pair young occurred in forest fragments that supported a single pair. Males that sired extra-pair young held territories in the same forest (Evans et al. 2009). In contiguous forest in Pennsylvania, 40% of young were extra-pair. In another Pennsylvania study, 11 of 14 nestlings (78.6%) were extra-pair and 6 of 7 nests (86%) contained extra-pair young. Of 14 nests, 64% contained at least 1 extra-pair young and 57% of young were extra-pair. Two extra-pair sires held territories 1.0 and 1.2 km away from the females that they had mated with (Hung et al. 2008).

Foraging occurs in the lower canopy 0.3-22 m from ground, but mostly at heights of 1.3-4 m. Limited evidence suggests that males may forage higher than females. The Acadian Flycatcher catches prey by hovering and gleaning from vertical tree trunks, undersides of leaves, or clusters of dead leaves, after sitting on an exposed perch searching for prey. It tends to flycatch more in forests with open subcanopies and preferentially fed in beeches in West Virginia. On cool days, it may glean insects from leaves and branches without flycatching; occasionally it forages on the ground. Sallies from perches are mostly directed at prey on leaves. Most sallies are directed upward reflecting its tendency to take prey from the bottom of leaves. In Illinois, it was selective in the trees that it used for foraging. Of species that occur in Ontario, in order of preference, red maple, silver maple, white elm, Manitoba maple, blue beech, shellbark hickory, and sycamore were used more than their availability. From most to least avoided, pumpkin ash, pin oak, green ash, Shumard oak, and bitternut hickory were used less than their availability. Two of the preferred trees, silver maple and shellbark hickory, were uncommon and ranked 18th and 11th in abundance, respectively. The pumpkin ash was strongly avoided, yet was the second-most abundant tree species. A sample of 100 stomachs contained 97% animal matter, predominantly insects. Food consisted of 40.0% wasps, bees, and ants; 18.9% adult and larval moths; 13.8% beetles (weevils and ground, lady, and tiger beetles); 8.2% flies (house and crane flies); 6.4% crickets; 6.0% bugs (leafhoppers, treehoppers, stink bugs, and assassin bugs); 1.0% miscellaneous insects (dragonflies and scorpionflies); and 2.9% spiders, harvestmen, and millipedes. Raspberries were found in 5 stomachs. In West Virginia, 78 food items from 9 stomachs included 22% spiders, 20% caterpillars, 20% beetles, 15% hymenopterans, 13% flies, and 10% bugs. Other invertebrates the Acadian Flycatcher has eaten include damselflies, aphids, cockroaches, termites, isopods, deer flies, and mosquitoes. Food selected ranges from 2 to 12 mm in length. It eats fruits of common elderberry and rough-leaved dogwood (Allen et al. 2020; Christy in Bent 1942; Gabbe et al. 2002; Graber et al. 1974; Hespenheide 1971b; Maurer and Whitmore 1981; Mumford 1964; Schumacher 1995).

The Acadian Flycatcher is subject to parasitism by the Brown-headed Cowbird. Eighteen of 133 Ontario nests (13.5%) were parasitized. Parasitism rates vary geographically: 50% in Illinois and in Missouri in fragmented habitat, 14.5% in contiguous forest in Illinois, 12-17% in Wisconsin, 24% in Michigan, 21% in Arkansas, 5% in Pennsylvania, 7.5% in forested areas of Indiana, 3% in Missouri forested landscapes, and 0% in Georgia and South Carolina (but low sample sizes in these areas). In Missouri, 34 of 264 nests (12.9%) were parasitized. Parasitized nests rarely fledge Acadian Flycatchers; only about 2% of parasitized nests fledge both flycatchers and cowbirds. Cowbirds may remove host eggs and the flycatcher may abandon the nest and start another clutch, remove the cowbird egg,

or build a second floor in the nest over the cowbird egg. Early nests have the highest rate of parasitism. Nests initiated in July usually are not parasitized. In Arkansas, unparasitized nests were significantly higher (6.2 m) than parasitized nests (4.5 m). In Wisconsin, the rate of cowbird parasitism was unrelated to distance from edge, with similar parasitism rates near the edge as 300 m into forest interior. In the Midwestern states, the rate of parasitism was negatively correlated with percent forest cover, percentage of forest interior, and mean patch size. In central Indiana, 5.6% of nests further than 5 km from a field were parasitized compared with 13.5% of nests in forests adjacent to clear-cuts. In Illinois, the probability of parasitism decreased with increasing percentages of anthropogenic habitats within 500 m of nests. Parasitism decreased with percent water within 500 m and as the breeding season progressed, but the magnitude of these trends was negligible. Another southern Illinois study found that nests within 550 m of forest edge experienced higher rates of parasitism and predation (Allen et al. 2020; Bielefeldt and Rosenfield 1997; Brittingham and Temple 1996; Chapa-Vargas and Robinson 2007, 2013; Christy in Bent 1942; Graber et al. 1974; Heagy 2010; Jenkins et al. 2016; Kilgo and Moorman 2003; Mumford 1964; Page and Cadman 1994a; Peck and James 1997; Walk et al. 2011; Walkinshaw 1961, 1966a; Wilson and Cooper 1998a, 1998b). In Ohio, Rodewald (2009) examined factors that affected parasitism rates of Acadian Flycatchers. Density of woody stems in the nest patch was positively related to brood parasitism, with parasitized nests surrounded by 1.6 times more stems than unparasitized nests. Parasitized nests were in landscapes with more than twice the amount of urbanization within 1 km as unparasitized nests. There was a significant relationship between urbanization and habitat around the nest. The primary habitat characteristic associated with increasing urbanization was an increase in woody stems. The dominant species was an invasive exotic shrub that may have provided increased perches for cowbirds or increased visibility of nests. Cowbird abundance was not associated with increasing urbanization. In Wisconsin, canopy cover within 10 m of the nest was more open (89.0%) at parasitized than unparasitized (96.3%) nests. No other variables that were measured differed between parasitized and unparasitized nests (Brittingham and Temple 1996).

The amount of suitable habitat for the Acadian Flycatcher has declined in Ontario. By 1920, only 11% of southern Ontario was forested. This increased to 19% by 1986, but most of it is second-growth forest that is regularly harvested. Some of its preferred nest-tree species are at risk due to pests or diseases. These include hemlock (affected by the hemlock woolly adelgid), beech (beech bark canker fungus), and flowering dogwood (dogwood anthracnose fungus). Heagy (2010) stated that the hemlock woolly adelgid had not yet reached Ontario, but it is now present and steadily spreading northward.

Forest fragmentation is one of the greatest limiting factors to the Acadian Flycatcher in Ontario. Many of the remaining woodlands in Ontario and other areas are too small to support viable populations. Sixty-seven percent of woodlots in southern Ontario are smaller than 5 ha and only 431 patches are larger than 100 ha (Heagy 2010; Mossman 1988; Page and Cadman 1994a). Farwell et al. (2019) examined the response of the Acadian Flycatcher to forest fragmentation by shale gas infrastructure (well pads, access roads, and pipelines) in contiguous forest in West Virginia. It exhibited no significant response, possibly because it was present in low numbers. In the eastern

United States, approximately 42% of its detections on Breeding Bird Survey (BBS) routes were in fragmented landscapes (Donovan and Flather 2002).

Forest management and other activities that open up the forest canopy are detrimental to the Acadian Flycatcher. Several Ontario populations apparently disappeared as a result of intensive logging. It will tolerate light selection cutting and thinning of understorey trees. Any thinning that opens up the canopy results in an increase in shrub and sapling growth and is detrimental. Diameter-limit harvesting is widely practised in southern Ontario woodlots and is incompatible with the habitat requirements of the Acadian Flycatcher. At Rondeau, alteration of the forest canopy by high water levels and severe winds probably contributed to its decline in this area (Bushman and Therres 1988; Friesen et al. 2012; McCracken 1999a; Page and Cadman 1994). In Illinois, Robinson and Robinson (1999) created openings of 0.02-0.4 ha within a 2,000-ha forest. There were no significant differences in the abundance of Acadian Flycatchers in cut forests compared with controls, or in different age classes of cuts.

In Indiana, the Acadian Flycatcher exhibited a significant response to fire, rarely occurring in burned areas and least likely to occur in burns of the 31 species studied (Grundel and Pavlovic 2007b). In pine-oak forests in North Carolina, Rose and Simons (2016) determined that the Acadian Flycatcher was adversely affected by severe- and moderate-intensity fires, with negative effects persisting for as long as 25 years.

The amount of urban habitat in the landscape matrix is important in determining if woodlands will be used for breeding by the Acadian Flycatcher. In Ohio, it was more than 3 times abundant in riparian stands with 1% or less urban development. Nest success was greatest in areas with limited urban development within 1 km, and in wider forests (Bakermans and Rodewald 2006). Shustack and Rodewald (2010) studied the effects of urbanization on the breeding season of the Acadian Flycatcher in Ohio. They examined the timing of breeding of birds in 35 woodlands along a rural to urban gradient. The dates of the first singing male and initiation of the first clutch was later in urban woodlands. Urbanization reduced the length of the breeding season with the result that birds initiated fewer nests and fledged fewer young than rural birds. This may be because urban forests are less desirable and are selected later by smaller females that initiate clutches later than larger females. Kearns and Rodewald (2017) considered the Acadian Flycatcher an urban avoider in Ohio. It settled more densely in rural than urban areas and its condition and overall reproductive productivity declined with increasing urbanization. In North Carolina, abundance of the Acadian Flycatcher was negatively correlated with the density of houses and other buildings within 200 m (Lumpkin and Pearson 2013).

Kearns and Rodewald (2017) studied nest locations of the Acadian Flycatcher relative to predator abundance. Nest location was unrelated to any type of predator activity, including mammalian and avian predators, and specifically Blue Jays. Variation in daily nest survival was best explained by mammalian predator activity. Nest survival was low when avian predator activity was high and mammalian predator activity was low. In all other situations, nest survival was greatest in areas with high predator activity. There was no evidence that it used predator density information to select nest sites.

Invasive plant species may make habitat unsuitable for the Acadian Flycatcher. It is absent in some otherwise apparently suitable ravines along Lake Erie where there is a profusion of garlic mustard or multiflora rose. In some woodlands in Middlesex County, common buckthorn dominates the understorey and renders the habitat unsuitable (Friesen et al. 2012).

Excessive browsing by deer may be a significant limiting factor. The decline at Rondeau Provincial Park was attributed in part to heavy browsing by deer, and deer have been implicated in declines in other areas. Deer may consume vegetation within 2 m of the ground and therefore eliminate suitable nesting sites (Gates and Giffen 1991; Mumford 1964; Page and Cadman 1994). In Delaware, the Acadian Flycatcher was significantly more abundant in areas that supported low (10 or fewer per km^2) and moderate (11-19 per km^2) deer densities than in areas that supported 20 or more deer per km^2 (Tymkiew et al. 2013).

Drought may be a significant limiting factor. If woodland pools or watercourses dry up, habitat becomes unsuitable and breeding may not occur (McCracken 1999a).

Price (2004) suggested that the range of the Acadian Flycatcher could expand within southern Ontario if the average summer temperature increased by 2°C. In North Carolina, its abundance was correlated with temperature, suggesting that climate change may be beneficial to it in this area. The study area was in the Appalachian Mountains where it is colder than other areas at this latitude (Lumpkin and Pearson 2013).

Status

Page and Cadman (1994a) presumed that the Acadian Flycatcher was widely distributed in the Carolinian Forest Region prior to settlement and clearing, but there were no ornithologists present at that time to verify this. By the mid-1800s, much of the Carolinian Forest had been cleared, and it was rare in the remnant forests south of Ontario. McIlwraith (1894) knew of no Ontario records, but correctly predicted that it would be found along the north shore of Lake Erie. The first Ontario record was a specimen collected in Middlesex County in 1882, and 2 years later the first nest was found near Dunnville. Several birds were taken in Chatham-Kent in 1909, including a breeding female. In the early 1900s, there were 2 breeding reports from Middlesex County. Breeding was confirmed at Rondeau in 1931 and 1933 and, by 1937, this was the only known nesting location. By 1994, there were 8 locations where repeat nesting had occurred (Rondeau Provincial Park, Wheatley Provincial Park, Springwater Forest Conservation Area, the Wilson Tract, Mistele-Baker Bush, Dundas Valley, Westover, and Point Abino Marcy Woods). At this time, numbers were greatly reduced at Rondeau with no recent records from Wheatley or Point Abino. A 1973 breeding record in Pickering Township was the most northerly and easterly in the province. The Haldimand-Norfolk Natural Areas Inventory documented breeding at 5 locations (South Walsingham Sand Ridges, Vanessa Swamp, Delhi–Big Creek Valley, Deer Creek Valley, and northeast of Sweets Corners). During the first atlas, the breeding population was estimated at 40-75 pairs. In 1992, only 38 birds were reported, 10 of which were migrants. In 1997, 34 singing males were found at 13 sites, including 3 new areas. Some of these were thought to be late migrants, and the Ontario breeding population was estimated at 20-100 pairs, but probably fewer than 50. The population appeared to remain stable during the 1990s, and the 1998 breeding population was estimated at 35-50 pairs. As of 2011, the population appeared to be stable at 35-50 pairs. Since 1997, 5-10 nests have been found annually in Elgin County suggesting

that this area supports a viable population (Austen et al. 1994; Baillie and Harrington 1937; Friesen and Stabb 2001; Heagy 1997; Lancaster et al. 2004; McCracken 1999a; McLaren 1974; Page and Cadman 1994a). Heagy (2010) estimated the Ontario and Canadian population at 112 adults, including 64 territorial males and 48 pairs. She concluded that the population had been stable for the past 10 years, but that it was not self-sustaining and required continuous immigration from other populations.

The probability of observation of the Acadian Flycatcher increased significantly between atlases by 86%. Martin (in Cadman et al. 2007) attributed the apparent increase to directed searches for the species by the recovery team rather than an actual increase. He concluded that its distribution was well documented in the Carolinian Forest Region but that it may have been missed in larger woodlands in the Great Lakes–St. Lawrence Forest Region south of the Canadian Shield. The population estimate at that time was 27-35 pairs in any given year, with concentrations occurring in larger forest blocks in southwest Middlesex, southeast Elgin, and Norfolk counties. Sites generally support flycatchers for a few to several years followed by a period of abandonment and then recolonization (Martin in Cadman et al. 2007).

The Acadian Flycatcher is designated endangered nationally and provincially. The initial recovery plan target was establishment of 250 pairs at 10 discrete sites. Since then, research has indicated that recruitment of only a single immigrating breeding pair every 2 years may be sufficient to prevent its extirpation in Ontario. The current target is to maintain the existing population of 35-50 pairs (Friesen et al. 2012).

POSTFLEGING PERIOD

Young cannot fly well until they are 14 or 15 days old, and may continue to be fed by adults until they are 25 days old. In Missouri, fledglings attained independence a mean of 19.5 days after fledging (Jenkins et al. 2016).

In Ohio, adult and juvenile Acadian Flycatchers were common during the postbreeding period in densely regenerating clear-cuts. These and other early successional habitats may be important late in the breeding season as a source of dense cover and abundant food (Vitz and Rodewald 2006, 2007). In Missouri, Porneluzi et al. (2014) netted birds during the postfledging period in an oak-pine-hickory forest for 2-15 years after it was clear-cut. The Acadian Flycatcher was one of the more common species captured. Its abundance showed a curvilinear trend that approached significance. It increased gradually to a peak around 6-9 years after harvesting and declined thereafter.

Ausprey and Rodewald (2011) studied the survivorship of fledgling Acadian Flycatchers in mature Ohio hardwood forests in a gradient from rural to urban environments. Survivorship was associated with the number of small trees and negatively associated with the number of large trees. Microhabitats selected were not significantly different from those in random areas. Fledglings selected areas with 3 times more nonnative honeysuckle cover and 2.4 times more native shrub cover than occurred at nest sites. Survivorship was not related to the degree of urbanization despite higher densities of predators in urban areas. The authors concluded that urban forests may provide suitable habitat for juvenile Acadian Flycatchers.

In mature deciduous forests in Ohio, mean home range of fledglings while still on the natal territory was 2.33 ha (range 0.74-3.67 ha). Home range sizes on natal territories were associated with increasing coverage by nonnative honeysuckles, suggesting that honeysuckles provided inferior habitat (Ausprey and Rodewald 2013).

Jenkins et al. (2016) radiotracked fledgling Acadian Flycatchers in Missouri. Nests and locations of juveniles differed significantly in mean canopy cover, total tree density, and total basal area, with all parameters higher for fledgling locations. Mean characteristics for nests and fledgling locations, respectively, were: canopy cover, 94.97% and 95.87%; total tree density per ha, 975 and 1,278; and basal area, 54.26 and 59.59 m^2 per ha. Fledgling survival was negatively correlated with tree stem density, but positively correlated with more big trees and high litter depths. Family groups used both mid- and high-canopy areas for foraging. Fledglings also used areas with high tree densities such as forest edges or patches of cedar. Distance to edge did not affect fledgling survival rates.

MIGRATION

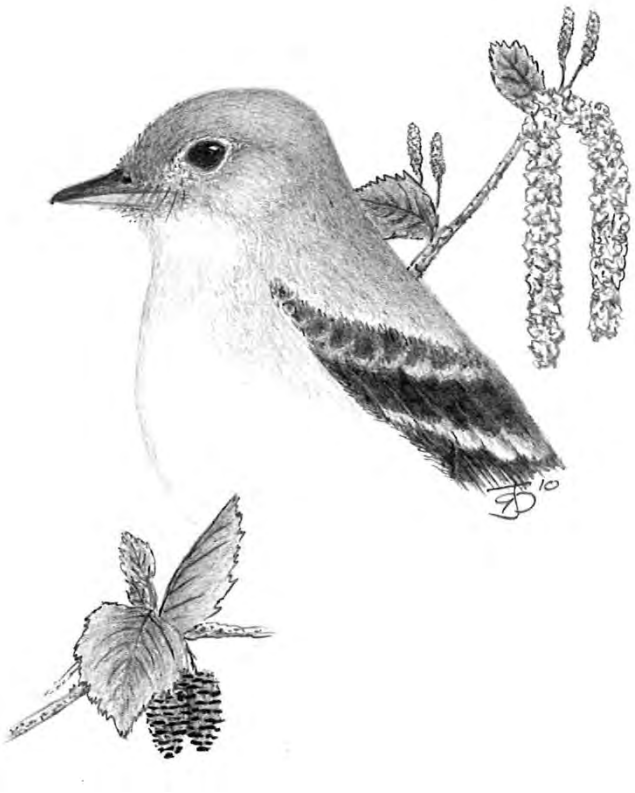
Limited information is available on migration timing. At Point Pelee, the Acadian Flycatcher is most often present in late May and the first week of June. Typical arrival in Ontario is in mid-May, but it has been documented in late April (Burrell et al. 2015; James 1991; Page and Cadman 1994a). Males arrive on the breeding grounds about a week before females (Allen et al. 2020). Most leave the province by the end of August, but it has been recorded in late September (James 1991). In Indiana, adults appeared to leave well before juveniles (Allen et al. 2020).

During migration, the Acadian Flycatcher inhabits a broad range of forest types, all ages of forests, forest edges, and urban woodlots (Heagy 2010). In Pennsylvania, Keller and Yahner (2007) found that it was most abundant in larger woodlands in unfragmented landscapes during spring migration, but had insufficient information to determine any relationships during autumn migration.

The Acadian Flycatcher is a rare migrant in the south. During spring migration, it occurs in very low numbers along the northern shore of Lake Erie. Usually only 2 or 3 are banded at Long Point in spring, with a range of 0-8 (James 1991; Page and Cadman 1994a).

Alder Flycatcher

Empidonax alnorum



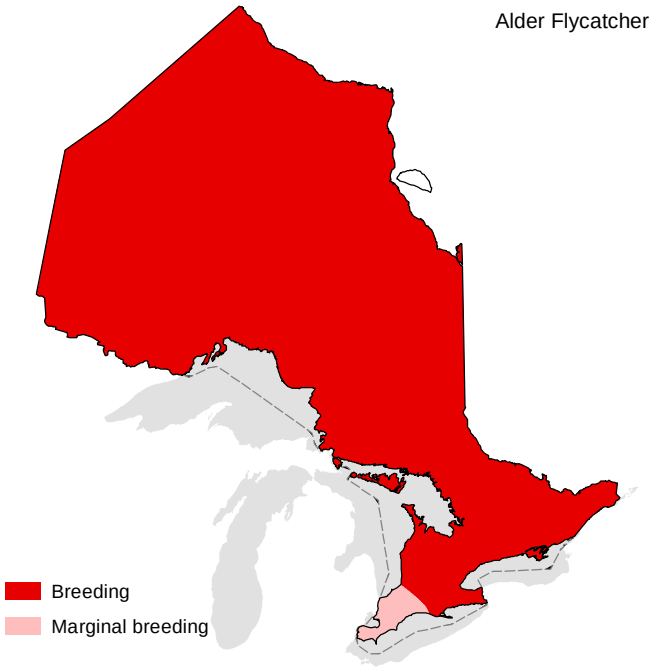
BREEDING SEASON

Habitat Requirements

The Alder Flycatcher prefers shrubby moist to wet areas, but occasionally nests in dry sites (Peck and James 1987).

In the Hudson Bay Lowland, the Alder Flycatcher bred in virtually all willow thickets along the Ontario James Bay coast (Manning 1952).

In the Boreal Forest Region, Rempel (2007) characterized the Alder Flycatcher as a species of young mixed-wood forests with open canopy and an interspersion of young and old forest. It occurred in areas of high edge among vegetation communities, where there was a low proportion of mature and old forest, in young stands, and in areas dominated by softwoods. In general, it occurred in softwood stands with openings. Rempel et al. (2007) concluded that it was associated



with younger, more open hardwood forests, with high disturbance and edge levels. It preferred moist, dense growths of alder and willows along the northeastern shore of Lake Superior (Baillie and Hope 1943). Near Pickle Lake, it occurred primarily along rivers and disturbed upland areas where alders were common (James 1980). Near Hearst, it nested in uncut lowland coniferous stands and clear-cuts 3-24 years old. It was most abundant in 9-11-year-old clear-cuts in lowland forests (Welsh and Fillman 1980). Near White River, it was significantly more frequent in clear-cuts that were 8-10 years old than in younger or older clear-cuts or mature stands (Venier and Pearce 2005). In the Clay Belt, it was common in alder wetlands (Smith 1957) and did not occur in stands older than 14 years old (Welsh 1993).

In the Great Lakes–St. Lawrence Forest Region near Gogama, the Alder Flycatcher appeared in jack pine stands 6 or 7 years after cutting or a burn once there was ample shrubby growth. It disappeared when the stand was 20-25 years old when trees matured and shaded the ground (James and Peck 1995a). Near Kingston, it preferred alder and willow thickets, especially those along edges of woodlands (Weir 2008). Snyder (1953) reported it breeding in Ontario in alder, willow, and grape along creeks, and occasionally in regenerating aspens 1.3-3 m tall. Unlike the Willow Flycatcher, the Alder Flycatcher did not appear to breed in urban shade trees, cemeteries, orchards, or other dry habitats.

In boreal Canada, it occurs in burns and clear-cuts in the early shrubby stages of succession, wet areas dominated by sedges and low shrubs such as sweet gale and willows, abandoned farmland, bogs and fens dominated by low shrubs, and young deciduous and mixed stands (Erskine 1977; Kirk et al. 1996; McLaren and McLaren 1981).

Similar habitat preferences have been reported from British Columbia, Quebec, and the United States. In addition, it may nest in damp to wet buckthorn, dogwood, elderberry, or viburnum thickets, and young plantations. The Alder Flycatcher may use edges created by roads, airstrips, hedgerows, and clear-cuts. Where it occurs with Willow Flycatcher, the Alder Flycatcher tends to nest in denser and taller shrubs with a wet substrate. In Michigan Great Lakes coastal wetlands, it was positively associated with increasing shrub density, shrub foliage diversity, and frequency of willow, open water, floating vegetation, and deciduous trees. It preferred meadows with abundant grass cover and scattered coniferous snags as well as willow thickets. In Quebec, it occurred on burns and clear-cuts with saplings shorter than 2 m and 2-5 m tall. It was not observed in young or mature forest. It was significantly more abundant in clear-cuts than burns. Clear-cuts supported more

deciduous saplings but fewer snags than burns (Campbell et al. 1997; Dawson 1979; Imbeau et al. 1999; Lowther 2020a; Mossman et al. 1991; Niemi and Pfannmuller 1979; Noon et al. 1979; Riffell et al. 2001; Seutin in Gauthier and Aubry 1996; Temple et al. 1979; Zink and Fall 1981).

Most Ontario nests were in deciduous shrubs, trees, and vines; occasionally they were in coniferous trees, and rarely among grasses and herbs. Plant species most frequently selected for a nest site were willows, dogwoods, beaked hazel, and hawthorns. Most nests were in crotches, occasionally attached to upright stalks, and were 0.3-1.8 m from the ground, with most 0.6-0.9 m up (Peck and James 1987).

Ontario nests were typical of those reported throughout its range. Other species that nests have been found in are gray dogwood, red-osier dogwood, red raspberry, black raspberry, meadowsweet, beaked willow, crack willow, nannyberry, wild raisin, juneberry, honeysuckle, and cow parsnip (Campbell et al. 1997; Lowther 2020a; Seutin in Gauthier and Aubry 1996; Snyder 1953; Walkinshaw 1966b).

An exclusive territory is defended, but there is limited information on territory size. Territory sizes averaged 1.3, 1.5, and 3.0 ha for 3 populations in New York, and 0.2 ha in Connecticut (Lowther 2020a; Seutin in Gauthier and Aubry 1996).

No information is available on natal philopatry and limited information is available on adult site fidelity. In Connecticut, 3 of 3 females and 1 of 9 males returned the next year (Lowther 2020a).

Limiting Factors

Eggs have been reported in Ontario nests from mid-June until the end of July, with most clutches present in the last third of June and the first week of July (Peck and James 1997). In Algonquin Park, eggs are present from mid-June to mid-July, a nest with young was found in late July, and recently fledged young have been seen from mid-July until mid-August (Tozer 2012).

It takes approximately 36 hours for the female to build the nest, and eggs are laid at the rate of one a day. The incubation period has been reported as 12-14 days, but 3 Ontario nests had incubation periods of approximately 11 days. If disturbed, nestlings may leave the nest when they are as young as 11 days, but fledging normally occurs at age 13-16 days (Lowther 2020a; Peck and James 1987; Seutin in Gauthier and Aubry 1996).

A single brood is raised in a season, but renesting in the same territory occurs if a clutch is lost. The normal clutch size is 2-4 eggs, with most clutches containing 3 or 4 eggs, but 1 Ontario clutch contained 5 eggs (Campbell et al. 1997; Lowther 2020a; Peck and James 1987, 1997).

The age at first breeding is presumed to be 1 year, and the Alder Flycatcher breeds every year thereafter. The mating system is monogamous (Lowther 2020a).

The Alder Flycatcher feeds almost exclusively on insects hawked from the air, but occasionally it gleans from foliage, sometimes by hovering. Although it captures most food while it is in flight, it may snap and capture food while it is perched. It usually forages from perches 2.5-4.4 m high in deciduous trees or shrubs. In the Northwest Territories, 82% of foraging occurred in deciduous species and 18% in conifers. Near Stouffville and Ottawa, it consistently foraged more in trees and less in the open than the Willow Flycatcher. The 2 species used similar foraging strategies, with the

greatest difference being in habitat selection, although there was considerable overlap at Stouffville. It is uncertain if the 2 species compete for food (Barlow and McGillivray 1983; Greenberg et al. 1999; Lowther 2020a).

Little is known about the diet of the Alder Flycatcher, and the most definitive work pooled results for the Traill's Flycatcher. That study determined that it ate 96% animal matter including 41% hymenopterans, 18% beetles, 14% flies, 8% moths and butterflies, and 4% grasshoppers. Adults feed young spread-winged damselflies, long-horned grasshoppers, and robber, snipe, march, and crane flies (Lowther 2020a). North of Lake Nipigon, Kendeigh (1947) analyzed the contents of 4 stomachs. By frequency, the diet consisted of 42.1% beetles (mostly click beetles but also soldier beetles), 19.0% lepidopterans, 10.3% house flies, 8.6% true bugs (including stink bugs), 7.7% hymenopterans (including ichneumonid wasps), 7.2% spiders, 4.1% short-horned grasshoppers, 1.0% soft-winged bugs, and isopods. Nancekivell and Nocera (2025) completed a DNA analysis of the adult diet in New Brunswick and compared the diet of the Alder Flycatcher with those of the Least Flycatcher and Bank, Tree, Barn, and Cliff swallows. All species differed in their dietary breadth and prey preferences. The 2 flycatcher species and the Barn Swallow ate a greater diversity of terrestrial flies whereas the other species ate more aquatic taxa. The 2 flycatcher species and the Barn and Tree swallows had broader, more generalized diets than the Bank and Cliff Swallows. The approximate frequencies of occurrence of invertebrate groups in the diet of the Alder Flycatcher were 60% aquatic flies, 45% terrestrial flies, 40% lepidopterans, 30% bugs 20% terrestrial beetles, and 5% each for aquatic flies, hymenopterans, neuropterans, and caddisflies. Mosquitoes were the most frequently ingested family of invertebrates, followed by long-legged flies, flower flies, bristle beetles, leafroller moths, and midges. Near Manitouwadge, abundance of the Alder Flycatcher was not correlated with spruce budworm abundance (Venier et al. 2009).

The Brown-headed Cowbird parasitizes the Alder Flycatcher, but at a fairly low rate. In Ontario, 14.6% of 55 nests were parasitized. Parasitism rates elsewhere include 5% in Quebec, 10% in British Columbia, 7.5% in 1 area of Michigan, and 5.3% in another Michigan area. In response to parasitism, the Alder Flycatcher may destroy cowbird eggs or incorporate them into the bottom of the nest (Campbell et al. 1997; Lowther 2020a; Peck and James 1997; Walkinshaw 1961).

Habitat for the Alder Flycatcher may have increased initially after European settlement. Forest clearing in the south and forest management in the north would have created more suitable habitat. After clearing in the south, habitat increased again as some farms were abandoned, but now some of these areas are being converted to urban areas or are succeeding into forest habitat. Many wetlands have been lost in the south resulting in decreases in shrub thickets.

The Willow Flycatcher may be the greatest limiting factor to the Alder Flycatcher. The Willow Flycatcher has expanded its range northward. The 2 species attempt to expel each other from their territories. The Willow Flycatcher is more aggressive and may take over Alder Flycatcher territories. When this occurred near Guelph, the displaced Alder Flycatchers did not remain in the area to breed. Initially, the Willow Flycatcher was found only in extreme southwestern Ontario, but it has since spread northward to Ottawa and Sudbury. To date, there is no evidence of a decline in Alder Flycatchers due to expansion of the Willow Flycatcher's range (Barlow and McGillivray 1983; Lowther 2020a; Prescott 1987; Seutin in Gauthier and Aubry 1996; Snyder 1953).

In the Canadian Shield of Ontario, there was no difference in the abundance of the Alder Flycatcher in early successional clear-cuts and burns, but it was significantly more abundant in mid-successional clear-cuts than mid-successional burns. It was significantly more abundant in early successional than mature stands and equally abundant in mid-successional and mature stands (Zimmerling et al. 2017). In Nova Scotia, it was absent in uncut and thinned hardwood stands, but was common in clear-cuts (Freedman et al. 1981). In the Boreal Forest Region of Ontario, Rempel et al. (2007) predicted that it would be more abundant in harvested forests when current management guidelines were applied than it would be under uncut conditions or simulated natural disturbances.

On Anticosti Island, the Alder Flycatcher was present only when deer density was 7.5 per km^2 or less. White birch had diminished regeneration at higher deer densities, and the flycatcher's abundance increased with birch abundance (Cardinal et al. 2012). Many areas of southern Ontario have deer densities in excess of 7.5 per km^2.

In Alberta, the Alder Flycatcher was equally abundant near noisy compressor stations and quiet well pads. It showed no apparent response to chronic noise (Bayne et al. 2008).

In Alberta, the Alder Flycatcher was more abundant at pipelines and well pads than in forest interior adjacent to these features. There was no difference in its abundance at seismic lines and adjacent forest interior; the openings created by seismic lines were probably too narrow to attract it (Bayne et al. 2016; Kalukapuge et al. 2024).

In Minnesota, blowdown of spruce-fir forest resulted in an 80% loss of canopy and a 100% increase in shrubs. The Alder Flycatcher was common in blowdown, but absent in control plots (Burris and Haney 2005).

Price (2004) predicted that the Alder Flycatcher could become extirpated as a breeding species in southern Ontario if the average summer temperature increased by 2°C.

Status

Early estimates of abundance were confounded by the Alder and Willow flycatchers being collectively termed Traill's Flycatcher. Along the northeast shore of Lake Superior, where the Willow Flycatcher did not occur, Baillie and Hope (1943) considered it very common. It is common throughout the province except in the extreme southwest and extreme north, where it is local and uncommon (James 1991; Prescott in Cadman et al. 1987).

The second atlas indicated that the probability of observation of the Alder Flycatcher had increased significantly province-wide since the first atlas. Significant increases were observed in all atlas regions except the Carolinian Forest Region, where there was a nonsignificant decline. Highest densities occurred in the Boreal Forest Region and southern portion of the Hudson Bay Lowland where it may be most abundant in regenerating cutovers. It occurs in low density south of the Canadian Shield, with slightly higher concentrations in eastern Ontario, the central and eastern portions of the Oak Ridges Moraine, and Dufferin and eastern Grey counties. These are all areas with higher than average wetland density (McLaren in Cadman et al. 2007).

The long-term (1978-2021) trends determined by the Breeding Bird Survey were annual decreases of 0.018% in Canada and 0.18% in Ontario. The short-term (2011-21) trends were annual

decreases of 0.962% in Canada and 0.461% in Ontario. All results were of medium reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Major and Desrochers (2012) captured Alder Flycatchers during the postfledging period in clear-cuts in Quebec. It was equally common in control plots and in those where the fruit had been removed. During the postfledging period in Pennsylvania, Stoleson (2013) captured 11 adults and 4 fledglings in clear-cuts and none in forested habitat.

MIGRATION

The Alder Flycatcher is a nocturnal migrant. It is late spring migrant. Although it has been recorded in the province in late April, the peak of migration is in late May. At Long Point, it seldom arrives prior to 25 May, slightly later than the Willow Flycatcher, and 90% are recorded between 30 May and 10 June. Males arrive prior to females, and most birds after 5 June are probably females (Hussell 1991b; James 1991). Timing of autumn migration is more difficult to determine because birds are not as vocal, and it is difficult to distinguish between Alder and Willow flycatchers even when they are in hand. In autumn, juveniles migrate approximately 2 weeks later than adults. At Long Point, the Alder Flycatcher occurs from mid-July to mid-September, with the peak of migration occurring in the last half of August. Ninety percent of adults occurred in the 35-day period of 20 July until 23 August. Juveniles appeared in the first 10 days of August with the peak 27-31 August. Stragglers may occur in the province until early October (Hussell 1991c; James 1991).

Little information is available on the Alder Flycatcher's migration habitat preferences. Presumably, it prefers areas of low shrubs and also graminoid wetlands with some shrub coverage. In Pennsylvania, it was significantly more abundant in shrub than forest habitat during spring migration (Smith and Hatch 2008).

The Alder Flycatcher is common during migration (James 1991).

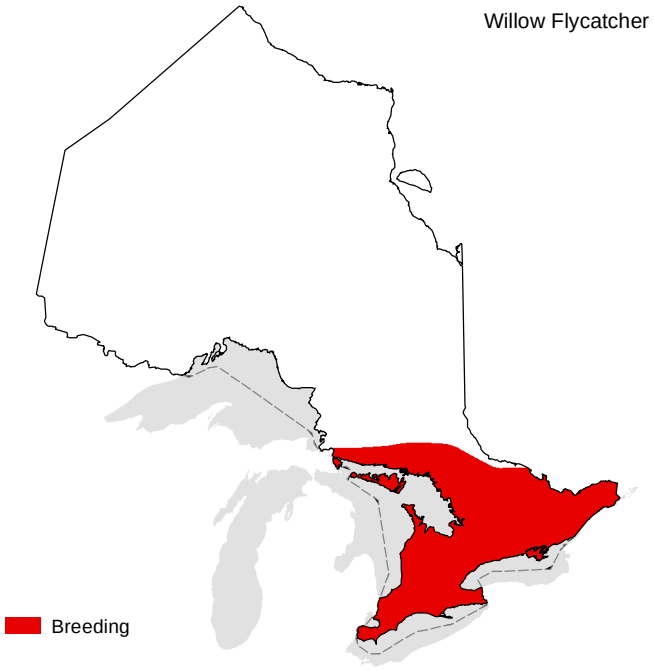
Willow Flycatcher

Empidonax traillii

BREEDING SEASON

Habitat Requirements

In Ontario, the Willow Flycatcher nests in much drier habitats than the Alder Flycatcher. The most commonly used breeding habitats are shrubby fields and pastures dominated by hawthorns, often with other woody species present such as apple, dogwood, willow, and a variety of other species. Less frequently, it nests in willow or willow-dogwood thickets, borders of marshes, and young coniferous plantations with some deciduous trees or shrubs. Miscellaneous habitats where nests were reported include a dogwood ridge in a marsh, small islands in rivers, and in an alder thicket (Peck and James 1987). On Pelee Island, it nested on pastured limestone outcroppings with scattered hawthorns, fragrant sumac, and red cedar (Snyder 1953). Near Stouffville and Ottawa, it appears to have moved into mesic habitat more similar to habitat selected by Alder Flycatchers than



the drier habitats chosen by Willow Flycatchers in Chatham-Kent. This adaptation to wetter habitat may have been essential to its expansion into central Ontario (Barlow and McGillivray 1983; Speirs and Orenstein 1975).

Habitats used in Ontario are similar to those reported throughout the Willow Flycatcher's range, except in the southwestern states. The subspecies that inhabits this area is dependent almost entirely on riparian willows, actively selects willow as the nest-site species, always nests near or over water, and is mildly area sensitive. Habitat selected by other subspecies includes damp and wet shrubby areas as well as upland meadows dominated by shrubs. Upland shrub stands of gray dogwood, beaked willow, pussy willow, common elderberry, hazelnut, roses, northern prickly-ash, juneberry, chokecherry, ninebark, swamp birch, apple, and sweet crabapple are frequently used. Alder thickets tend to be avoided as do wet willow thickets. Shrub thickets appear to be preferred to areas with scattered shrubs. In many areas, it formerly nested in cities and orchards, but is essentially absent from these habitats now (Bent 1942; B.T. Brown 1988; Campbell et al. 1997; DeSmet and Conrad 1988; Finch and Stoleson 2000; Graber et al. 1974; Harris et al. 1987; King 1955; McCabe 1991; Mossman 1988; Sedgwick 2020; Sedgwick and Knopf 1989, 1992; Seutin in Gauthier and Aubry 1996; Taylor and Littlefield 1986; Walkinshaw 1966b). In Iowa wetlands, presence of the Willow Flycatcher was positively correlated with the edge-to-interior ratio, being more likely to occur in irregularly shaped wetlands (Fairbairn and Dinsmore 2001a). In Utah, it was associated with high shrub density with little canopy cover and a moderate amount of ground cover. It was considered a habitat specialist, having the lowest habitat use value of all species studied. It was confined to areas with shrub density of 70-100%, and trees of any size seldom occurred in its territories (Whitmore 1977). In Colorado, it occurred in tall vegetation with more foliage volume above 3 m and fewer trees than average. Its nesting habitat was most similar to that of the Yellow Warbler, and the 2 species often nested within 4 m of each other (Brown and Trosset 1989).

At the landscape scale, the Willow Flycatcher preferred areas that were 8-16% forested in North Dakota (Cunningham and Johnson 2019).

In Ontario, the Willow Flycatcher exhibits no evidence of area sensitivity, occurring regularly in small habitat patches.

Most Ontario nests were in deciduous trees and shrubs, although one was in a conifer. Species selected, in order of preference, were hawthorn, apple, dogwood, and willow. Nests were usually in crotches in horizontal branches, but occasionally in upright crotches, 0.2-1.8 m from the centre of

the nest tree or shrub. Nests were 0.5-3.7 m from the ground, with most 1.1-1.5 m up (Peck and James 1987, 1997).

There are some disparities between Ontario nest sites and those reported elsewhere. Sedgwick (2020) stated that nests were built most frequently in willow, and that the Willow Flycatcher actively selects willow. This is biased due to the intensive research that has been undertaken on the Southwestern Willow Flycatcher. Other subspecies appear to actively select against willow, and use it when it is the only species available. Its aversion to willow has particularly been noted in British Columbia and Wisconsin. In Wisconsin, the preferred nesting species was common elderberry, which appeared to offer the best concealment. In 1 area almost totally dominated by willows, the single nest present was in an elderberry, 1 of the 2 shrubs that were not willow. Other species it has nested in include swamp birch, red-osier dogwood, white elm, basswood, grape, hazelnut, honey locust, tartarian honeysuckle, plum, stinging nettle, blackberry, sycamore, rose, Manitoba maple, buttonbush, pear, bracken fern, cow parsnip, chokecherry, lilac, ninebark, cottonwood, juneberry, aspen, pine, and red elderberry. Unlike in Ontario, most nests were in upright crotches, and those on horizontal branches were fastened to an upright stem. In Wisconsin, the mean diameter of the main stem supporting the nest was 1.3 cm, rarely as large as 1.9 cm. Nests have been reported 0.5-18 m from the ground, but nests higher than 2.5 m are rare. The average nest height is similar to that reported from Ontario. Nests are rarely built in trees or shrubs taller than 3 m (B.T. Brown 1988; Campbell et al. 1997; Finch and Stoleson 2000; Flett and Sanders 1987; Graber et al. 1974; King 1955; McCabe 1991; Sedgwick 2020; Taylor and Littlefield 1986; Walkinshaw 1966b).

The Willow Flycatcher is territorial, and may expel other species from the defended area. In Ontario, it may be aggressive toward the Alder Flycatcher and usurp its territories. There appear to be 2 territories, a small one around the nest that is aggressively defended by the female, and a larger one defended by the male. Territories are usually larger than required to raise a brood, possibly to compensate for lost clutches and the potential need to renest. Adults occasionally leave the territory, so the home range is larger, but its size has not been quantified. Ontario territories were 0.11-0.47 ha (average 0.29 ha). Territory size averaged 0.22 ha during territory establishment, 0.26 ha through nest building and incubation, and 0.41 ha during the nestling and fledging periods. Territory sizes reported elsewhere are 0.08-0.7 ha and 0.06-2.3 ha in 2 study areas in California, 0.32-1.17 ha (average 0.69 ha) for 73 territories in Michigan, 1.72 ha in Colorado, 1.1-1.8 ha in New York, and 0.31 ha in Wisconsin. In Wisconsin, most birds remained within an area of 45 m^2, and territories dissolved 5-7 days after the young fledged. In Wisconsin, the mean distance between nests was 54 m: 37.5 m in thickets and 77 m in scattered shrubs (Finch and Stoleson 2000; Flett and Sanders 1987; McCabe 1991; Prescott 1986, 1987; Prescott and Middleton 1988; Sedgwick 2020; Walkinshaw 1966b).

Natal philopatry appears low and has been reported as 1.4%, 7.5%, 7.8%, 23%, and 25.9%. An exception occurs in populations nesting in montane meadows in California, where natal meadow fidelity was 34.3% and the mean distance of the first nest from the natal nest was 5.65 km. For those individuals that dispersed from their natal meadow, the mean natal dispersal distance was 8.36 km. One female dispersed 134 km. Higher return rates may have been reported in the California study area because the researchers searched over a much wider area than is done in most studies. Another

California study also documented high rates of natal philopatry. Seventeen to 36% of fledglings returned to breed annually. Returning birds entered the breeding population the year after fledging except for 2 that returned 2 years later and 1 that returned 3 years later (Finch and Stoleson 2000; Kus et al. 2017; Matthewson et al. 2013; Sedgwick 2004, 2020; Sedgwick and Knopf 1989; Walkinshaw 1966b). Natal philopatry rates are similar for males and females. Those returning may nest 20-1,600 m from the natal site.

Adult site fidelity is strong, particularly in adult birds that bred successfully the previous year. Breeding site fidelity has been reported at 40-62%, which would account for a high proportion of individuals when mortality is factored in. Higher return rates have been reported in California, with 73.7% of breeding adults returning and 89.3% of those returning to the previous year's breeding site. In Michigan, 40% of males returned the following year, 22.7% the third year, 13.6% the fourth year, and 4.5% the fifth year. Females had a lower return rate of 22.6% the second year and only 3.2% the following 4 years. In Arizona, site fidelity of adult males (52.0%) and females (51.3%) was similar as were median dispersal distances between breeding seasons (16 and 19 m). Breeding success affected female return rates, with 64.4% of females rearing young returning compared with 40.0% for unsuccessful females. Of those that returned, successful females dispersed 15 m compared with 33 m for unsuccessful females. New residents were more site faithful than former residents. Probability of female site fidelity was highest for previously successful birds, those with greater fecundity, novice residents, and unparasitized females. Territorial fidelity by females was related predominantly to breeding performance. Male territorial fidelity was unrelated to residency, site quality, or breeding performance (Finch and Stoleson 2000; Matthewson et al. 2013; Sedgwick 2004, 2020; Sedgwick and Knopf 1989; Walkinshaw 1966b).

Limiting Factors

Eggs have been found in Ontario nests from mid-June until the third week of July, with most present in the last week of June and first week of July (Peck and James 1997). Nest construction usually starts about 4 days after the female arrives, and it may take 36 hours to 10 days to build, with 4 or 5 days typical. Eggs are laid at the rate of 1 a day, except in 4-egg clutches where a day may be skipped. An Ontario 4-egg clutch took 6 days to complete. Some incubation occurs before the clutch is complete, so eggs may hatch over a 1-3-day interval. Incubation periods reported in Ontario are at least 11 days to 14 days. Elsewhere, incubation periods of 11-20 days have been reported. Mean incubation periods of 13.2-13.6 days were reported in California. Cowbird parasitism may prolong incubation. In British Columbia, unparasitized nests had incubation periods of 12-17 days (median 14 days); parasitized nests had incubation periods of 14-20 days (median 16 days). The age at first flight is 11-16 days, typically 14 or 15 days, rarely as long as 19 days. The mean nestling periods were 14.3-14.7 days in California (Campbell et al. 1997; Ettinger and King 1980; Finch and Stoleson 2000; Graber et al. 1974; King 1955; Matthewson et al. 2013; McCabe 1991; Peck and James 1987, 1997; Prescott 1986; Sedgwick 2020; Seutin in Gauthier and Aubry 1996; Walkinshaw 1966b).

Typically 1 brood is raised annually. Double broods are very rare in the north with 1 recorded out of 882 pairs (0.1%), but are more frequent in the south where 5-10% of pairs may raise 2 broods. Renesting is common if a clutch is lost. Usually 1 or 2 replacement nests are attempted if necessary, but 1 female attempted 6 nests in a season. Replacement nests are in the same territory within a

short distance of the previous nest, occasionally in the same tree or shrub. Clutches of 2-4 eggs have been documented in Ontario, with most containing 4 eggs. Clutches of 1-5 eggs have been reported elsewhere, with 3- and 4-egg clutches typical. One-egg clutches are likely a result of egg loss due to predation or disturbance. One clutch of 7 eggs was probably laid by more than 1 female. Replacement clutches tend to be smaller than first clutches and clutch size decreases as the season progresses (Campbell et al. 1997; Finch and Stoleson 2000; Graber et al. 1974; King 1955; Matthewson et al. 2013; McCabe 1991; Prescott and Middleton 1988; Sedgwick 2020; Sedgwick and Knopf 1989; Walkinshaw 1966b).

First breeding occurs at age 1 year, and the Willow Flycatcher breeds every year thereafter. An Arizona population included nonbreeding floaters that were 85.0% males. Most (76%) were yearling males and only 1 bird (0.8%) floated in more than 1 year. In the year following floating, 23.9% settled in the habitat patch where they were first detected and the remainder established a territory in a different patch. Thirteen percent became established at the other side of a lake approximately 30 km distant. An additional 4.3% settled about 100 km distant. The number of territorial birds of both sexes was lowest and the percentage of floaters was highest in a year of severe drought (Theimer et al. 2018).

Most birds are monogamous, but Prescott (1986) documented the first apparent North American incidence of polygyny near Guelph. Two females mated to a single male nested 80 m apart and 6 young were fledged from the territory. In southern populations, it has since been determined that the rate of polygyny is occasionally as high as 15-50%. Factors that may favour polygyny are different chronology of the nests of the 2 females, the ability of females to raise young with limited assistance from the male, shortage of males in combination with high female site fidelity, and female tolerance of other females. In a California population, annual sex ratio explained 68% of the variability in the number of males that were polygynous. Of 43 polygynous males, 65% mated with 2 females simultaneously, 23% mated with 3 females, 5% mated with 4 females, and 7% mated with 5 females. Eighteen males bred polygynously in more than 1 year. Twelve of these (66.7%) switched mating types between years: 8 switched between monogamous and polygynous; 2 switched between monogamous, polygynous, and single (unmated); and 2 switched between polygynous and single. Mate fidelity is strong, and some pairs have remained together for as long as 5 years. Mate switching does occur and birds readily remate if one is lost (Finch and Stoleson 2000; Kus et al. 2017; Pearson et al. 2006; Prescott 1986; Prescott and Middleton 1988; Sedgwick 2020; Sedgwick and Knopf 1989).

The Willow Flycatcher is predominantly an aerial forager, sitting on a perch and then hawking or hover-gleaning insects. It typically perches, often on dead branches at heights of 0.3-3 m, and flies horizontally to capture prey within 3-5 m. it does not use large trees for perching. It may also land on the ground to capture invertebrates. Females sitting on nests may pluck insects crawling nearby. When it is raining, insects tend to move under leaves, and it then flutters to glean. A Wisconsin study found that 30% of invertebrates in the diet were terrestrial, suggesting that these were gleaned from foliage or the ground. There was little relationship between what was eaten and the insects that were available. At Stouffville, there was considerable overlap in the foraging niches of Willow and Alder flycatchers. Willow Flycatchers selected prey more in the open whereas Alder

Flycatchers captured invertebrates more in the interior of trees and shrubs (Barlow and McGillivray 1983; Finch and Stoleson 2000; McCabe 1991; Sedgwick 2020).

At nests near Guelph, nestlings were fed 56.4% adult flies, 16.8% bugs, 6.0% adult moths and butterflies, 5.7% spiders, 4.5% orthopterans, 2.2% adult hymenopterans, 2.1% adult beetles, 1.2% molluscs, 1.2% isopods, and 0.3% larval hymenopterans. In Wisconsin, food items consumed by nestlings were, in order of frequency, deer flies, flower flies, skippers, spiders, spittlebugs, snails, small beetles, lady beetles, dragonflies, ichneumonid wasps, bugs, and a millipede. Captive young in Michigan ate spiders, moths, grasshoppers, flies, mosquitoes, and crickets. Adults have been documented eating flying ants, dragonflies, hymenopterans, flies, and bugs. An earlier study of Traill's Flycatcher diet determined that 96% of the diet was animal matter: 41.4% hymenopterans, 17.9% beetles, 14.2% flies (crane, robber, house, and flesh flies), 7.7% moths and butterflies, 7.2% bugs, 3.9% grasshoppers, and a few dragonflies, mayflies, cattle ticks, spiders, and millipedes. Fruit consumed included elderberries, blackberries, dogwood berries, juniper berries, and chokecherries (Bent 1942; Finch and Stoleson 2000; McCabe 1991; Prescott and Middleton 1988; Sedgwick 2020; Walkinshaw 1966b).

Wiesenborn and Heydon (2007) examined food remains in 56 fecal samples from Southwestern Willow Flycatchers collected from 3 locations in Nevada. Eight orders of invertebrates were represented in the diet including spiders, odonates, cockroaches, beetles, hymenopterans, lepidopterans, bugs, and flies. Leafhoppers were the most abundant arthropod in the samples. Size of prey ranged from 2 to 40 mm and included aquatic water boatmen, terrestrial spiders, arboreal leafhoppers, and ground-dwelling cockroaches. It adapted its diet to consume the insects that were most readily available. Spiders comprised 7.4% of the diet at all sampling locations suggesting that their consumption rate may have been independent of availability. Diets of males and females were similar. It fed more on arthropods captured on plants than insects in flight. Durst et al. (2008) completed a similar 5-year study in Arizona. Approximately 70% of the diet was from 5 prey categories: hymenopterans, flies, leafhoppers, beetles, and ants. The relative abundance of these and other taxa differed significantly among years. Diets of adult males and females were similar but differed from that of nestlings. Adults ate a higher proportion of hymenopterans and nestlings ate more flies.

Parasitism rates by the cowbird vary considerably regionally. Most reported rates are probably underestimates because parasitized nests may be abandoned or the cowbird egg may be woven into the bottom of the nest where it is difficult to detect. In Ontario, 22 of 91 nests were parasitized (24.2%). Generally, parasitism rates are lower in the east, with an average of 11% for 6 studies that reported on 859 nests. In some eastern areas, parasitism rates are quite low: 5.3% in Michigan, 9% in Wisconsin, 4.4% in Ohio, and only 1 known case in Illinois. In the west, parasitism rates of 40.7% have been reported in Colorado, and it is the most heavily parasitized species in California at 63% of nests. In 3 montane meadows in California, lower parasitism rates of 8.4%, 11%, and 18.4% occurred. In New Mexico, 20.2% of 491 nests were parasitized. In British Columbia, 36% of nests were parasitized. Due to the chronology of cowbird egg laying, late nests and replacement clutches of flycatchers are seldom parasitized. Flycatchers rarely fledge any of their own young from parasitized nests, and success rates for cowbirds from Willow Flycatcher nests is also low (Brodhead et al. 2007; B.T. Brown

1988; Campbell et al. 1997; Finch and Stoleson 2000; Graber et al. 1974; Mathewson et al. 2013; McCabe 1991; Peck and James 1997; Sedgwick 2020; Sedgwick and Knopf 1988; Walkinshaw 1966b).

Habitat destruction and degradation may affect local populations. Drainage of thicket swamps is still occurring, and this may eliminate suitable nesting habitat. Old-field habitat continues to decline due to conversion to agricultural or urban lands, or to forested areas as a result of natural succession. Cattle grazing may affect the quality of breeding habitat. Often shrubs are denuded to a height where they are no longer suitable for nesting. Cattle also compact soils, inhibiting regeneration of shrubs and trees (Finch and Stoleson 2000; Harris et al. 1987, 1988; Sedgwick 2020; Taylor and Littlefield 1986).

Birds are very sensitive to disturbance early in the nesting season. During the nest-construction period until the first egg is laid, even slight disturbances may result in nest desertion (McCabe 1991).

Cool spring weather may delay the onset of the breeding season. Late springs retard shrub blooming which may affect insect availability. In Washington, the total span of the nesting season was 67 days in 1 year and 46 days in a year with a cool spring (King 1955). In California, late-spring storms and low temperatures delayed the start of the breeding season and influenced reproductive success by reducing the likelihood of renesting (Matthewson et al. 2013).

Price (2004) predicted that the range of the Willow Flycatcher would contract in southern Ontario if the average summer temperature increased by 2°C.

Status

Snyder (1953) stated that the Willow Flycatcher occurred only in the extreme southern portion of Ontario at that time, north to approximately latitude 43°N. Peck and James (1987) questioned this and thought that it was more widespread then. Nonetheless, it has experienced a recent and significant range expansion in Ontario. Barlow and McGillivray (1983) reported that it first arrived at Stouffville in 1953, and that the range at that time extended to Sudbury and Ottawa. The first nest in the Kingston area was found in 1979, and a substantial increase in the number of pairs occurred in 1981. South of the Canadian Shield, it was more numerous than the Alder Flycatcher, while the Alder Flycatcher dominated on the Shield. The population is probably increasing as a result of range expansion, but breeding densities at given locations are not changing substantially (Barlow and McGillivray 1983; Sedgwick 2020; Weir 2008). During the first atlas, the Willow Flycatcher occurred in most squares south of the Canadian Shield and there was a sizable population in the Sudbury area (Prescott in Cadman et al. 1987). James (1991) considered the Willow Flycatcher locally common in southern agricultural areas, becoming rare north to Sudbury.

The second atlas indicated that there was no significant change in the probability of observation of the Willow Flycatcher between atlases for the entire province. There was a significant increase in the southern Shield consistent with a modest range expansion into this area. Highest densities occurred in Prince Edward County, the Kingston area south of the Shield, from Long Point north to Hamilton and throughout Niagara Region, and in Lambton and Middlesex counties (Sandilands in Cadman et al. 2007).

Range expansions have also occurred in Quebec and British Columbia. The Willow Flycatcher was first recorded in Quebec in 1971, and started to increase significantly in the early 1980s. It was still expanding its range in southern Quebec in the mid-1990s; except for the House Finch, no other species in Quebec had spread as far or rapidly. In British Columbia, it started to become more common around 1975 and increased its range eastward (Campbell et al. 1997; Sedgwick 2020; Seutin in Gauthier and Aubry 1996).

Long-term (1978-2021) population trends on the Breeding Bird Survey were annual decreases of 1.12% in Canada and 1.44% in Ontario. During 2011-21, there were annual decreases of 0.395% in Canada and 3.87% in Ontario. The short-term trends for Ontario were of medium reliability; the long-term trends were highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Young remain near the nest for 3 or 4 days then follow the adults through the territory for the next 2 or 3 weeks begging for food (Sedgwick 2020).

Vormvald et al. (2011) studied the Willow Flycatcher during the postbreeding period in the Sierra Nevada, California. In shrubby meadows, family groups moved an average of 48 m from the nest in 1 year and 23 m the following year. Ninety-four percent of sightings of families in both years were in riparian willow shrubs within a meadow. The remaining observations were in edges of upland forest surrounding the meadow. The mean 95% home range size for families was 1.8 ha and the mean 50% core area was 0.3 ha. Movement patterns were most often characterized by clustering activity around the central natal area with occasional trips away from the central area. Fledglings gradually moved away from the nest during the dependence period. Distance from the nest increased with age but movements back to the nest also occurred. The authors reported the results of another study in Arizona that found that the mean postbreeding season home range of adults was 143.2 ha, compared with 9.9 ha in the prenesting season and 0.38 ha during breeding.

MIGRATION

Migration is nocturnal and males tend to migrate earlier in spring than females by as much as 1 or 2 weeks. Both sexes compress spring arrival into a 10-14-day period. At Long Point, 90% of birds passed through between 21 May and 9 June, with migration essentially complete by 10 June (Hussell 1991b; Sedgwick 2020). Timing of autumn migration appears to be stimulated by declining abundance of aerial insects. Adults migrate prior to juveniles. At Long Point, the middle 90% of adults passed through between 17 July and 23 August compared with 11 August to 9 September for juveniles. This pattern has been confirmed throughout the Willow Flycatcher's range. It has been documented in the province in late September and early October (Hussell 1991c; James 1991; Sedgwick 2020).

Habitat used during migration is similar to the breeding season. The Willow Flycatcher is most likely to occur in shrubby areas and areas with scattered, small trees. Pastures and dry meadows with scattered shrubs are less likely to be used during migration than in the breeding season. During autumn migration in California, individuals remained at a site an average of 6 days, with a range of 2-19 days (Finch and Stoleson 2000; McCabe 1991; Otahal 1998; Sedgwick 2020).

The highest annual mortality rate occurs during migration. Paxton et al. (2017) studied survival rates of Southwestern Willow Flycatcher populations that wintered in Costa Rica. Although migration constituted only 25% of the annual cycle, it accounted for 62% of the annual mortality.

James (1991) termed the Willow Flycatcher an uncommon migrant, with spring vagrants wandering as far north as Rainy River and Manitouwadge.

Least Flycatcher

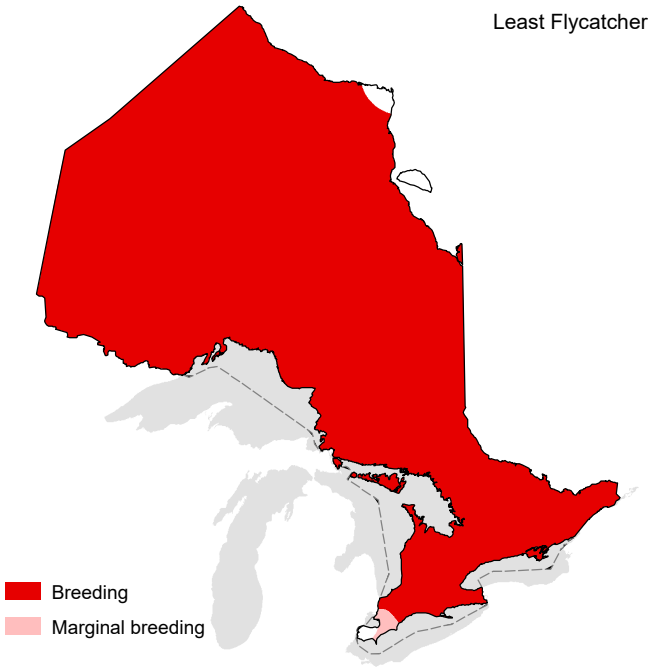
Empidonax minimus

BREEDING SEASON

Habitat Requirements

In Ontario, the Least Flycatcher has nested in semi-open immature deciduous and mixed forests and occasionally in groves of conifers, burns, edges of swamps and bogs, orchards, and shrubby fields. Nesting occurred once in a deciduous grove on a sand dune. Nests are usually near openings such as forest clearings and edges, water, roads, and cottages (Peck and James 1987).

In the Boreal Forest Region of Ontario, the Least Flycatcher was associated with immature to younger hardwoods with fairly open conditions. It was also associated with a high amount of edge which was a measure of forest cover configuration and age-class interspersion (Rempel 2007). Baillie and Hope (1943) found it in a variety of habitats along the northeastern shore of Lake Superior, but it was most abundant in shrubby growth in recent burns. Near Hearst, it inhabited uncut upland mixed and lowland coniferous stands and clear-cuts 11-24 years old (Welsh and Fillman 1980). In the Clay Belt, it was most abundant in stands dominated by poplars or black spruce, but was absent in jack pine stands (Welsh and Lougheed 1996). In boreal Ontario and the Clay Belt, it is most



abundant in deciduous forests, predominantly poplar or birch, but also in sugar maple–beech stands. Less frequently, it occurs in mixed forests, coniferous forests (usually a mix of balsam fir and spruce, rarely hemlock or tamarack), and in deciduous, mixed, and coniferous shrubs. It avoids white, red, and pitch pine stands (Erskine 1977; McLaren and McLaren 1981).

In the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region, the Least Flycatcher nests in mature and old-growth white pine stands. Its abundance was significantly correlated with the basal area of deciduous species and stand age, although there was no significant difference in its abundance in mature and old-growth stands (Kirk et al. 2012). Near Quetico Park, it was equally abundant in young (1-23 years) stands and old-growth forests over 350 years old, twice as abundant in intermediate-aged stands (67-73 years), and half as abundant in mature stands (112-176 years; Apfelbaum and Haney 1985). Near Gogama, it was absent in pure jack pine stands, but occurred in mixed jack pine–deciduous forests with open canopies of 25% or less. It was locally common only when trees exceeded 10 m in height and was always associated with trembling aspen and/or white birch (James and Peck 1995a). Similar habitat was selected at Pickle Lake (James 1980). In Algonquin Park, the Least Flycatcher was common in white birch–poplar forests, and it also nested in and at edges of sugar maple–yellow birch forests. It was absent in bogs, black spruce, black spruce–white cedar, fir-spruce, immature white pine, pure white cedar, and fir-spruce-hardwood stands (Martin 1960). In Muskoka District and Haliburton County, its nest locations were associated with very high tree density and canopy volume, and less than average shrub density. It inhabited areas that had been cleared and allowed to proceed to an early successional forest stage (Clark et al. 1983).

In the Great Lakes–St. Lawrence Forest Region south of the Shield, the Least Flycatcher preferred forest edges or openings in wooded wilderness areas. It also occurred in alder thickets along streams or in damp depressions, birch stands, mature aspen-poplar forests, second-growth hardwoods, orchards, and shade trees around houses (Snyder 1953). In Durham Region, it occurred in a mature maple-oak stand with an open canopy (Speirs and Orenstein 1975). McIlwraith (1894) stated that it nested at forest edges and in orchards in the Carolinian Forest Region. In the north, the Least Flycatcher is associated mostly with poplars and birch; in the south it may also nest in hardwood stands. Its usage of orchards appears to have declined significantly since earlier reports. It nested in red pine plantations south of Peterborough. The plantations were 25-70 years old and were managed by row thinning and selective thinning every 10-15 years. Thinning promoted the growth

of red oak and black cherry saplings as well as a ground cover of poison ivy. Occupied areas had more (34%) deciduous trees at least 8 cm diameter at breast height (DBH); unoccupied sites had only 4% deciduous trees. Canopy cover at occupied sites (84.2%) was significantly greater than at unoccupied sites (71.3%). This was the first reported use of pine plantations by nesting Least Flycatchers (Geboers and Nol 2009). The deciduous regeneration that appears after thinning is likely the greatest attractant, along with the well-developed canopy layer and relatively open understorey.

Elsewhere, the habitat requirements of the Least Flycatcher are similar to those in Ontario, but there is considerable disparity in reported preferences. In some areas, it is considered an edge species, nesting on forest edges, adjacent to clearings, and in shrubby areas. Other studies indicate that it prefers dense forests. Information on preferred age of forest is also conflicting. Most studies found that it was associated with young stands and a long-term study associated its decline with forest maturation. In other areas, particularly in the west, it appears to be restricted to mature hardwood stands. In Alberta aspen stands, it was significantly more abundant in old-growth stands than in mature or young stands. In Minnesota, it nested in low density in clear-cuts in forests dominated mostly by trembling aspen and white birch mixed with pine, spruce, and balsam fir. Most early authors stated that it was most common in orchards, scattered trees around houses, and in urban woodlots, and that it tended to avoid forests. The most recent of these studies is over 30 years old, and nesting in these habitats now appears to be rare. The 1 common theme is that it is common in aspen and birch stands as well as those dominated by sugar maple, often with associates of beech or yellow birch, less frequently with oaks. Coniferous forests are usually avoided and, in mixed forests, it selects pockets of deciduous cover, usually poplar or birch. In some areas, it prefers hemlock–yellow birch stands. In eastern Quebec, it nested in riparian stands of balsam fir and white cedar. Other habitats it has nested in included stands dominated by Hill's oak, oak and maple, juneberry, Manitoba maple–willow, and lowland ash-basswood. Many territories are bounded by open areas on 1 side, such as lakes, roads, and forest clearings (Back 1979; Bent 1942; Beals 1960; Bielefeldt and Rosenfield 1994; Campbell et al. 1997; Darveau in Gauthier and Aubry 1996; Erskine 1977; Faanes and Andrew 1983; Flack 1976; Graber et al. 1974; Haney 1999; Holmes and Sherry 2001; Holmes and Sturges 1975; Johnston 1971; Kirk et al. 1996; LaRue et al. 1995; MacQueen 1950; Mossman 1988; Mossman and Hoffman 1989; Mousley 1916a; Niemi and Hanowski 1984a; Niemi and Pfannmuller 1979; Niemi et al. 1995; Noon et al. 1979; Schieck et al. 1995; Tarof and Briskie 2020; Taylor and Taylor 1979; Temple et al. 1979).

In North Dakota at the landscape level, the Least Flycatcher preferred areas that were 51-75% forested; no areas were more than 75% forested (Cunningham and Johnson 2019). In North Dakota 400-m-radius landscapes, its probability of occurrence increased with the amount of tree cover within 100 m. Results were similar in landscapes with more than and less than 30% tree cover (Cunningham and Johnson 2016).

Several studies determined microhabitat preferences of the Least Flycatcher. In Quebec, it occurred where the canopy was tall, well developed, and contained a higher proportion of sugar maple than unused areas. In order, the most important habitat predictors were the height of the first leaved branch, total crown height, proportion of sugar maple, and percent coverage in medium and tall tree strata. It was negatively associated with herbaceous coverage (Darveau et al. 1992). It

prefers drier woodlands than other eastern *Empidonax* flycatchers. Usually it is found in more densely vegetated habitats than the Eastern Wood-Pewee, but in less densely vegetated forests than the Acadian Flycatcher (Hespenheide 1971a; Tarof and Briskie 2020). Unlike Quebec results, which appear to be more typical of Ontario conditions, some studies found it correlated with openness of the canopy and presence of ground cover rather than with closed canopy with little shrub or herbaceous cover. It is positively associated with forest size and negatively associated with woodlot isolation. It is not particularly area sensitive and may occur in woodlands as small as 0.2 ha. In burns and clear-cuts, breeding density may be highly dependent on the number of residual snags (Back 1979; Breckenridge 1956; Campbell et al. 1997; Faanes and Andrew 1983; Hespenheide 1971a; Johnston 1971; Kasumovic et al. 2009; Kirk et al. 1996; MacKenzie et al. 1982; MacQueen 1950; Niemi and Pfannmuller 1979; Samson 1979; Tarof and Briskie 2020; Tarof and Ratcliffe 2004; Temple et al. 1979). In New Hampshire and Maine, it occurred in all ages of stands. It was most abundant in white birch and northern hardwood stands and occurred much less frequently in spruce-fir stands. It was absent in stands dominated by aspens, swamp hardwoods, balsam fir, white pine, or hemlock. Its abundance was positively correlated with canopy closure, total foliage volume of coniferous trees larger than 10 cm DBH, and total foliage volume of deciduous trees 2-10 cm DBH and less than 2 cm DBH. It was negatively correlated with percent ground cover, coniferous trees 2-10 cm DBH, and number of woody stems per ha (DeGraaf et al. 1998). In Alberta, nest habitat parameters were 12.5 m canopy height, 95% canopy cover, 8% shrub coverage, 95% ground cover, and basal area of 29.22 m^2 per ha. Within a 5-m radius around the nest, there were 21.8 trees, 14.9 saplings, and 9.5 snags (Van Brempt et al. 2023).

Near Ottawa, presence of the Least Flycatcher in landscapes was negatively correlated with the total amount of forest edge. Probability of detecting it in a 2.5-by-2.5-km square was 80% when there was less than 10 km of forest edge, 50% at approximately 15 km of edge, and 10% at 25 or more km of edge (Villard et al. 1999). Villard et al. (2007) considered the Least Flycatcher a habitat generalist that was not particularly attracted to either forest edge or interior. They mapped its distribution prior to and after creation of edges by clear-cutting in Saskatchewan. It did not exhibit an avoidance reaction to edge and showed a significant attraction to edge in 1 of 2 experimental plots. Lindell et al. (2007) reported on 2 studies: 1 demonstrated that the Least Flycatcher showed no response to forest edge, the other found that it was more abundant in edge habitat. Near Kingston, breeding density and reproductive success were similar in fragmented and contiguous forest (Tarof and Briskie 2020; Tarof and Ratcliffe 2004).

All Ontario nests were in trees, with 88.8% in deciduous trees, and most were in live trees. Saplings and small trees were selected over large trees. In order of preference, nest tree species were birch, maple, poplar, and pine. Most nests were in crotches or forks, with some on horizontal branches where they were supported by small lateral branches. Some nests were 0.6-2.0 m from the tree trunk. Nests were 0.6-15 m from the ground, with most 3-8 m up. Occasionally nests were built of material from old nests (Peck and James 1987; Tarof and Briskie 2020). Kendeigh (1947) reported a nest north of Lake Nipigon that was 18.3 m from the ground in a 21-m-tall white birch.

Elsewhere, nests have been reported in apple, willows (sandbar and peach-leaved), sugar maple, beech, yellow birch, red maple, Manitoba maple, green ash, cottonwood, common elderberry, black

cherry, oaks (white, red, and black), trembling aspen, hemlock, white birch, pines (white and jack), witch-hazel, balsam poplar, red-osier dogwood, mountain ash, pear, sycamore, locust, sumac, spruce, tamarack, and alder. In Quebec, sugar maple, beech, yellow birch, and red maple were used according to their availability, with no apparent preference for tree species. In Manitoba, green ash, Manitoba maple, and sandbar willow were selected. Other species were used less frequently than expected, particularly peach-leaved willow. Most nests are in upright crotches of small trees, usually where there are 3 or 4 branches in the fork. They may also be on horizontal branches or in vertical crotches of small branches away from the trunk. Nest heights range from 0.6 to 20 m (average 3.5-8.5 m). In Alberta, mean height of nests was 3.63 m, mean height of the nest tree was 10.1 m, mean DBH of the nest tree was 9.85 cm, and the mean amount of cover over the nest was 7%. Seventy-five percent of nests were in trembling aspen and 25% were in balsam poplar. Nests are usually in the lower to middle portions of the canopy. Material from active or old nests of Least Flycatcher and other species may be taken to construct the nest. There is 1 reported instance of it nesting in an abandoned Yellow Warbler nest that contained 1 warbler egg; no attempt was made to repair the nest. Rarely, nests may be reused, with 1 British Columbia nest being used in 3 successive years (Baillie and Hope 1943; Bent 1942; Breckenridge 1956; Briskie and Sealy 1988; Briskie et al. 1990; Campbell et al. 1997; Darveau et al. 1993; Davis 1959; Goossen 1977; Graber et al. 1974; Johnston 1971; Nice and Collias 1961; Tarof and Briskie 2020; Van Brempt et al. 2023).

The Least Flycatcher appears to be colonial, nesting in groups in small portions of suitable breeding habitat. In northern Ontario, it usually occurred in jack pine stands only where there were large enough patches of deciduous trees to support several pairs; it rarely nested singly. Colonial behaviour has been documented elsewhere in Ontario, Quebec, Virginia, Minnesota, and Michigan. Nests have been found as close together as 20 m (Breckenridge 1956; Darveau et al. 1992; Davis 1959; James and Peck 1995a; Peck and James 1997; Perry et al. 2008; Tarof and Briskie 2020). Near Kingston, territories averaged 0.1 ha with contiguous boundaries in dense clusters, but large areas of apparently suitable habitat were unoccupied. Clusters contained 2-30 territories with a density in excess of 11 territories per ha. Distances between clusters averaged 1,245 m (range 346-2,402 m). Clustered breeding may promote extra-pair copulations. The locations of clusters varies annually (Tarof and Ratcliffe 2004). Not all Least Flycatcher populations are colonial. In eastern Ontario, approximately 10% of males settled solitarily. Territory size of solitary males averaged 0.29 ha (range 0.11-0.84 ha). Solitary males may establish territories as far as 2.1 km from other Least Flycatchers (Tarof and Briskie 2020). In Minnesota, clusters of breeding Least Flycatchers contained 5-84 territorial males. Locations of 157 nests ranged 0-170 m from the edge of the cluster. Nests 45 m or more from the edge of a cluster had 34-38% lower predation rates, probably due to the dramatic vocal responses of flycatchers to predators (Perry et al. 2008).

The Least Flycatcher is territorial and actively excludes other Least Flycatchers and particularly the American Redstart, a direct competitor, from the territory. Territories may overlap extensively with other flycatcher species such as Eastern Wood-Pewee, Eastern Phoebe, and Great Crested Flycatcher. The female defends a radius of about 6 m (0.01 ha) around the nest; the male defends a larger area. Because of its colonial habit, territory sizes are small. North of Lake Nipigon, territories averaged 0.52 ha (range 0.40-0.65 ha). In Algonquin Park, territories averaged 0.13 ha (range 0.03-

0.38 ha). In Quebec, territories averaged 0.13 ha in healthy sugar maple stands and 0.23 in declining stands. In New Hampshire, territories averaged 0.18 ha; the average in Michigan was 0.07 ha (range 0.01-0.20 ha). In Virginia, territories ranged from 0.05 to 1.1 ha, but most were smaller than 0.22 ha. The male with the largest territory had a neighbour on 1 side only. During the nestling-feeding phase, his territory shrunk to 0.12 ha. Territories are largest during laying and incubation. Home ranges are larger than the territory. Nearby openings may be shared by pairs as feeding areas (Breckenridge 1956; Davis 1959; DesGranges et al. 1987; Johnston 1971; Kendeigh 1947; MacQueen 1950; Martin 1960; Sherry 1979; Sherry and Holmes 1988; Tarof and Briskie 2020).

The Least Flycatcher exhibits low natal philopatry. In Manitoba, 4.2% of 410 nestlings returned to nest the following year; in Michigan 0 of 46 nestlings returned. In eastern Ontario, 1 of 20 nestlings (5%) returned to breed the following year and it bred in a different cluster more than 1 km from its natal site (Tarof and Briskie 2020).

Adult site fidelity is variable. In eastern Ontario, only 4 of 98 adults (4.1%) returned to breed in the subsequent year. One female occupied the same solitary territory, 1 male occupied the same territory in the same cluster, and 2 males occupied territories in clusters more than 10 km from where they were banded. In Michigan, the adults of 4 pairs were banded. All 4 males and 2 females returned the next year, but none returned the following year (Tarof and Briskie 2020).

Limiting Factors

Eggs have been found in Ontario nests from mid-May until late July, with most present from the second week of June until late June (Peck and James 1987). In eastern Ontario, the earliest egg date was 16 May and the latest was 14 June (Tarof and Briskie 2020). In Algonquin Park, nests are under construction from mid-May to late June, eggs are present from late May until mid-July, nestlings are present from mid-June to late July, and recently fledged young occur from late June to late July (Tozer 2012).

The Least Flycatcher has a compressed nesting season in Ontario. Based on banding results at Long Point, Hussell (1981) determined that it spent an average of no more than 64 days on the breeding grounds. In Manitoba, Sealy and Biermann (1983) reported a nesting season that totalled 58 days. The pre-egg stage was approximately 13 days, 3 days for egg laying, about 13 days for incubation, 15 days for fledging, and postfledging parental care for at least 14 days. In eastern Ontario, males established territories on 11 May, about 6 days before females arrived. Nests are built 1 or 2 weeks after arrival over a period of 5-7 days, usually starting about 2 days after the female's arrival. Three Ontario nests took 6, 6, and 9 days to complete. Usually 1 egg is laid a day, but occasionally a day is skipped between the third and fourth egg. In Manitoba, the mean egg-laying interval was 1.14 days. Incubation begins full-time with the laying of the last egg, although some time may be spent on the nest before the clutch is complete. Eggs hatch slightly asynchronously (1.1 day for 3-egg clutches, 1.5 day for 4-egg clutches, and 1.9 day for 5-egg clutches). The incubation period of 2 Ontario nests was at least 13 days and 14 days at another. Overall, incubation periods of 12-15 days have been reported. Young fledge when they are 12-17 days old, usually at 13-15 days. The mean age at fledging in eastern Ontario was 13.6 days (Bent 1942; Briskie and Sealy 1987a, 1989a, 1989b; Campbell et al. 1997; Darveau in Gauthier and Aubry 1996; Davis 1959; Holmes et al.

1979; MacQueen 1950; Nice and Collias 1961; Peck and James 1987; Tarof and Briskie 2020; Walkinshaw 1961).

One brood is typically raised in a year. Two instances of double brooding were documented in Manitoba. Double brooding is likely to be detected only in intensive studies but detailed research in eastern Ontario found no evidence of second broods. In Manitoba, females laid their first egg in the second clutch 7-8 days after the first brood fledged. New nests were built in both cases; 1 was 3.5 m from the original nest. A pair must remain on the breeding grounds approximately 40 days longer if a second brood is raised. Renesting is common if a clutch is lost. Usually a new nest is built for the replacement clutch; the same nest is rarely used again. Second-attempt clutches are often smaller and have low survival rates. Ontario clutches contained 2-5 eggs, with most (61.4%) containing 4 eggs; 3-egg clutches comprised 26.1% of nests. Near Kingston, the average clutch size was 3.9 eggs (range 3-4 eggs). Overall, the most frequent clutch size is 4 eggs, followed by 3. Two- and 5-egg clutches are rare; 2-egg clutches are frequently replacement clutches. Clutches of 6 and 7 eggs are very rare and may be due to intraspecific egg dumping. A brood of 6 young in British Columbia was attended by 3 adults and the only 7-egg clutch reported was known to be produced by 2 females (Bent 1942; Briskie and Sealy 1987a, 1988, 1989a; Campbell et al. 1997; Darveau et al. 1993; Davis 1959; Graber et al. 1974; Keast 1990; Mousley 1916a; Sealy and Biermann 1983; Tarof and Briskie 2020).

The age at first breeding is 1 year for both sexes, and breeding occurs every year. The normal mating system is monogamy, but polygyny was documented once in Manitoba. Nests of the 2 females were 21 m apart, and both were successful. The male delivered about 55% of the food to 1 nest, but less than 9% to the other (Briskie 1994; Briskie and Sealy 1987a). In Michigan, both members of 2 pairs returned the following year and both pairs remained mated (Tarof and Briskie 2020). Near Kingston, extra-pair paternity was common in colonial nesters (Tarof and Ratcliffe 2004) and in large, contiguous forest (50% of nests) but was less prevalent (11%) in fragmented forest (Kasumovic et al. 2009). Females prefer males holding territories within clusters; solitary territorial males are often unpaired (Tarof and Briskie 2020).

Most (81%) foraging is done by making short sallies (about 1.2 m, seldom more than 2-2.5 m) from perches to hawk insects; 19% of prey is captured by gleaning, including hover-gleaning. The Least Flycatcher forages at heights of 1-20 m (mostly 3-15 m), usually in the space from the top of the shrub and sapling stratum to the lower canopy. It forages at lower heights than the Eastern Wood-Pewee and Great Crested Flycatcher, but there is some overlap with the wood-pewee. About 75% of its perches are dead branches and almost 20% are live branches, with a small proportion of perches being inanimate objects. The Least Flycatcher forages in deciduous species 90-93% of the time with the remainder of time spent in conifers. In Wisconsin, it foraged on trees according to their availability, except for pines which were seldom used. In New Hampshire, it foraged mostly on yellow birch; used beech, sugar maple, and white ash considerably less than their availability; and avoided conifers. Yellow birch appeared to support a higher density of lepidopteran larvae than other tree species (Breckenridge 1956; Greenberg et al. 1999; Holmes and Schultz 1986; Johnston 1971; Robinson and Holmes 1982; Rogers 1985; Sherry 1979; Tarof and Briskie 2020). In New

Hampshire, there was no difference in the sexes' foraging heights (mean of 10.5 m for males and 10.4 m for females), their foraging techniques, or tree species usage (Holmes 1986).

Ninety-eight percent of the diet consists of invertebrates. Over 40% of food consists of hymenopterans, especially ants and parasitic wasps. The remainder of invertebrates eaten are approximately 20% beetles (weevils and long-horned beetles), 10% bugs (leaf and leaf-footed bugs, treehoppers, leafhoppers, and spittlebugs), 10% flies (crane, dance, blow, snipe, and anthomyiid flies), 7% lepidopterans, and 2% orthopterans. Kendeigh (1947) examined the stomach contents of 4 Least Flycatchers from north of Lake Nipigon. The diet consisted of 40.4% stink bugs, 21.8% lepidopterans, 13.1% beetles (including scarab and soldier beetles), 8.4% spiders, 6.5% flies (mostly house flies), 5.5% hymenopterans (including ichneumonid wasps and ants), and 4.4% brown lacewings. At Delta Marsh, midges were the most frequently consumed prey. In Quebec, nestlings were fed mostly beetles (especially the brown leaf beetle), and caterpillars. In New Hampshire, the diet consisted of 49.8% beetles, 21.4% flies, 15% hymenopterans, 8.0% bugs, 4.8% caterpillars, 0.5% spiders, and 0.5% others. Other items that have been fed to nestlings include bugs, dobsonflies, damselflies, and snails. In addition to these foods, adults occasionally eat mayflies, fruit (raspberries, pokeweed, and elderberries), and timothy seeds. Insects consumed ranged in length from 2 to 14 mm, but most were 2-8 mm long. In Virginia, the Least Flycatcher's diet overlapped 46% with the Eastern Wood-Pewee and 28% with the Great Crested Flycatcher. The other 2 flycatchers selected slightly larger invertebrates (Bent 1942; Briskie 1988; Darveau et al. 1993; Graber et al. 1974; Hespenheide 1971b; Johnston 1971; Robinson and Holmes 1982; Tarof and Briskie 2020). Nancekivell and Nocera (2025) used DNA to analyze the adult diet in New Brunswick and compared the diet of the Least Flycatcher to those of the Alder Flycatcher and the Bank, Tree, Barn, and Cliff swallows. All species differed in their dietary breadth and prey preferences. The Least and Alder flycatchers and the Barn Swallow ate a greater diversity of terrestrial flies than the other species, which ate more aquatic taxa. The 2 flycatcher species and the Barn and Tree swallows had broader generalist diets compared with the Bank and Cliff swallows. The approximate frequencies of occurrence of invertebrate groups in the diet of the Least Flycatcher were 80% aquatic flies, 60% terrestrial flies, 60% lepidopterans, 40% aquatic beetles, 40% terrestrial beetles, and 10% neuropterans. The approximate frequencies of invertebrate families in the diet of the Least Flycatcher were 50% mosquitoes, 50% leafroller moths, 40% snipe flies, 40% limoniid crane flies, 40% long-legged flies, 40% marsh beetles, 40% weevils, and 20% bristle flies. Near Manitouwadge, Venier et al. (2009) observed no relationship between the abundance of the Least Flycatcher and the spruce budworm. Morris et al. (1958) reported similar findings in New Brunswick.

The Least Flycatcher is infrequently parasitized by the Brown-headed Cowbird. Of 143 Ontario nests, 3.5% were parasitized. Parasitism rates reported elsewhere are 0% and 13.3% in Quebec, 9.3% and 11.9% in Michigan, 2.8% in Manitoba, and 19% in British Columbia. It usually accepts cowbird eggs, but may occasionally abandon the nest. Hatching of a cowbird egg typically results in no flycatchers fledging. In Manitoba, Yellow Warbler nests were parasitized 6 times more frequently, although the 2 species nested in the same habitat. Lower incidence of flycatcher parasitism was thought to be due to later clutch initiation and nests being better concealed and higher than the warbler's. Flycatcher nests below 2 m had a parasitism rate of 6.1% compared with 1.9% for higher

nests (Briskie and Sealy 1987b; Briskie et al. 1990; Brittingham and Temple 1996; Campbell et al. 1997; Darveau et al. 1993; Peck and James 1997; Tarof and Briskie 2020; Walkinshaw 1961).

Forest management may affect the Least Flycatcher depending upon the treatment used. Vanderwel et al. (2007, 2009) reviewed studies on the effects of partial harvest of forests in the Boreal Forest Region of Ontario. They concluded that its abundance was unchanged when 30% of trees were removed, but that it declined when 50% or 70% of trees were removed. It experienced a 25% decrease when 40% of trees were removed, a 50% decrease when 60% of trees were removed, and a 75% decrease when 75% of trees were removed. In the Boreal Forest Region of Ontario, Rempel et al. (2007) modelled the effects of timber harvesting on the Least Flycatcher. They predicted no change in habitat availability over 100 years if no spatial guidelines were applied, if all guidelines for featured values were adhered to, or if natural disturbance patterns were emulated. In Algonquin Park, it increased 1-2 years after intensive group selection of trees. This involved cutting 0.05-ha circular plots resulting in almost 4 gaps per ha or about 20% of the area. Typical group selection cutting, which affected about 5% of the stand area, had no effect on its abundance (Tozer et al. 2010). Single-tree selection in Algonquin Park also had no effect on the abundance of the Least Flycatcher (Jobes et al. 2004). Near Sault Ste. Marie, it responded positively to single-tree selection thinning in northern hardwoods, increasing in abundance 1-2 years after harvesting. Its abundance was closely associated with sedge and grass cover and tall shrub density (Holmes and Pitt 2007). In the Canadian Shield of Ontario, there was no difference in its abundance in early successional clear-cuts and burns, but it was significantly less abundant in mid-successional clear-cuts than in mid-successional burns. There was no difference in its abundance in early successional and mature stands, but it was significantly more abundant in mid-successional than mature stands (Zimmerling et al. 2017). In Minnesota, it increased in riparian buffer strips that were partially harvested (Hanowski et al. 2002). In large forest tracts, it responds to logging by shifting into forest interior away from disturbance. In New York, the Least Flycatcher was adversely affected by logging and considered a true species of undisturbed forest, contrary to results observed in Ontario. In uncut forests, it constituted 5.1% of the birds present and was seventh in abundance, and this dropped to 2.2% and fourteenth in forests where 25% of trees were cut. Further declines occurred as logging intensity increased. In Vermont, it tended to avoid logged areas, particularly centres of small clear-cuts. It declined in Quebec forests managed for sugar maple production. Beech and yellow birch are eliminated in these forests, and these species are preferred for foraging above sugar maple. In Nova Scotia, the Least Flycatcher occurred both in uncut and strip clear-cut areas. It was one of the dominant species in uncut forest and was absent in clear-cuts, but present in thinned and strip-cut plots at approximately half the density. In areas of Nova Scotia where clear-cutting occurred, it first returned as a regularly breeding species when regenerating forest was 20 years old (Darveau in Gauthier and Aubry 1996; Freedman et al. 1981; Lent and Capen 1995; Morgan and Freedman 1986; Noon et al. 1979; Tarof and Briskie 2020; Webb et al. 1977). In Minnesota, blowdown of spruce-fir forest resulted in an 80% loss of canopy cover and a 100% increase in shrub cover. The Least Flycatcher was more common in the blowdown area, but not significantly (Burris and Haney 2005). In Muskoka District and Haliburton County, Clark et al. (1983) predicted the impact of cottage-lot development on the Least Flycatcher. They concluded that selective tree removal that opened the

canopy would provide good habitat, but that extensive tree removal or reductions in the shrub or sapling layer would be detrimental.

Declines in health of sugar maple stands in Quebec affected the Least Flycatcher. It declined with the amount of die-back in maples, and numbers tended to fluctuate more in declining areas. The mean number of pairs per 0.5 ha was 2.3 in healthy stands compared with 1.0 in die-back stands, a decrease of 57%. There appeared to be no significant differences in breeding success in healthy and declining stands (Darveau et al. 1992, 1993; DesGranges et al. 1987).

The Least Flycatcher appears to decline during drought years. Large reductions in breeding numbers occurred in western aspen forests during drought years. Similar declines were documented in dry years in Michigan and Wisconsin (Blake et al. 1992; Flack 1976). Insects may be less abundant in dry years.

In Pennsylvania, densities were lower in areas highly browsed by deer (Niemi et al. 1995). Deer browsing may be a limiting factor in some areas of southern Ontario and similar problems have been identified in the northeastern United States. It has been suggested that deer populations should not exceed 4-8 animals per km^2 to avoid habitat damage. Southern Ontario populations are generally much higher than that (Tarof and Briskie 2020).

In Edmonton, abundance of the Least Flycatcher was negatively correlated with noise (Proppe et al. 2013). Anthropogenic noise, particularly from roads, was a factor in its local decline. Traffic noise masks the lower note of the song. Females that do not hear this note may not adequately perceive and assess the singing male, or may deem him to be an ill-suited mate. It was more abundant near quiet well pads than noisy compressor stations, suggesting that it was affected by chronic noise (Bayne et al. 2008).

Bayne et al. (2016) assessed the impact of forest fragmentation by energy sector facilities in Alberta. The Least Flycatcher was more abundant in adjacent forest interior than along seismic lines, was similar in abundance along pipelines and in adjacent forest, and was more abundant near well pads than in adjacent forest interior.

The American Redstart has evolved to become very flycatcher-like, and it and the Least Flycatcher appear to be in direct competition. Their habitat niches are so strongly correlated that their abundance changes are synchronous. Both occupy the same forest types, inhabit the stratum between the top of the shrub and sapling layer to the lower canopy, forage by flycatching and hovering for insects, and have very similar bill structures. The flycatcher is usually dominant and successful in excluding the redstart from nesting in its territory. Diet of the 2 species is also similar, being dominated by flies, hymenopterans, and beetles (79% of the redstart's diet, 92% of the flycatcher's diet), but the Least Flycatcher eats considerably more caterpillars (Sherry 1979; Sherry and Holmes 1988).

In Illinois, all 5 Least Flycatchers that were examined were contaminated with DDE, dieldrin, and heptachlor. Concentrations in flycatchers were high compared with species that eat fruit or seeds (Tarof and Briskie 2020).

Price (2004) concluded that the range of the Least Flycatcher would contract in southern Ontario if average summer temperatures increased by 2°C.

Status

It is likely that the Least Flycatcher was more abundant prior to extensive forest clearing in the south. It has always been a common breeder in the province. McIlwraith (1894) considered it very common, Baillie and Hope (1943) reported it very common along the northeast shore of Lake Superior, Baillie and Harrington (1937) considered it a common breeder north to southern Kenora District and the southern portion of James Bay, and Smith (1957) termed it common in the Clay Belt. During the first atlas, breeding evidence was obtained throughout the province except in the northeastern portion of the Hudson Bay Lowland; it bred sporadically in the remainder of this geographic area. It was most abundant in forested areas south of the Canadian Shield (Fraser in Cadman et al. 1987). James (1991) considered it common to locally abundant north to Big Trout Lake and Fort Albany, and rare and local to Fort Severn in the west.

The second atlas demonstrated that there had been no change in the distribution of the Least Flycatcher since the first atlas, except that it apparently disappeared from many squares in the highly agricultural areas of Lambton County. There was no significant change in its probability of observation throughout the province, but there were changes in some regions. A significant increase was noted in the Hudson Bay Lowland that may have been a reflection of better coverage. A statistically significant decline in the area south of the Shield occurred, although it was observed in almost the exactly same number of squares during both atlases. It was most abundant in the Shield in both the Boreal and Great Lakes–St. Lawrence forest regions. Lowest abundance occurred south of the Shield, in all but the eastern portion of the Hudson Bay Lowland, and in the extreme northern portion of the Shield (Mills in Cadman et al. 2007).

Long-term (1970-2021) Breeding Bird Survey data indicate annual decreases of 1.12% in Canada and 1.44% in Ontario. Short-term (2011-21) trends were annual decreases of 0.395% in Canada and 1.65% in Ontario. All results were highly reliable except that the short-term Ontario trend was of medium reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Young may remain in the vicinity of the nest and be attended by the parents for 10-15 days after fledging, occasionally for as long as a month (Tarof and Briskie 2020).

Akresh et al. (2009) studied habitat use of postbreeding adults and independent juveniles in Michigan. Although sample sizes were small (3 adults and 9 juveniles), all birds were captured in riparian forest and none were captured in upland forest. In Minnesota regenerating clear-cuts, Streby et al. (2011b) captured 4 Least Flycatchers during the breeding period, but caught 73 adults and 153 fledglings during the postbreeding season. Of the 28 species in the study area that nested in mature forest, the Least Flycatcher constituted 12.9% of those that were captured in regenerating clear-cuts during the postfledging period. Shrubby areas and areas with dense sapling growth appear to be important to it during the postfledging period.

Major and Desrochers (2012) captured Least Flycatchers in clear-cuts in Quebec. Similar numbers were captured in control plots and in those where the fruit had been removed. In

Pennsylvania during the postfledging period, Stoleson (2013) captured 3 adults and 24 juveniles in clear-cuts and none in nearby mature forests with a dense understorey.

MIGRATION

Migration appears to be predominantly nocturnal. The median arrival date in southern Ontario is 18 May. At Long Point, the Least Flycatcher may occur in very early May, but the first large influx always occurs after mid-May, with migrants occurring almost as late as mid-June. Males arrived an average of 8.2 days earlier than females, and older females arrived slightly before yearling females. In other areas, it has also been verified that males precede females (Brewer et al. 2018; Hussell 1981; Mills 2005a). In autumn, adults migrate about a month earlier than juveniles. At Long Point, adults occur as early as the first week of July, with the first migrants probably being failed breeders. Migration of adults continues until the end of August. Over a 3-year period in the 1960s, the mid-90% of adults occurred in a 34-day period between 11 July and 13 August, with an overall median date of 22 July. Juveniles appeared in the first 10 days of August, with their migration peaking in the last week of August and first week of September, with stragglers until mid-October. The mid-90% of juveniles occurred in the 28-day period between 17 August and 13 September, with a median date of 29 August, 38 days later than adults. There was no apparent differential timing in migration by sexes (Hussell 1980, 1981; Hussell et al. 1967; Keast 1990; Tarof and Briskie 2020). During autumn migration in Alberta, adults migrated an average of 13 days earlier than juveniles when the sexes were combined and females migrated 5 days before males when the age classes were combined. Adult females migrated 4 days earlier than adult males and 14 days earlier than juvenile females. Adult males migrated 8 days before juvenile males. There was no difference in the timing of migration of juvenile males and females. Over a 32-year period, the median date of autumn migration advanced by 14 days (4.5 days per decade) for adults but only 2 days (0.65 day per decade) for juveniles (Van Brempt et al. 2025).

During migration, the Least Flycatcher occurs in a variety of habitats: aspen groves, alder and willow thickets, birches, forest edges, and shrubby areas along watercourses and water bodies. It is particularly common near ponds and small lakes and other sources of water bordered by thick growths of aspen, willow, or birch. It may also occur in forest understorey among shrubs and small trees (Campbell et al. 1997). In Kansas, migrating Least Flycatchers occur predominantly in wooded habitats along watercourses, gullies, and windbreaks, but occasionally in tall weedy growth and isolated trees (Tarof and Briskie 2020). During spring migration in Pennsylvania, it was most abundant in mature forests and especially edge-dominated mature forests (forest-agricultural edges and suburban forests). Highest abundance was in suburban forests followed by shrub-sapling forest, forest-agricultural edge, forest interior, and pole-stage forest (Rodewald and Brittingham 2007). During spring migration in Ohio, it was significantly more abundant in mature upland forest stands than in similar riparian forests (Rodewald and Matthews 2005). During autumn migration, juveniles are significantly more abundant in lower-quality planted woodlots and agricultural habitat than the more forested habitats used by adults (Tarof and Briskie 2020).

Mills (2005b) examined first arrival dates of Least Flycatchers during spring migration at Long Point during 1975-2000 to determine if there had been a response to global warming. Examining the results by quartiles revealed that the trend toward earlier arrival was significant. Both sexes

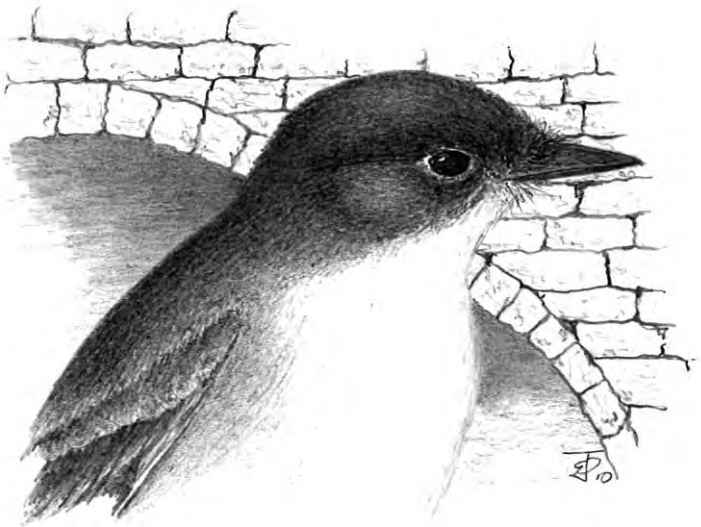
migrated progressively earlier in spring at a rate of 2.7 days per decade. The date of autumn departure was progressively later. The delay in the first quartile during autumn migration was significant suggesting that adults, which migrate in advance of juveniles, contributed to the trend toward delay of autumn migration.

In Pennsylvania, an infestation of the viburnum leaf beetle resulted in almost complete mortality of the southern arrowwood, which was formerly the third-most abundant shrub species. Spring migrating Least Flycatchers declined significantly after the infestation (Smith and Hatch 2017).

The Least Flycatcher is common during migration (James 1991). At Long Point, Badzinski (2000) reported that the number of spring migrant Least Flycatchers had increased by 1% per year since the early 1960s, but that autumn numbers had decreased slightly. There was a decline in the 1960s, an increase in the 1970s, and a smaller decline in the 1980s. Between 1961 and 1988 there was a significant decline of 2.3% per year. Populations fluctuated in concert with budworm-dependent warblers suggesting that it may benefit from budworm outbreaks (Hussell 1980; Hussell et al. 1992).

Eastern Phoebe

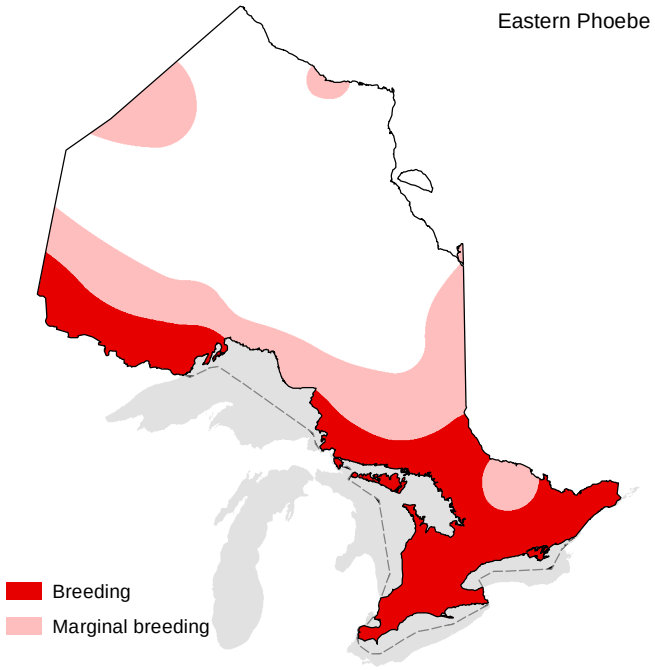
Sayornis phoebe



BREEDING SEASON

Habitat Requirements

The Eastern Phoebe nests in a variety of habitats in Ontario, but usually in open or semi-open areas where there are suitable nest sites. It nests in upland and lowland forests, primarily in mixed and deciduous stands, but occasionally in coniferous forest, with about a third of Ontario nests in forested habitat. Forested areas it selected for nesting were usually open, or the nest was near forest edge. Many birds breed in anthropogenic habitat such as around farms, rural residences, cottages, parks, gardens, gravel pits, and golf courses. Less frequently it nests at shorelines of lakes and rivers, along road and railway rights-of-way, and on dams. It occasionally nests on rock cliffs and rocky outcrops, in marshes, and at dunes and beaches. Key habitat components for nesting are open areas for foraging and a rock outcrop or human-made structure suitable for nest placement (Peck and James 1987). In Algonquin Park, many nests were low on rocky cliffs (Tozer 2012). In Elgin County, the phoebe nests in wooded ravines (Lancaster et al. 2004). In Muskoka and Parry Sound districts, it



was associated with slightly higher than average canopy volume and tree density, features indicative of the edge of a clearing. It requires an open area for flycatching and some canopy for perching. Its preference for low shrub cover and its ability to find nest locations on buildings makes it compatible with cottage lots (Clark et al. 1983).

Similar nesting habitat has been reported elsewhere. Typically associated with woodland and edge habitat near water, the phoebe occasionally nests on rock outcrops in forests several hundred metres from water and openings. It requires some wooded habitat that is more extensive than a hedgerow, but this may include scattered trees around dwellings. In Kansas, nests under bridges were more frequent where there was continuous tree cover along the watercourse, occasional where woodland cover was discontinuous or patchy, and rare where the stream was open. In boreal Canada, it may occur in early stages of succession after a burn or clear-cut if suitable nest sites are present. Woodland types it has nested in include northern hardwoods, lowland hardwoods, birch-maple, aspen-birch, upland and swamp mixed woods, floodplain forests, pine and oak barrens, and spruce-aspen. One study characterized it as a species of upland openings (Back 1979; Campbell et al. 1997; Erskine 1977; Graber et al. 1974; Hill and Gates 1988; Hoffman 1989a; Johnston 1971; Lemieux and Rail in Gauthier and Aubry 1996; Mossman 1988; Mossman and Hoffman 1989; Mossman et al. 1991; Noon et al. 1979; Samson 1979; Schukman 1993; Speirs and Orenstein 1975; Taylor and Taylor 1979; Temple et al. 1979; Weeks 1979, 2020).

Brennen and Schnell (2007) used Breeding Bird Survey (BBS) data from the south-central states to determine landscape-level features affecting the Eastern Phoebe. It was most abundant in relatively undisturbed areas with a high ratio of edge to interior. Population numbers tended to be higher in densely wooded areas and lower in more sparsely wooded locations.

In Kansas, the Eastern Phoebe nested mostly along primary and secondary streams and only infrequently along tertiary streams. It was predominantly a forest and edge species that nested along a habitat gradient from woodland streams to draws with sparse or no woodland, but chose the former preferentially (Schukman et al. 2011).

Nests are on either a ledge or vertical surface, greatly limiting the number of natural nest sites. Much of the nest is constructed of mud, so there must be a nearby source of water and the nest must have overhead protection from the elements or it falls down or disintegrates during rain. In Ontario, 96% of nests were on human-made structures, especially buildings and bridges.

Approximately half were on or in buildings on ledges, eaves, beams and posts, electrical fixtures and wires, ceilings and roofs, drain pipes and eavestroughs, and stovepipes. About 30% were on bridges and culverts, 3% on cliffs and in caves, 1.7% under earthen-bank overhangs, and 0.2% in tree roots and stubs. Unusual nest sites included a pitchfork handle, a hanging pile of harness, the seat of a canoe, a piece of loose wallpaper, a hanging electric motor, a metal can, a gate, a partially sunken boat, a mailbox, a cattle-feeding trough, in an old well, and in an overturned car. Old nests were often reused, with 1 used 8 consecutive years. Occasionally, old Barn Swallow or American Robin nests were repaired and used, and nesting frequently occurs near Barn and Cliff swallow colonies (Peck and James 1987). Mills (1981) reported a nest in a hole in an earthen road embankment near Snug Harbour. In Elgin County, the phoebe has nested in natural habitat several times. In these cases, nests were built into root masses of upturned trees or were in cavities in steep ravine slopes (Lancaster et al. 2004). In the Kingston area, 88 nests were on cottages, 23 were on natural rock outcrops, 46 were on human-made structures no longer frequented by humans (abandoned barns and cabins, old cars), and 35 were on outbuildings (Conrad and Robertson 1993a). Ontario nests on buildings were 0.8-9 m from ground, with most 2.1-3 m up. On bridges and culverts, nest heights ranged from 0.3-9 m (average 1.2-2.4 m). Nests on rock faces were 0.6-7.6 m from the ground (average 1.2-2.4 m). Most nests were against a vertical surface and were therefore flat on 1 side and circular on the remainder. Two- and 5-tier nests were reported resulting from materials being added in subsequent years (Peck and James 1987, 1997).

In heavily forested areas such as the Appalachians, nests are as likely to be in natural situations as on human-made features. In areas dominated by open habitats, over 90% of nests are on human-made structures. A Wisconsin study found that all nests under bridges were at the end of the bridge that had the deepest water, and all but one were within 2 m of the upstream edge of the bridge. Nests over deeper water may be better protected from predators. Unusual nest locations include in a woodpile and in a vertical cave about 2 m in diameter. The birds had to drop 2-3 m into the cave entrance to reach the nest. In Kentucky, nests were found in all large cave entrances examined. Typically 50-75% of nests present at the beginning of a season are reused. New material is always added, resulting in nests with as many as 6 tiers. Old nests are usually reused for second broods. Some nest sites have been used for 15-30 consecutive years. The phoebe readily uses nesting platforms placed in culverts (Campbell et al. 1997; Faanes 1980; Fitch 1958; Graber et al. 1974; Hill 1987; Hill and Gates 1988; McClure 1946; McIlwraith 1894; Palmer-Ball and MacGregor 1989; Tyler in Bent 1942; Weeks 1977, 1978, 1979, 2020).

The phoebe is highly territorial, particularly early in the breeding season, and territorial disputes may be common. Due to its special requirements for nest sites, territories often are not contiguous and large areas of apparently suitable habitat may be devoid of phoebes. Usually only 1 nest is present on a structure and, when 2 nests are present, this has been attributed to polygynous nesting. Three occupied nests were found on an Ontario bridge. Nests have been found as close together as 75 m on buildings and 13 m on a cliff. Limited information is available on territory size. One territory in an Illinois floodplain forest was estimated at 0.3 ha; 2 Kansas territories were 1.3 and 2.9 ha. There is no information on home range size, but it has been assumed to be larger than 3 ha. In Indiana, breeding adults were never seen further than 100 m from the nest, so the home range was less than

3 ha (Fitch 1958; Graber et al. 1974; Hill and Gates 1988; Johnston 1971; Peck and James 1987; Weeks 2020).

Natal philopatry has been reported to be very low in areas other than Ontario. In Indiana, only 1 of 11,847 nestlings bred at its natal site and only 218 (1.8%) were subsequently found breeding on the 250 km^2 study area (Weeks 2020). Three of 167 nestlings (1.8%) returned to a Kansas study area. One young banded in Virginia was recovered during the breeding season in Alberta, approximately 1,100 km from its natal area (Brewer et al. 2018). Near Kingston, 24% of young returned. In the same study area, 38% of adults returned the next year, and 25% of adults returned in Kansas. In Indiana, 40% of both males and females returned; multiple-brooded birds were more likely to return than those that had a single brood the previous year. Most retained the same territory for their entire life. Weeks (2020) stated that site fidelity by adults was very high, probably in excess of 80%, and that it was likely that all surviving adults returned to the same area. During a breeding season, adults seldom move from the original territory to renest or raise a second brood. In Indiana, only 15.7% of birds dispersed to another territory between years, and 0.9% dispersed within a breeding season (usually birds that had failed to raise the previous brood) (Beheler et al. 2003; Conrad and Robertson 1993b; Peck and James 1987; Schukman 1993; Weeks 2020).

Limiting Factors

Eggs have been found in Ontario nests from early April until early August, with most present from the last week of May until the last week of June (Peck and James 1987). In Algonquin Park, nests are under construction from mid-April to late May, eggs are present from mid-April to mid-July, nestlings are present from late May to mid-August, and fledglings have been observed from early June to early September (Tozer 2012).

Nest building begins shortly after pair formation and takes 7-14 days. If an old nest is used, it may be repaired and completed in 2-5 days. Nests built for second broods may be finished 5 days quicker than new first nests. After the nest is complete, 1 or 2 weeks pass before the first egg is laid, but occasionally as long as 3 weeks elapse. One egg is laid a day, but a day may rarely be missed. The incubation periods of 45 Ontario nests ranged from 13 to 18 days with most eggs hatching in 14 or 15 days. Eggs were present in 2 nests 21 and 22 days, suggesting that onset of incubation was delayed. Elsewhere, the incubation period has been reported as 14-17 days (average 16 days). Incubation begins with the laying of the last egg, but does not start in earnest until the next day. Eggs may hatch over a 1-3-day period with hatching asynchrony greater in second clutches. Young fledge when they are 13-20 days old, usually in 15-17 days. Approximately 10 days pass between fledging of the first brood and initiation of the second clutch. It takes about 45 days to raise a single brood and 117 days to raise 2 broods (Conrad and Robertson 1993a; Faanes 1980; Graber et al. 1974; Hill and Gates 1988; Keast 1990; Lemieux and Rail in Gauthier and Aubry 1996; Murphy 1994; Peck and James 1987, 1997; Smith 1942; Tyler in Bent 1942; Weeks 1978, 1979, 2020).

The phoebe may raise 1, 2, or even 3 broods a season, and renesting is common if the first clutch is lost. Females that lose the first brood to predation are more likely to forego nesting until the next year. Usually it raises 2 broods a year, but only one may be raised depending on age of the female and whether the first nest was successful. In the Kingston area, about half of females attempted second broods. Both yearlings and older birds tried to raise 2 broods, but almost all single-brooded

females were yearlings. All successful older females attempted a second brood compared with 69% for unsuccessful birds. Three triple broods have been reported. Clutches of 2-8 eggs have been found in Ontario, with 4- and 5-egg clutches constituting more than 82% of clutches; other clutch sizes were rare. Elsewhere, clutches of 2-8 eggs have been reported, with the normal clutch size 3-5 eggs. In many studies, over 90% of nests contained 4 or 5 eggs. Clutches larger than 6 eggs may be due to intraspecific parasitism. Second clutches may average slightly smaller than first ones, but usually this difference is not significant. Clutches of replacement nests are significantly smaller than those of first and second nestings (Beheler et al. 2003; Conrad and Robertson 1993a, 1993b, 1993c; Conrad et al. 1998; Faanes 1980; Graber et al. 1974; Hill and Gates 1988; Lemieux and Rail in Gauthier and Aubry 1996; Murphy 1994; Peck and James 1987; Schukman 1993; Tyler in Bent 1942; Weeks 1978, 1979, 2020).

The age at first breeding is 1 year. The phoebe is typically monogamous, with pairs remaining mated for the entire breeding season. In Indiana, 2.4% of females and 4.8% of males divorced and remated for their next breeding attempt within the year. Many pairs remate and nest in the same location over multiple years. Polygyny occurs rarely. In New York, 2 females had a common mate, nested 20 m apart, and successfully fledged full broods. Neither female attempted a second brood (Gretch 1999; Weeks 2020). In Indiana, 17.2% of nests contained extra-pair young in at least 1 brood. Overall, 9.2% of broods contained extra-pair young and 5.1% of nestlings were extra-pair. Second broods were significantly more likely to contain extra-pair young (13.8%) than first broods (4.6%). In first broods, only 1 nestling was not related to the female's mate compared with more than 50% of nestlings in second broods. This genetic study also revealed 2 instances of intraspecific parasitism where young were not related to either adult attending the nest (Beheler and Rhodes 2003).

The Eastern Phoebe forages mostly from a perch less than 10 m from ground, typically in the lower half of the canopy. Perches are in edge habitats or lower limbs of closed-canopy forest. In Illinois, most perches were in hawthorns, willows, black cherry, and apple. In British Columbia, perches were usually dead branches of trembling aspen, willow, or snags. Foraging occurs mostly in the morning, and flycatching is the typical method of capturing prey. When it flycatches, about 75% of food is caught by hawking and the remainder by hover-gleaning from twigs and leaves. During winter in Texas, 54.1% of foraging movements were aerial hawks, 29.5% were sally gleans, and 15.6% were perch-to-ground sallies. It rarely took prey from the surface of water. The percentage of foraging movements that involved aerial hawking increased with ambient temperature. Temperature probably affects phoebe foraging techniques in Ontario during cold spring and early autumn periods. Average perch height in Texas was 3.77 m. The phoebe occasionally pursues flying insects to the ground or pounces on ground-dwelling invertebrates. Rarely, it perches on humans and deer and flycatches insects attracted to them. It occasionally fishes by perching 50-60 cm above water and diving or hover-diving to catch fish once they come within 5-8 cm of the surface. Typically, only the bird's head and breast touch the water. It was observed hawking moths at night during autumn migration under the bright lights of a football stadium (Binford 1957; Campbell et al. 1997; Fitch 1958; Graber et al. 1974; Lebbin et al. 2007; McKenzie and Noble 1975; Troy and Baccus 2009; Weeks 2020).

Near Kingston, nestlings of first nests were fed different prey than second broods due to changing availability of invertebrates. First broods were fed mostly beetles and flies; second broods were fed caterpillars, moths, caddisflies, and damselflies. Other food items brought to nestlings included oligochaetes, snails, spiders, midges, and hymenopterans (Keast 1990). Near Cambridge, Sandilands and Morningstar (2018) analyzed prey items in nestlings' feces collected under a nest. Each of the 2 broods consumed 15 taxa of invertebrates for a total of 24 taxa. Only 6 taxa (25.0%) were consumed by both broods. These included stream mayflies, dobsonflies, gypsy moths, oblique-banded leafrollers (a moth), and blow flies. Fowl mites occurred in samples of both broods, but it is possible that these dropped or were dropped on the feces rather than being ingested. The first brood consumed narrow-winged damselflies and skimmers (Odonates), earwigs, tiger and owlet moths, spruce budworms, giant casemaker caddisflies, flesh flies, and horse flies. The second brood consumed leafhoppers, crambid snout moths, tiger moths, root-maggot flies, frit flies, and flesh flies. Results of both Ontario studies indicate that the 2 broods have differing diets probably because of differing seasonal prey availability. The food items fed to the broods were different in Kingston and Cambridge, suggesting that adults capture prey opportunistically based upon its local abundance.

Limited information is available on the adults' diet, with the most definitive analysis completed more than a century ago. This study found that 89.2% of the diet was animal material, mostly insects. Hymenopterans were the most important food, comprising 26.7% of the diet, constituting the largest percentage of the diet in almost every month. Beetles comprised 15.3% of the diet and were eaten year round, but mostly in spring and early summer. Orthopterans constituted 12.9% of the diet, bugs 18.5%, lepidopterans 8.9%, flies 6.9%, and spiders, ticks, and millipedes 5.8%. The phoebe frequently eats dragonflies and readily adapts to outbreaks of insects such as cicadas and forest tent caterpillars. It actively selects beetles 2-10 mm long. Other animal foods it has eaten include mosquitoes, skippers (butterflies), small frogs, and fish as long as 6 cm. Vegetation is eaten chiefly early in spring and autumn, but also during unfavourable weather. It eats mostly seeds and berries, including pokeweed, wild cherries, elderberries, raspberries and blackberries, and juniper berries (Beal 1897a; Binford 1957; Graber et al. 1974; Hespenheide 1971b; Keast 1990; McKenzie and Noble 1975; Tyler in Bent 1942; Weeks 2020).

The phoebe is commonly parasitized by the Brown-headed Cowbird. The phoebe is a receptor species, rarely ejecting an egg, burying it in the lining, or abandoning the nest. About 10% of parasitized nests fledge both phoebes and cowbirds although fewer phoebes fledge from parasitized than unparasitized nests. Cowbirds frequently remove a phoebe egg prior to depositing an egg of their own, thereby reducing production even in successful nests. Parasitism rates depend on timing of phoebe nesting, nest location, and whether the nest has previously been parasitized. In New York over 2 years, parasitism rates of first phoebe nest attempts were 37% and 42% compared with 11% and 13% for later nests. Parasitism rates under eaves were 46% and 57% compared with 11% and 6.7% under bridges, and 50% of nests parasitized the previous year were parasitized again compared with 6.2% for nests that were not previously parasitized. Parasitism rates vary greatly depending on habitat, relative abundance of host and parasite, and sample size. In Ontario, 179 of 1,498 nests (11.9%) were parasitized. Other parasitism rates include 0%, 14%, 29%,

and 33% in 4 Illinois study areas; 1% in southern Wisconsin and Tennessee; 15%, 24%, and 18.2-36% in Kansas; 11% and 14% in Michigan; 5% in Indiana; and 0% in Maryland and British Columbia (Campbell et al. 1997; Faanes 1980; Graber et al. 1974; Hauber 2001; Peck and James 1997; Rivers et al. 2010; Weeks 1979, 2020). In Maryland, parasitism rates of phoebe nests were dependent upon the habitat where the nest was situated. In field and edge habitats, 0 of 22 nests were parasitized compared with 8 of 19 nests (42.1%) within forest habitat (Hahn and Hatfield 1995). In New York, Wagner et al. (2013) examined phoebe nests for parasitism from 2009 to 2011, observing the same nest sites that had been studied 1999-2002. Nests that were more likely to be parasitized in the later period had also been parasitized more frequently from 1999 to 2002. Cowbirds demonstrate a consistent preference for particular phoebe nest sites, even across generations of birds.

The greatest limiting factor to phoebes is availability of suitable nest sites. Consequently, many birds capable of mating are forced to be floaters. When a mated bird dies, it is replaced very quickly. Replacement males may attempt to kill the female's young to increase the likelihood of raising their own young. Large areas of otherwise suitable habitat may not be used if there are no appropriate nest sites. Good nest sites may become unusable if adjacent woody vegetation is removed. Out of necessity, some nests are placed in less than ideal situations where they are not totally protected from precipitation and dampness. These nests are vulnerable to falling. Nests under bridges are more likely to fall than those under eaves. Initial human settlement greatly increased nest-site availability. Nest sites are now declining due to replacement of old cement and wooden culverts and bridges with corrugated pipes and removal of derelict buildings (Badzinski 2000; Fitch 1958; Hauber 2001; Lemieux and Rail in Gauthier and Aubry 1996; Ritchison and Ritchison 2010; Sheppard et al. 1936; Weeks 2020).

Cold weather may have adverse effects on phoebes. Severe winters in the south may result in population crashes. In 1958, early spring storms occurred in the southern states and declines were noted in the Kingston area in 1958 and 1959. Periodic population declines have occurred since. Weather may also affect the breeding cycle. Timing of initiation of first clutches varies significantly year to year, depending on temperatures. Nest-building activities appear to cease when temperatures drop below 10°C. Cold spring weather may result in nesting delays as long as 3 weeks. This may affect clutch size or the number of broods that may be raised (Badzinski 2000; Graber et al. 1974; Murphy 1994; Weeks 1979, 2020; Weir 2008).

Insect abundance may affect timing and success of nesting. Studies in the Kingston area found that insects were scarce until late April or early May, abundant mid-May to mid-June, and scarce after mid-June. A similar pattern was documented in Kansas. If insects are particularly scarce in spring, nest initiation may be delayed. With the rapid spring increase in arthropods, there is ample food for nestlings of the first brood. Food may be limited when the second clutch hatches, and nestling starvation occasionally occurs. Hatching asynchrony is greatest in second broods, and this appears related to the relative scarcity of food. Spraying of pesticides may further reduce insect availability (Keast 1990; Lemieux and Rail in Gauthier and Aubry 1996; Murphy 1994).

Nests in culverts and under bridges may be washed away during floods (Schukman 1993; Weeks 1978, 1979). Peak flow rates in many Ontario streams have increased as a result of deforestation, urbanization, and other land-use practices.

In North Carolina, abundance of the phoebe was correlated with temperature, suggesting that it would benefit from climate change (Lumpkin and Pearson 2013). DesGranges and Morneau (2010) considered it highly sensitive to climate change in Quebec where it is near the northern extent of its range.

Status

The phoebe is undoubtedly more common now than prior to European settlement. Human-made structures have increased availability of nest sites and allowed it to inhabit much more area. McIlwraith (1894) considered it common in southern Ontario and Baillie and Harrington (1937) considered it common north to the transcontinental railway and west to the Lake of the Woods area. Baillie and Hope (1943, 1947) determined that it was rare along the northeast shore of Lake Superior but common in the Sudbury area. Smith (1957) considered it rare in the Clay Belt. During the first atlas, the Eastern Phoebe was widespread south of the Canadian Shield and in the Great Lakes–St. Lawrence Forest Region in the Shield. There were gaps in its distribution in the unbroken forests of Algonquin Park, Chatham-Kent where there are few wooded patches, and the alvars of Manitoulin Island. The most northerly record was at Pickle Lake (Helleiner in Cadman et al. 1987). James (1991) stated that it was common in the south but rare and local in heavily forested areas north to Pickle Lake and Timmins.

The second atlas indicated little change in the distribution of the phoebe since the first atlas. It was seen in many more squares in extreme southwestern Ontario and on Manitoulin Island than during the first atlas. Its probability of observation increased during the second atlas province-wide and in the Carolinian and Great Lakes–St. Lawrence forest regions. There were 2 areas in the province where it exhibited high abundance. The largest area was along the southern edge of the Canadian Shield from Renfrew County to Lake Ontario to the southern portion of Georgian Bay, and inland through Muskoka District. The other area was the Bruce Peninsula and Manitoulin Island. These areas support considerable forest cover and numerous bridges and buildings that could provide potential nest sites. Density was low in the Boreal Forest Region and the Algonquin Highlands, possibly due to extensive forest cover with a scarcity of bridges and buildings, and in extreme southwestern Ontario, possibly due to scarcity of forest cover (McLaren in Cadman et al. 2007).

Long-term (1970-2021) BBS data indicated annual decreases of 1.43% in Canada and 0.376% in Ontario. Over the short-term (2011-21), there were annual decreases of 2.16% in Canada and 1.89% in Ontario. All results were highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Fledglings occasionally return to the nest when they are young and continue to be fed by the adults for 2-3 weeks after fledging. Adults leave the territory shortly after the last brood fledges, usually in early July, looking for more diverse habitats where invertebrates are more abundant (Weeks 2020).

In Ohio, adult and juvenile Eastern Phoebes used densely regenerating clear-cuts during the postbreeding period. These and other early successional habitats may be important sources of dense cover and abundant food late in the breeding season (Vitz and Rodewald 2006, 2007). In Michigan, 86% of juvenile phoebes were captured in riparian forests during the postbreeding period; 14% occurred in upland forests. Riparian forests had a dense woody understorey whereas

upland forests had sparse coverage by shrubs and saplings (Akresh et al. 2009). During the postfledging period in Pennsylvania, Stoleson (2013) captured 1 adult and 9 fledglings in clear-cuts compared with 1 adult and 0 fledgling in mature, closed-canopy forest. Shrub density did not differ between clear-cuts and forests, but clear-cuts supported a high density of fruit-bearing shrubs.

MIGRATION

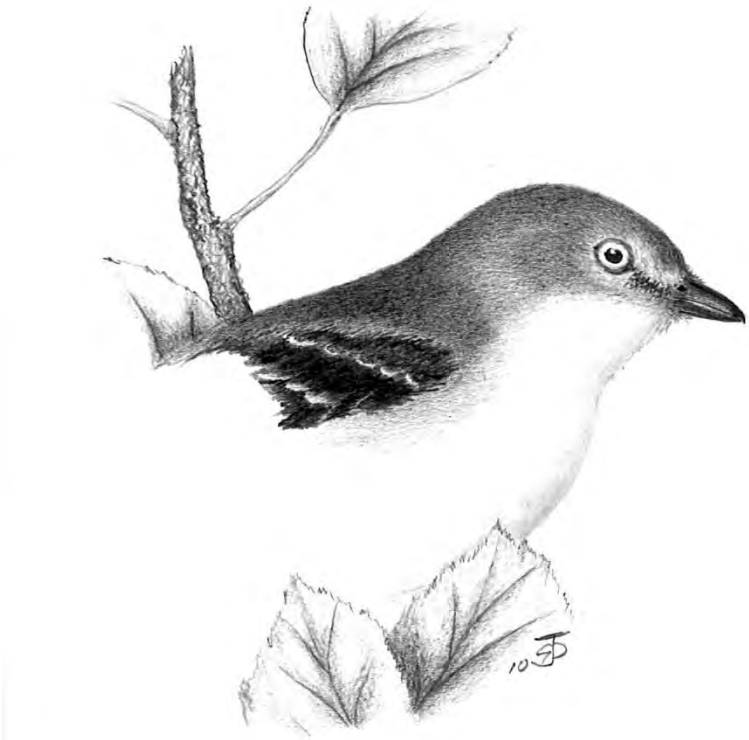
The phoebe is a solitary migrant and it is uncertain if it migrates diurnally, nocturnally, or both (Graber et al. 1974; Weeks 2020). In spring, it appears to follow the frost line and insect emergence northward. In much of its range, first birds arrive in March, although it may not occur in the northernmost portions of its range until early May. Males are thought to arrive before females, but this has yet to be confirmed. First arrivals may precede the peak of migration by more than a month. It arrives in Ontario in early April or late March, with the peak of migration in mid-April and stragglers continuing until about the end of May (Keast 1990; Weeks 2020). In the Kingston area, some autumn migrants appear in mid-July, including juveniles and adults, and another wave of juveniles occurs in mid-August. Autumn migration begins in earnest in mid-September and continues until the end of October, with the peak from the very end of September until mid-October. The phoebe moves southward gradually as insect numbers decline and may often remain in the province until early November (Keast 1990; Weeks 2020; Weir 2008).

During migration, the phoebe occurs in a variety of habitats. These include woodlands typical of breeding habitat; riparian growth along rivers, lakes, marshes, and beaver ponds; edges of deciduous and mixed forest; agricultural land; and rural residential areas. Presence of water appears to be more important during spring migration (Campbell et al. 1997; Weeks 2020).

The Eastern Phoebe is common during migration in Ontario (James 1991). Long Point migration data indicate that it has increased significantly at a rate of 4% annually since 1961. There was an increase in the 1960s, a decline in the 1970s, and a steady increase throughout the 1980s and 1990s (Badzinski 2000; Hussell et al. 1992).

White-eyed Vireo

Vireo griseus



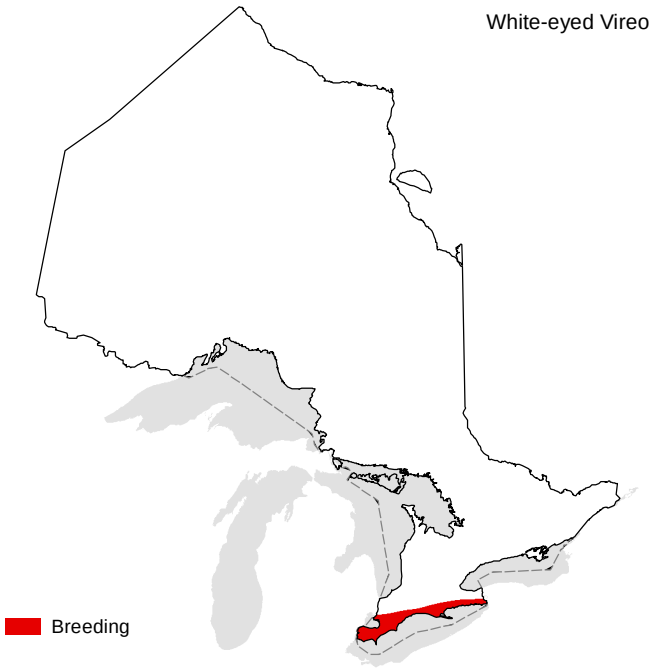
BREEDING SEASON

Habitat Requirements

In Ontario, the White-eyed Vireo has nested in thickets, savannahs, a dense tamarack stand near a marsh, overgrown fields, young second-growth woodlands, open shrubby beaches, woodland edges and clearings, and open swampy forests (Austen et al. 1994; Peck and James 1987).

Throughout its range, the White-eyed Vireo demonstrates a preference for overgrown old fields, young regenerating forests, and thickets along streams. In addition to habitats used in Ontario, it may nest in shrub thicket swamps, shrubs adjacent to marshes, near tree-fall gaps in deciduous forests, very dense second growth, cleared hydro rights-of-way, and abandoned pastures and cemeteries. In Illinois, it preferred successional fields, with numbers peaking on old farmland 44 years after abandonment. It did not appear on strip-mined areas until 18-20 years after mining. It occurred in small numbers in forested areas, preferring lowland forests. In Texas, it nested in low, shrubby vegetation with very high foliage density 0-1 m from ground, with a high diversity of shrub species.

Its density was inversely related to increased vegetation height, foliage density at 12-15 m, density of pole-sized trees, and percent canopy closure. In New Jersey, the White-eyed Vireo was significantly more abundant in hardwood swamp than in oak-pine forest. In Indiana, it nested in fields of grasses with blackberry thickets that contained numerous dense stands of small trees 1-7 m tall, and shrubby fields where about half the ground was shaded during part of the day either by saplings about 7 m tall or by nearly continuous stands of dense hawthorns. In Illinois and Virginia, 20-50-year-old abandoned pastures supported highest densities. It preferred areas with maple and elm saplings and a variety of other small trees and shrubs such as chokecherry, plum, witch-hazel, dogwoods, willows, and blackberries. Overall, it prefers variable habitat with extensive undergrowth, shrubs, raspberries, and saplings interspersed with taller trees on 10-20% of the area (Bent 1950; Bradley 1980; Fitch 1958; Graber et al. 1985; Hopp et al. 2020; Nolan 1963; Remson et al. 1998; Rich et al. 1994).



In Texas, abundance of the White-eyed Vireo was positively correlated with the number of shrub species, number of shrub stems, and foliage density at 1 and 3 m. It was negatively correlated with vegetation height, canopy closure, foliage density at 12-15 m, percent coverage by pines 17-32 cm diameter at breast height (DBH), and the number of tree stems 17-32 cm DBH (Conner et al. 1983). In the mid-Atlantic states, it was positively associated with foliage density 1-2 m tall, number of trees larger than 3 cm DBH per ha, and number of trees larger than 38 cm DBH per ha. It was negatively associated with percent ground cover and number of trees in a 0.04-ha circle at the pointing count (Robbins et al. 1989). In Texas, it was equally abundant in shrublands and woodlands with an understorey of oaks. It tended to nest in taller, more closed, later successional (woodland-like) habitat than the Black-capped Vireo, although there was considerable overlap in habitat (Kovar et al. 2018).

Lindell et al. (2007) summarized studies that determined species' abundance in relation to forest edge. The White-eyed Vireo was found to exploit edges and avoid forest interior. In South Carolina, almost all records were from forest edges and gaps during spring and autumn migration and the breeding and postbreeding seasons. There were very few records from forest interior (Bowen et al. 2007). In shrubby clear-cuts in Ohio, Rodewald and Vitz (2005) set mist nets 20, 50, and 80 m from the edge of a mature forest. There were no significant differences in its abundance at different distances from edge.

In forested riparian corridors in Georgia, the White-eyed Vireo was significantly more abundant in medium-sized (440-610 m) than narrow (36-330 m) or wide (1,320-2,088) corridors. It was negatively associated with basal area and canopy cover and positively associated with shrub cover (Hodges and Krementz 1996).

Shake et al. (2012) studied the White-eyed Vireo in shrublands in North Carolina to determine if it was area sensitive or affected by the shape of the habitat patch. They found no significant correlations between these parameters and its abundance. In Ohio, Lehnen and Rodewald (2009a) observed no evidence of area sensitivity by this vireo in clear-cuts. Patch size had no effect on annual survival or juvenile recruitment. Rodewald and Vitz (2005) found no difference in its abundance in small (4-8 ha) or large (13-16 ha) clear-cuts in Ohio.

Ontario nests were about 1 m from the ground in chokecherry, oak saplings, gray dogwood, raspberry, tamarack, and white pine (Peck and James 1987, 1997; Rayner 1988a). The nest site is often a Y-shaped horizontal deciduous branch close to ground, and the nest is usually surrounded by dense vegetation. Most often the nest is within a few metres of the edge of the territory. A high diversity of tree and shrub species is used for nesting. The species of plant may be unimportant provided that there is an abundance of stems and leaves for foraging close to the ground. Species commonly used for nesting include poison ivy, arrowwood, red cedar, multiflora rose, dogwood, plum, blackberry, blue beech, hawthorn, and saplings of elm, oak, sugar maple, hophornbeam, sassafras, hackberry, yellow birch, and cherry. Nests are close to ground, with an overall range of 0.2-2.6 m. Most are less than 1 m up, with average heights of 0.70 m, 0.74 m, 0.8 m, 0.94 m, and 1.45 m reported from Indiana, Kansas, Illinois, Virginia, and Texas, respectively (Bent 1950; Fitch 1958; Graber et al. 1985; Hopp et al. 2020; Kovar et al. 2018; Nolan 1963).

Males are territorial, but females may tolerate other females. Territory size varies depending on habitat quality, if there are neighbouring pairs, and on the experience of the bird. In Florida, some males defended lone territories surrounded by unsuitable habitat; others had many neighbours. In a 14-ha patch, there were 11 territories, a mean size of 1.3 ha. Two territories in Illinois averaged 0.14 ha; another Illinois territory in a swamp thicket was 0.13 ha and one in forest edge was 1.4 ha. Another territory in Illinois that contained 3 ponds surrounded by young second-growth forest was 0.13 ha. In Virginia, 16 territories averaged 1.03 ha (range 0.6-1.8 ha). In Kansas, 1 territory was 2.6 ha 1 year and 2.1 ha the next, but covered the same general area (Bradley 1980; Brewer 1955; Fitch 1958; Graber et al. 1985; Hopp et al. 1999, 2020).

Natal site fidelity appears to be low. None of 42 young returned in Virginia; in Massachusetts, 1 yearling was recovered breeding 20 km from its natal area. In Ohio, 7 of 273 juveniles (2.8%) returned as adults, and 6 of the 7 were encountered again at the natal site. Adult site fidelity is high, particularly for males. Of 74 male adults in Virginia, 54% returned the year after banding, 26% 2 years later, 7% 3 years later, 4% 4 years later, 3% 5 years later, and 0% 6 years later. Of returning males, 67 of 69 (97%) returned to their previous territory. The other 2 remained within 800 m of their original territory. Of 5 females, 3 returned the year after banding and 1 each returned in the second and third years. None of the females returned to the same territory and none paired with the same male in subsequent years. The nearest female movement was to the adjacent territory and the furthest was 3 territories away, a distance of 750 m. In Ohio shrubland habitat, 67 of 285 adults (23.5%) returned

and 66 of these were encountered at the same site (Hopp et al. 1999, 2020; Lehnen and Rodewald 2009b).

Limiting Factors

Eggs are most likely to be present in Ontario nests from mid-May until the end of June (Peck and James 1987, 1997). Nest building is initiated shortly after courtship and takes 3-5 days. Egg laying begins 1-3 days after the nest is complete. Eggs are laid at the rate of 1 a day but occasionally a day is skipped. Incubation begins with the laying of the third or fourth egg. If cowbird eggs are present in the nest, incubation may begin with the second vireo egg. The incubation period at 1 Ontario nest was 11 or 12 days. Elsewhere, the incubation period has been reported as 12-16 days, with most eggs taking 13-15 days to hatch. Fledging occurs at age 9-11 days (Bent 1950; Bradley 1980; Graber et al. 1985; Hopp et al. 2020; Kovar et al. 2018; Peck and James 1997; Nolan 1963; Saunders 1915).

In Virginia, the White-eyed Vireo frequently produces 2 broods a year, but it is unknown if double broods occur as far north as Ontario. It is a persistent renester and may attempt as many as 4 clutches if earlier attempts are unsuccessful. After an Ontario nest failed, a new nest was built approximately 300 m away for the second clutch. Ontario clutches contained 3 or 4 eggs. Five-egg clutches are rare and the mean North American clutch size is 3.74 eggs (Bent 1950; Hopp et al. 2020; Peck and James 1997; Rayner 1988a).

The breeding system is monogamous and the age at first breeding is 1 year. Some yearling males fail to attract mates. Once breeding is initiated, it occurs every year (Hopp et al. 2020).

The White-eyed Vireo forages in deciduous trees, shrubs, and vines at low to intermediate heights. It forages from the ground to 15 m, but captured 90% of food 0.6-6 m from ground in 1 study and 87% between 1.2 and 10.7 m in another study. In the latter study, average height of trees used for foraging was 10.0 m and 64.5% of foraging occurred in the middle portion of the tree. It forages by gleaning from vegetation by picking or hovering. In 1 study, 61.5% of captures were made while perched and the remainder by aerial hovering. Eighty-five percent of prey was captured on leaves. In Maryland, most foraging was by gleaning, less frequently by hovering and pecking; hawking was not observed (Hopp et al. 2020; Nolan and Wooldridge 1962; Williamson 1971).

The diet consists of 90% animals, mostly insects; caterpillars are especially important. Some fruit is eaten year round, but particularly in early spring, autumn, and winter when insects are less available. Lepidopterans may constitute a third of the diet yearly, being consumed every month, with peaks in April, May, June, and August. Beetles (weevils and ground, lady, click, long-horned, metallic wood-boring, and leaf beetles) and bugs (stink bugs, leafhoppers, and scale insects) are important prey. Other invertebrates commonly eaten include ichneumonid and other wasps, bees, flies, grasshoppers, and spiders and their egg cases. Miscellaneous insects occasionally eaten include dragonflies, damselflies, walkingsticks, stoneflies, and lacewings. Snails and lizards are rarely consumed. Plant food includes fruit of sumac, dogwood, poison ivy, pokeweed, and wild grape (Chapin 1925; Hopp et al. 2020; Nolan and Wooldridge 1962).

The White-eyed Vireo is an acceptor of Brown-headed Cowbird eggs, and the rate of parasitism is very high, about 50% overall. Cowbirds typically lay in the first 2 days of laying by vireos and lay 1 or 2 eggs. Some parasitized nests are abandoned. In Ontario, 4 of 7 nests (57%) were parasitized.

Parasitism rates in other areas include: 40% in Louisiana, 48.9% in Virginia, 50% in Indiana, 83% in Illinois, and 11.1% in Georgia and South Carolina (Bent 1950; Hopp et al. 2020; Kilgo and Moorman 2003; Lowther 1997; Peck and James 1997; Rayner 1988a).

Habitat availability and loss may be limiting factors. Suitable habitat is patchy and unevenly distributed. The White-eyed Vireo has expanded its range northward in Ontario since 1950, primarily due to habitat creation through abandonment of marginal farmland. This new habitat may be temporary because much of it may regenerate naturally into forest. Its preferred habitat is usually not considered significant by humans and is often converted to other land uses (Austen et al. 1994; Hopp et al. 2020; James in Cadman et al. 1987).

Robinson and Robinson (1998) cut openings of 0.02-0.4 ha within a 2,000-ha forest in Illinois. The White-eyed Vireo was common in recent cuts, rare in older cuts, and absent in uncut forest.

Price (2004) predicted that the breeding range of the White-eyed Vireo would increase in Ontario if the average summer temperature increased by 2°C.

Status

In the late 1800s and early 1900s, the White-eyed Vireo was considered accidental in Ontario. The first record was an autumn migrant collected near Listowel in 1890. In the same year, breeding was reported in Welland County and it was reported nesting near Toronto in 1898. These early breeding records were never substantiated and are probably in error. Excluding these records, only 7 had been confirmed in the province by 1939. These were all spring or autumn records. In addition to the Listowel record, it was documented at Woodstock, Mount Forest, Ashbridges Bay in Toronto, Point Pelee, and on Pelee Island. Breeding was first confirmed in 1971 when 2 unsuccessful nests were found near Rondeau Provincial Park. One or 2 pairs may breed annually near the park, but some years none breed successfully. It is a rare to local breeder near Lake Erie, with the largest population near Point Pelee, where at least 6 pairs nested in 1992. Several pairs have been recorded near Fish Point on Pelee Island, but breeding has not been confirmed on the island. Other sites where it has bred include the Fingal Wildlife Management Area in Elgin County, the St. Williams forest, and at Long Point. Isolated pairs may nest sporadically anywhere within the Carolinian Forest Region. It is a rare to locally uncommon breeder in extreme southwestern Ontario (Austen et al. 1994; James in Cadman et al. 1987; James 1991; Lewis 1948; Mowat 1947; Rayner 1988a).

The second atlas indicated that there had been no changes in the distribution or probability of observation of the White-eyed Vireo since the first atlas. It is a regular but rare breeder in the Carolinian Forest Region, with most breeding records along the northern shore of Lake Erie, particularly at Point Pelee, Rondeau, and Long Point (James in Cadman et al. 2007).

POSTFLEDGING PERIOD

In Florida, juveniles often followed the male around the territory and helped to defend it. Juveniles continue to sing after dispersal from the natal territory and may establish and defend a vacant or abandoned territory (Hopp et al. 2020).

Vitz and Rodewald (2006) captured 79 adult and 178 juvenile White-eyed Vireos in regenerating clear-cuts in Ohio during the postbreeding period. They did not state whether it nested in this

habitat. Dense shrubby areas may be important during the postfledging period. In Missouri, Porneluzi et al. (2014) netted birds during the postfledging period 2-15 years after an oak-pine-hickory forest was clear-cut. The White-eyed Vireo was the third most abundant species captured. Its numbers peaked shortly after cutting and declined annually thereafter.

MIGRATION

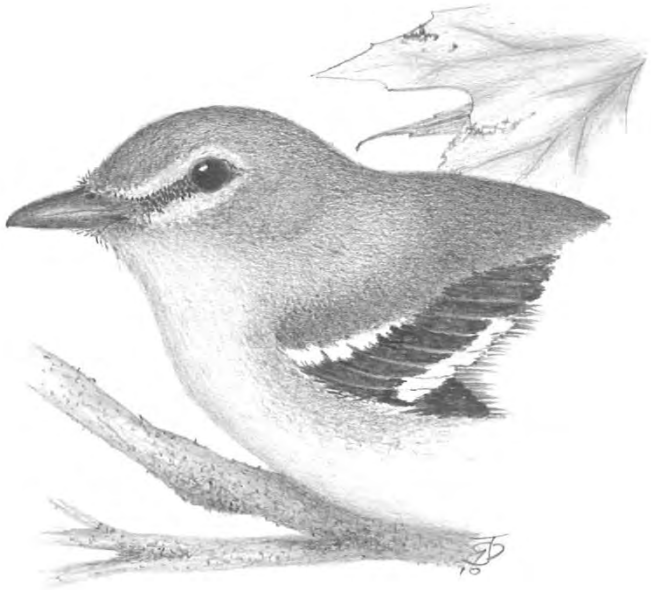
Based on kills at television towers, it has been presumed that the White-eyed Vireo migrates nocturnally. During migration, it prefers habitat similar to that used during the breeding season. During migration in Illinois, numbers were highest in forest edge and shrub habitats. It also occurred in lowland and upland forests (Graber et al. 1985; Hopp et al. 2020; Nolan and Wooldridge 1962).

In spring, older birds arrive sooner than yearlings, but only by a couple of days. The White-eyed Vireo typically arrives in the province in early May, but has occurred in early April. In autumn, juveniles leave first. Migration in Ontario occurs from mid-September to mid-October, with stragglers rarely remaining until late December (Hopp et al. 1999, 2020; James 1991).

James (1991) considered the White-eyed Vireo a rare migrant in the south and a vagrant in the north.

Yellow-throated Vireo

Vireo flavifrons

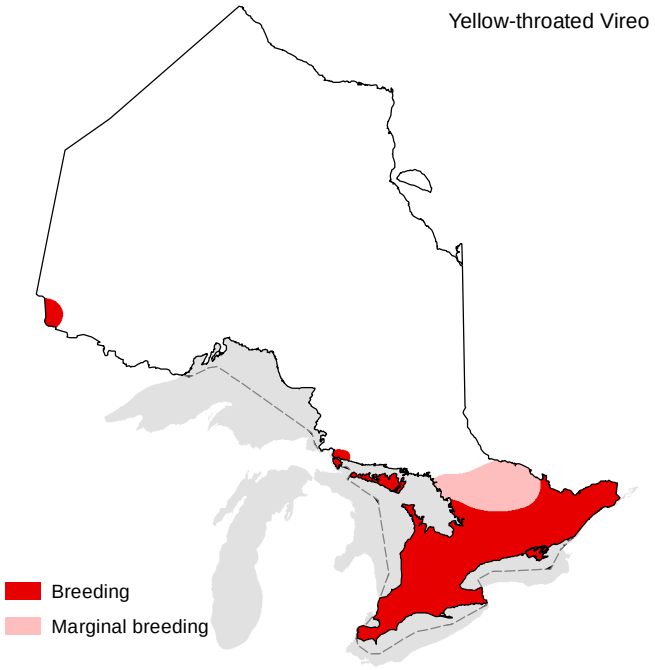


BREEDING SEASON

Habitat Requirements

In Ontario, the Yellow-throated Warbler breeds in deciduous and mixed woods that are usually semi-open, or near clearings and edges. It also nests in beaver ponds with scattered trees, in swamps with standing water, in treed fencerows and roadsides, along streams, in aspen-poplar groves, and seldom in treed village streets and campus parking lots (Peck and James 1987). It particularly favours red oak upland forests and lowland maple swamps (James in Cadman et al. 2007).

Older Ontario data suggested that the Yellow-throated Vireo preferred forests dominated by beech (McIlwraith 1894) and mature sugar maple–beech (Speirs and Orenstein 1975), and that it occasionally nested in parks in towns (Baillie and Harrington 1937). More detailed information was presented by James (1979b). It typically inhabits very open deciduous forests with mature trees. Habitat used in southern Ontario varies from mature deciduous forest to open woodlands with scattered large trees. Usually there are tall mature trees and scattered trees of varying ages, and there are often patches of grassland among tree groves. Nesting areas are often open, allowing growth of trees and shrubs that do not normally occur in forests. Dominant trees in Ontario territories were sugar maple, white elm, white oak, balsam poplar, trembling aspen, and white birch.



Other species included hemlock, basswood, ash, white pine, black walnut, hophornbeam, white cedar, hickory, beech, cherry, hawthorn, butternut, and apple. Detailed habitat characteristics in Ontario and Pennsylvania, respectively, were: trees per ha, 297 and 525; mean distance between trees, 5.8 m and 4.4 m; basal area, 16.8 m^2 and 23.5 m^2; mean crown volume per tree, 140.7 m^2 and 80.8 m^2; canopy cover, 62% and 90%. In Ontario, habitat always contains tall, old trees. Based on crown volume, Pennsylvania habitat was almost twice as dense as in Ontario. When it nests near other vireo species, it may adjust its habitat usage. Near Eastern Warbling-Vireos, both species nest in open habitats. Near Red-eyed Vireos, the Yellow-throated Vireo tends to occupy more open areas of forests or areas with little understorey. In these situations, it may have a preference for large oak trees (James 1976).

Habitat preferences elsewhere are similar to those in Ontario. The Yellow-throated Vireo prefers lowland and upland deciduous and mixed forests and avoids coniferous forests. Mature, open stands are selected, or edges and openings in closed stands are preferred. It typically nests on edges of forests created by watercourses, swamps, and roads, but may breed near forest gaps caused by treefall. Although it formerly nested in towns, suburban areas, orchards, and cities, these habitats were abandoned early in the 20th century. In Louisiana, habitat included tall trees in open woodlands, usually at edges, and at forest-interior openings large enough to create a sunny edge within the forest. In the mid-Atlantic states, it was positively correlated with the number of trees with diameter at breast height (DBH) larger than 38 cm, basal area, amount of foliage density between 0.3 and 1.0 m, and mean canopy height. It was negatively correlated with the number of dead standing trees and presence of conifers in the canopy. In southern Wisconsin, breeding territories had more large trees 37-52 cm DBH, more white oaks, and fewer shrubs 1-3-m tall than random areas. In Missouri, habitat surrounding singing perches was characterized by canopies taller than 16 m, 70-90% canopy closure, and 50-90% subcanopy coverage. Because of its preference for open canopy, the Yellow-throated Vireo is positively associated with shrub density, but negatively with forest isolation. Although typically associated with mature forests, it tolerates younger stands if there are scattered older trees. It breeds in a variety of deciduous and mixed forest communities including oak-hickory, sugar maple–hickory, sugar maple–basswood, sugar maple–yellow birch, pine-oak barrens that are almost forest, bur oak–green ash, oak–black gum, oak-poplar, elm-ash-cottonwood, sugar maple–beech-birch, white oak–tulip-poplar, and sycamore-ash-elm. In Illinois, it preferred woodlands with high numbers of large trees (Bent 1950; Bond 1957; Bushman and Therres 1988; Cyr and Henderson in Gauthier and Aubry 1996; Faanes and Andrew 1983; Graber et al. 1985;

Hoffman 1989a; Lynch 1987; Mossman 1988; Mossman and Hoffman 1989; Mossman et al. 1991; Noon et al. 1979; Remson et al. 1998; Robbins et al. 1989; Rodewald and James 2020; Samson 1979; Sutton 1949; Temple et al. 1979).

The Yellow-throated Vireo preferred landscapes with 51-75% forest cover in North Dakota; no areas had more than 75% forest cover (Cunningham and Johnson 2019). In North Dakota 400-m landscapes with less than 30% tree cover, its probability of occurrence increased greatly with increasing tree cover within 100 m and was 0% at 0-18% tree cover, 5% at 40% tree cover, and almost 15% at 70% tree cover. It also increased with increasing tree cover in landscapes with more than 30% tree cover, but less dramatically. Its probability of occurrence was 3% at 30-70% tree cover, increasing to 8% at 90% tree cover (Cunningham and Johnson 2016).

With the exception of Hayden et al. (1985), most researchers consider the Yellow-throated Vireo area sensitive. Even though it nests on forest edges, it requires large tracts and has disappeared or declined significantly where forest sizes have diminished. In Wisconsin, it was found in woodlots as small as 6.5 ha, but was at least 50% more common in larger woodlands. In western Maryland, it was only encountered in forests larger than 4,000 ha; in Wisconsin, highest frequencies were in woodlots larger than 32 ha; in Illinois, it occurred in woodlots 6-16 ha in area; in eastern Maryland, it disappeared from woodlands smaller than 70 ha; in Connecticut, average patch size it occurred in was 1,366 ha, and the minimum woodlot size it occurred in was 347 ha. In Maryland, it was estimated that 100 ha of forest as well as a high percentage of regional forest cover with large, deciduous trees were required to support a viable population. In Texas, it was absent in riparian forests with widths less than 70 m (Askins et al. 1987; Bond 1957; Bushman and Therres 1988; Robbins 1979; Rodewald and James 2020). Although it occasionally occurs in Ontario woodlands smaller than 100 ha, it is unknown if self-sustaining populations occur in smaller areas.

Ontario nests were in deciduous trees and all but one were living. Large, mature trees were greatly preferred for nesting. Trees selected for nesting, in order of preference, were maples, poplars, oaks, and elms. DBH of 3 nest trees was 36, 41, and 41 cm. Nests were usually in forks of horizontal branches. Their positions ranged from near the trunk (77%) to ends of branches at the tree periphery (23%). Distances from trunk were 0.3-3 m, mostly 0.6-1.2 m. Nests were 1.2-24 m from the ground, with most 7.5-13.5 m up (Peck and James 1987). Nest height may be influenced by presence of the Red-eyed Vireo. Overall average height of Ontario nests was 11.2 m; 14.4 m when the Red-eyed Vireo was present and 9.5 m when it was absent, a significant difference (James 1997a).

Throughout its range, the Yellow-throated Vireo nests almost exclusively in deciduous trees, rarely in conifers, usually at the edge of mature forests or in widely spaced trees near woodlands. It nests mostly in maples and oaks, but also in beech and elm, and in pines in the south. Other nest tree species include hickory, black cherry, apple, honey locust, balsam poplar, trembling aspen, large-toothed aspen, and black walnut. Nests are usually suspended from prongs of a forked twig in the crown of a tree. Most are well concealed, but some may be exposed; exposed nests are still in shade most of the time. Occasionally nests overhung cottages, outbuildings, or parking lots. Nests tend to be at a height of 0.5-0.75 of the tree height, and closer to the centre of the tree than the outside. Nests were reported 1-24 m from the ground with most more than 10 m up (Bent 1950; James 1976, 1979b, 1999b; Rodewald and James 2020; Sutton 1949; Whitelaw 1997).

The Yellow-throated Vireo is only mildly territorial. Intruders are expelled, but usually only when they land in the same tree. Some territories may be close to the ground; others are high in the canopy. It is possible that 1 territory may be over another. Due to its scattered distribution, most territories have no neighbours and there is no need for defence. When neighbours are present, they are tolerated within close range; 2 active nests in Oxford County were only 15 m apart. Eastern Warbling- and Red-eyed vireos are tolerated unless they approach very close to the nest. Nests have been found within 25 m of a Red-eyed Vireo nest and nest trees of Yellow-throated and Eastern Warbling- vireos had intertwining branches. No information on home range is available. One territory in the eastern states was estimated at 4 ha. Four Illinois territories averaged 0.8 ha (range 0.7- 1.0 ha), and Williamson (1971) reported a territory size of about 4 ha in Maryland. Once Ontario birds are mated, they seldom stray further than 100 m from the nest (3 ha), but may travel 500 m if the habitat is irregular or linear (Cyr and Henderson in Gauthier and Aubry 1996; James 1976, 1996a, 1999b; Peck and James 1997; Rodewald and James 2020; Smith et al. 1978; Sutton 1949).

There is limited information on site fidelity. One bird banded during the breeding season in Maryland was recaptured at the same site 6 years later (Rodewald and James 2020).

Limiting Factors

Eggs have been found in Ontario nests from the last week of May until mid-July, with most present in the first half of June (Peck and James 1987). Once females arrive, pairing occurs quickly and nest initiation is within 4-12 hours. The first nest takes about 8 days to complete. Nests for second attempts may be built in 5 days or take as long as the first nest. Egg laying begins the day after the nest is finished, and 1 egg is laid a day. Incubation starts once the clutch is complete. The incubation period is usually 12 or 13 days, but may be 15-16 days when cowbird eggs are present. One of 3 eggs in an Elgin County nest hatched in 10 days; there was a delay of at least 5 days between laying of the first and third eggs in this nest. Young leave the nest when they are 13-15 days old, but can fly only weakly (Bent 1950; Cyr and Henderson in Gauthier and Aubry 1996; James 1978a, 1996a, 1996b, 1997a, 1997b, 1999c; Peck and James 1987, 1997; Rodewald and James 2020).

Although Sutton (1949) stated that the Yellow-throated Vireo typically reared 2 broods in Michigan, Rodewald and James (2020) and James (1999c) concluded that it only raises 1 brood annually. This was based on the lengthy dependency of young on adults and the fact that second broods have not actually been confirmed. Renesting is common if a clutch is lost and as many as 3 nesting attempts may be made. Renesting occurs in a new nest, often within 100 m of the first nest but occasionally as far as 400 m away. Typical clutch size is 4 eggs, sometimes 3 eggs, rarely 5. Nests parasitized by cowbirds may contain only 1 or 2 vireo eggs (Bent 1950; Cyr and Henderson in Gauthier and Aubry 1996; James 1997b; Peck and James 1987; Rodewald and James 2020; Sutton 1949).

The age at first breeding is 1 year, and breeding occurs every year thereafter if a mate is obtained. The mating system is monogamous (Rodewald and James 2020).

The Yellow-throated Vireo forages mostly on branches in the interior of trees in Ontario. In Maryland, it foraged on the outer portions of trees early in the season and moved more towards the interior later. It chooses trees significantly shorter than expected for feeding. Males forage at

significantly higher heights than females. Overall mean foraging heights were 6.7 m in Ontario, 11.7 m in Pennsylvania, and 16.1 m in Arkansas. It forages around 0.5-0.75 of tree height, at greater heights than Red-eyed and Eastern Warbling- vireos, and forages higher when Red-eyed Vireos are present. The Yellow-throated Vireo rarely feeds on the ground. It forages on every tree species in the territory, including conifers, often in proportion to their availability. In Ontario and Pennsylvania, important trees for foraging were sugar maple, white elm, white oak, and balsam poplar; trembling aspen, ash, and hawthorn were also frequently used. In Illinois, it exhibited selectivity in the tree species that it foraged in. Of tree species found in Ontario, in order of decreasing preference, pin oak, sycamore, white elm, bitternut hickory, Shumard oak, black gum, and Manitoba maple were used more than their availability. In order of decreasing avoidance, pumpkin ash, red maple, blue beech, silver maple, green ash, and shellbark hickory were used less than their availability. Bitternut hickory was selected, yet it was 19th and last in abundance of tree species. Pumpkin ash and blue beech were avoided, but they were second and seventh in abundance, respectively. In Ontario and Pennsylvania, canopy closure at foraging sites averaged 62% (range 30-90%), significantly more than for the Eastern Warbling-Vireo and significantly less than for the Red-eyed Vireo. The Yellow-throated Vireo preferred to forage on dead limbs and favoured completely dead trees or oaks or aspens, which often have large numbers of dead lower limbs. Foraging perches were 76.5% dead, 21.5% unfoliated, and 2.0% foliaged. It gleans most food from tree bark. Foraging is concentrated on basal portion of limbs, and it frequently moves near and around the trunk in a spiral fashion. Eight-four percent of food is taken from branches and the rest from leaves. Over 80% of food is taken centrally in trees, the remainder from the periphery. About 55-69% of food is obtained by stalking and gleaning (significantly different from Red-eyed and Eastern Warbling- vireos), 23-29% by sallying and hovering (significantly different from Red-eyed and Eastern Warbling- vireos), and 2-5% by hawking (Gabbe et al. 2002; Hamilton 1958; James 1976, 1979b; Rodewald and James 2020; Williamson 1971).

Nestlings are initially fed mostly soft-bodied green caterpillars, but later a wider variety of arthropods including moths and dragonflies. Most food brought is fresh, but adults occasionally regurgitate food for young nestlings. The diet of adults consisted of more than 98% animals: 95.8% insects, 2.4% spiders, and 0.06% other invertebrates (based on a sample of 160 stomachs). Over 42% of the diet consisted of lepidopterans including 23.1% caterpillars and 19.4% moths; butterflies were seldom consumed. Other invertebrates it ate included 12.9% beetles (weevils and lady, metallic wood-boring, leaf, click, dung, and scarab beetles), 7.4% flies (midges and horse flies), 5.1% hymenopterans (bees, sawflies, and ichneumonid wasps), 4.9% other insects (grasshoppers, crickets, locusts, and dragonflies), and snails. It eats plant material only in late summer and autumn, including sassafras berries, wild grape, pokeweed berries, lamb's-quarters seeds, and multiflora rose hips (Chapin 1925; James 1999c; Rodewald and James 2020; Sutton 1949).

Many nests are parasitized by Brown-headed Cowbirds, including replacement nests. The incidence of parasitism varies geographically; in Ontario, 23 of 48 nests (47.9%) were parasitized. Twenty-seven of 95 nests (28%) throughout the Yellow-throated Vireo's range were parasitized. It is a cowbird egg acceptor. Very rarely, it abandons a parasitized nest or buries cowbird eggs. Cowbirds frequently remove vireo eggs from nests, and there may be as many as 3 cowbird eggs in a nest. Vireo production in parasitized nests is low. Unless a vireo is hatched first, it usually dies due to

squashing or being out-competed for food. Parasitized nests average 0.6 vireo fledglings compared with 3.4 for unparasitized nests (Bent 1950; James 1997b; Lowther 1997; Peck and James 1997; Robinson 1992; Rodewald and James 2020; Sutton 1949).

Habitat loss and degradation may affect populations. Forest fragmentation may result in woodlands becoming too small to support a viable population. Effects of logging are uncertain, although extensive clear-cutting is detrimental. With its preference for an open canopy, the Yellow-throated Vireo may tolerate a broad range of silvicultural practices. Selective logging that creates small canopy openings may be beneficial, but may make nests more vulnerable to cowbird parasitism. Selective thinning tends to remove mature trees, which are important to the Yellow-throated Vireo (Bushman and Therres 1988; Cyr and Henderson in Gauthier and Aubry 1996; Rodewald and James 2020).

Current impacts of pesticides and contaminants are unknown. The Yellow-throated Vireo suffered direct mortality and local extirpations due to spraying for Dutch elm disease and gypsy moths. These practices are thought to have been responsible for its disappearance as a breeding species from towns, suburban areas, cities, and orchards (Bent 1950; Rodewald and James 2020).

In New Jersey and Pennsylvania over a 15-year period, hemlock declined from 56% of the total basal area to 46% due to the hemlock woolly adelgid; the amount of deciduous understorey increased. The Yellow-throated Vireo responded positively to hemlock decline and increased (Toenies et al. 2018).

Human disturbance may be a factor, depending on the stage of nesting. If disturbed during pair formation and early nest building, the nest site is typically abandoned and the female may desert the male. Once incubation starts, the Yellow-throated Vireo is insensitive to disturbance. Once adults cease to brood young, they become much more agitated by humans and other predators (James 1996b, 1999c; Rodewald and James 2020).

Price (2004) predicted that the range of the Yellow-throated Vireo could expand in southern Ontario if the average summer temperature increased by 2°C.

Status

The Yellow-throated Vireo has never been common in Ontario. McIlwraith (1894) considered it uncommon but generally distributed in the south, with records from London and Ottawa. The first record for the Kingston area was in 1919 (Weir 2008). Baillie and Harrington (1937) considered it uncommon in extreme southern Ontario, breeding north and east to Peterborough and Ottawa. They also had summer records from Grey County, Muskoka and Parry Sound districts, the Lake Nipissing area, Kenora, and Sault Ste. Marie. During the first atlas, it was uncommon in the south, with highest numbers along the southern edge of the Canadian Shield and along the Niagara Escarpment (James 1996a; James in Cadman et al. 1987). James (1991) considered it uncommon to locally common in the south north to Bruce County and Ottawa and occasional and rare to Sault Ste. Marie and Manitoulin Island and in western Rainy River District. A nest reported from Sudbury District in 1996 is the most northerly one confirmed to date (Peck and James 1997; Whitelaw 1997). James (in Cadman et al. 1987) concluded that it probably declined with settlement and forest

fragmentation, but that populations were stable at that time. It suffered a significant decline in the first half of the 20th century due to pesticide spraying.

The second atlas revealed that there was no significant change in the breeding distribution of the Yellow-throated Vireo, although there were more northern records in the Canadian Shield south of the North Bay area. This may represent a real range extension, or may be mostly singing territorial males that are unmated and contribute little to the population. There was significant turnover in the squares in which it was detected between atlases. This may reflect changes in forest cover or be related to a small and dispersed population shifting around. There was no significant change in its probability of observation province-wide between atlases, but there was a significant decline in the Carolinian Forest Region. The Frontenac Axis was the largest area of high abundance, with patches of high abundance along the southern edge of the Shield and on the Bruce Peninsula. In the Carolinian Forest Region, the larger areas of mature forests in northern Lambton County and in Norfolk County supported high densities (James in Cadman et al. 2007).

Long-term (1970-2021) population trends determined from Breeding Bird Survey results indicate increases of 0.903% annually in Canada and 0.5% in Ontario. The short-term (2011-21) trends were annual increases of 5.09% in Canada and 5.51% in Ontario. The long-term trends were highly reliable. The short-term results were of medium reliability for Canada and low reliability for Ontario (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Fledglings remain near the nest site most of the summer. They are typically within 100 m of the nest the first week, 200 m by the second week, and still within 400-500 m by late summer. After fledging, each adult cares for 1 or 2 young. Fledglings start looking for food 16 days after leaving the nest, but are occasionally fed by adults until a month after fledging. Family groups may remain on the breeding territory until autumn departure (Rodewald and James 2020).

In Ohio, adult and juvenile Yellow-throated Vireos used densely regenerating clear-cuts during the postbreeding period. These and other early successional habitats may be important in providing dense cover and abundant food (Vitz and Rodewald 2006, 2007). In Missouri, Porneluzi et al. (2014) netted birds during the postfledging period in an oak-pine-hickory forest 2-15 years after it had been clear-cut. Twenty Yellow-throated Vireos were captured during this period.

MIGRATION

Most migration is nocturnal, but some daytime movement occurs. The Yellow-throated Vireo typically migrates solely or in mixed flocks of chickadees and warblers (Bent 1950; Rodewald and James 2020).

In Ontario and southern Quebec, the Yellow-throated Vireo may arrive as early as late April, but most arrive in May with the peak in the last two thirds of May. Adult males arrive a few days before females (Cyr and Henderson in Gauthier and Aubry 1996; James 1996a; Rodewald and James 2020). Autumn departure timing is not well known, but is from mid- or late August to mid-September. Stragglers have occurred in the province until mid-November (James 1991; Rodewald and James 2020).

During migration, the Yellow-throated Vireo uses a variety of habitats, some of which may not be used during the breeding season. It may occur anywhere there are trees. It is most frequent in a variety of deciduous and mixed woods, usually at forest edge. It may also occur away from forests, such as on shrubby beach barriers (Bent 1950; Rodewald and James 2020) and along treed roadsides (personal observation). In Illinois, spring densities were higher in bottomland forests than upland forests (Graber et al. 1985). In Ohio, there was no difference in its abundance during spring migration in riparian forests and upland forests (Rodewald and Matthews 2005).

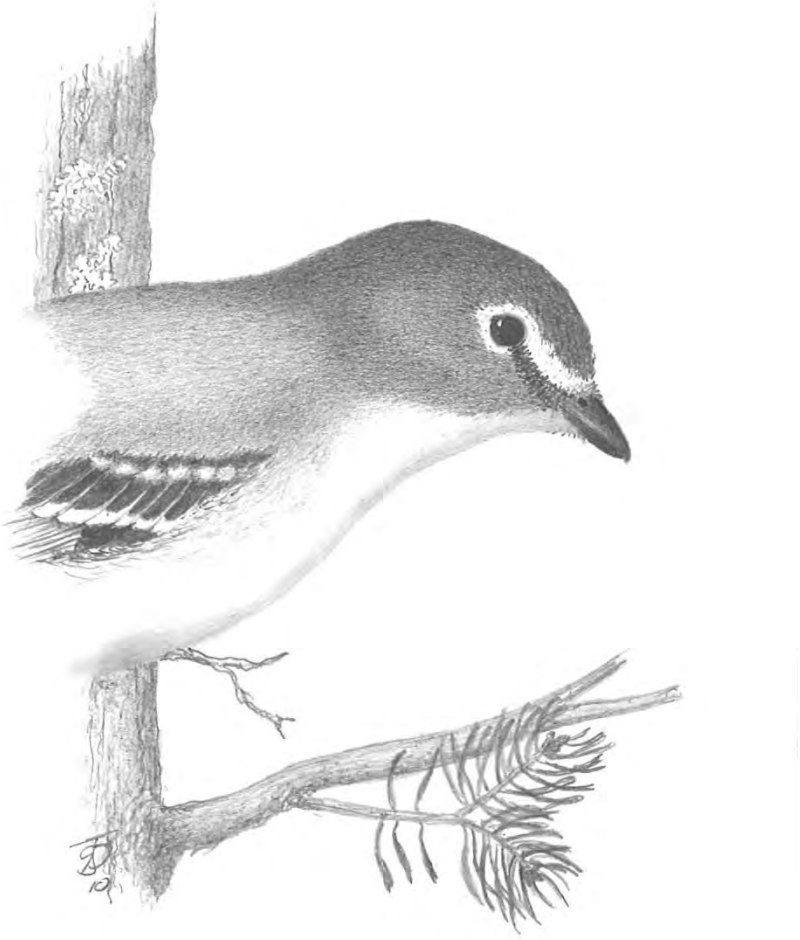
The Yellow-throated Vireo is often killed at structures at night while migrating, but kills are much less common than for most other species. Eighteen were reported killed at the Lennox Generating Station chimneys (Rodewald and James 2020; Weir 2008).

The Yellow-throated Vireo is a rare migrant. It tends to fly straight to the breeding territories in spring, remain there until autumn then depart abruptly. It is seldom seen outside of breeding areas (James 1991).

Data from the Haldimand Bird Observatory's Ruthven banding station indicated that the Yellow-throated Vireo may be increasing. This is the only banding station in Ontario that detects sufficient individuals to generate a trend (James in Cadman et al. 2007).

Blue-headed Vireo

Vireo solitarius



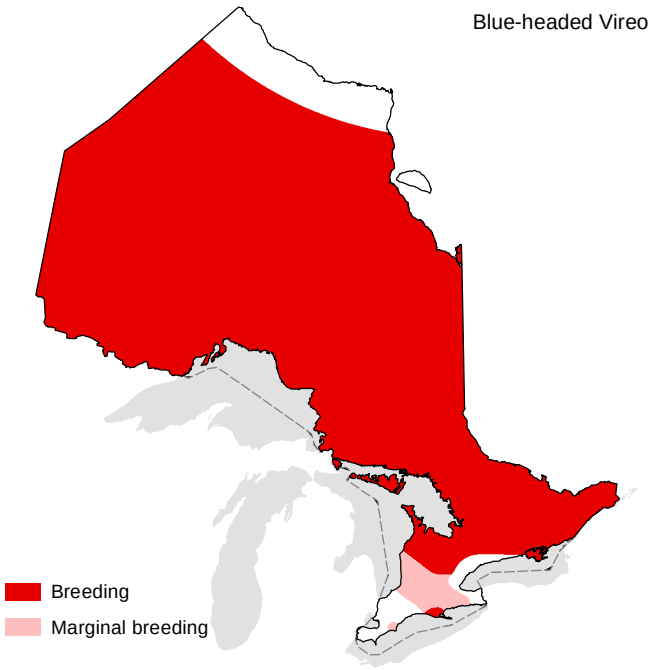
BREEDING SEASON

Habitat Requirements

The Blue-headed Vireo nests mostly in woodlands in Ontario, preferring mixed stands above coniferous stands and seldom nesting in deciduous woods. Two nests were in open areas: a dry rock ridge and an overgrown pasture. Several nests were near water, but it is uncertain if it prefers sites near water or if this was a reflection of the habitat preference of conifers (Peck and James 1987).

In northwestern Ontario in the Boreal Forest Region, the Blue-headed Vireo occurred in coniferous shrubs, mixed shrubs, coniferous forest, and deciduous forest (McLaren and McLaren 1981). Near Pickle Lake, it occurred regularly in low numbers in coniferous forest (James 1980). Near Hearst, it occurred at low densities in 5- and 6-year-old clear-cuts in upland mixed forest and in

uncut upland stands. It was not detected in upland clear-cuts that were 3 and 9-24 years old and it was absent in uncut and cut lowland conifer stands (Welsh and Fillman 1980). In jack pine stands near White River, it was significantly more frequent in stands 40-100 years old than in stands 3-25 years old. It was an indicator of mature forest (Venier and Pearce 2005). In the Clay Belt, it was most frequent in wet stands with a rich nutrient status (Welsh and Lougheed 1996). In the Boreal Forest Region of Ontario, it did not have any strong associations for the variables that Rempel (2007) tested. It tended to be associated with low edge amounts and relatively intact forests of moderate age with more coniferous than deciduous trees.



In the Great Lakes–St. Lawrence Forest Region in the Canadian Shield, the Blue-headed Vireo nests in both mature and old-growth white pine stands. Presence of super-canopy trees was important to it as was presence of large to medium-sized pines (Kirk et al. 2012). Near Gogama, it was characteristic of jack pine stands yet uncommon, rarely straying into adjacent mixed forest. It first began to nest when trees reached approximately 10 m in height, and nested and foraged where canopy closure was greater than 75%. It was most numerous in mature forest and absent in stands younger than 20 years old (James and Peck 1995a). Near Parry Sound, it occurred in low density in a mixed jack pine stand 10 m tall with 50% canopy closure, but was absent in stands with more open canopy (James 1979a). In Algonquin Park, Martin (1960) considered it characteristic of hemlock stands, where it occurred only in mature stands. It was absent in birch-poplar, birch-poplar-fir-spruce, fir-spruce, immature white pine, fir-spruce-hardwood, and hardwood stands. Near Dwight, it occurred predominantly in mixed forests. Often these forests were on slopes with deciduous trees at the top gradually replaced by conifers down gradient. Canopy closure was 90% and trees were always tall and usually old. Forests used for nesting had a moderately dense understorey, often of balsam fir, but it avoided areas with dense or no understorey. It also avoided young forest stands. The 4 main tree species in territories were sugar maple, balsam fir, yellow birch, and hemlock. It appeared to prefer greater tree density than the Yellow-throated Vireo (James 1979b).

In the Carolinian Forest Region, the Blue-headed Vireo has recently begun to nest in the Hamilton area in maturing coniferous plantations (Curry 2006). In southern Ontario, it occurs mostly in large, mature coniferous plantations that have developed an understorey (James in Cadman et al. 1987).

Morton and James (2020) summarized the Canada-wide habitat preferences of the Blue-headed Vireo. It usually occurs where trees are intermediate-aged to mature, where there is more than 75% canopy closure, where there is some (but not dense) understorey of shrubs or saplings, and often near small openings or edges of wetlands and lakes. It is normally associated with coniferous or mixed forests with spruce, fir, hemlock, or pine. Common deciduous associates are poplar, birch, and maple. It is most frequent in landscapes dominated by forests. In boreal Canada, Erskine (1977) considered it characteristic of coniferous forests, particularly spruce stands with deciduous species in the understorey. It is also characteristic of balsam fir stands and frequent in jack pine forests. It may occur in swamps and floodplains dominated by balsam poplar with willows and alders, plus patches of conifers. In Quebec, it was common in 60-year-old second-growth forests dominated by balsam fir, black spruce, white spruce, and white birch. It was significantly more frequent in well-forested landscapes. Remnant patches sufficiently large (5 ha) to support a territory were inadequate in clear-cut-dominated landscapes and were not occupied (Drolet et al. 1999). In Quebec balsam fir–white cedar forests, the Blue-headed Vireo was significantly more abundant in riparian than nonriparian stands; there were no differences in the vegetative structure of the 2 types of stands (LaRue et al. 1995). In Quebec, it appeared to prefer young, mature, and overmature spruce stands with openings. It also nested in mixed and deciduous forests with clearings and underbrush and in coniferous plantations. It was less common in deciduous forests and avoided densely populated areas (Langevin and Lafontaine in Gauthier and Aubry 1996). In British Columbia, it appears to prefer more open forests. Mixed forests on dry rocky sites, pine forests, poplar-pine-spruce stands, and intermediate-aged regenerating forests on dry sites are preferred (Campbell et al. 1997). In the northeastern United States, it may nest in pure deciduous stands of beech, maple, oak, and hickory (Morton and James 2020). Other authors reported it nesting in stands of white pine, aspen, birch–white cedar, hemlock, sugar maple–beech-hemlock with considerable understorey, pine-oak barrens with large patches of pine-dominated savannah, coniferous plantations, natural pine stands, spruce, and spruce-fir stands (Beals 1960; Bent 1950; Bielefeldt and Rosenfield 1994; Capen 1979; Crawford and Titterington 1979; Mossman et al. 1991; Niemi and Pfannmuller 1979; Noon et al. 1979; Temple et al. 1979; Thompson and Capen 1988).

Brooks and Bonter (2010) surveyed the number of Blue-headed Vireo territories in a field, a forest, and a managed Christmas tree plantation where natural succession occurred over 35 years. The number of territories increased significantly in the successional field but did not change in the forest; it was absent in the Christmas tree plantation.

In New Jersey, Benzinger (1994) considered the Blue-headed Vireo an obligate hemlock species, closely associated with the Black-throated Green Warbler. It occupies deciduous forests and coniferous plantations more frequently than the warbler. He considered its habitat associations as approximately 75% hemlock, 20% hardwoods with pine, and 5% coniferous plantation. It occupied a wide range of forest types from spruce-fir to pine, to pure deciduous. It exhibited an aversion for stands with dense undergrowth. In New Hampshire and Maine, it showed a significant affinity for sawtimber-sized trees and hemlock stands (DeGraaf and Chadwick 1987). In Maryland, it was strongly associated with hemlock bottomland forest (Gates and Giffen 1991). In New Jersey and Pennsylvania over a 15-year period, hemlock declined from representing 56% of the total basal area

to 46% due to the hemlock woolly adelgid; the amount of deciduous understorey increased. It was adversely affected by the decline of hemlock and also declined (Toenies et al. 2018).

In Pennsylvania, the Blue-headed Vireo breeds in pure deciduous stands, often with Yellow-throated Vireos. Although the Blue-headed Vireo occurs there mostly in mature stands, it also nests in younger stands with some understorey (James 1979b). Haney (1999) considered it an old-growth associate in Pennsylvania, rather than an obligate. It occurred in 100% of old-growth forests, 48% of forests on the Appalachian Plateau, and 30% of statewide forests.

In New Hampshire subalpine communities, streams were a key component of territories (Sabo 1980). This may have been incidental rather than a habitat requirement. In subalpine areas of New Hampshire, abundance of the Blue-headed Vireo was negatively correlated with the number of deciduous trees 2-10 cm diameter at breast height (DBH) and the total foliage volume of coniferous stems smaller than 2 cm DBH (DeGraaf et al. 1998). From Virginia southward, it uses more deciduous species such as hazel, chokecherry, birch, oak, maple, hickory, and beech. It usually occurs in large forests in a shady humid environment, but often near natural edges or small openings (Morton and James 2020).

Lindell et al. (2007) summarized studies that determined abundance of the Blue-headed Vireo in relation to edge. In 1 study, it showed no response to edge; in another it avoided edge.

Ontario nests were in trees, and all but one in a dead white cedar were in living trees. Coniferous trees (85.5% of nests) were preferred to deciduous trees. Trees selected, in order of preference, were balsam fir, spruce, and hemlock. Nests were suspended from horizontal branches, usually near the tip of the branch but occasionally closer to the trunk. Nest distances from tree trunks ranged from 0.07 to 3 m, mostly 0.3-1.8 m. Two thirds of nests were in small trees and saplings rather than large trees, and they were more frequently near the tops of small trees than in lower branches of bigger trees. Nest heights ranged from 0.9 to 11 m, averaging 2-4.3 m (James 1997a; Morton and James 2020; Peck and James 1987). One nest in Elgin County was 3 m up in a black cherry sapling (Lancaster et al. 2004).

In the northern part of its range, the Blue-headed Vireo typically nests in conifers, particularly spruce, balsam fir, and hemlock, but also in jack pine, sugar maple, yellow birch, and hophornbeam. In New Jersey, half of nests were in young hemlock. In Pennsylvania, all nests were in hemlock or pine. Further south, it may nest in oaks, pines, white cedar, magnolia, pear, apple, gray birch, beech, hickory, and walnut. Nests have been reported 1.2-18.9 m from ground, but most are 2-5 m up. It is not known to reuse nests (Bent 1950; Benzinger 1994; James 1978a; Morton and James 2020).

Males arrive before females and wander as far as 800 m from a central point over several days and as far as 400 m in a day. Unmated males may have territories as large as 50-200 ha. As soon as birds are mated, the territory immediately shrinks to a radius of about 100 m (3 ha), provided that the surrounding habitat is suitable. In New Hampshire, where territories were linear along watercourses, territory size was about 5 ha (James 1978a, 1996a; Sabo 1980). Pairs tend to be well spaced, with little conflict among them. Much apparently suitable habitat is unoccupied. Once nesting is underway, territorial defence is essentially non-existent (James 1996a; Morton and James 2020). Blue-headed and Red-eyed vireo territories frequently overlap and the 2 species have

structurally similar habitats. These species forage and nest at the same heights without conflict, and have been observed foraging together in the same tree. Nesting in conifers by the Blue-headed Vireos may be a mechanism for avoiding competition with the Red-eyed Vireo (Hudman and Chandler 2002; James 1997a, 1999b; Morton and James 2020).

No information is available on natal philopatry. Early returns to territories occupied the previous year suggest some adult site fidelity, but there are no data to confirm this (Morton and James 2020).

Limiting Factors

Eggs may be present in Ontario nests from mid-May until early August, mostly in the first 3 weeks of June (Peck and James 1987). Later egg dates may represent replacement clutches or second broods. In Algonquin Park, nests are under construction from early May to mid-June, eggs are present from late May to early July, nestlings are present from early June to mid-August, and dependent fledglings are present from mid-June to mid-September (Tozer 2012).

Pairing occurs almost immediately after the females arrive. The first nest takes 8 days to complete. Nests for replacement clutches may be built in 4-5 days or may take as long as the first nest to build. The first egg is laid the day after the nest is complete, and one is laid a day. Continuous incubation starts when the clutch is complete. The incubation period is typically 13 or 14 days, but may be 15 days in cold weather. Young fledge when they are 12 or 13 days old, but can fly only weakly (James 1978a, 1996a, 1996b, 1997a, 1997b, 1999c; Morton and James 2020; Peck and James 1987).

One brood is typically raised in Ontario; a second brood is rarely raised. In Pennsylvania, second broods occurred in 2 or 3 pairs of 37; double broods are probably common in the southern Appalachians. Renesting is typical if the first clutch or brood is lost. A new nest is built for replacement clutches, often within 100 m of the first but rarely as far away as 400 m. Clutches of 3-5 eggs have been reported in Ontario, with most containing 4 eggs. This is typical throughout the Blue-headed Vireo's range, with 5-egg clutches rare (Bent 1950; James 1997b, 1999b; Morton and James 2020; Peck and James 1987, 1997).

The age at first breeding is unknown, but the Blue-headed Vireo is probably capable of breeding at age 1 year. It is likely that breeding occurs every year provided that birds are successful in attracting a mate. The nesting system is monogamous (James 1996a; Morton and James 2020) and there are no records of extra-pair copulations or young (Morton and James 2020).

The Blue-headed Vireo searches slowly on inner branches, foliage, and tree trunks for prey. In New Hampshire, it captured 55.2% of prey on bark and 38.2% on leaves. In Ontario, 68% of foraging was in the interior of a tree and 32% at the periphery. In Pennsylvania, 81% of foraging was in the interior of trees compared with 43% in New Hampshire. In Saskatchewan, it foraged in conifers significantly more on the inner and middle portions of branches and less near the tops of trees than lower areas. Trees selected for foraging were significantly shorter than random and shorter than those selected by Yellow-throated Vireos. There was no difference in foraging heights of the sexes. Mean foraging height in Ontario was 7.7 m at 55.7% of tree height; mean foraging height in Pennsylvania was 56.1% of tree height. In Saskatchewan, mean foraging height was 6.1 m in coniferous trees and 6.3 m in deciduous trees. It seldom forages near treetops or the ground. It

forages on any tree species within the territory, often in proportion to availability. But in Saskatchewan, it foraged more in balsam fir than expected and less than expected in trembling aspen. It used deciduous trees more than their availability in mixed forests in Ontario, exhibited high use of conifers in New Hampshire, and fed preferentially on yellow birch probably because insect densities were highest on this species. It takes 55-60% of prey from branches and most of the rest from leaves. It uses live branches for foraging 50-80% of the time. Usually 45-65% of food is captured by short sallies. Average sally distances were 0.8 m in Maine, 0.6-1.2 m in New Hampshire, and 1.5 m in Virginia. The proportion of food taken by sallying varies depending upon types of insects available. In Maine 95% of food items were captured by sallying but only 15% were captured by this method in New Hampshire. It captures most other prey at a perch, but about 5% may be taken by flycatching. Apparent flycatching is used near the nest to deceive potential predators. When nestlings are present, adults often appear to flycatch immediately before attending the nest, but prey is taken only a small proportion of the time (Cumming 2004; James 1979b, 1979c; Morton and James 2020; Robinson and Holmes 1982; Sabo 1980).

The young are initially fed mostly soft-bodied green caterpillars. Larger food is brought once they are older, including large dragonflies. Occasionally, adults regurgitate food to older nestlings. An analysis of more than 300 stomachs determined that adults ate in excess of 95% animal matter, almost all insects. In spring, the Blue-headed Vireo may feed heavily on tent caterpillars. Lepidopterans dominated the diet and they were mostly caterpillars; they comprised more than 30% of the diet annually and 40% certain months. The diet also consisted of about 20% bugs (predominately stink bugs), 13.5% beetles (weevils, and lady, metallic wood-boring, and click beetles), 6.9% hymenopterans (sawflies and ants), and 4.3% flies and miscellaneous insects (stoneflies, dragonflies, grasshoppers, crickets, and locusts). Miscellaneous invertebrates eaten include spiders and snails. The vegetable matter it consumes is mostly fleshy fruits such as wild grape, dogwood, viburnums, greenbrier, sumac, and elderberry (Bent 1950; Chapin 1925; James 1999c; Morton and James 2020; Remsen et al. 1998; Robinson and Holmes 1982). In New Hampshire and Maine, the Blue-headed Vireo ate few spruce budworms when they occurred at low density, but increased consumption exponentially as budworm numbers increased. The abundance of vireos and budworms was not correlated (Crawford and Jennings 1989). Venier et al. (2009) noted that the response of the Blue-headed Vireo to spruce budworms was inconsistent, with some studies reporting that it increased with increasing budworm populations but no response was observed in other studies. In their study area near Manitouwadge, the number of territories in mature black spruce–balsam fir–aspen stands increased significantly from 3.7 to 7.75 when budworms became numerous. Response was limited in young and intermediate-aged stands. In New Brunswick, it exhibited no response to spruce budworm populations (Morris et al. 1958). Over 2 years in Maine, spruce budworm larvae and pupae constituted 34% of the invertebrates consumed in both years (Mitchell 1952).

In the north, the Blue-headed Vireo is infrequently parasitized by cowbirds because it nests in extensively forested areas. It usually accepts cowbird eggs, rarely abandoning the nest or burying the parasitic egg in the nest lining. Eggs removed by cowbirds are not replaced. In Ontario, 4 of 50 nests (8%) were parasitized. In the northern United States and eastern Canada, 13.5% of nests were

parasitized. Parasitism rates in other areas include 21.2% and 46.5% of nests in 2 Virginia areas and 42.1% of nests in the southern United States. Parasitism greatly reduces nest success. In eastern Canada and northern United States, a mean of 2.9 young fledged in unparasitized nests; 0 fledged in parasitized nests (James 1997b; Morton and James 2020; Peck and James 1997).

The distribution of the Blue-headed Vireo in southern Ontario is limited by forest clearing and fragmentation. It was probably more widespread prior to settlement. It is now starting to reoccupy areas that were reforested, notably in the St. Williams forest in Norfolk County and the Oak Ridges Moraine. Local declines may result from forest clearing or death of trees due to acidification. It tolerates light timber harvesting, although pairing rates may decline. Heavy forest thinning promotes dense growth of understorey, making habitat unsuitable. In southern Ontario and further south, its distribution is patchy due to the distribution of suitable habitat. In New Jersey, where it is a hemlock obligate, increasing fragmentation of hemlock growth makes it more difficult for dispersing birds to locate suitable habitat, leading to reduced site occupancy and possibly local extinctions (Benzinger 1994; Morton and James 2020).

Forestry practices have varying effects depending on the harvest prescription used. Tozer et al. (2010) studied the effects of group-selection harvesting of timber in Algonquin Park. Typical group-selection consisted of cutting about 5% of the stand; intensive group-selection affected 20% of the stand area. Neither treatment had any effect on the abundance of the Blue-headed Vireo. Vanderwel et al. (2009) examined the effects of partial tree harvesting in the Boreal Forest Region of Ontario. It decreased when 30 or 50% of tree cover was removed, but was relatively unaffected when 70% of trees were cut. In Ontario in the Canadian Shield, there was no difference in its abundance in early successional stands after clear-cutting or fire. It was significantly less abundant in mid-successional clear-cuts than in similarly aged stands after fire. There was no difference in its abundance in early successional and mature stands but it was significantly more abundant in mid-successional than mature stands (Zimmerling et al. 2017). In Nova Scotia hardwood forests, the Blue-headed Vireo was common, but it was absent in clear-cuts and thinned plots and much less common in strip-cut plots (Freedman et al. 1981). Also in Nova Scotia, it was absent or present only in trace numbers in hardwood forests younger than 40 years (Morgan and Freedman 1986). In Vermont, territories encompassed both uncut and clear-cut hardwood forest (Lent and Capen 1995). In Virginia, the ability of males to find a mate after group-selection harvest was less than 50% over 2 years compared with more than 80% in unharvested forest over 3 years (Morton and James 2020). In New York, Keller et al. (2003) recorded bird species usage of clear-cuts for several years after harvest. The Blue-headed Vireo was in a guild with 3 warbler species and all 4 species were associated predominantly with hemlock. This tree did not become prominent in the canopy and subcanopy until 55-75 years after cutting. This guild was absent in stands younger than 55 years but ranked third in abundance from 75 years postharvest onward.

In Minnesota, blowdown of spruce-fir forest resulted in an 80% decline in canopy cover and a 100% increase in shrubs. The Blue-headed Vireo nested in the blowdown area but was absent from the control plots (Burris and Haney 2005).

Rose and Simons (2016) studied the effects of fire in North Carolina pine-oak forests. The Blue-headed Vireo generally responded negatively to fires, but did occur more frequently after low-severity burns.

The Blue-headed Vireo is very sensitive to human disturbance during pairing and early nest building. If disturbed, the female readily abandons the nest and occasionally her mate. Once eggs are laid and during incubation, it is very tolerant of human intrusion, and may allow humans to touch it on the nest. If nestlings are removed from the nest for banding in the presence of the female, she will abandon the nest; the young then die of exposure. Once the female ceases brooding nestlings, it becomes sensitive to disturbance again. It is sensitive only to humans that pay attention to the nest and may nest in busy locations such as campgrounds if the nest is not disturbed (Bent 1950; James 1996b, 1999b; Morton and James 2020).

In Alberta, Bayne et al. (2016) studied the effects of forest fragmentation by energy-sector facilities on the Blue-headed Vireo. There were no significant differences in its abundance at seismic lines and pipelines than in forest interior adjacent to these features. It was significant less abundant at well pads than in adjacent forest interior. Farwell et al. (2019) detected no significant responses to well pads, access roads, and pipelines in extensive forest in West Virginia.

Price (2004) concluded that the breeding range of the Blue-headed Vireo might exclude southern Ontario if the average summer temperature increased by 2°C. In Quebec and Labrador, its abundance was associated with increasing numbers of growing-degree days, or areas experiencing the warmest summer weather (DesGranges and LeBlanc 2012). This suggests that climate warming may be beneficial to this species where it is near the northern extent of its range. In North Carolina, its abundance was negatively correlated with temperature, suggesting that climate change could be detrimental to it in this area (Lumpkin and Pearson 2013).

Status

McIlwraith (1894) had no breeding records for the Blue-headed Vireo, but it probably bred through much of southern Ontario prior to European settlement. Most of his records were from southern Ontario, and it undoubtedly nested in the Canadian Shield at that time. Baillie and Harrington (1937) considered it an uncommon breeder in central Ontario from Muskoka District and Algonquin Park north to the intercontinental railway. Their only definite breeding records were from Thunder Bay, Chapleau, and Algonquin Park. They noted 1 summer record from Fisher Glen in Norfolk County, where it still breeds. In 1991, it was confirmed breeding in Elgin County for the first time, the most southwesterly breeding record (Lancaster et al. 2004). During the first atlas, James (in Cadman et al. 1987) concluded that habitat was suitable in the Shield from central Georgian Bay and Ottawa northward. He considered it common in the Shield, becoming scarce or absent in the northern portion of the Hudson Bay Lowland where trees are scattered, with isolated birds occurring in the agricultural south.

The second atlas indicated that the probability of observation of the Blue-headed Vireo increased significantly since the first atlas. Increases occurred province-wide and in all regions, and all increases were significant except in the Carolinian Forest Region where it remained rare. The greatest increase, almost 300%, occurred in the Great Lakes–St. Lawrence Forest Region south of the

Canadian Shield. Increases may be related to maturation of coniferous plantations. It was most abundant in the Shield, with lower densities in the Clay Belt, the Hudson Bay Lowland, and south of the Shield (James in Cadman et al. 2007).

Long-term (1970-2021) population trends determined by the Breeding Bird Survey indicate annual increases of 3.04% in Canada and 2.71% in Ontario. The short-term (2011-21) trends were annual increases of 17% in Canada and 1.98% in Ontario. Results were of medium reliability, except for the short-term Ontario results, which were of low reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Young are fully dependent on the adults for the first week after fledging then the adults split up, each taking half the young. Fledglings are partially dependent for 2-4 weeks, and usually remain with the adults within 1 km of the nest until autumn migration (Morton and James 2020).

During the postfledging period in Pennsylvania, Stoleson (2013) netted 18 adults and 8 fledglings in clear-cuts compared with 4 adults and 0 fledgling in forest habitat.

MIGRATION

The Blue-headed Vireo is probably a nocturnal migrant. It travels singly or in mixed flocks of warblers and kinglets, but not in flocks of its own species (James 1999c; Morton and James 2020).

Adult males arrive in spring a few days before females. The Blue-headed Vireo typically arrives in mid-April with large numbers present by early May; some arrive in late March. Despite its early arrival, some males do not find mates until early June. Some birds remain on or near the territory until the first week of September, others are moving south at that time, and most have moved south by mid-September (James 1991, 1996a, 1999c; Morton and James 2020).

During migration, the Blue-headed Vireo may occur in any type of wooded area, from shrubs to treetops. Deciduous, mixed, coniferous, open to dense, and dry to moist woodlands are used. It seldom occurs away from wooded areas, but it rarely uses well-treed urban areas and rural lots (Morton and James 2020).

During autumn migration in Pennsylvania, the Blue-headed Vireo was most abundant at forest edges including hydro rights-of-way, open-canopy forest roads, and edges of forest cuts. It was second in abundance in forest interior, suburban forest, and areas of shrubs and saplings. There were no statistical differences in usage of the top 4 habitats. Other habitats used to a lesser extent were pole-stage forest and forest-agriculture edges. Structurally heterogeneous habitats were used most (Rodewald and Brittingham 2002). Suomala et al. (2010) examined abundance of the Blue-headed Vireo on 2 islands in the Gulf of Maine during migration. During spring migration, it was most abundant on the island dominated by trees. It was more abundant on the shrub-dominated island in autumn. In Pennsylvania, it was significantly more abundant in forest than shrub habitats during spring migration (Smith and Hatch 2008). In Ohio, it occurred significantly more in mature upland forest than mature riparian forest during spring migration (Rodewald and Matthews 2005).

The Blue-headed Vireo is occasionally killed at tall structures during migration, but in low numbers. It represented less than 0.01% of the total kill at lighted office towers in Toronto, and 19 were killed at the Lennox chimneys near Kingston. It is one of the species least vulnerable to striking

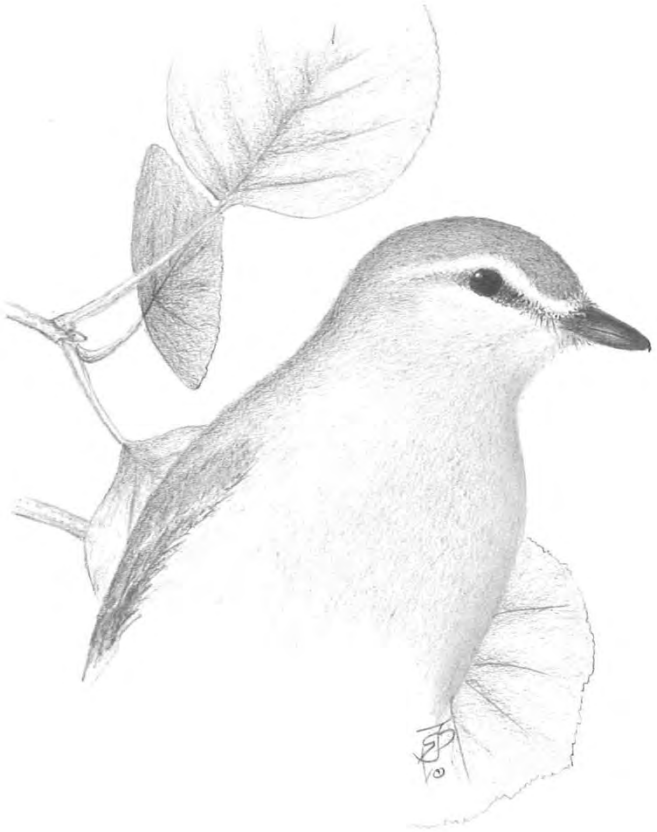
high-rise buildings in Toronto (Colling et al. 2022; Morton and James 2020; Remsen et al. 1996; Weir 2008).

In New York, Zelt et al. (2017) compared spring arrival dates, autumn departure dates, and length of the breeding season during 1888-1939 and 1967-2012. There was limited climate change during the first period but significant warming during the second period. The Blue-headed Vireo arrived significantly earlier in the second period but there were no differences between periods for autumn departure dates and length of the breeding season.

The Blue-headed Vireo is uncommon during migration (James 1991). Migration data at Long Point Bird Observatory showed a nonsignificant 1.0% annual increase 1979-88 (Hussell et al. 1992).

Philadelphia Vireo

Vireo philadelphicus

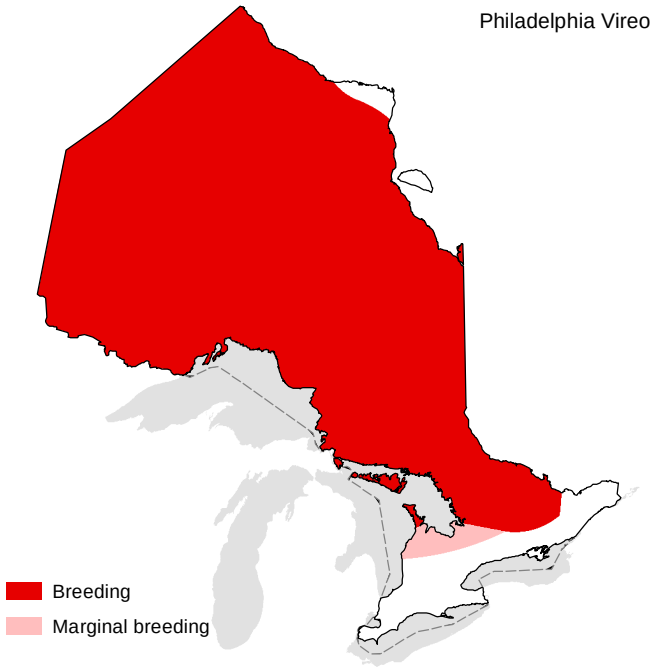


BREEDING SEASON

Habitat Requirements

In Ontario, the Philadelphia Vireo nests primarily in deciduous forests dominated by poplars and sometimes birch, less frequently in mixed woods of poplar and spruce, and occasionally in alder thickets that often contain dogwoods and willows. Forested areas where breeding occurred often had an understorey of alder. Breeding was confirmed in 1 southern deciduous forest dominated by maple (Peck and James 1987).

In the Englehart area, the Philadelphia Vireo was restricted to alder thickets and aspen or yellow birch groves, usually with an understory of these same species or alder (Barlow and Power 1970; Barlow and Rice 1977). In northern Ontario, Schueler et al. (1974) found it primarily in tall stands of balsam poplar. On the northeast shore of Lake Superior, it preferred moist alder patches to drier poplar and birch woods (Baillie and Hope 1943). In the Clay Belt, Smith (1957) considered it a species of wet alder patches. In this region, it was associated with rich, wet stands (Welsh and Lougheed



1996). Near Gogama, it was common only in deciduous portions of older mixed forests where trees were taller than 10 m. It showed a strong preference for trembling aspen; rarely, white birch constituted a third of the trees in a territory (James and Peck 1995a). Near Hearst, it occurred in 9- and 24-year-old clear-cuts in upland mixed forests. It was not observed in lowland coniferous forests that were intact or clear-cut, in upland uncut forests, or upland clear-cuts 3-6 and 11-19 years old (Welsh and Fillman 1980).

Throughout its range, the Philadelphia Vireo inhabits early to mid-successional forests and forest edges, aspen parklands, and shrub thickets, with preference for aspen, birch, alder, and ash. It also nests in mixed woods and older forests as long as the favoured tree species are present. Second growth of aspens and birches on burned and logged areas, young cherry coppices, and willow and alder thickets along streams are good habitat. It may inhabit dense patches of mountain maple. It usually avoids residences but 1 Quebec nest was in a rural yard at the edge of 5-7 km^2 of open forest of red oak and white birch. In Quebec, it was uncommon in landscapes dominated by extensive black spruce forest. It was documented only in recent clear-cuts where shrubs and saplings were less than 2 m tall. In the Boreal Forest Region of Canada, it was absent in black spruce and species-poor jack pine stands, and was associated with mesic mixed and deciduous stands with moderate nutrient richness. It occurred in 50% of aspen stands 0-9 years old, 33% of 15-20-year-old aspen stands, 67% of 40-year-old stands, and 3.3% of 80-year-old stands. It was associated with openings or young stands, and occupied shrubs in open areas as well as tall, deciduous shrubs under a dense poplar canopy. Typical British Columbia habitat consists of dense, tall, rapidly growing young stands of trembling aspen or balsam poplar with 80% canopy closure and an understorey of highbush cranberry, alder, and willow. Riparian forest is important breeding habitat. In Quebec, it is typical of second-growth forests of trembling aspen saplings and shrubs. Sugar maple stands and agricultural areas in the St. Lawrence River plain are less suitable habitat. In New Hampshire, it inhabited late-successional hardwoods dominated by sugar maple–beech, and yellow birch with occasional ash. It preferred areas where there were several openings in the canopy created by fallen trees and where white ash and yellow birch were abundant. As this forest community matured, the Philadelphia Vireo disappeared (Back 1979; Bent 1950; Brewster 1903; Campbell et al. 1997; Erskine 1977; Faanes and Andrew 1983; Hobson and Bayne 2000; Imbeau et al. 1999; Kirk et al. 1996; Lewis 1921; Moskoff and Robinson 2020; Robinson 1981; Robinson and Holmes 1984; Villard in Gauthier and Aubry 1996).

Moskoff and Robinson (2020) thought that the Philadelphia Vireo may require large forest tracts to avoid high rates of nest predation and parasitism. In Saskatchewan, it was randomly distributed within a fragmented landscape and its abundance was unaffected by forest fragment size or amount of forest cover within a radius of 5 km. It was more common than expected in fragmented landscapes (Hobson and Bayne 2000).

Most Ontario nests (77.8%) were in trees, but some were in shrubs. Poplar species were favoured nest sites, supporting 70% of nests, followed by alder (24%), birch (2.7%), and maple (2.7%). Most nests were suspended from horizontal forks of lateral branches from very near the trunk to 1.5 m from it. Two nests were at the periphery of very large aspen trees. Nests were 1.8-21 m from the ground, mostly 3-15 m up (Peck and James 1987).

Few nests have been reported outside Ontario, and most were similar in placement. Nests in trees are almost always very near the top. Nests are frequently near water. The Philadelphia Vireo apparently does not use materials from old nests and old nests are not reused (Bent 1950; Brewster 1903; Campbell et al. 1997; Levin 1921; Moskoff and Robinson 2020).

Territorial defence begins as soon as birds arrive on the breeding grounds. Peaks in territoriality occur when territories are being established and during the nestling stage when there is competition for food resources. Territories are usually exclusive, but may overlap considerably when food is abundant. Territory size varies considerably among study areas and years due to breeding density and habitat quality. Near North Bay and Englehart, 54 territories averaged 0.3 ha; territories as large as 0.8 ha have been reported in Ontario. New Hampshire territories were 0.5-4 ha (Barlow and Rice 1977; Moskoff and Robinson 2020; Rice 1978a, 1978b).

The Philadelphia Vireo has a complicated relationship with the Red-eyed Vireo. The 2 species' songs are very similar. It appears as though the Philadelphia Vireo can discriminate between them but the Red-eyed Vireo cannot. Near Englehart, there were no significant differences between the species in their habitat preferences or foraging behaviours or heights. Their territories appeared to be mutually exclusive, with Philadelphia Vireos involved in as many territorial disputes with Red-eyed as Philadelphia vireos. In other areas, including Gogama, territories may overlap. Where overlap occurs, the Philadelphia Vireo nests and forages above the Red-eyed Vireo, so that the species are separated vertically. During the late nestling period, vertical separation disappears as adult Philadelphia Vireos expand their foraging range to include the shrub and sapling layers. Fledglings spend their first 2-5 days out of the nest among shrubs. During these periods, aggression between the 2 species may be intense and physical. The Red-eyed Vireo is usually dominant at this time (Barlow and Power 1970; James and Peck 1986; Moskoff and Robinson 2020; Rice 1978b, 1978c; Robinson 1981).

No information is available on natal philopatry. Adult site fidelity occurs, but its extent is unknown. Some adults reoccupy the same territories in consecutive years. Near Englehart, no areas were consistently occupied over a 3-year study (Moskoff and Robinson 2020; Rice 1978c).

Limiting Factors

Eggs have been found in Ontario nests from mid-May to mid-July, with most present in the first half of June (Peck and James 1987). In Algonquin Park, nest construction occurs in mid-May, eggs are present from mid-June to early July, nestlings are present from late June to mid-July, and dependent fledglings have been seen from late July to mid-August (Tozer 2012).

The female selects the nest site and builds the nest in about 6 days. Eggs are laid at the rate of one a day and incubation starts with laying of the first egg. The incubation period of 1 Ontario clutch was 11-13 days; incubation periods of 11-14 days have been reported. Hatching is asynchronous, with as long as 2 days between hatching of the first and last eggs. Nestlings fledge in approximately 14 days (Barlow and Rice 1977; Bent 1950; Lewis 1921; Moskoff and Robinson 2020).

A single brood is raised annually. Moskoff and Robinson (2020) suggested that second broods might occur during major caterpillar outbreaks, but this has not been confirmed. Renesting occurs if a clutch is lost or abandoned. Clutches of 3 and 4 eggs have been found in Ontario, with 70% containing 4 eggs. Normally 3 or 4 eggs are laid and most clutches contain 4 eggs; 5-egg clutches are rare (Bent 1950; Campbell et al. 1997; Moskoff and Robinson 2020).

The mating system is seasonally monogamous. At least 1 pair remained together for 2 breeding seasons. There is no information available on age at first breeding, but breeding probably occurs in the first year (Moskoff and Robinson 2020).

The Philadelphia Vireo usually forages on deciduous leaves high in the canopy, more often at the periphery of a tree than near its centre. In Ontario, it captured most food on foliage while perched; in New Hampshire, it obtained most food by sally-gleaning. In the Clay Belt of Ontario, all foraging occurred in deciduous species, and 83% of foraging occurred in foliage. Foraging techniques included 68.6% aerial attacks, 8.5% hanging, and 19.0% hovering. The mean foraging height was 13.7 m. In New Hampshire, 83.2% of attacks were on leaves and 10.5% on bark; most food was taken from the lower surface of leaves by hovering. It attacked prey in beech and yellow birch in proportion to caterpillar abundance and more in sugar maple than expected. Within the canopy, it attacked prey almost 3 times more often in ash and yellow birch than in beech. In the subcanopy layer, its attack rate was higher in sugar maple and yellow birch than beech. In Ontario, there were no significant differences in foraging heights or techniques between Red-eyed and Philadelphia vireos, other than for rarely used techniques. This was in an area where the 2 species had mutually exclusive territories. Male Philadelphia Vireos tended to forage higher than females, but not significantly. In New Hampshire, these differences were significant with males foraging at a mean height of 14.6 m compared with 13.5 m for females. There were no significant differences in the foraging techniques of the sexes, but males foraged more in sugar maple and less in white ash than females. In a New Hampshire study area, where territories of the 2 species overlapped, there were differences in foraging habits. The Philadelphia Vireo foraged preferentially on yellow birch and white ash in the canopy; the Red-eyed Vireo foraged in all tree species. In the subcanopy-sapling

layer, the Philadelphia Vireo foraged significantly less in beech and there was no difference in the sapling-shrub layer. Mean foraging height for the Philadelphia Vireo during territory establishment was 18.9 m (12.6 m for Red-eyed Vireo), 21.9 m during incubation and early nesting (13.4 m for Red-eyed Vireo), 11.2 m in the late nestling and early fledging stages (10.5 m for Red-eyed Vireo), and 18.7 m during late fledging (10.3 m for Red-eyed Vireo). The New Hampshire study area was not typical breeding habitat (Holmes 1986; Holmes and Schutz 1988; Moskoff and Robinson 2020; Rice 1978c; Robinson 1981; Robinson and Holmes 1982, 1984).

The young are fed mostly hairless caterpillars but also a variety of flying insects, including mayflies; small snails are rarely fed to young. One study examined 75 stomachs of adults that contained 92.5% animal material and 7.2% plant material. Insects comprised 88.4% of the diet and spiders constituted the remainder of the animal food. Lepidopterans were most important in the diet, forming 26.3% of the overall diet (24.1% caterpillars). More were eaten as the breeding season progressed to a high of 45.5% in September. Beetles were important in the diet at 24.8%, mostly leaf and lady beetles, but also scarab beetles and weevils, with small numbers of click, long-horned, and metallic wood-boring beetles. Fourteen percent of the diet consisted of wasps, bees, and other hymenopterans (ichneumonid and chalcid wasps, ants, and sawflies). Flies totalled 11.8% of the diet, mostly midges; 10.5% were bugs, especially stink bugs; and 1.1% were miscellaneous insects. Another study found that the diet consisted of 54.2% lepidopterans (50% larvae), 20.8% bugs, 4.2% hymenopterans, 8.3% beetles, 4.1% flies, 4.1% spiders, and 4.1% miscellaneous. The Philadelphia Vireo consumes fruit late in the breeding season and early autumn, including rough-leaved dogwood berries, rose hips, grapes, spicebush berries, and Virginia creeper berries (Barlow and Rice 1977; Chapin 1925; Graber et al. 1985; Lewis 1921; Moskoff and Robinson 2020; Remsen et al. 1998). Near Manitouwadge, it tended to increase with increasing populations of spruce budworms, but not significantly (Venier et al. 2009).

Cowbird parasitism has been documented in Ontario, but apparently not elsewhere. A male vireo was observed feeding an almost fully-grown cowbird fledgling in Sudbury District. Two of 14 Ontario nests (14.3%) were parasitized (Baillie and Hope 1947; Moskoff and Robinson 2020; Peck and James 1997).

The Philadelphia Vireo prefers poplar stands, so clear-cutting, logging, and fire may all be beneficial. The current practice of planting clear-cuts with conifer seedlings may be detrimental. Forest maturation may make habitat unsuitable (Holmes and Sherry 2001; James in Cadman et al. 2007; Moskoff and Robinson 2020; Villard in Gauthier and Aubry 1996). In the Canadian Shield of Ontario, it was significantly less abundant in early successional clear-cuts than in early successional burns, but there was no difference in its abundance in mid-successional clear-cuts and burns. There was no difference in its abundance in early successional and mature stands, but it was significantly more abundant in mid-successional than mature stands (Zimmerling et al. 2017).

In Alberta, the Philadelphia Vireo was significantly more abundant at pipelines than in adjacent forest interior. There was no difference in its abundance at seismic lines and well pads than in forest interior adjacent to these features (Bayne et al. 2016).

Price (2004) concluded that the Philadelphia Vireo could disappear as a breeding species from southern Ontario if the average summer temperature increased by 2°C. In Quebec, DesGranges and Morneau (2010) concluded that it was very sensitive to climate change.

Status

The status of the Philadelphia Vireo is somewhat difficult to determine due to the similarity of its song to the Red-eyed Vireo and its habit of remaining high in the canopy. The first Ontario record was a bird taken in May 1884 in Hamilton (McIlwraith 1894). Baillie and Harrington (1937) concluded that it was a more or less common breeder from northern Lennox and Addington County north to Moose Factory and west to Lac Seul. Schueler et al. (1974) considered it fairly common at Attawapiskat. Near Pickle Lake, it was uncommon, but more numerous than the Red-eyed Vireo (James 1980). It is a rare breeder in the Kingston area in the Canadian Shield (Weir 2008). James (in Cadman et al. 1987) stated that it was widespread and common in northern Ontario, reaching its greatest abundance in the Boreal Forest Region. At Moosonee, it outnumbers the Red-eyed Vireo 2:1. James (1991) considered it an uncommon to common breeder across the north to Big Trout Lake and Attawapiskat, and possibly Fort Severn, and occasional and rare in the south as far south as the Bruce Peninsula and central Peterborough and northern Leeds counties.

The second atlas indicated that the Philadelphia Vireo had extended its range both northward and southward since the first atlas. It was found in several 100-km blocks north of where it was detected during the first atlas. In the south, it occurred in many more squares in the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region, and also south of the Shield and notably on Manitoulin Island. The reasons for its northward range extension are uncertain but may be due in part to better coverage. Expansion southward may be due to increasing amounts of poplar on abandoned farmland. As these stands evolve to tolerant hardwoods, the Philadelphia Vireo may retract its range in the south. It was most abundant in the Boreal Forest Region in a broad band between latitudes 49°N and 53°N, from south of James Bay to the angle of the western border with Manitoba (James in Cadman et al. 2007).

Long-term (1970-2021) population trends determined by the Breeding Bird Survey indicated annual increases of 1.9% in Canada and 2.5% in Ontario. Short-term (2011-21) trends included an annual increase of 4.13% in Canada and an annual decrease of 0.255% in Ontario. Results were of medium reliability for the long-term trends and of low reliability for the short-term trends (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Fledglings remain with the parents for about 10 days after leaving the nest, with the brood split between the parents (Moskoff and Robinson 2020).

Major and Desrochers (2012) captured Philadelphia Vireos in clear-cuts in Quebec during the postfledging period. There was no difference in usage between control plots and those in which the fruit had been removed.

MIGRATION

The Philadelphia Vireo migrates nocturnally singly or in small groups of 3-5 and frequently joins mixed-species flocks. The average stopover period for autumn migrants in Maine was 3.4 days

(range 1-8 days). Birds gained significant weight during this period indicating that stopover areas are important in providing resources for migration (Bent 1950; Moskoff and Robinson 2020).

Both sexes arrive on the breeding grounds together and all usually arrive within a short period. The Philadelphia Vireo typically arrives in the province in mid-May, but has been seen in late April. In Muskoka and Parry Sound districts, it starts moving southward in late July. Autumn migrants are evident in Algonquin Park from mid-August until mid-September. Most leave the province by late September with stragglers remaining until early November (James 1991; Mills 1981; Tozer 2012).

During migration, the Philadelphia Vireo appears to prefer deciduous second growth, thickets, forest edges, and particularly shrubs along streams or marshes. It shows a strong preference for willow thickets during migration. In Illinois, it was 10 times more abundant in mid-successional forests and thickets than old fields or mature forests. During autumn migration in Pennsylvania, it occurred in all habitats studied (forest interior, forest edge, forest-agricultural edge, suburban forest, pole-stage forest, shrub-sapling forest), but numbers observed were insufficient to determine preferences. In urban areas of Ohio, there was no significant difference in its abundance during spring migration in mature riparian forests and mature upland forests. In British Columbia, it prefers woodlands and thickets during migration and is seldom seen in suburban or rural habitats (Bent 1950; Campbell et al. 1997; Graber et al. 1985; Moskoff and Robinson 2020; Rodewald and Matthews 2005; Rodewald and Brittingham 2002).

The Philadelphia Vireo is occasionally killed at television towers and other tall structures during migration. From 1972 to 1982, 189 were killed at the Lennox chimneys near Kingston (Graber et al. 1985; Moskoff and Robinson 2020; Weir 2008).

The Philadelphia Vireo is uncommon in Ontario during migration (James 1991).

Eastern Warbling-Vireo

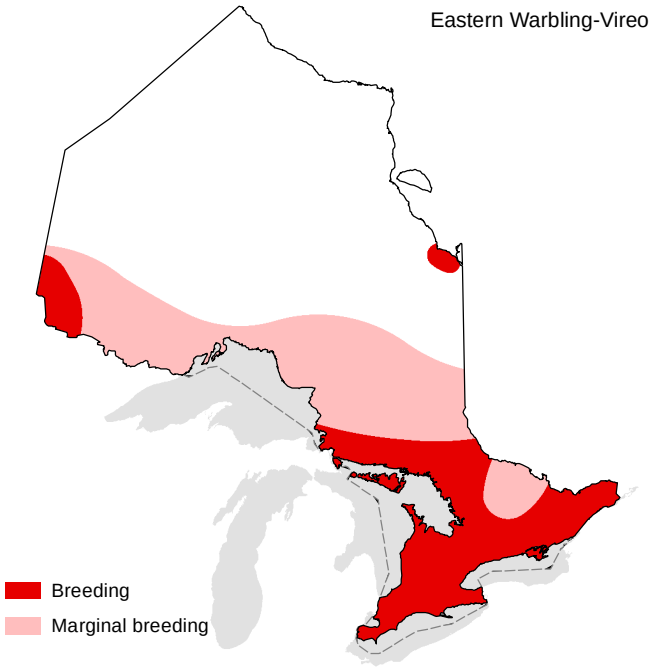
Vireo gilvus

BREEDING SEASON

Habitat Requirements

In 2025, the Warbling Vireo was split into 2 species, the Eastern Warbling-Vireo and Western Warbling-Vireo. The Eastern Warbling-Vireo nests from central Alberta eastward and the Western Warbling-Vireo nests further west. The 2 new species were identified due to differences in genetics, morphology, song, moult and migration, and response to brood parasitism (Chesser et al. 2025b). Because there are no known differences in the habitat preferences of the 2 species, relevant information on the western species is also included in the species account.

The Eastern Warbling-Vireo nests mostly in deciduous and mixed woodlands in Ontario (64% of nests), usually at edges or openings (65.5% of woodland nests). Other nesting habitat includes urban parks and gardens (19.8%), in agricultural habitat and fencerows (15.1%), and an aspen clump in a pine plantation (1.2%). Most nests were in edge habitats such as roadsides, pond and river



shorelines, swamp and marsh openings, beaver ponds, and cottage clearings (Peck and James 1987). McIlwraith (1894) stated that it preferred isolated ornamental trees in parks and gardens and shade trees in cities. In the Kingston area, it is present wherever there are mature deciduous trees, including those along city streets and highways, and in parks (Weir 2008). More detailed studies were completed by James (1976, 1979a). In the south, it nested in open habitat such as parkland with isolated trees, small groves, and forest edges. It selected habitat based on its structure rather than tree species composition. Habitat selected by Eastern Warbling-Vireos was more open than that of Yellow-throated Vireos, although not significantly, and significantly more open than Red-eyed Vireo habitat. In Parry Sound District, the Eastern Warbling-Vireo was absent in pure jack pine stands, but present in an immature open (less than 25% canopy closure) jack pine stand mixed with trembling aspen, white birch, white pine, and silver maple. In southern Ontario, it frequently occurs in small riparian stands dominated by poplars or willow trees (personal observation).

Throughout its range, the warbling-vireo inhabits a variety of deciduous and mixed forest types, with a strong penchant for riparian areas. During the breeding season in British Columbia, 70% of observations were in riparian habitats compared with 60% during spring migration and almost 90% during autumn migration. It exhibits a strong preference for mature deciduous woodlands, especially along streams, ponds, marshes, and lakes, but occasionally inhabits upland areas away from water. Nesting also occurs in young deciduous stands regenerating after clear-cuts or fires, in treed suburban areas, urban parks, orchards, and farm fencerows. It is strongly associated with poplar throughout its range but silver maple stands are important in Illinois. It keys in on overall habitat structure, selecting large, deciduous trees with a semi-open canopy (usually less than 75% canopy closure), and appears fairly indifferent to understorey density. It is most common in edges and small, disjunct patches, and is not area sensitive. In Washington, it was more abundant along large streams than small ones, possibly due to a more contiguous band of deciduous trees. In Colorado montane areas, it was associated with aspen stands and avoided riparian willow stands. In British Columbia, all nests in 1 study area were within 15 m of forest edge, and all but 4 were within 5 m of edge. When it nests in coniferous stands or plantations, it selects patches with more deciduous vegetation for nesting than is generally available. It avoids extensively forested areas. Historically, it was probably restricted to riparian areas and recent burns. It occurs in almost all age classes of deciduous stands, but reaches highest densities in mature and old-growth stands; mature poplar and aspen stands may be as young as 50 years. In Michigan, it nested in fringes of trees along

low, wet areas and preferred scattered poplars, ash, elm, and silver maple. Overall, it is associated with early successional, open or scattered forest, typically adjacent to water. In addition to poplar, aspen, and cottonwood stands, it breeds in ash-basswood, birches, sugar maple, silver maple, Manitoba maple, green ash, and willow. It is the most abundant species in most western aspen forests. In California, it nests regularly in coniferous forests and is most abundant and productive at mid-elevation areas where cowbird parasitism is absent or rare (Bent 1950; Campbell et al. 1997; Easton and Martin 2002; Erskine 1977; Faanes and Andrew 1983; Flack 1976; Gardali and Ballard 2020; Glass and Floyd 2015; Graber et al. 1985; James in Cadman et al. 2007; Kirk et al. 1996; Mossman 1988; Mossman et al. 1991; Noon et al. 1979; Paradis in Gauthier and Aubry 1996; Purcell 2006, 2007; Rumble and Gobeille 1998; Samson 1978; Sutton 1949; Temple et al. 1979; Ward and Smith 2000; Wiebe and Martin 1998).

At the landscape level, the warbling-vireo preferred areas that were 10-34% forested in North Dakota (Cunningham and Johnson 2019).

In North Dakota aspen stands, the probability of occurrence of the warbling-vireo was positively correlated with the percentage of ground cover (Grant and Berkey 1999). High percentages of ground cover are typically associated with open sites, forest edges, and woodlands with fairly open canopies. Whitmore (1977) considered the warbling-vireo a habitat specialist in Utah, preferring forests with low ground cover and high shrub density, also an indication of open-canopy stands.

Ontario nests were in deciduous trees and shrubs. The most common species used were poplar (41.2% of nests), maple (39.2%), elm (7.2%), birch (6.2%), and oak (6.2%). Nests were pensile and in forks of lateral limbs, usually near the end of the branch and periphery of the tree, occasionally close to the trunk. Distances of nests from trunks were 0.3-6 m, mostly 1.2-3 m. Nests were 1.4-18 m from the ground, mostly 6-9 m (James 1976; Peck and James 1987).

The warbling-vireo typically nests in deciduous trees and shrubs, although the western species occasionally nests in pines. In California, 69% of nests at 1 study area were in conifers, although deciduous trees were used for nest sites more than their availability. Nests are most frequently in aspens and poplars, particularly trembling aspen, but also balsam poplar, large-toothed aspen, cottonwood, and black poplar. In Manitoba, 17.6% of nests were in cottonwoods, but they were only 0.9% of trees present and occurred in clumps. Other nest-tree species include white ash, elm, basswood, sugar maple, silver maple, Manitoba maple, willow, black walnut, sycamore, apple, and pear. In Manitoba, peach-leaved willow was the dominant tree, but was not used for nesting. The warbling-vireo may nest in shrubs and saplings including red-osier dogwood, elderberries, willows, and poplars. In California, trees selected for nesting were taller, had larger diameters, and had higher foliage density than randomly selected trees. Basal area and canopy cover at nest sites did not differ from random sites and nest orientation was random. Nests are usually in the upper and middle periphery of trees, less frequently in the upper central portion or lower periphery. Nests tend to be at an average of 65% or more of tree height. Overall nest heights reported are 1.1-37 m. Nest height varies considerably depending on availability of trees and shrubs. Average heights were 2.1 m in 1 Arizona study area and 13.2 m in another, 8.3 m in 1 California study and 7 m and 15.7 m in 2 others, 6.2 m in 1 British Columbia study and 61% between 2 and 6 m for the province, and 8.4 m and 12.6 m in Manitoba. Some nests were situated where they received little shade. In Arizona, 2.4 times more

sky was visible on east halves of nests than west halves. This resulted in 90% more exposure to sunlight in the morning and was thought to be an adaptation to reduce afternoon heat stress (Bent 1950; Campbell et al. 1997; Easton and Martin 2002; Gardali and Ballard 2020; Graber et al. 1985; James 1976; MacKenzie et al. 1982; Purcell 2007; Sutton 1949; Ward and Smith 2000).

The warbling-vireo is not strongly territorial. Territoriality is most evident prior to nest building, dropping off sharply during nest building and largely ceasing thereafter. Females may forage outside males' territories and steal nest materials from other warbling-vireos; these intruders may be attacked. Two nests were in a single tree in Ontario. Limited information is available on territory size. Two pairs in Arizona had territories of 1.2 ha each, 9 territories in California averaged 1.45 ha, 19 in California averaged 1.2 ha, 1 in Illinois was 1.2 ha, 3 in southern Ontario were 1.2-1.5 ha, 2 in Alberta were 1.5 ha each. No information is available on home range size. When nesting in open habitat, it frequently flies as far as 100 m to find suitable foraging areas, suggesting a home range size of about 3 ha (Gardali and Ballard 2020; Howes-Jones 1985a; James 1976; Peck and James 1987).

Limited data suggest that natal philopatry is low. One percent of young were recovered from 19 years of mist-net data in California. Of 38 adults in British Columbia, 13 (34.2%) returned, all males. All males returned to their original territory and 3 returned the subsequent year (Gardali and Ballard 2020; Ward and Smith 2000). Two birds banded in Alberta during the breeding season were recaptured in another breeding season at the original banding site, suggesting site fidelity (Brewer et al. 2018).

Limiting Factors

Eggs have been found in Ontario nests from mid-May to mid-July, with most present in the first half of June (Peck and James 1987). About a week after arrival, the female starts to look for potential nest sites. Females may begin and abandon 1-3 nests before completing the final nest. Abandoned nests were worked on for 1-3 days. First Ontario nests took an average of 7.2 days to complete and usually 1-2 days elapsed after they were completed before egg laying was initiated. Replacement nests took an average of 6.0 days to complete and egg laying commenced as soon as they were complete. Occasionally the old nest was dismantled and its materials were used to construct the next one. Material may be taken from Yellow Warbler nests. Ontario replacement nests averaged 33 m from the first nest, except for one 30 cm away. In Montana, nest construction took an average of 5.4 days; elsewhere, 1 nest took 8 days to build. Eggs are laid at the rate of 1 per day. Incubation may begin with laying of the second egg. The incubation period at Ontario nests was 13 or 14 days. In Arizona, Idaho, and Montana, the mean incubation period was 12.5 days (range 10.5-16 days, mode 12 days). Fledging occurred at an average of 12 days in Ontario. In Arizona, Idaho, and Montana, mean fledging age was 14 days, with a range of 10.5-19 days and a mode of 13 days (Bent 1950; Gardali and Ballard 2020; Howes-Jones 1985a, 1985b).

Double broods have been reported in Montana and California, and double-brooding is probably common in areas with a long breeding season. Double broods have not been reported in Ontario or the eastern population. Renesting may occur, particularly in warmer areas. In California, females may lay as many as 5 clutches in an attempt to raise young. In Ontario, 1 renest may occur but a replacement clutch may not be attempted if loss occurs during late incubation. Clutches of 1-4 eggs have been reported in Ontario, mostly 3 or 4 eggs; 25 of 54 clutches (46.3%) contained 4 eggs.

Clutches of 1-5 eggs have been documented throughout the warbling-vireo's range, with about two thirds containing 3 or 4 eggs; 4 eggs is the most frequent clutch size (Bent 1950; Campbell et al. 1997; Gardali and Ballard 2020; Howes-Jones 1985a, 1985b; Peck and James 1997; Ward and Smith 2000).

The mating system is monogamous. The age at first breeding is unknown, but is probably 1 year (Gardali and Ballard 2020).

James (1976) studied the Eastern Warbling-Vireo's foraging behaviour in southern Ontario. Its foraging techniques and locations were similar to those of the Red-eyed Vireo but significantly different from the Yellow-throated Vireo: 32.0% by stalking, 59.0% by hovering, and 10.0% by hawking. It captured 97% of food items on leaves and 3.0% on branches. In California, 80% of prey was taken from twigs suggesting that it is opportunistic (Gardali and Ballard 2020). In Ontario, 88% of foraging was in the periphery of a tree (40% in the upper portion, 40% in the middle, 8% in the lower portion) and 12% in the centre of a tree (6% upper, 6% middle, 0% lower). Foraging perches were 51.5% unfoliated, 39.0% foliated, and 9.5% dead. It spent much time foraging within an individual tree, feeding mainly on tips of live branches. It foraged in almost all tree species in territories (sugar maple, white elm, red oak, balsam poplar, trembling aspen, white birch, ash, apple, basswood, hophornbeam, hickory, walnut, cherry) except for beech, willow, spruce, and white pine. Mean foraging height was 7.7 m (range 0.15-21 m) on trees a mean height of 10.0 m, mostly in trees 12-15 m tall (James 1976). In addition to foraging for invertebrates, the warbling-vireo drinks from wet vegetation and small streams (Gardali and Ballard 2020). In the Northwest Territories, 94.3% of foraging occurred in deciduous species and 5.7% occurred in conifers. Ninety percent of foraging occurred on foliage and the mean foraging height was 8.2 m (Greenberg et al. 1999).

The main food delivered to nestlings appears to be small green caterpillars, but also dogwood berries and large moths after the wings are torn off. An analysis of 340 adult stomachs indicated that the warbling-vireo ate 94.2% animal food, almost all insects, and 5.8% plant material. Lepidopterans dominated the diet at 40.4% (35.4% caterpillars). Beetles comprised 15.5% of food, especially lady beetles, but also weevils and metallic wood-boring and leaf beetles. The remainder of the diet consisted of 16.7% bugs (mostly stink bugs), 9.5% flies, 6.0% hymenopterans, 4.4% grasshoppers and other insects, and trace amounts of spiders and snails. Vegetation consumed included fruits of cherry, sassafras, and blackberry. Another study reported similar results: 95% insects of which lepidopterans were most important at 43% (mostly caterpillars but also moth pupae). Other prey included 21% bugs, 19% lady beetles, 7% other beetles, 4% other insects, and 2% spiders. In Illinois, 3 spring migrants ate 79% caterpillars and 15% beetles, of which about a third were ground beetles. In autumn, the warbling-vireo may also eat elderberries and pokeweed berries (Bent 1950; Chapin 1925; Gardali and Ballard 2020; Graber et al. 1985).

The Western Warbling-Vireo typically accepts cowbird eggs whereas the Eastern Warbling-Vireo usually rejects them. The Eastern Warbling-Vireo may eject cowbird eggs from the nest or abandon parasitized nests. In Manitoba, 0.13 vireo egg was lost per ejected cowbird egg; ejection greatly improved reproductive success over acceptance. The Western Warbling-Vireo is highly parasitized and is one of the most frequently parasitized species in British Columbia with an overall rate of 49%, and 75%, 79.1%, and 61.7% in 3 studies. Parasitism was so high in some areas that local vireo

extirpations would occur without immigration. Other western parasitism rates are 50% in Wyoming, 63% in Montana, 75% in Colorado, and 80% in California. In Oregon, 46% of nest failures were attributed to parasitism, the highest rate of the 5 species studied, and it was the only species for which parasitism losses were greater than those due to predation. The overall parasitism rate was 47%. Parasitism rates are much lower in the Eastern Warbling-Vireo, possibly because observers do not detect rejected eggs. The rate is 11.3% in Ontario and 3.6% in Manitoba. Parasitism has not been documented in Quebec, Michigan, Illinois, or Kansas. Cowbirds may remove vireo eggs, reducing clutch size. In Montana, clutch size averaged 3.8 eggs in unparasitized nests and 3.16 in parasitized nests. Results were 3.36 eggs in unparasitized nests and 2.75 eggs for parasitized nests in British Columbia. If a cowbird egg is accepted, typically the entire vireo brood is lost. The mean number of young surviving per parasitized nest was 0.1 in British Columbia; only 2.6% of parasitized Montana nests produced young. In the Sierra Nevada of California, Western Warbling-Vireo abundance was negatively correlated with cowbird abundance. In British Columbia, parasitism rate was not correlated with nest height (Bent 1950; Campbell et al. 1997; Gardali and Ballard 2020; Heltzel and Earnst 2006; Howes-Jones 1985a; Lowther 1997; Ortega and Ortega 2003; Peck and James 1997; Sealy 1996; Siegel and DeSante 2003; Sutton 1949; Underwood and Sealy 2011; Ward and Smith 2000).

Habitat loss does not appear to be a significant problem for the warbling-vireo. Clear-cutting coniferous stands and leaving deciduous trees in or near openings may be beneficial. Forest fragmentation in the south may have benefitted it (Gardali and Ballard 2020; Paradis in Gauthier and Aubry 1996). In California, it was more numerous in commercially thinned forests than unthinned forests (Siegel and DeSante 2003). Further loss of forest fragments and drainage of wetland pockets in the south may be detrimental. Vanderwel et al. (2007, 2009) summarized studies that examined the effects of partial forest harvest on breeding birds in the Boreal Forest Region, with an emphasis on Ontario. They concluded that there was no change in abundance of the warbling-vireo when 30%, 50%, or 70% of trees were removed. Bayne et al. (2016) examined bird responses to forest fragmentation due to energy sector disturbances in the western boreal forest. The Western Warbling-Vireo was significantly more abundant along pipelines than in forest interior.

In Oregon, abundance of the Western Warbling-Vireo increased significantly after cattle were excluded from grazing in riparian trembling aspen stands. Significant regeneration of aspen occurred once grazing ceased (Earnst et al. 2012). It is possible that grazing by white-tailed deer could adversely affect habitat for it in southern Ontario.

Price (2004) predicted that the range of the Eastern Warbling-Vireo could contract in southern Ontario if the average summer temperature increased by 2°C. DesGranges and Morneau (2010) considered the Eastern Warbling-Vireo very sensitive to climate change in Quebec.

Status

McIlwraith (1894) considered the Eastern Warbling-Vireo very common during the breeding season. It was common in eastern Ontario in the latter part of the 19th century, having moved northward as forests were cleared (Weir 2008). Baillie and Harrington (1937) reported that it was a widespread and common breeder in southern Ontario, particularly in urban centres. Breeding occurred north at that time to at least Parry Sound District and North Bay, northern Frontenac County, and Ottawa,

and in the Thunder Bay area. Breeding had been documented on the Manitoba side of Lake of the Woods, but not in Ontario. The first atlas demonstrated that it was well established in Rainy River District and that it had expanded its range northward to the Clay Belt. Population gaps were evident in the heavily treed Algonquin Highlands and in some squares in Essex County with essentially no tree cover (James in Cadman et al. 1987). James (1991) considered it common in the south, except for being absent from the Algonquin Highlands, and common in western Rainy River District.

The second atlas indicated that there had been little change in the distribution of the Eastern Warbling-Vireo since the first atlas. A small population became established in the Moosonee area, but there were few records from the Boreal Forest Region and the Algonquin Highlands. There was no difference in its probability of observation province-wide or in any atlas region except the southern Canadian Shield which experienced a significant decline that may have been related to forest maturation. Highest densities occurred along the shore of eastern Lake Ontario, on the southern edge of the Shield, along the St. Lawrence River, and in a small area east of Lake Huron (James in Cadman et al. 2007).

Long-term (1970-2021) population trends determined by the Breeding Bird Survey indicate that the warbling-vireo increased at annual rates of 0.841% in Canada and 1.24% in Ontario. The short-term (2011-21) trends were an annual increase of 0.255% in Canada and an annual decrease of 0.951% in Ontario. All results were highly reliable except that the Canadian long-term trend was of medium reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

At Ontario nests, fledglings seldom ventured more than 10 m from the nest on the first day, were 30-100 m from the nest the second and third day, and by the fourth or fifth day were widely dispersed and often outside the territory. Within a week or 2 of fledging, young become independent and the family abandons the territory (Bent 1950; Howes-Jones 1985a, 1985b).

MIGRATION

The Eastern Warbling-Vireo migrates nocturnally either singly or joins mixed-species flocks. Of 20 pairs observed in Hamilton, both sexes of 13 pairs arrived together. The female arrived 1 day after the male in 5 cases, 3 days later in 1 case, and 4 days later in 1 case. Spring migrants usually arrive in early May, but some appear in mid-April. Some birds leave in August but many remain until mid- to late September with stragglers occurring into early October or rarely as late as mid-November (Curry 2006; Gardali and Ballard 2020; Howes-Jones 1985a; James 1991). In Idaho, adults arrived in autumn 21.1 days before juveniles (Carlisle et al. 2005).

During migration, the warbling-vireo uses a wide variety of forested and shrubby habitats, but avoids coniferous forests. It may occur in urban areas during migration (Campbell et al. 1997; Gardali and Ballard 2020). Favoured habitat during spring migration in Algonquin Park includes small patches and strips of trees along lakes and rivers, utility and road corridors, clearings, aspen stands, silver maple swamps, and floodplain groves (Tozer 2012). In Illinois, it was most abundant during spring migration in bottomland forests, forest edges, and shrubby areas (Graber et al. 1984). During spring migration in Wisconsin and Minnesota, it was significantly more abundant in floodplain forests than upland forests (Kirsch et al. 2013).

Keast (1980) studied the foraging strategies of the Eastern Warbling-Vireo during autumn migration at Prince Edward Point. Foraging substrates included 49% outer leaves, 7% twigs and inner leaves, 15% outer branches, 24% sapling foliage, 7% sapling branches, and 5% low shrubs. It did not forage in the air or on inner branches, tree trunks, or the ground. It foraged at heights of 1.4-12.9 m, most frequently at 7 m.

Carlisle et al. (2012) examined the diet of Western Warbling-Vireos during autumn migration in Idaho. Prey consumed more than expected based on their availability included bugs (mostly stink and spittle bugs), lepidopterans, and larvae. Prey consumed less than expected included spiders, stilt bugs, leafhoppers, jumping plant lice, hymenopterans (including ants, wasps, and yellowjackets), moths, and flies.

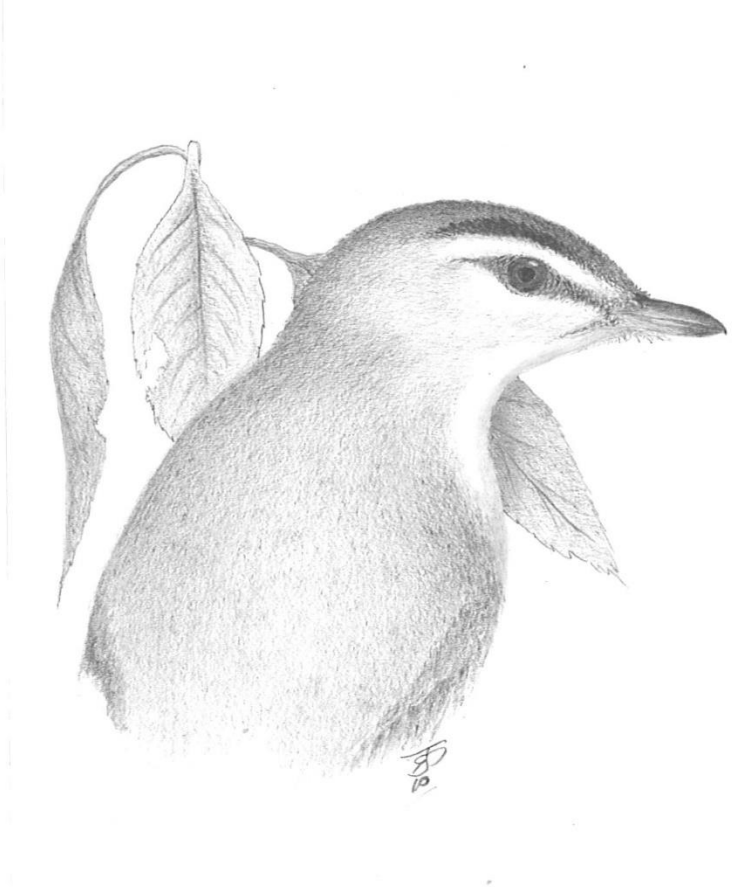
The warbling-vireo is occasionally killed at tall structures during migration, but typically in low numbers. Forty-two were reported killed at the Lennox chimneys near Kingston (Gardali and Ballard 2020; Weir 2008).

Ellwood et al. (2010) determined that spring arrival dates of the Eastern Warbling-Vireo were significantly correlated with temperature at Concord, Massachusetts. It was expected to arrive earlier in response to climate change. In New York, Zelt et al. (2017) compared spring arrival dates, autumn departure dates, and length of the breeding season for 1888-1939 and 1967-2012. There was little climate change during the first period but significant warming during the second period. The Eastern Warbling-Vireo arrived significantly earlier in spring during the second period but there were no differences in its autumn departure dates or length of the breeding season.

James (1991) considered the Eastern Warbling-Vireo an uncommon migrant in Ontario.

Red-eyed Vireo

Vireo olivaceus

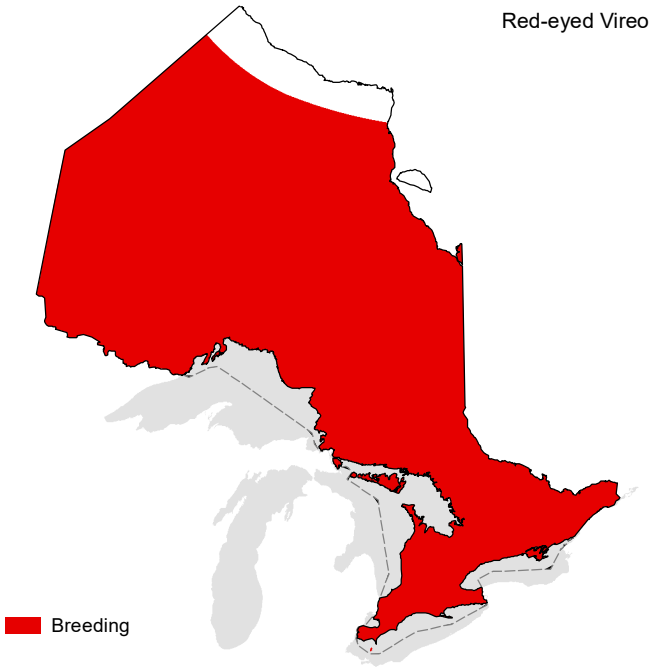


BREEDING SEASON

Habitat Requirements

In Ontario, the Red-eyed Vireo nests mostly in deciduous (38.7% of nests) and mixed woods (38.4%). It also nests in coniferous woods (1.5%); in gardens, cottage areas, campgrounds, and parks (11.9%); in overgrown fields and thickets (3.6%); in overgrown rocky outcroppings (3.3%); on road rights-of-way (0.9%); in mine clearings (0.3%); and in treed sand dunes (0.3%). Second-growth and mature stands were used for nesting as were open and closed stands. Many nests were at edges, along shorelines, or near roads or paths (Peck and James 1987). It may occur wherever tree canopy closure is 25% or more, and even in more open areas containing mature trees, such as city parks, savannahs, and rural gardens (James in Cadman et al. 2007).

In the Boreal Forest Region near Pickle Lake, the Red-eyed Vireo occurred in deciduous forests, mostly those dominated by poplar. It also occurred occasionally in coniferous forest and deciduous and mixed tall shrubs (James 1980; McLaren and McLaren 1981). In mixed-wood forests near Hearst, it occurred in upland clear-cuts 3-24 years old and in uncut stands. It was absent in most lowland coniferous stands, including uncut areas, but occurred in low density in 6- and 9-year-old lowland



clear-cuts (Welsh and Fillman 1980). In mixed jack pine forests near White River, it was significantly more abundant in 23-25-year-old stands than in younger (3-20 years) stands or mature uncut stands 40-100 years old. It was 1 of 4 significant indicator species of this forest age class and was most strongly associated with vertical structure in the 2.5-5 m stratum (Venier and Pearce 2005). It was common in the Clay Belt, where it preferred poplar woods (Smith 1957) and mid-succession forests (Welsh 1993). In the Ontario Boreal Forest Region, it occurred in immature to younger hardwoods with open conditions. It was associated with a high amount of edge, low amount and intactness of forest older than 80 years, and a high component of young hardwoods (Rempel 2007). It was associated with more disturbed, less intact, closed hardwood stands (Rempel et al. 2007).

Near Engelhart in the Great Lakes–St. Lawrence Forest Region in the Canadian Shield, the Red-eyed Vireo was present in deciduous and mixed forests and alder thickets, as well as in open stands with considerable regeneration and ash-elm riparian forest (Barlow and Power 1970; Barlow and Rice 1977; Rice 1978c). In Quetico Park, it was almost ubiquitous in forests. It was most dominant in stands to age approximately 75 years, but was also common in mature stands and present in old-growth forest (Apfelbaum and Haney 1985). In jack pine stands near Gogama and Parry Sound, it was absent as a breeder in pure pine forests, but occasionally wandered into them from adjacent deciduous areas. It always required some deciduous trees and was common in pure deciduous groves and in open, mixed stands. It first appeared once trees became 3-4 m tall, but preferred older forests (James 1979a; James and Peck 1995a). In the southern Boreal Forest Region and Great Lakes–St. Lawrence Forest Region in the Canadian Shield, the Red-eyed Vireo commonly nests in mature and old-growth white pine stands, where it is second in abundance to the Ovenbird (Kirk et al. 2012). Near Rutherglen, it occurred in extensive forest as well as woodlots in more open landscapes, and was also present in shade trees in North Bay. In forests, it preferred south and east slopes, and areas where water, rock outcrops, fires, or forestry had created openings. It was absent where undergrowth was totally lacking and where there was an absence or scarcity of deciduous trees in the overstorey (Lawrence 1953a). In Algonquin Park, it occurred in all treed habitats except bogs and pure stands of balsam fir and spruce; it was the most widely distributed bird species. It was the most abundant species in sugar maple–yellow birch stands, second in abundance in birch-poplar stands, and third in abundance in pure hemlock stands. Although density was lower in mixed birch-poplar-fir-spruce stands, it was still one of the more common species (MacLulich 1938; Martin 1960).

In Durham Region in the Great Lakes–St. Lawrence Forest Region south of the Shield, the Red-eyed Vireo occurred in all forest types and was the most abundant species in mature sugar maple–oak. Speirs and Orenstein (1975) considered it a late-succession, full canopy species, but other Ontario studies demonstrated that it uses all stages of succession and canopy closure. Near Ottawa, parameters that were of high importance to it were canopy cover, tree height, and percent deciduous species. Parameters of moderate importance were tree diameter at breast height (DBH), shrub height, tree density, and tree species richness. Percent living ground cover, leaf litter depth, and herb height were of low importance. Forest patch size was a significant predictor of abundance but the amount of surrounding forest was not (Lee et al. 2002).

In the Carolinian Forest Region in Halton Region, 9 of 10 nests were in forests with abundant understorey and the other was in a shrub near a grove of trees. Canopy closure at nest sites ranged from 50% to more than 90% and averaged 78%. Habitat appeared to be selected for its structure rather than tree species composition (James 1976). In the Walsingham Forest in Norfolk County, nests were associated with shrubs 0.3-1.0 m tall and increasing basal area of trees larger than 38 cm DBH (McCracken et al. 1998).

Habitat preferences reported elsewhere are very similar to those in Ontario. The Red-eyed Vireo occurs in virtually all types of deciduous and mixed forests and all age classes, but requires a moderate amount of shrubs and saplings in the subcanopy layer. Rarely, it breeds in coniferous plantations, tamarack bog forests, pine-hemlock stands, balsam fir–white cedar stands, and fir-pine stands. It tends to be absent in pure spruce or pine stands. In Georgia, it is one of the dominant species in climax pine stands, but these forests typically have an understorey of deciduous trees. Other than the requirement for shrubs, it is a habitat generalist, usually occupying the entirety of a woodlot with no other major habitat preferences. In New Hampshire and Maine, it occurred in all forest types but was most abundant in those dominated by white birch, northern hardwoods, swamp hardwoods, aspen, and hemlock. It was less common in white pine, spruce-fir, and balsam fir stands. It demonstrates increased abundance with age of stand and mesic soils. In eastern Quebec balsam fir–white cedar forests, it was significantly more abundant in nonriparian than riparian stands (LaRue et al. 1995). In Alberta aspen stands, it occurred in all age classes and was associated with the lower strata of the forest. In Missouri, the Red-eyed Vireo was most abundant in mature forests, followed by riparian forests and 9-year-old clear-cuts. It was absent in 3-year-old clear-cuts. In New York clear-cuts, its density was significantly correlated with the development of a deciduous canopy taller than 7 m. It was the dominant species in all stands 55-120 years old, with peak densities occurring in stands 75 and 100 years old. It is not typically an old-growth species. In Pennsylvania, it occurred in 100% of old-growth forests, but in 95.9% of forests in the Appalachians, and in 93.1% of forests in the state. In maple, birch, and aspen forests, it may be the dominant species, or be codominant with the Ovenbird. Although the Red-eyed Vireo occasionally occurs in suburban and urban areas, including parks and cemeteries, numbers in these habitats are usually quite low. In Illinois, it was most abundant in upland forests followed by floodplain forests and savannahs; it was not observed in urban habitats. In Indiana, most nested in deciduous forests but some nests were in grassy fields with thickets of blackberries that also contained dense stands of trees 1-7 m tall, and in shrubby fields where about half the ground was shaded part of the day either by saplings about

7 m tall or by dense hawthorns (Anderson and Shugart 1974; Back 1979; Beals 1960; Bielefeldt and Rosenfield 1994; Blake and Karr 1987; Bond 1957; Bushman and Therres 1988; Campbell et al. 1997; Crawford and Titterington 1979; Darveau in Gauthier and Aubry 1996; Darveau et al. 1992; DeGraaf et al. 1998; Erskine 1977; Faanes and Andrew 1983; Flack 1976; Graber et al. 1985; Haney 1999; Hoffman 1989a; Johnston and Odum 1956; Keller et al. 2003; Kirk et al. 1996; LaRue et al. 1995; Lent and Capen 1995; Mossman 1988; Mossman and Hoffman 1989; Mossman et al. 1991; Niemi and Pfannmuller 1979; Nolan 1963; Noon et al. 1979; Pagen et al. 2000; Schieck et al. 1995; Stauffer and Best 1980; Sutton 1949; Temple et al. 1979; Thompson and Capen 1988; Tyler in Bent 1950; Walk et al. 2011).

The Red-eyed Vireo preferred landscapes that were 59-75% forested in North Dakota; no areas were more than 75% forested. In New York, it preferred landscapes that were 82-100% forested (Cunningham and Johnson 2019). In North Dakota 400-m landscapes, it increased with increasing tree cover within 100 m but its probability of occurrence attained 50% in landscapes with more than 30% tree cover compared with 25% in landscapes with less than 30% tree cover (Cunningham and Johnson 2016).

In Pennsylvania, vegetation structure differed significantly between used and unused sites. Nests were closer to adjacent trees (4.99 m compared with 6.99 m), had greater canopy coverage (71.25% compared with 55.6%), less ground cover (31.94% compared with 46.25%), and fewer stems 0.5-1.0 m tall (2.03 compared with 3.40) than random sites. Coverage by ground vegetation was significantly lower at successful than unsuccessful nests (Siepielski et al. 2001). In Indiana, the Red-eyed Vireo was most abundant in forests with more than 90% canopy closure and in shrubby areas densely regenerating with oak saplings. It was next in abundance in savannahs and woodlands with 50-90% canopy closure and least abundant where there was less than 20% canopy closure (Grundel and Pavlovic 2007a). In the same state, it was common in 2-9-year-old regenerating clear-cuts. Its abundance was positively correlated with leaf litter depth (Ruhl et al. 2020). In New Hampshire and Maine, it was positively correlated with the total foliage volume of both deciduous and coniferous trees larger than 10 cm DBH and the total foliage volume of deciduous trees smaller than 2 cm and 2-10 cm DBH. It was negatively correlated with the number of coniferous trees larger than 10 cm DBH and the total foliage volume of coniferous trees smaller than 2 cm DBH (DeGraaf et al. 1998). In southern New Jersey, the Red-eyed Vireo was significantly more abundant in hardwood swamp than in oak-pine forest (Rich et al. 1994). In Texas, its abundance was positively correlated with vegetation height, number of tree and shrub species, canopy closure, foliage density at 7 m to greater than 20 m, percent coverage by hardwoods 5 cm to more than 32 cm DBH, and number of tree stems larger than 32 cm DBH. It was negatively correlated with percent coverage by pines 5-16 cm DBH. It used fairly mature pine-hardwood forests (Conner et al. 1983). In a Connecticut woodlot over 59 years, there was a progressive shift to larger trees, a sparser shrub layer, and a less diverse tree canopy dominated more by oaks and maples as a result of a severe decline in hemlock. There were no significant changes in the abundance of the Red-eyed Vireo (Buchanan et al. 2016).

The Red-eyed Vireo is not particularly area sensitive in Ontario. Near Peterborough, territories and nests were no further from edge than random, and nest success and parasitism and predation rates were unaffected by distance to edge, forest size, or amount of forest within 2- and 10-km radii.

Breeding density increased with the amount of forest cover within 2 km, but did not vary with forest size or amount of forest within 10 km (Dunford et al. 2002). Near Ottawa, its abundance was associated with forest size but not with the amount of forest cover (Lee et al. 2002). In southern Ontario, its probability of detection was positively correlated with the amount of forest 100 m or more from edge, the amount of forest within 2 km, and regional forest cover, but negatively correlated with forest size. The only significant associations were those with amount of local and regional forest cover, which were significant at the 0.10 level (Austen et al. 2001). Nol et al. (2005) studied the distribution of the Red-eyed Vireo in southern Ontario and found that occupancy of small woodlots by this species was not influenced by distance to the nearest large forest. Near Lake Simcoe, Red-eyed Vireos nested on 3 occasions in a sugar maple that had open habitat on 3 sides of it and 1 nested in an isolated white birch about 5 m from a house (Ross James, personal communication). These observations indicate that the Red-eyed Vireo is not an obligate area-sensitive or forest-interior species in Ontario.

It appears as though northern populations are not area sensitive, but area sensitivity increases southward. In western boreal Canada, distribution of the Red-eyed Vireo was influenced only by forest type, and not by forest size or the amount of forest within 5 km (Hobson and Bayne 2000). In Wisconsin, there was little evidence of it being affected by forest size, although when it occurred in more pioneer stands, it tended to be more abundant in larger woods (Bond 1957). Howe (1979) confirmed it breeding on islands as small as 0.4-1.1 ha in Wisconsin. Donovan et al. (1995) studied the Red-eyed Vireo in contiguous forests and fragmented woodlots in Wisconsin, Michigan, and Missouri. In the northern states, there was no difference in its abundance in contiguous and fragmented forests, but it was significantly more abundant in contiguous than fragmented forests in Missouri. In all 3 states, nest survival rates were greater in contiguous forests, which acted as sources; forest fragments were sinks. In Rhode Island, its distribution was unaffected by forest size, where Golet et al. (2001) concluded that the amount of forest in a landscape may be more important than forest size. A 2-year Illinois study found that its distribution was significantly correlated with forest size 1 year, but not the other (Blake and Karr 1987). In North Dakota, its probability of occurrence was positively correlated with forest size. Grant and Berkey (1999) considered it an area-sensitive species, despite the fact that its probability of occurrence was 100% in woodlots as small as 3 ha. Its probability of occurrence in 1-ha woodlots was 11%. In Maryland and the mid-Atlantic states, the Red-eyed Vireo was considered area sensitive. Its distribution was significantly correlated with forest size, and a sharp decline occurred in woodlands smaller than 4 ha. Although it occurred in most forests larger than 20 ha, it was predicted that 100 ha of forest were required to support a viable population. Despite these predictions, it occurred in woodlots as small as 0.1 ha, and was unaffected by forest size in Maine. In Pennsylvania, it was associated with unfragmented landscapes and larger woodlands (Bushman and Therres 1988; Keller and Yahner 2007; Lynch 1987; Robbins 1979; Robbins et al. 1989). Kilgo et al. (1997) considered the Red-eyed Vireo area sensitive in South Carolina. In Missouri, the smallest woodlot it was observed in was 4.6 ha, and it did not reach 100% occurrence until woodlands were larger than 340 ha (Hayden et al. 1985). There are some estimates of minimum widths of riparian forests to support Red-eyed Vireos. These are from more southern locations and are not directly relevant to Ontario where forest width may not be important. In Iowa, the minimum corridor width it was found in was 40 m (Stauffer and Best 1980). In Maryland and

Delaware, its probability of occurrence increased significantly with corridor width, from about 60% at 50 m to almost 100% at 300 m (Keller et al. 1993). In Georgia, it was more abundant in medium-sized than narrow or wide riparian forests, but the differences were not significant. Its abundance was positively correlated with basal area and canopy cover and negatively correlated with shrub cover (Hodges and Krementz 1996).

Villard et al. (2007) reclassified the Red-eyed Vireo as a forest-interior specialist because it consistently avoided edges in other studies reviewed by Villard (1998). In Saskatchewan, Villard et al. (2007) mapped Red-eyed Vireo territories before and after creating edge through clear-cutting. Significant edge avoidance by the Red-eyed Vireo was observed in 2 cases. They concluded that its response to edge will vary both with landscape context and time since edge creation. In Minnesota, it demonstrated no edge effect, with nest success unrelated to distance from edge (Hanski et al. 1996). In New Hampshire, it was significantly more abundant in forest interior than near clear-cut edges but its distribution did not differ from that of randomly placed simulated territories. The lower abundance in edge areas was not necessarily evidence of edge avoidance but may be due to the absence of suitable habitat beyond clear-cut borders (King et al. 1997). Lindell et al. (2007) completed a review of other studies and determined that some studies found that the Red-eyed Vireo avoided edges whereas others found that it exploited edges. In New Jersey, Rich et al. (1994) found no difference in its abundance in forest interior and along 3 types of open corridors with average widths of 8.3 m, 16.3 m, and 22.5 m, with an overall range of 6.2-41.0 m. In Tennessee, its breeding density increased with increasing distance from edge. Results were not significant and Kroodsma (1984) concluded that it did not demonstrate an edge effect.

Ontario nests were in live trees and shrubs, mostly in deciduous species (89.7%). Trees most commonly used were maples, less frequently birches, poplars, oaks, alder, and white cedar. Saplings and shrubs were used for nesting more than larger trees. Nests were pensile and suspended in horizontal forks, usually away from the trunk and often at the end of a limb. Distances of nests from trunks ranged from 0.3-6 m, mostly 1.1-2.4 m. Nests were 0.5-21 m from the ground, but mostly 1.8-3.7 m up (Peck and James 1987). Near Rutherglen, 77% of nests were in deciduous species and the remainder were in conifers. In order of frequency, nests were in white birch, beaked hazel, red maple, trembling aspen, white cedar, balsam fir, mountain maple, large-toothed aspen, juneberry, willow, and red pine. Nests were 0.9-16.8 m from the ground; 73% were lower than 4.6 m. Second and third nests tended to be higher than first nests. One pair nested at 2.4 m, 6.1 m, and 15.2 m; one at 1.5 m and 9.1 m; one at 2.4 m and 4.6 m; one at 5.5 m and 3.0 m; and one at 1.1 m and 1.1 m. Nests were at edges of clearings, along a lakeshore, or over water, but all had dense foliage beside or above the nest where birds could approach inconspicuously. Nests were often built close to the previous year's nest; old nests were not reused (Lawrence 1953a). A nest near Lake Nipigon was 9.8 m from the ground in a balsam fir (Kendeigh 1947). Of 10 southern Ontario nests, 3 were in the upper periphery of a tree, 4 in the middle periphery, 2 in the lower periphery, and 1 in the upper central. Nest trees included sugar maple, white elm, balsam poplar, beech, hickory, and hawthorn (James 1976). One Ontario nest was in a mountain-ash (MacLulich 1938).

In addition to species reported in Ontario, the Red-eyed Vireo has nested in hackberry, white ash, basswood, sassafras, black locust, sycamore, grape, honeysuckle, witch-hazel, chokecherry,

blackberry, bur oak, American chestnut, and hemlock. Nests are typically where they are completely shaded all day, but with an unobstructed view. Nests have been found 0.4-21.3 m from the ground, with average height ranging from 2.5 to 4.3 m, but averaging 10.7 m and 11.1 m in New Hampshire (Campbell et al. 1997; Cimprich et al. 2020; Darveau in Gauthier and Aubry 1996; Graber et al. 1985; Holmes et al. 1979; Robinson 1981; Sutton 1949; Tyler in Bent 1950; Williams 1946; Williamson 1971).

Near Englehart, males initially patrolled an area of about 2 ha, but the defended area declined to about 0.7 ha as more males arrived, with territory size varying with habitat. Mean size of more than 70 territories near Englehart and North Bay was 0.37 ha. In Algonquin Park, 139 territories averaged 0.19 ha (range 0.02-0.62 ha). Near Rutherglen, 5 territories averaged 0.57 ha 1 year; the next year 4 territories averaged 0.85 ha. There were 2 distinct portions to territories: the song area where the male spent most of his time, and the nest area. Near Lake Nipigon, 6 territories averaged 0.77 ha (range 0.61-0.85 ha). Nests may be near the edge of territories; active Ontario nests have been found as close together as 15 m, 18 m, and 30 m (Barlow and Rice 1977; Kendeigh 1947; Lawrence 1953a; Martin 1960; Peck and James 1987; Rice 1978b, 1979c). Illinois territory sizes averaged 1.2 ha in virgin floodplain forest, 0.7 ha in upland forest (range 0.3-1.0 ha), 0.6 ha in mature bottomland forest 1 year (range 0.2-1.0 ha), 0.8 ha the following year (range 0.8-1.0 ha), and 0.7 ha in an urban park. Territory size was inversely proportional to population size (Graber et al. 1985). Territories averaged 0.53 ha in Maryland and Florida (Williamson 1971) and ranged from 0.3-0.8 ha in Quebec (Darveau in Gauthier and Aubry 1996; DesGranges et al. 1987). One Kansas territory was 1.0 ha and adjoining territories averaged 0.58 ha (Fitch 1958). Mean territory size in Michigan aspen forests was 0.69 ha. In 1 Illinois study, territories were 3.0 ha in elm-maple forest 1 year but half this size when the number of territorial males doubled. Females range beyond the territory boundaries and have a larger home range (Cimprich et al. 2020). Near Quebec City, territories were aggregated together rather than spread uniformly through forested habitat. Forests may have to be larger than 1 territory size to support it (Bourque and Desrochers 2006).

Near Englehart, Red-eyed and Philadelphia vireos defended mutually exclusive territories. Red-eyed Vireos could not distinguish the songs of the 2 species, but Philadelphia Vireos could (Rice 1978b, 1978c). Near Gogama, territories of the 2 species overlapped although they may have been separated vertically with Philadelphia Vireos occupying space above Red-eyed Vireos (James and Peck 1986). In New Hampshire, territories of Red-eyed and Philadelphia vireos overlapped significantly. Overlap was 100% 1 year when Red-eyed Vireos occupied the entire study area; overlap other years was 40%, 50%, and 75%. Aggressive encounters occurred between the 2 species, most frequently during territory establishment and the late nestling and early fledgling stages. Aggression seldom occurred during incubation and the early nestling and late fledgling stages (Robinson 1981).

Little information is available on natal site fidelity. In 4,600 ha of the Ganaraska Forest in southeastern Ontario, 3 of 25 nestlings (12%) returned to breed. Of these, 1 male was found on territory 9,870 m from its natal nest, but no nest of this bird was found. One yearling male nested 70 m from its natal nest and a female nested 4,090 m from its natal nest (Walters and Nol 2011a). The return rate of 12% is high compared with the average of other studies (3.7%), but this may be due to the much larger than normal study area. None of 17 nestlings returned near Rutherglen (Lawrence 1953a).

In the Ganaraska Forest, 4 of 27 yearling birds (15%) and 5 of 56 older birds (9.0%) returned. Mean dispersal distances from the previous nest were 275 m for 2 second-year males (200 and 350 m), 210 m for 2 second-year females (170 and 250 m), and 540 m for 5 after-second-year males (range 40-2,040 m). In West Virginia, 49% of 96 males and 1 of 2 females returned; in Ontario, a single banded male returned the following year; in Illinois, 0 of 2 adults returned (Cimprich et al. 2020; Lawrence 1953a; Robinson 1992; Walters and Nol 2011a). Canadian banding records indicate high breeding season fidelity; 73% of encounters represent birds returning to the same breeding site in subsequent years (Brewer et al. 2018).

Limiting Factors

Eggs have been found in Ontario nests from late May until mid-August, with most present from mid-June through the first week of July (Peck and James 1987). In Algonquin Park, nests are under construction from late May to early July, eggs are present from late May to late July, nestlings are present from mid-June to early August, and dependent fledglings are present from late June to late September (Tozer 2012).

Females begin prospecting for a nest site shortly after arrival, but take 5 or 6 days to select one. For second nests, 3 or 4 days are spent selecting a site; third nests are typically well under construction a day after the second nest is abandoned. The female builds the nest within 4 or 5 days. Two to 4 days elapse between nest completion and laying of the first egg, and 1 egg is laid per day. Incubation begins with the laying of the third egg, even if there are 4 eggs in the clutch. The incubation period of Ontario nests was 11-15 days, mostly 12 or 13 days, typical of throughout its range. Most young left Ontario nests when they were 10 days old, but some remained another day. Elsewhere, some young remained in the nest 12 days (Barlow and Rice 1977; Campbell et al. 1997; Cimprich et al. 2020; Lawrence 1953a; Peck and James 1987; Tyler in Bent 1950).

Cimprich et al. (2020) concluded that 1 brood is raised per year south to Virginia, but 2 broods are raised in Louisiana. Near Rutherglen, Lawrence (1953a) observed 1 case of possible double brooding and Peck and James (1987) concluded that double broods might occur in Ontario. Graber et al. (1985) stated that the long laying period in Illinois suggested second broods, but this was not verified. Renesting occurs 4-9 days after a clutch is lost, and as many as 3 nesting attempts may be made. Clutches of 2-5 eggs have been reported in Ontario, mostly 3 or 4 eggs; 5-egg clutches were rare (1.2% of clutches). Clutches of 1-5 eggs have been documented elsewhere. The most frequent clutch size is 4 eggs, 3-egg clutches are common, and 5-egg clutches are rare. Second or third nesting attempts typically have a maximum of 3 eggs (Campbell et al. 1997; Cimprich et al. 2020; Graber et al. 1985; Lawrence 1953a; Tyler in Bent 1950; Williamson 1971).

The age at first breeding is 1 year and the mating system is typically monogamous (Cimprich et al. 2020). Mountjoy (1997) reported a possible case of polygyny in Nebraska. One male defended 2 distinct territories separated by the territory of another bird and unsuitable habitat. It participated in a nesting attempt on 1 territory and was associated with a female that may have had a nest in the other territory.

James (1976) studied the Red-eyed Vireo's foraging techniques in southern Ontario. It took 99% of food items from leaves and 1% from branches; 61% by hovering, 28% by stalking, and 11.5% by

hawking. Perches used for foraging were 65% unfoliated, 22% foliated, and 14% dead. Foraging occurred from the canopy to the ground, although it seldom occurred on the ground. Most (93.5%) foraging was in the periphery of trees (38.5% in the upper portion, 42% in the middle, and 13% in the lower portion), and 6.5% centrally (1.5% in the upper portion, 5.0 in the middle). Mean foraging height was 7.8 m in trees averaging 15.1 m tall. Significant and repeated use was made of the understorey for foraging. It foraged on most tree species within the territory except spruce, white pine, white cedar, and black walnut. No differences were noted in foraging heights of the sexes. Near Englehart, males foraged higher than females, but not significantly (Rice 1978c). Near Rutherglen, males foraged in the crowns of trees down to the middle branches and occasionally in the shrubbery when they accompanied females. Females foraged near or even on the ground (Lawrence 1953a). Mills (2007) studied the foraging strategies of the Red-eyed Vireo in central Ontario during the breeding season, in midsummer, and in autumn. During the breeding season, it was associated with early successional hardwoods. In midsummer, it was associated with hardwood forests and was highly associated with white birch in autumn. Foraging heights were similar during the breeding season and autumn and ranged from 4 to 14 m. It foraged predominantly by gleaning, with less frequent hovering and flycatching. In the Clay Belt of Ontario and near White River and Marathon, 91% of foraging occurred in deciduous species and 9% occurred in conifers. Foraging techniques included 70.7% aerial attacks, 14.0% hanging, and 14.1% hovering (Greenberg et al. 1999). In New Hampshire, females foraged significantly higher (12.5 m) than males (11.8 m). On leaves, males hovered more and gleaned less than females, and males foraged more on sugar maple and less on yellow birch and white ash than females (Holmes 1986). In New Hampshire, where it was sympatric with the Philadelphia Vireo, the Red-eyed Vireo was a bird of the middle and lower canopy, with the Philadelphia Vireo foraging in the upper canopy. The Red-eyed Vireo foraged in all tree species within its territory but the Philadelphia Vireo was more selective. During the late nestling and early fledgling stages, the Philadelphia Vireo foraged in the understorey and the 2 species appeared to be in direct competition. As in Ontario, the Red-eyed Vireo captured most prey from leaves in the outer periphery of the tree by hovering; 83.4% of attacks on prey were on leaves, 9.5% on bark (Robinson 1981; Robinson and Holmes 1982). Another New Hampshire study found that most prey was taken from the underside of leaves. Prey attacks in yellow birch were in proportion to caterpillar abundance, but greater than expected in beech and sugar maple (Holmes and Schultz 1988). Foraging techniques documented in Maryland, Florida, Louisiana, and Vermont were similar to those in Ontario. In Vermont, 30% of foraging was by hanging upside down to glean insects from leaves, and in Maryland and Florida a higher percentage (31%) of foraging occurred centrally near the trunk of the tree. There were significant differences in foraging heights of the sexes: mean 6-7 m for males compared with 3.7 m for females (Cimprich et al. 2020; Lent and Capen 1995; Williamson 1971). Hartung and Brawn (2005) studied Red-eyed Vireo foraging techniques in Illinois savannahs. Eighty-five percent of foraging was in oaks, 9% in hickory, 3% in black cherry, and 3% in other species, approximately in relation to tree availability. In closed-canopy forest, it exhibited strong preferences for tree species, using oak and hickory more than their availability and sugar maple, red elm, and black cherry less than their availability. Percent use of different foliage layers was 3% for 0-5 m, 20% for 6-10 m, 17% for 11-15 m, and 60% above 16 m in open-canopy forest. Percentages in closed-canopy forest were similar except that the 0-5 m layer was not used. More than 75% of foraging was

by gleaning, hovering, and hanging. Gabbe et al. (2002) examined tree-species preferences of foraging Red-eyed Vireos in Illinois floodplain forests. In order of preference, pin oak, Manitoba maple, black gum, shellbark hickory, silver maple, sycamore, green ash, and Shumard oak were used more than their availability. Species used less than their abundance, in declining order of avoidance, were pumpkin ash, blue beech, red maple, and bitternut hickory. Silver maple was one of the preferred trees, but was 18th in abundance. Pumpkin ash was strongly avoided but was the second-most abundant tree. Although it showed preferences for tree species, it was among the least selective of the bird species studied. There is 1 observation of a bird capturing prey by repeatedly diving into a shallow woodland pool from a branch 20 cm above the water (Tyler in Bent 1950).

Food delivered to nestlings at Rutherglen consisted of 65% caterpillars, 13% spiders, 16% dragonflies, 3% mayflies, and 3% flies. Similar food was presented to nestlings at Lake Opinicon, plus moths (Keast 1990; Lawrence 1953a). Chapin (1925) analyzed 569 stomachs of adults. The diet consisted of 85.28% animals and 14.72% vegetable matter. Lepidopterans constituted 32.4% of the diet; only 2.8% of these were adults. Caterpillars consumed frequently included those of sphinx moths, swallowtail butterflies, tent caterpillars, and codling moths. Other insects in the diet included 10.29% beetles (weevils and lady, leaf, scarab, click, ground, rove, metallic wood-boring, and long-horned beetles), 15.4% bugs (cicadas, scale insects, leafhoppers, and stink, squash, and assassin bugs), 10.7% hymenopterans (ants and ichneumonid wasps), 4.5% flies (crane flies and midges), and 4.6% other insects (katydids, stoneflies, and tree crickets). Other invertebrates eaten included a few small snails and 4.1% spiders. It eats fruit mostly from August on, including mulberries, barberries, currants, blackberries, elderberries, blueberries, spicebush, and Virginia creeper, plus some grass seeds and flower and leaf buds. Other studies noted its dependence on insects, particularly caterpillars, beetles, bugs, and flies early in the season, with increasing dependence on fruit as the summer passes. Other invertebrates its eats include walkingsticks, spittle bugs, treehoppers, sawflies, carpenter ants, and tussock moth egg masses. In declining sugar maple forests in Quebec, 44% of the diet was comprised of beetles (28% brown leaf weevils) and 29% was caterpillars. Near Rutherglen, nesting females fed mostly on small snails and ants. Other fruits reported in the diet include those of rough-leaved dogwood, prickly ash, black cherry, wild grape, pokeweed, multiflora rose, poison ivy, and northern arrowwood. It also consumes mountain-ash berries (personal observation). In New Hampshire and Maine and at Manitouwadge, the Red-eyed Vireo ate budworms but its abundance was not correlated with budworm abundance. It does not normally feed on low-density spruce budworm larval or pupal populations. In Maine over 2 years, spruce budworm larvae and pupae constituted 11.6% and 48% of the invertebrates it consumed (Cimprich et al. 2020; Crawford and Jennings 1989; DesGranges et al. 1987; Holt 1918; Lawrence 1953a; McIlwraith 1894; Mitchell 1952; Remsen et al. 1998; Tyler in Bent 1950; Venier et al. 2009; Williamson 1971).

The Red-eyed Vireo is one of the species most frequently parasitized by the Brown-headed Cowbird in North America. Parasitism rates vary considerably depending on the character of the landscape and relative abundance of cowbirds. In Indiana, the parasitism rate was 22% in forested landscapes and 80% in agricultural landscapes with twice as many young produced in forested areas. This appears to be true in Ontario, with higher parasitism rates in the agricultural south than

in the Canadian Shield. Of 387 Ontario nests, 154 (39.8%) were parasitized. In Waterloo Region, 10 of 13 nests (76.9%) were parasitized. Near Peterborough, 25.5% of nests were parasitized and 6% fledged only cowbirds; 23.9% were parasitized in south-central Ontario, including sites in and off the Shield. Parasitism resulted in a significant reduction in the number of vireo fledglings produced. Parasitism rates were significantly higher within 100 m of edge. Near Rutherglen, no nests were parasitized, although cowbirds were present and parasitized other species. Parasitism rates reported elsewhere are: British Columbia, 27%; Quebec, 42.7%; Michigan, 72%; Illinois, 83.3-100%; Minnesota, 13.6%; and Ohio, 42%. The Red-eyed Vireo is generally an acceptor of cowbird eggs and may continue incubation even if no vireo eggs are present. Parasitized nests may be abandoned early in the nesting cycle or if more than 1 cowbird egg is laid; it rarely buries cowbird eggs in the nest. Cowbirds may eject vireo eggs, thereby reducing vireo clutch size. Mean clutch size for unparasitized nests was 4.0 in Illinois compared with 2.5 for parasitized nests. Both vireos and cowbirds may fledge from parasitized nests, but vireo nest success in parasitized nests is less than half that of unparasitized nests. In Michigan 38-48% of parasitized nests fledged vireos, but usually only one fledged (Burke and Nol 2000; Campbell et al. 1997; Cimprich et al. 2020; Dunford et al. 2002; Ford et al. 2001; Graber et al. 1985; Hahn and Hatfield 1995; Hanski et al. 1996; Lawrence 1953a; Lowther 1985, 1997; Peck and James 1987, 1997; Rothstein 1975; Sutton 1949; Tyler in Bent 1950).

Habitat loss and degradation do not currently appear to be significant for the Red-eyed Vireo, although considerably more habitat was available prior to European settlement. Densities occasionally decline with maturation of forest as prolonged, complete canopy closure eventually eliminates the essential shrub and sapling layers. Rempel et al. (2007) modelled the potential impacts of forest management in the Ontario Boreal Forest Region when forest management guidelines for target species were applied. They predicted an increase in the Red-eyed Vireo relative to simulated natural variation in the forest. Vanderwel et al. (2007) summarized the effects of partial tree harvesting on the Red-eyed Vireo with particular reference to the Ontario portion of the Boreal Forest Region. Tree removal from forests had a negative impact on it. It experienced a 25% decrease in population when 40% of trees were removed and a 50% decrease when 67% of trees were removed. In the Canadian Shield of Ontario, there were no differences in its abundance in early successional and mid-successional clear-cuts and in similarly aged stands created by fire. There was no difference in its abundance in early successional, mid-successional, and mature stands (Zimmerling et al. 2017). In Algonquin Park, typical and intense group-selection timber harvesting had no effects on abundance of the Red-eyed Vireo, nor did single-tree selection (Jobes et al. 2004; Tozer et al. 2010). In the Carolinian Forest Region of Ontario, it was equally abundant in uncut forests, in those where selection cutting had occurred, and in woodlots that had been heavily harvested by diameter-limit cuts (Holmes et al. 2004). In Alberta, it declined significantly when 80-100% of trees in deciduous forests were removed. In Minnesota, partially harvested riparian buffers supported significantly more Red-eyed Vireos than unharvested riparian strips. A Pennsylvania study concluded that thinning of overstorey trees was deleterious because it selected areas where overstorey trees were close together and canopy closure was high. Another Pennsylvania study found that the Red-eyed Vireo declined by 72% in a forest where the density of tall shrubs increased but density of overstorey and subcanopy trees and short shrubs declined. It is tolerant of small canopy openings created by forest thinning, and usually recolonizes clear-cuts in less than 10 years. In Quebec,

densities were 30% lower in maple stands affected by die-back than in healthy stands (Bushman and Therres 1988; Cimprich et al. 2020; Darveau in Gauthier and Aubry 1996; DesGranges et al. 1987; Graber et al. 1985; Hanowski et al. 2002, 2005; Harrison et al. 2005; Litwin and Smith 1992; Morgan and Freedman 1986; Rohnke and Yahner 2008; Siepielski et al. 2001; Webb et al. 1977). In Illinois, Robinson and Robinson (1999) cut 0.02-0.4-ha openings within a 2,000-ha forest. The Red-eyed Vireo was significantly more abundant on uncut than cut ridges, but there was no significant difference in its abundance in cut and uncut areas in ravines. It was only 1 of 2 forest species that experienced a significant decline as a result of cutting. In Nova Scotia, it disappeared from forests that were clear-cut, but continued to be one of the dominant species in forests where strip-cutting occurred (Freedman et al. 1981). In Maine, it occurred in all seral stages from 2-year-old clear-cuts to dense overstoreys of conifers with an open forest floor. It was most characteristic of hardwood regeneration taller than 2 m with a well-developed but slower growing coniferous regeneration layer. These stands were 7-12 years post clear-cutting (Titterington et al. 1979). In Vermont, territories occurred in both undisturbed forest and in clear-cuts. It was the most abundant breeding bird and was associated with high abundance of sugar maple, moderate abundance of red maple, and low abundance of poplar and white pine (Lent and Capen 1995).

Forest size had a significant effect on the reproductive success of the Red-eyed Vireo in south-central Ontario. Burke and Nol (2000) examined forests ranging in size from 11.8 ha to more than 10,000 ha with core areas more than 100 m from edge of 0 ha to more than 5,000 ha. Local forest cover within a 10-km radius ranged from 13.8% to more than 80%. Nest predation rates were not affected by patch size or the amount of forest in the landscape. Failure due to nest abandonment was high: 32% in forest fragments and 6% in continuous forest. Parasitism rates did not vary with forest size or the amount of local forest, but no parasitism was observed in contiguous forest. Woodland size was the most important factor affecting reproductive success; the amount of local forest cover had no significant effect. Success was significantly higher in contiguous forest than in fragments, but birds breeding in small fragments were just as successful as those breeding in large fragments. Fecundity in forest fragments was less than half that in contiguous forest. Populations in forest fragments were sinks, with females not replacing themselves; populations in contiguous forests were close to being self-sustaining. Without constant immigration from contiguous forests, populations in fragments would become locally extirpated. Populations remained relatively constant suggesting a source-sink metapopulation.

The Red-eyed Vireo may be adversely affected by invasive shrub species such as honeysuckles and common buckthorn. In urban forests in Chicago, its abundance was positively correlated with the amount of litter but was negatively correlated with coverage by honeysuckles. Areas dominated by buckthorns had very little leaf litter (Schneider and Miller 2014).

Ford and Flaspohler (2010) studied abundance of birds in a cottage development along the Lake Superior shoreline and compared results to the undeveloped forested area across the road. The Red-eyed Vireo was significantly less abundant in the cottage development. In central Ontario, it was associated with deciduous woods with some understorey for singing posts and nest sites. Removal of shrubs and saplings associated with cottage lots could reduce habitat suitability for it

(Clark et al. 1983). In North Carolina, its abundance was negatively correlated with the number of houses and other buildings within 200 m (Lumpkin and Pearson 2013).

In New Jersey and Pennsylvania over a 15-year period, hemlock declined from 56% of the total basal area to 46% due to the hemlock woolly adelgid; the amount of deciduous understorey increased. It responded positively to hemlock decline and increased in abundance (Toenies et al. 2019).

In Minnesota, blowdown of spruce-fir forest resulted in an 80% decline in canopy cover and a 100% increase in shrub cover. The Red-eyed Vireo was significantly more abundant in blowdown plots than control plots (Burris and Haney 2005).

Grundel and Pavlovic (2007b) studied the effects of habitat structure and fire on Indiana birds. Density of the Red-eyed Vireo increased as tree height increased from 8 m to 20 m and started to decline as trees continued to get taller. Density was greatest when fire frequency was 0 in 15 years and quickly declined to near 0 when there were 4 or more fires within 15 years. They concluded that it was strongly sensitive to fire frequency and that large changes in abundance could occur as a result of fire.

In Wisconsin and Michigan, the Red-eyed Vireo showed significant variation in numbers and densities over several years. Lowest populations were associated with dry periods, and it was one of the species most affected by drought (Blake et al. 1992).

In Alberta, the Red-eyed Vireo was equally abundant near noisy compressors and quiet well pads. It did not appear to be affected by chronic noise (Bayne et al. 2008).

In Alberta, the Red-eyed Vireo was more abundant in forest interior than near energy sector disturbances. It was 14-35% less abundant along seismic lines, 26-32% less abundant along pipelines, and 21-66% less abundant at well pads compared with adjacent forest interior (Bayne et al. 2016). Farwell et al. (2019) examined its response to shale gas infrastructure (well pads, access roads, and pipelines) in a contiguous forest in West Virginia. It was adversely affected and significantly more abundant with increasing distance from infrastructure.

In Delaware, there was no difference in abundance of the Red-eyed Vireo in areas supporting low, moderate, and high density of white-tailed deer (Tymkiw et al. 2013).

Status

The Red-eyed Vireo is one of the most abundant breeding birds in Ontario. McIlwraith (1894) termed it a very common summer resident. Baillie and Harrington (1937) stated that it bred throughout the province from the extreme south north to Lake of the Woods, Kapuskasing, and Lake Abitibi. North of this, it was very common along the Mattagami and Moose rivers, and they concluded that it probably bred north to southern James Bay. The first atlas demonstrated that it was abundant throughout the province, with probable or confirmed nesting as far north as Fort Albany and Big Trout Lake (James in Cadman et al. 1987). James (1991) considered it an abundant summer resident north to Big Trout Lake and Attawapiskat and probably to Fort Severn along major rivers in the west. In the Walsingham Forest in Norfolk County, it was the most abundant species, representing 14.75%

of all records. It and the Ovenbird accounted for over 75% of records, typical of this region and northeastern North America in general (McCracken et al. 1998).

The second atlas demonstrated that the range of the Red-eyed Vireo had not changed since the first atlas. Its probability of observation increased significantly province-wide and in the Canadian Shield. It was most abundant in the Shield in the Great Lakes–St. Lawrence Forest Region. There were also locally high concentrations on the Bruce Peninsula and on eastern Manitoulin Island. Numbers declined gradually northward, possibly due to greater abundance of coniferous cover, and south of the Shield due to habitat fragmentation by agriculture and urbanization (James in Cadman et al. 2007).

Long-term (1970-2021) population trends determined from the Breeding Bird Survey indicate annual increases of 1.08% in Canada and 0.85% in Ontario. The short-term (2011-21) trends were annual increases of 1.94% in Canada and 2.06% in Ontario. All results were highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Young can only fly 5-10 m when they leave the nest and it is unknown when they become proficient fliers. Young may remain with the parents 25 days after fledging; 1 family remained together until autumn migration (Barlow and Rice 1977; Cimprich et al. 2020).

In Ohio, adult and juvenile Red-eyed Vireos made extensive use of densely regenerating clear-cuts during the postbreeding period. The most important factors determining its presence in clear-cuts, in descending order of importance, were abundance of low vegetation, presence of canopy and low vegetation, and amount of canopy. Early successional habitats may be important for it after breeding because they provide dense cover and abundant food (Vitz and Rodewald 2006, 2007). McDermott and Wood (2010) examined its abundance in West Virginia clear-cuts in varying stages of succession during the postbreeding period. It was positively associated with vertical complexity of the habitat and richness of arthropod abundance, but was negatively associated with basal area and understorey stem density. In Minnesota, Streby et al. (2011b) captured only 5 Red-eyed Vireos during the breeding season in regenerating clear-cuts, but caught 378 adults and 46 fledglings during the postbreeding period. In Missouri, the number of adult and juvenile Red-eyed Vireos in 3-4- and 9-year-old clear-cuts increased during the postfledging period. They were more common in early successional habitat than in mature or riparian forest (Pagen et al. 2000). Porneluzi et al. (2014) netted birds during the postfledging period in a Missouri oak-pine-hickory forest 2-15 years after it was clear-cut. The Red-eyed Vireo was the most abundant species captured. There was no significant change in its abundance during the sampling period. In Virginia and West Virginia, it was 1 of the 6 forest-breeding species that was most frequently captured in regenerating clear-cuts during the postfledging period. Four adult males captured in the clear-cut area during the postfledging period were located in forest plots during the breeding season in subsequent years. Their territories averaged 235 m (range 101-358 m) from the mist net where they were originally captured. Two of these were originally captured with dependent young during the postfledging period. This suggests that some birds move as family groups to early successional areas after young leave the nest. In Pennsylvania during the postfledging period, Stoleson (2013) captured 46 adults

and 19 juveniles in clear-cuts compared with 0 adult and 5 juveniles in mature forest with a dense understorey.

In Missouri, Burke et al. (2017) radiotracked juvenile Red-eyed Vireos that had been captured in 3-6-year-old deciduous clear-cuts. The mean distance travelled between relocations was 434 m (range 15.5-4,032.6 m). Forested areas were selected in addition to clear-cuts. The probability of use was greater for small-tree (52%) than pole (32%) or sawtimber (16%) stands. Probability of use was greater for clear-cuts (53%) than partial cuts (30%) or unharvested stands (17%). The bird that moved the greatest distance used locations that were split equally between pole-sized partial cuts and unharvested sawtimber stands; it appeared to alternate between these habitats in subsequent moves. It disappeared for 3 days then reappeared in a partial cut more than 4 km from any previous location. This vireo appears to make use of both early successional habitats and mature forests during the postfledging period.

MIGRATION

Migration is along a broad front and occurs at night (Cimprich et al. 2020). Birds mostly arrive in the province in mid-May, rarely by late April. The Red-eyed Vireo does not become common until the last week of May, and passage continues through the first week of June (James 1991). At Rutherglen, birds remained within the territory until they flew south. Adults migrate earlier in autumn, and there is no difference in timing by the sexes. Juveniles migrate over a much longer period than adults. At Rutherglen, most left in the first week of September. Near Kingston, migration begins in early August, but the main passage is in late August and early September (Cimprich et al. 2020; Lawrence 1953a; Weir 2008). During autumn migration at Long Point and 2 other locations in eastern North America, adults migrated significantly earlier than juveniles. Median passage dates for the 2 age classes differed by 21 days at Long Point (Woodrey and Chandler 1997).

During migration, the Red-eyed Vireo uses a wider variety of habitats than during the breeding season, but it still prefers deciduous cover. In addition to deciduous and mixed woods, it may be found in city parks, suburban and rural areas, open areas with scattered trees, along forest edges, and in deciduous shrubs. In British Columbia, it prefers groves of deciduous trees and shrubs in valley bottoms and riparian habitats, and avoids areas of continuous forest cover. It appears to have slightly different habitat preferences in spring than in autumn. In Illinois, it was much more frequent in forest interior than on edges in spring, but more frequent on forest edge in autumn. Preferences for forest edge during autumn were also demonstrated in Pennsylvania, Maryland, and Florida. In Pennsylvania, it occurred during autumn migration in all habitats studied. It was most abundant in forest edge, followed by forest-agricultural edge, forest interior, suburban forest, pole-stage forest, and shrub-sapling areas. Numbers were significantly lower in the latter 2 habitats. Follow-up work by the same authors found that it was most abundant in forest-agricultural edges and significantly more abundant than in forest interior and suburban forests. Abundance in pole-stage and shrub-sapling stage forests was intermediate. Another Pennsylvania study found that mist nets in shrubby areas caught Red-eyed Vireos at a significantly higher rate than those in forest, although it was observed on transects through forest significantly more than in shrub habitat. On 2 islands in the Gulf of Maine, it was significantly more common on an island dominated by trees than one dominated by shrubs during both spring and autumn migration. In Minnesota and Wisconsin, it was

more abundant in upland than floodplain forests during spring migration, but not significantly (Campbell et al. 1997; Cimprich et al. 2020; Graber et al. 1985; Kirsch et al. 2013; Rodewald and Brittingham 2002, 2004; Smith and Hatch 2008; Suomala et al. 2010; Williamson 1971).

The Red-eyed Vireo is less specific in its foraging techniques and substrates during migration than during the breeding season. It may forage on branches as much as leaves, often hangs upside down to capture prey, and forages at all heights in the vegetation and equally on the inner, middle, and outer portions of trees. Mean foraging height is lower than in the breeding season, averaging 4.4 m in Maryland and Florida, with a range of 0.9-16.8 m (Cimprich et al. 2020; Loria and Moore 1990; Rodewald and Brittingham 2002; Tyler in Bent 1950; Williamson 1971). Keast (1980) quantified the foraging substrates of the Red-eyed Vireo during autumn migration at Prince Edward Point. Fifty-one percent of foraging occurred on outer leaves of trees, 20% on sapling foliage, 15% on outer branches, 10% on twigs and inner leaves, and 5% on tree trunks. It did not forage aerially, on inner tree branches, on sapling branches, on low shrubs, or on the ground. Birds killed by striking an adjacent hydro tower had fed on plant material, snails, and beetles 12-16 mm long.

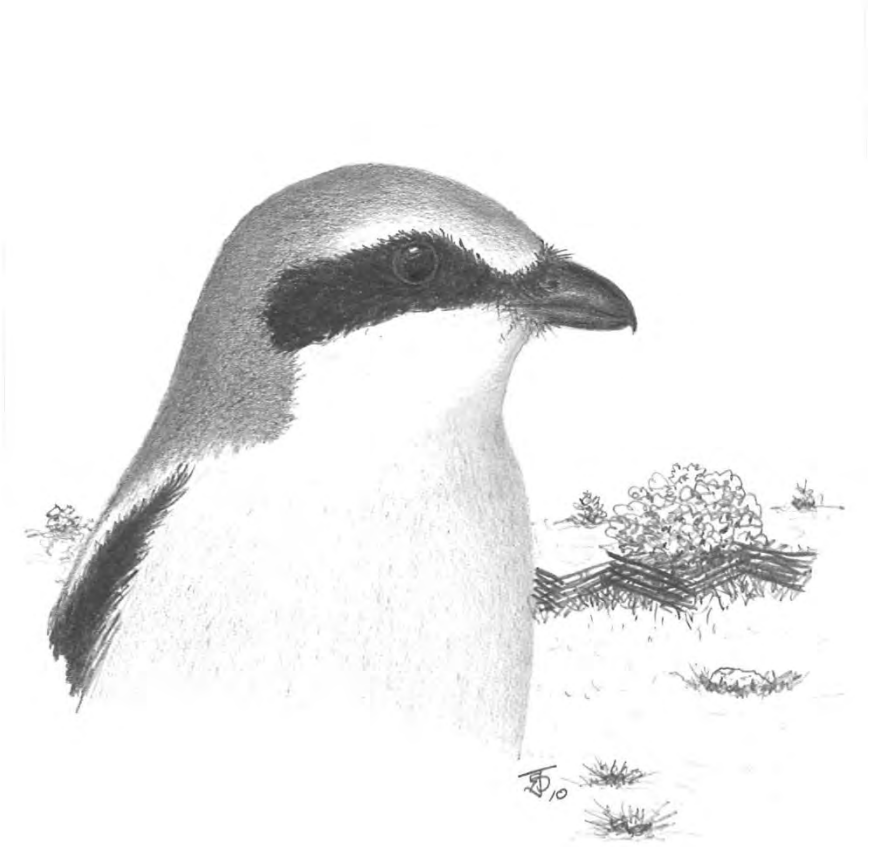
The Red-eyed Vireo is one of the most common species killed at television towers and other tall structures during migration. Between 1972 and 1982, 2,182 were killed at the Lennox chimneys near Kingston, with over 500 on 2 separate nights (Cimprich et al. 2020; Graber et al. 1985; Weir 2008).

Smith and Paton (2011) analyzed 48 years of banding data from a Rhode Island station and found that the Red-eyed Vireo migrated south significantly later in recent years. The delay in migration was attributed to climate change. In New York, Zelt et al. (2017) compared spring arrival dates, autumn departure dates, and length of the breeding season for 1888-1939 and 1967-2012. There was little climate change during the first period but significant warming in the second period. The Red-eyed Vireo arrived significantly earlier during the second period but there were no significant differences in its autumn departure dates or length of the breeding season.

The Red-eyed Vireo is a common migrant in Ontario (James 1991).

Loggerhead Shrike

Lanius ludovicianus



BREEDING SEASON

Habitat Requirements

In Ontario, the primary breeding habitat for the Loggerhead Shrike is sparsely treed alvars in Carden Township and near Napanee and Smiths Falls. Formerly, when it was more abundant, it also nested in hedgerows, along roadsides, and in fields, pastures, and old orchards. Single nests were reported in a rural schoolyard, on a golf course, and in a mixed-wood swamp near some buildings (Peck and James 1987).

Habitat in the core Ontario breeding areas is different than elsewhere in its Ontario and Quebec range, and may be superior. These are limestone plains adjacent to the Canadian Shield that are flat or gently rolling and mostly open. They occur in rural areas with very low human populations and limited cultivation. Breeding sites within the core area are extensive fields of rough pasture with sparse grass on thin soils. Occupied territories near Lindsay were characterized by grazed pasture

with at least 20 2-m-tall hawthorns per 10 ha, suitable hunting perches, and a minimum of human disturbance. Nearby sites lacking one or more of these characteristics were unoccupied, and this appears to be the case across Canada. Of 167 Ontario nests, over 87% of habitat descriptions were of roadsides, farmland, hedgerows, pastures, and hawthorn meadows. Preferred ground cover in Ontario appears to be pasture, frequently with emergent stones and stone piles. Viper's bugloss is abundant in core areas and considered a good indicator of shrike habitat. Usually herbaceous hedgerows are present as are scattered shrubs such as hawthorns near Lindsay and red cedar and hawthorn near Napanee (Cadman 1985, 1990; Norris 1992).

Chabot et al. (2001b) detailed habitat in Ontario and Quebec, although there were few Quebec records. Fifty-one nests (63.8%) were in actively grazed pastures with scattered trees and shrubs, 18 (22.5%) in idle pastures, 7 (8.8%) in hayfields, 4 (5%) in old fields, and 0 in row crops. Vegetation height at nest sites ranged from 30.3 to 36.7 cm and was not significantly different at apparently suitable unoccupied sites (24.6-34.9 cm). They examined several other habitat parameters and found no significant differences among occupied and apparently suitable unoccupied sites. This suggested random habitat selection within a core breeding site except for selection of the nest tree. Habitat parameters at nest sites were: 213-364 shrubs shorter than 1 m per ha, 197-299 shrubs taller than 1 m per ha, average of 96.0-137.8 m from a road, 245.9-344.9 m to a house, and 310.0-608.6 m to the nearest source of disturbance (railway tracks, gravel pit, quarry). Within the Ontario core areas, hedgerows are scarce, although they are preferred habitat in most areas. In Quebec, 86% of nests were in hedgerows compared with 13% in Ontario. Chabot et al. (2001a) characterized habitat at Ontario core areas as unimproved pasture on limestone plain with scattered hawthorns and red cedars. Pastures were dominated by poverty grass, Canada and Kentucky bluegrass, foxtails, timothy, and sedges. Chabot et al. (2001b) found that grazers were important in maintaining habitat, with 86% of nest sites in active and idle pastures. Grazers create a mosaic of tall and short grasses that provide diverse habitats for insects: tall grasses around droppings and short grasses in grazed areas. There was no evidence that the Loggerhead Shrike actively nested near roads as has been reported elsewhere. Habitat suitability is affected by the amount of habitat around a nest site and amount of useable habitat within a core area. In the late 19th century, it was common in southern Ontario away from the core breeding areas. Habitat included roadsides in agricultural areas, hedgerows, pastures, and railway rights-of-way (McIlwraith 1894). Prior to settlement, it was probably confined to the existing core areas and prairies and savannahs in the southwestern portion of the province with

remnants eastward to Rice Lake. Most prairie and savannah habitat has since been destroyed or reduced to remnant fragments too small to support shrikes (Austen et al. 1994).

The Ontario limestone alvars are the prime breeding habitat for the Loggerhead Shrike, supporting the largest and most consistent population. This habitat is unique to the range of the eastern population. There are numerous other descriptions of shrike breeding habitat, but these tend to be either for the western population or for suboptimal habitat for the eastern population. Nonetheless, there are many similarities in habitat requirements reported from elsewhere. It prefers open areas with short vegetation such as pastures with fencerows, old orchards, mowed roadsides (particularly along gravel roads), cemeteries, golf courses, edges of agricultural fields, riparian areas, shelterbelts, and very open woodlands. In most areas, its abundance is correlated with the amount of pastureland; almost all nest sites in Illinois, New York, and Missouri were associated with pasture. In Indiana, it occurs only where Amish farmers have retained fencerows. It prefers areas of short grasses, typically 15-35 cm tall, where there are several suitable perches for hunting and an abundance of insects. Territories in the eastern states include more land in pasture and less in old fields than expected, and have greater lengths of fences, utility wires, and rights-of-way. In Kansas, it nested in habitat that may be similar to historical southwestern Ontario. It was positively associated with savannah habitat at the landscape level. Its presence was correlated with undisturbed tallgrass prairie, increasing cover of standing dead vegetation, increasing litter depth, and decreasing cover of live grasses and forbs within 10 cm of the ground. In North Carolina, preferred nest sites had low variation in ground vegetation but high variation in vegetation height, with few trees and shrubs. In western Canada, it prefers untilled prairie as well as land seeded with introduced grasses and legumes. It has also nested in isolated trees in farmyards and on rural and suburban lawns. Near Winnipeg, most nests were in areas where a mixture of mowed yards or parks, small pastures, idle grassy areas, and roadside ditches occurred in close proximity, and over half of nests were in ornamental spruce trees. In another area of Manitoba, it preferred to nest in single willows or clumps of willows or other deciduous trees. These areas contained significantly more pasture, fewer trees, and longer fencerows than random areas. In Alberta, it was more common in large blocks containing more than 100 clusters of trees and shrubs than it was in blocks containing 50 or fewer clusters (Bent 1950; Bjorge and Prescott 1996; Bohall-Wood 1987; Burton 1989, 1990; Dechant et al. 2002d; De Geus and Best 1991; Esely and Bollinger 2001; Fitch 1958; Froehly et al. 2020; Gawlik and Bildstein 1990; Hands et al. 1989a; Kirk et al. 2015; Kridelbaugh 1983; Michaels and Cully 1998; Novak 1986; Robert et al. in Gauthier and Aubry 1996; Smith and Kruse 1992; Sprunt in Bent 1950; Telfer 1992; Telfer et al. 1992; Yosef 2020).

The Loggerhead Shrike also nests in urban areas in Florida, Louisiana, South Carolina, Alabama, Georgia, and Texas. It nests in areas where mowing and other human activities create a mix of short grasses and bare ground. In a South Carolina urban area, territories were most often in less developed grassy parts of commercial or industrial parks or in intensive developments such as mall parking lots as long as there was a grassy verge nearby. These areas were located along a highway corridor. Shrikes nested most often in trees and shrubs lining or within parking lots associated with stores, businesses, or a large mall, but also in a cemetery, on college campuses, and on a golf course. These shrikes were nonmigratory and maintained their territories year round (Maddox and Hill 2024).

Most Ontario nests were in deciduous trees, shrubs, and vines (87.9%) and less frequently in conifers. Hawthorn was greatly preferred, being selected more than all other species combined (74.5% of nests). Nests were also in apple (9.2%), spruce (5.9%), cedar (5.2%), and grape vines (5.2%). Most were in crotches at the trunk of trees and shrubs but a few were on horizontal branches as far as 1.8 m from the trunk. Usually nests were placed centrally in a tree or shrub, occasionally near the top. Nests were 0.3-12 m from the ground with most 1.3-3 m up. A new nest is usually built each year, but 1 nest was used in 2 years (Peck and James 1987). In a more recent Ontario study, Chabot et al. (2001b) reported 37 nests in hawthorn, 29 in red cedar, 5 in white cedar, and 1 in buckthorn, with most nests in the Napanee Plain in red cedars. Eighty-eight percent of nest trees were isolated and 8% were in hedgerows. Hawthorns selected for nesting had significantly less canopy concealment than unused hawthorns. Selected red cedars were significantly taller than the nearest-neighbouring trees.

Throughout its range, the Loggerhead Shrike prefers to nest in thorny trees and shrubs. In some areas it prefers isolated trees and shrubs for nesting. In other areas it has a greater propensity to nest in hedgerows; this may be a function of habitat availability. Hawthorn and red cedar are preferred where available, but it may use other thorny species further south such as Osage orange, honey locust, Russian olive, plum, crabapple, or rose bushes. Other tree and shrub species it has nested in include maple, sassafras, oak, mulberry, elm, honeysuckle, spruce, pine, apple, pear, Virginia creeper, willow, poplar, Manitoba maple, chokecherry, lilac, black cherry, cottonwood, and black locust. In the southeastern United States, it regularly nests high on limbs of mature pines in pine savannahs rather than in shrubs (Askins et al. 2007). Unusual nest locations include in Russian thistle, amaranths, and a pile of old chain-link fencing. Other anthropogenic nesting locations include on a portable fence corral, on a fence, on a utility pole, on a cable in a solar farm, on the side of a building, and under a raised house. Nests have been found 0.3-15 m from the ground, but typically 1-3 or 4 m up. Since it tends to nest centrally in the nest tree or shrub, average nest heights vary significantly geographically depending on the size of suitable woody vegetation available. Average nest height in Missouri was only 0.8 m compared with 4.4 m in South Carolina. First nests are significantly lower than subsequent nests in the same season. It occasionally reuses old nests or builds on top of them, or takes materials from old nests to build a new nest. It may also build on top of other species' nests including those of Black-billed Magpie, Brown Thrasher, Northern Mockingbird, Gray Catbird, and Common Grackle (Bent 1950; Burton 1989; Davidson 1988; Esely and Bollinger 2001; Gawlik and Bildstein 1990; Gawlik et al. 1991; Graber et al. 1973; Haas and Sloane 1989; Kiliaan 1996; Kridelbaugh 1983; Miller 1931; Robert et al. n.d., Robert et al. in Gauthier and Aubry 1996; Sanders et al. 2018; Scott and Morrison 1990; Sprunt in Bent 1950; Todaro et al. 2025; Tyler 1992; Woods and Cade 1996; Yosef 1994b, 2020).

The territory includes all areas used for foraging, mating, and raising young. Despite the Loggerhead Shrike's territoriality, it often occurs in clusters rather than being evenly distributed over what appears to be suitable habitat. It maintains a much larger territory than other insectivorous birds of similar size. Territories reported in Ontario were approximately 10 ha in area, with some as small as 7.5 ha, although Chabot (in Cadman et al. 2007) suggested that Ontario territories may be as large as 50 ha. Similar-sized territories were reported from Kansas. Other territory sizes were an

average of 13.4 ha in Alberta (range 6.5-23.5 ha), an average of 8.5 ha in another Alberta study; 34 ha on a California island, average of 8.5 ha on the California mainland (range 4.4-16.0 ha), average of 4.6 ha in Missouri (range 1.0-12.1 ha), average of 7.5 ha in New York (range 5.7-9.3 ha), average of 8.35 ha in Florida (range 3-9.6 ha), and 8.9 and 25 ha in Idaho. Territory size is highly variable depending on habitat quality, presence of barriers between pairs, shrike density, and period of the nesting season. Pairs nesting in areas with sparse tree cover may have territories 2-3 times larger than birds nesting in moderately treed areas. Perch density is inversely related to territory size and birds with more available perches tend to be in better nutritional condition. In Florida, artificial perches were added to shrike territories. Initially territories averaged 10.1 ha (range 4.7-17.5 ha). After manipulation, the same territories shrank to an average of 2.3 ha, a reduction of 76.6%. Territory sizes did not change when supplemental perches were provided in California, but shrikes shifted their focal foraging sites to areas where perches were installed. In this population, home ranges of shrikes were more than 100 m apart, so there was no requirement to reduce territory size to minimize territorial conflicts. Territories may be smaller when there are barriers between neighbours such as a road or a hill that obstructs vision. Territory sizes also tend to be smaller with higher density of shrikes. In Missouri, territories were 8 ha during incubation, 3 ha during the nestling period, and 5 ha during the fledging period. After fledging, the parents cease defending the nest site and defend an area around the young. In Alberta, nests have been observed as close together as 80 m (Bjorge and Prescott 1996; Burton 1989; Cadman 1985; Davidson 1988; Dechant et al. 2002d; Fitch 1958; Hands et al. 1989a; Lymn et al. 2006; Robert et al. in Gauthier and Aubry 1996: Scott and Morrison 1990; Yosef 2020; Yosef and Grubb 1994).

Natal philopatry is very low. Highest reported rates have been from captive-bred and released birds in Ontario where 3.6% returned; in 2008, the Ontario return rate was 6.4%. In North Dakota, 2 of 243 birds (0.8%) banded as nestlings or fledglings returned to nest 3.2 and 3.8 km from their natal site. In Alberta, 3 of 249 nestlings (1.2%) were reencountered within 4 km; over 6 years 2.7% of 589 nestlings were recaptured. In southwestern Manitoba, 27 of 3,176 nestlings (0.85%) returned the year after banding and 2.3% returned over the 6-year study period. In Minnesota, 0 of 196 nestlings returned to the natal area and 1% of Indiana young returned. Adult site fidelity is also low. Females may not be faithful to a nesting territory within a breeding season, occasionally deserting a territory and switching mates. In Alberta, 38% of males and 27% of females nested within 4 km of the previous year's territory; in Manitoba 23% of adult males and 9% of adult females returned. In Indiana, 55% of male adults returned compared with 19% for females. Of birds that returned in Ontario, all returned to the same core area. Two of 9 adults (22.2%) returned to their previous territories; some females moved as far as 8-25 km. In 2002, movement of birds between the Carden and Napanee areas was confirmed. Two nestlings banded in 2001 on the Carden Plain were observed on the Napanee Plain in 2002. In 2008, virtually all Ontario adults were captured and it was determined that several previously banded birds had lost their bands. Consequently, return rates of adults were probably underestimated. In Manitoba, 7.0% of adults that raised young the previous year returned to the same territory; 2.3% of unsuccessful birds returned. Mean dispersal distance for 15 males was 0.85 km compared with 5 km for 4 females. Territories are more often reoccupied by new birds than the previous occupants. Earlier studies with unbanded birds concluded that site fidelity was high, but this is incorrect. It has been suggested that low philopatry increases

vulnerability to extirpation once regional populations are broken into isolated sites as a result of habitat fragmentation (Burton 1990; Collister and De Smet 1997; Dechant et al. 2002d; Grooms 2001; Haas 1995; Haas and Sloane 1989; Hands et al. 1989a; Kridelbaugh 1983; Pittaway and Iron 2003; Scott and Morrison 1990; Stauffer 2007; Steiner and Williams 2008; Williams and Steiner 2008; Yosef 1994a, 2020).

Limiting Factors

Eggs have been found in Ontario nests from the beginning of April until very early August with most present in the last 3 weeks of May (Peck and James 1987). The female takes 5-11 days to build the nest. After the nest is complete, another 9-18 days may elapse before any eggs are laid. Eggs are laid at the rate of 1 a day, although a day may occasionally be skipped. Incubation usually starts with the penultimate egg. The incubation period at 4 Ontario nests was 12-16 days. Over 2 years in Alberta, the mean incubation period was 16.46 and 16.75 days. Elsewhere, incubation periods of 15-20 days have been reported with the mean approximately 16 days. Hatching is asynchronous over 24-36 hours in early nests, but as long as 60-70 hours in late-season nests. Young fledge when they are 16-21 days old. Renesting usually occurs within a week after loss. In the case of second broods, the first egg of the second clutch is laid 1-3 weeks after the first brood fledges (Collister and Wilson 2007; Gawlik and Bildstein 1990; Gawlik et al. 1991; Graber et al. 1973; Haas 1995; Hands et al. 1989a; Kingery 1989; Kridelbaugh 1983; Miller 1931; Scott and Morrison 1990; S.M. Smith 1972; Tyler 1992; Woods and Cade 1996; Yosef 2020).

One or 2 broods may be raised in a year, with the incidence of double-brooding increasing southward. Two probable double broods were previously reported in Ontario. The birds were unmarked, so second broods could not be positively confirmed. The difficulty in confirming double brooding is that females may desert their first family and move elsewhere to raise a second brood with a different male. Chabot et al. (2001b) reported 1 pair double brooding in Ontario in 1991 and 3 pairs in 1992, but it was unknown if double brooding was successful. In Illinois, no instances of double brooding were known. About a third of females were thought to be double brooded in Indiana. Other reported rates of double broods are 0% in Idaho and Colorado, 10.4% in Minnesota, 8% in South Carolina, 18% in Missouri, 7.7-27% over 4 years in Oklahoma, 15% in Alabama, and 96% in Florida. Suggestions of 3 broods in the south have not been confirmed and are probably incorrect. Renesting is typical after nest loss, usually in the same territory within a few 100 metres of the first nest. One pair laid 5 clutches before it successfully raised a brood. Clutches of 4-7 eggs have been reported in Ontario, with most containing 5 or 6 eggs. Overall, clutches of 1-9 eggs have been reported, but clutches of 1-3 eggs and 8 and 9 eggs are very rare. Most clutches contain 5 or 6 eggs; about 25% of clutches are of 4 or 7 eggs. Average clutch size increases northward and there is no difference in clutch sizes between first and subsequent nests in a season (Bent 1950; Brooks and Temple 1990; Burton 1989, 1990; Cadman 1985; Gawlik and Bildstein 1990; Graber et al. 1973; Hands et al. 1989a; Kridelbaugh 1983; Miller 1931; Peck and James 1987, 1997; Pittaway 1993; Scott and Morrison 1990; Sprunt in Bent 1950; Tyler 1992; Woods and Cade 1996; Yosef 2020).

The age at first breeding is 1 year. Territories that are abandoned during a year are usually not occupied until the following year suggesting that floaters are rare. Some birds may maintain territories for 1 or 2 years without attracting a mate, also indicating there are few floaters. The

Loggerhead Shrike is typically monogamous, but polygyny occurs rarely. In Florida, there were no significant differences in territory sizes or prey fed to young among monogamous and polygynous birds, but prey delivery rate was greater by polygynous males. The greatest difference was that polygynous males fledged almost twice as many young. There were 2 strategies in polygynous matings. In the first, the second female started laying 10-12 days after young at the first female's nest hatched. The male raised the first brood and fed both females and their young. In the second strategy, the second female laid after the first brood fledged and the male provided care for her fledglings for several weeks. Females display low mate fidelity and may desert their first mate for a second mate (Cadman 1985; Collister and De Smet 1997; Dechant et al. 2002d; Scott and Morrison 1990; Yosef 1992a, 2020).

The Loggerhead Shrike feeds in open landscapes characterized by well-spaced, usually spiny trees, and shrubs in areas with short grasses or bare ground or rock. It is a sit-and-wait predator, hunting from a perch and diving at prey. About 80% of attacks occur on or near the ground and 20% in the air, with most aerial attacks directed toward small- to medium-sized insects. Hunting perches are usually small shrubs and trees as well as anthropogenic features such as fence posts and utility wires and poles. Perch heights are usually low, but highly variable depending on availability. In Florida, most perches were lower than 5.5 m. They averaged 2.1 m in California, with almost half under a metre high. In Texas, perch heights ranged from 0.9 to 7.5 m, and shrikes foraged from taller trees than expected by chance. It may hunt within 15 m of the nest, about 150 m away, or as far away as 0.9 km, reflecting perch availability rather than preference. In addition to foraging from perches, it may forage opportunistically in recently plowed fields and on mowed lawns. It may also follow hawks and visit their perches to obtain meat scraps. Small prey may be consumed on site or transported and impaled on a thorn or barbed-wire fence; larger prey is always impaled. Due to its lack of talons, it has difficulty handling large prey; impaling it facilitates tearing it apart. Impaled prey also provides a cache of food for the female. Much of the food the female feeds nestlings is prey previously impaled by the male. The female often feeds from the cache during incubation breaks. Chemically noxious prey, such as monarch butterflies, may be left hanging for about 3 days then consumed after the chemicals have degraded. Young are first successful at wedging prey in a tree at age 28-30 days and at impaling at age 33-35 days (Anderson 1976; Applegate 1977; Becker et al. 2009; Bohall-Wood 1987; Busbee 1976; Craig 1978; Davidson 1988; Gawlik and Bildstein 1990; Gawlik et al. 1991; Graber et al. 1973; Hands et al. 1989a; Morrison 1980; Scott and Morrison 1990; S.M. Smith 1972; Telfer 1992; Yosef 2020).

The Loggerhead Shrike is a highly opportunistic feeder, preying on whatever is most abundant. The diet changes seasonally and even at different times of the day. When a given prey is abundant, it may feed exclusively on it until it is depleted. Therefore, diet analyses vary considerably in their conclusions and results also vary depending on study methods. Studies that examine stomach contents and prey delivered to nestlings are most accurate. Those that rely on observations of impaled prey are biased toward larger items which are frequently atypical of the diet. Overall, invertebrates are most important in its diet, and most of these are insects. Crickets, grasshoppers (mostly short-horned), and beetles are staples with important beetles being weevils, and scarab, ground, June, carrion, click, and long-horned beetles. Earwigs, hymenopterans (ants, bees, and

wasps), and moths and butterflies are also important in the diet. Other insects it takes infrequently are preying mantises, flies, ant-lions, mayflies, dragonflies, walkingsticks, cockroaches, bugs, and cicadas. It seldom eats spiders, centipedes, millipedes, earthworms, isopods, crayfish, and snails. Although few vertebrates are consumed, they are important from a biomass perspective, especially early in the spring before insects are abundant. Most vertebrates eaten are small mammals, particularly meadow voles. Of lesser importance are salamanders, small frogs, lizards, snakes (especially the common garter snake), and small birds. It attacks birds that are small in size such as sparrows and warblers and nestlings are preferred. It has trouble carrying prey as large as adult sparrows and House Finches. It has been documented killing birds as large as cardinals and Mourning Doves, but these are atypical prey. Unusual prey items include bats, small turtles, dried-up small fish, and cattle ticks. It takes prey ranging in size from 5-mm-long insects to mammals or snakes weighing as much as 25 g. It appears to prefer prey 16-26 mm long. A laboratory study determined that it preferred mice that weighed less than 13 g and most selected were less than 8.5 g. Occasionally it feeds on carrion. Habitat quality may have a direct impact on birds' diet and condition. In Florida, birds nesting in pastures were in better condition than those in old fields, and much better than those in citrus groves (Balda 1965; Bent 1950; Burton 1989, 1990; Craig 1978; Davidson 1988; Dirck 1986; Eells 1962; Gawlik et al. 1991; Graber et al. 1973; Grubb and Yosef 1994; Ingold and Ingold 1987; Johns and Johns 2001; Johnson 1949; Knowlton and Harmston 1944; Leonard 1992; McIlwraith 1894; Moriarity and Pfannmuller 1988; Morrison 1980; Reynolds 1979; Scott and Morrison 1990; Slack 1975; S.M. Smith 1972; Sprunt in Bent 1950; Wayne 1921; Yosef 2020). Beal and McAtee (1912) examined the contents of 212 Loggerhead Shrike stomachs: 124 from the western United States and 88 from the east. The diet of western birds was composed of 2.5% vegetable matter but no vegetable matter was consumed by eastern birds. Western birds consumed 83% insects, 12% vertebrates, and 2% spiders and snails; eastern birds ate 68% insects, 28% vertebrates, and 4% spiders. The most abundant prey items consisted of grasshoppers and crickets, which comprised 43% and 39% of the stomach contents of western and eastern birds, respectively. They were eaten every month of the year and constituted nearly 70% of the diet in August and September. Beetles were second in importance of the insects consumed (16% of the diet for western birds and somewhat more for eastern birds). Most were ground and carrion beetles, but smaller beetles such as leaf beetles and weevils were also eaten. Ants and wasps constituted 11% of the diet of western birds and 3% of the diet of eastern birds. Moths and caterpillars comprised 7% of the diet of western birds and 4% of the diet of eastern birds. Bugs and flies constituted 5% of the diet, including robber flies. Small quantities of spiders, snails, and small crustaceans were also consumed. The vertebrates included mammals, birds, and reptiles, with mammals most prominent in the diet, predominantly mice but some shrews. Few birds were consumed and the reptiles were mostly lizards consumed by western birds.

Parasitism by the Brown-headed Cowbird is extremely rare and has not been documented in Ontario. The Loggerhead Shrike is a rejecter of cowbird eggs. DeGeus and Best (1991) found 3 parasitized nests in Iowa and 2 of 1,661 Manitoba nests (0.1%) were parasitized (Dechant et al. 2002d), the only known incidences. Parasitism did not appear to affect shrike productivity. In 1 nest, it is likely that a cowbird fledged.

Habitat loss and degradation are significant factors throughout the Loggerhead Shrike's range. In many areas, including Ontario, it appears to be retracting to its presettlement range. Originally, it was probably restricted to prairies, savannahs, and alvars. These habitats were not surveyed by early Ontario ornithologists who assumed it was a recent arrival as a breeding bird. Once extensive forested areas were cleared, much new habitat was created for it. Early farming practices were beneficial, such as having extensive pasturelands and fallow fields and maintaining hedgerows around small fields. As farming evolved, the amount of pasture declined and hedgerows were removed to create larger fields. Canadian regions experiencing the most severe shrike decline had a 39% decline in the amount of unimproved pasture between 1946 and 1986 compared with 12% in areas that still retain substantial populations. In Ontario, there were approximately 1.2 million ha of pastureland in 1921 compared with 0.4 million in 1986. The original forest cover that was unsuitable became prime habitat for 70-100 years then once again became unsuitable as farming practices intensified or land was converted to urban areas. Roadsides were formerly sprayed with herbicides to kill woody growth, removing potential nesting sites and hunting perches. Some areas of marginal farmland were planted to trees or allowed to revert to forest. Natural succession is a problem in one of the core Ontario breeding areas. In many states and provinces where declines are most significant, it was probably absent prior to settlement. In these areas and Ontario, populations appear to be reverting to historical distribution. Declines due in part to loss of breeding habitat are also occurring in regions where it always occurred (Burton 1993; Cade and Woods 1997; Cadman 1985, 1990; Coffin and Pfannmuller 1988; Graber et al. 1973; Hands et al. 1989a; Michaels and Cully 1998; Norris 1992; Robert and Laporte 1991; Robert et al. n.d.; Robert et al. in Gauthier and Aubry 1996; Telfer 1992; Yosef 1994a, 2020; Yosef and Grubb 1994).

Scarcity of hunting perches within otherwise suitable breeding habitat appears to be a limiting factor. When artificial perches were added to Florida territories, the size of territories was reduced by an average of 76.6%. Where perches were added, 60% of nests were successful and fledged an average of 3.1 young per nest. Control territories had a 40% success rate and an average of 1.8 fledglings per nest. Yosef and Grubb (1994) concluded that perches are very important and that much of the defended area is unusable habitat. Chabot et al. (2001b) concluded that addition of perches to the core Ontario breeding areas would be beneficial.

Much suitable breeding habitat remains unoccupied indicating that other factors are contributing to the Loggerhead Shrike's decline. Loss and degradation of wintering habitat may be a significant limiting factor. Similar habitat is preferred in winter as during the breeding season, and wintering habitat has declined substantially since the 1940s and 1950s. Since 1954, the amount of suitable habitat declined by 600,000 ha in Alabama and 480,000 ha in Georgia; between 1964 and 1987, habitat losses were 850,000 ha in Louisiana and 1.1 million ha in Mississippi. Prime habitat in Arkansas has been completely eliminated. By 1979, only 17% of native grassland in Texas had not been converted to rice cultivation and other land uses, the habitat preferred by wintering shrikes. Fire ants have invaded all the Gulf States except Texas and are found on 100 million ha of land. The ants kill young trees and shrubs, thereby eliminating many perches. They are also direct competitors for food, eating grasshoppers and other insects as well as birds. There is also competition with resident shrikes that maintain their territories year round. Migrant shrikes are often forced to use

suboptimal habitat. In Indiana, it was concluded that only resident birds still bred in the state with the migrant population having been eradicated. Declines in Minnesota were attributed to low winter survival rates; it was concluded that conservation efforts on the breeding grounds would be ineffective in maintaining populations (Brooks and Temple 1990; Burton 1990; Cade and Woods 1997; Cadman 1985, 1990; Lymn and Temple 1981; Telfer 1992; Tyler 1992; Yosef 1994a, 2020).

Kirk et al. (2015) noted that the populations in the Carden and Napanee alvars are fairly stable and suggested that there might be a minimum size of local breeding populations needed to ensure persistence in a given area. When densities are low, returning birds have a reduced probability of finding a mate and breeding.

Presence of other raptor species may affect habitat use by Loggerhead Shrikes. In Texas, Northern Harriers forced shrikes to use habitats with more escape cover. Competition from American Kestrels prevented shrikes from using the same habitat patches (Kim et al. 2003). This study was conducted in winter, but may also be relevant to the breeding season.

Hudecki et al. (2020) reported that more than 20% of nests found in Ontario and Indiana had plastic incorporated into them. In Ontario, 3 cases of fledglings becoming entangled in plastic used as nesting material were reported. Slack (1992) reported nests where young were found hanging by pieces of string that were incorporated into the nest.

Environmental contaminants appear to have had an impact on shrike populations. The sudden decline in populations started in the 1940s before farming practices intensified, and coincides with initial usage of organochlorines. In Ontario, clutch and brood sizes declined after introduction of organochlorines. It is unknown if these were direct effects or indirect effects due to reduced prey populations. Major declines in the prairie provinces corresponded with dieldrin treatment of grasshoppers, a major component of the diet. In Illinois, eggshells were significantly thinner in 1971-72 than 1875-95 and most birds contained detectable concentrations of DDE. Breeding success was still high and there was no direct evidence that DDE had an impact on shrikes. In the wintering area between 1957 and 1977, aerial spraying of dieldrin, heptachlor, and mirex was undertaken in an attempt to control fire ants. Loggerhead Shrikes accumulated 8 ppm mirex compared with 1 ppm for most other vertebrates. In the 1950s and 1960s, pesticides were responsible for the direct death of adults, but this is no longer a factor. Young shrikes fed a diet treated with 2 ppm dieldrin all died within 103 days, and this dosage could be obtained by birds feeding in dieldrin-treated fields (Anderson and Duzan 1978; Blumton et al. 1990; Busbee 1977; Cade and Woods 1997; Cadman 1985; Hands et al. 1989a; Lymn and Temple 1981; Novak 1986; Yosef 1994a, 2020). The Loggerhead Shrike has been killed by carbofuran, a substance now banned in Canada (Mineau et al. 1999). The compound Dombind® is often used as a dust suppressant along roadsides. This increases the density of invertebrates along roadsides which may attract shrikes that may subsequently be affected by dioxins, furans, and other contaminants in this chemical. There is an increasing prevalence of brominated flame retardant chemicals in the food chain, including the eggs, blood, and tissues of predatory birds. These chemicals have been demonstrated to cause reproductive failure in captive American Kestrels, a species that shares similar habitats and dietary items with the Loggerhead Shrike. It is unknown if wild populations of shrikes breeding in Ontario have been exposed to these chemicals (Kirk et al. 2015).

In most areas, the Loggerhead Shrike has high nesting success. Fledgling and adult survival rates are very low compared to most passerines, however. Mortality rates from fledging to independence have been estimated at 33-53% in different areas. Several authors noted that nesting success was high, but autumn populations were lower than expected. Overwinter mortality rates may be as high as 50% in some populations. In Minnesota, it was estimated that 5.5 young would have to be produced per pair to offset the mortality rate. This would require almost 100% nest success or consistently successful double brooding; this is highly unlikely to occur. The high mortality rate appears to be due to a combination of all other limiting factors. A population viability analysis determined that the most sensitive factors affecting populations were overwinter survival and/or low recruitment rates to the breeding population by juvenile and young adult shrikes (Anderson and Duzan 1978; Brooks and Temple 1990; Collister and De Smet 1997; Graber et al. 1973; Kirk et al. 2015; Kridelbaugh 1983; Lymn and Temple 1981; Yosef 2020).

The Loggerhead Shrike appears to be vulnerable to West Nile virus. Five birds in the captive breeding program at the Toronto zoo died from this disease (Pittaway and Iron 2003). In California, Smallwood and Nakamoto (2009) found that it declined throughout their study region except in an area where West Nile vectors were aggressively controlled. It increased in areas where mosquito control was implemented. Lindgren et al. (2009) determined that 3 dead nestlings found in a Manitoba nest had died due to the West Nile virus.

Inclement spring weather may significantly reduce nesting success. High winds may blow nests out of trees, but cold, rainy weather is more devastating. Nestlings may die of hypothermia and there may be a scarcity of food. Under adverse weather conditions, brood reduction is common due to hypothermia, starvation, and siblicide, with youngest nestlings perishing first (Etterson et al. 2007; Hands et al. 1989a; Kridelbaugh 1983; Tyler 1992; Yosef 2020). In an Alberta population, daily nest survival was positively correlated with temperature and negatively correlated with precipitation (Collister and Wilson 2007).

Due to the exposed bedrock in the core Ontario breeding areas, these sites are of high quality for aggregate extraction. New gravel pit and quarry sites have the potential to affect Loggerhead Shrike habitat (Austen et al. 1994; Cadman 1985, 1990; Norris 1992).

Its flight habit makes the Loggerhead Shrike highly vulnerable to collisions with vehicles and to predation. It tends to perch at the top of shrubs or trees then swoop very low when flying. It is frequently killed by vehicles, particularly because of its habit of hunting along roadsides. Road-kill is a significant limiting factor in Ontario and most other areas. This problem is likely to escalate because of increasing traffic volumes. The conspicuous white patches on its wings make it highly vulnerable to avian predators (Austen et al. 1994; Cadman 1990; Chabot et al. 2001b; Gawlik and Bildstein 1990; Hands et al. 1989a; Norris 1992; Yosef 1994a, 2020).

Nest predation rates may be high, particularly when the Loggerhead Shrike nests in hedgerows and other linear habitats. The domestic cat may be a significant predator, although its impacts in Ontario are unknown. The proliferation of houses along roads in the core breeding areas may result in increased predation by cats. In South Carolina, nesting success was 71.4% where cats were not observed and 53.8% where they were present. In Missouri and Florida, nests near roads and in other

linear habitats were significantly less productive than those in pastures away from roads (Austen et al. 1994; Cadman 1990; Esely and Bollinger 2001; Gawlik and Bildstein 1990; Yosef 1994b, 2020).

In the core Ontario breeding areas, light grazing by cattle improves habitat by retarding natural succession and increasing habitat heterogeneity for insects. Pittaway (1999) documented that cattle regularly cause nest failure by rubbing and pushing against nest trees, frequently shaking eggs out of the nest.

Severe winter conditions occurred on the wintering grounds from 1976 to 1979. It is thought that this may have been a significant factor in the decline of the eastern population (Yosef 1994a).

Price (2004) predicted that the range of the Loggerhead Shrike could expand in southern Ontario if the summer temperature increased. It has other significant limiting factors that an increase in temperature may not overcome.

Status

The Loggerhead Shrike population has experienced major population fluctuations in Ontario. Historically, it was either absent or, more likely, confined to prairie, savannah, and alvar habitats. After forest clearing, it became common or even abundant. With the advent of pesticides followed by modern agricultural practices and increased urbanization, it declined significantly and is listed as endangered in Ontario. Its current distribution may be very similar to historical conditions, although it may have bred in prairies and savannahs in southwestern Ontario.

The Loggerhead Shrike was first recorded in Ontario in 1860 and became common by the turn of the 20th century. In the late 1880s, one could travel a short distance in any direction from Hamilton and find 1 or 2 pairs in suitable habitat. Around 1900, it was a regular uncommon summer resident in Toronto. By 1909, it was common along the St. Lawrence River and in Muskoka District and its range included the Bruce Peninsula. It continued to expand its range northward until the 1940s, when it was fairly common on Manitoulin Island, uncommon at Sault Ste. Marie, and nesting even occurred in Rainy River District in 1937. Shortly thereafter, its range started to contract southward and numbers declined. During the first atlas, it was estimated that there were 50-100 breeding pairs in the province concentrated from Manitoulin Island to Ottawa in a band along the southern edge of the Shield. A sharp decline in numbers was noted during the first atlas and it was concluded that there were probably only about 50 pairs left by the time the atlas was completed. Numbers and the extent of the range continued to shrink until by 1990 it was mostly confined to 2 core breeding areas (the Carden Plain and the Napanee area) with scattered nesting on the Bruce Peninsula and in the Ottawa area. In the early 1990s, there were 40-50 pairs in the province, as well as several unmated birds. The population dropped to a low of 18 pairs in 1997, but subsequently recovered to about 40 pairs. Numbers were fairly stable at 30-40 pairs annually for several years in the late 1990s and early 2000s, mostly confined to the 2 core breeding areas, but also on the Bruce Peninsula as a result of releasing captive-bred birds. No significant numbers of birds have been seen recently in the Smith Falls and Rainy River areas. The population has been supplemented through a captive breeding and release program since 2000. In 2006, the breeding population declined to 18 pairs once again, and was 20 pairs in 2007 and 27 pairs in 2008 (Austen et al. 1994; Baillie and Harrington 1937; Cade and Woods 1997; Cadman 1985, 1988, 1990; Cadman in Cadman et al. 1987;

Chabot in Cadman et al. 2007; Fleming 1907; Grand 1999; Grooms 2001; Heagy 1996; James 1991; Kirk et al. 2015; McIlwraith 1894; Norris 1992; Novak 1986; Stauffer 2007; Steiner and Williams 2007, 2008; Weir 2008). The Ontario population has been bolstered by the release of approximately 100 captive-reared fledglings annually from 2006 on. By 2008, 22.2% of wild pairs confirmed in Ontario contained a released bird (Williams 2007; Williams and Steiner 2008). In 2015, there were only 11 estimated pairs in the province but this increased to 21 pairs in 2022 (Olsen 2023). In 2024, 18 wild pairs were confirmed in the province, all at the Carden Alvar and Napanee Plain. Four single birds were observed on the Bruce Peninsula and Manitoulin Island, and single birds were also documented on Pelee Island and near North Bay. A total of 14 unpaired adults was recorded (Hess 2025).

The long-term (1970-2021) population trends determined by the Breeding Bird Survey were annual decreases of 3.08% in Canada and 8.94% in Ontario. The short-term (2011-21) trends were annual decreases of 1.287% in Canada and 3.82% in Ontario. The Ontario results were of low reliability. Canadian results were highly reliable for the long term and of medium reliability for the short term (A.C. Smith et al. 2023).

The short-term objective for the Loggerhead Shrike identified in the recovery strategy is to stabilize the existing population and prevent further declines. The long-term objective is to maintain at least 20 pairs in the Carden core area, 10 in the Napanee core area, 10 within a third core area, and at least 10 pairs elsewhere within the province for a total of 60 pairs (Kirk et al. 2015).

POSTFLEDGING PERIOD

Fledglings remain in the nest tree or dense foliage near it for 2-4 days after leaving the nest. They may then disperse as far as 7 km from the nest, but remain dependent on the adults for another 3-4 weeks, and considerably longer further south (Yosef 2020).

Twenty juvenile birds remained at the Carden site for several days before dispersing. Individuals were tracked to Beaverton, Duclos Point on Lake Simcoe, Virginia Corners (east of Toronto), and Hamilton (Williams and Steiner 2008).

MIGRATION

Northern birds are migratory, including those from Ontario; southern birds are resident. Most birds north of latitude 40°N migrate because the Loggerhead Shrike tends to avoid areas that have 10-30 days of snow cover in a year. Ontario birds winter approximately 900 km due south of the breeding grounds. During migration, birds move singly and during the day; it is unknown if nocturnal migration occurs. Migration is leisurely and birds may stay and feed in an area for a few days before moving another short distance (Burnside 1987; Miller 1931; Yosef 2020).

In Missouri, experienced males were the first to arrive and set up territories in spring. In Ontario, the Loggerhead Shrike arrives in late March or early April, very rarely by late February (James 1991; Kridelbaugh 1983). Autumn migration is in the first half of September, with occasional stragglers persisting into December (James 1991).

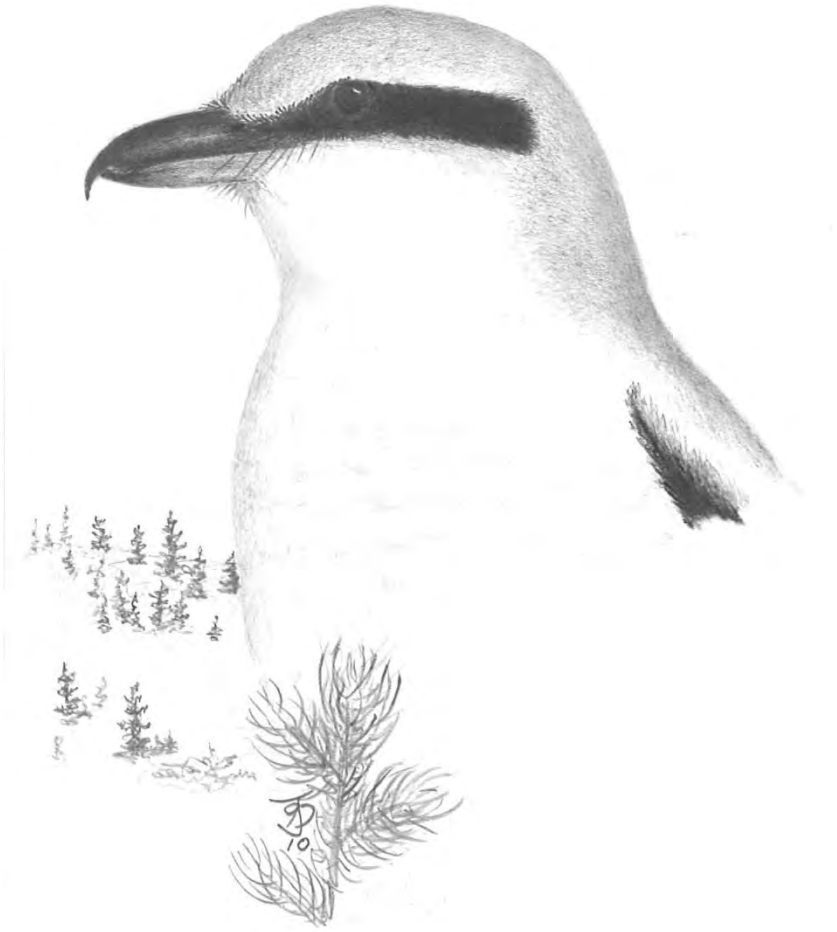
Migration habitat is very similar to breeding habitat. In British Columbia, where it is a nonbreeder, the Loggerhead Shrike prefers areas with short ground cover and frequently forages

from fence posts, telephone poles, or overhead wires. It occurs in open habitats such as beaches, brushy edges of fields, agricultural land, lakeshores with scattered shrubs, and open, mixed forests interspersed with grasslands (Campbell et al. 1997). Captive-reared juveniles inhabited pastures and hayfields as stopover sites during migration through southern Ontario (Kirk et al. 2015).

The Loggerhead Shrike is a rare migrant in Ontario (James 1991).

Northern Shrike

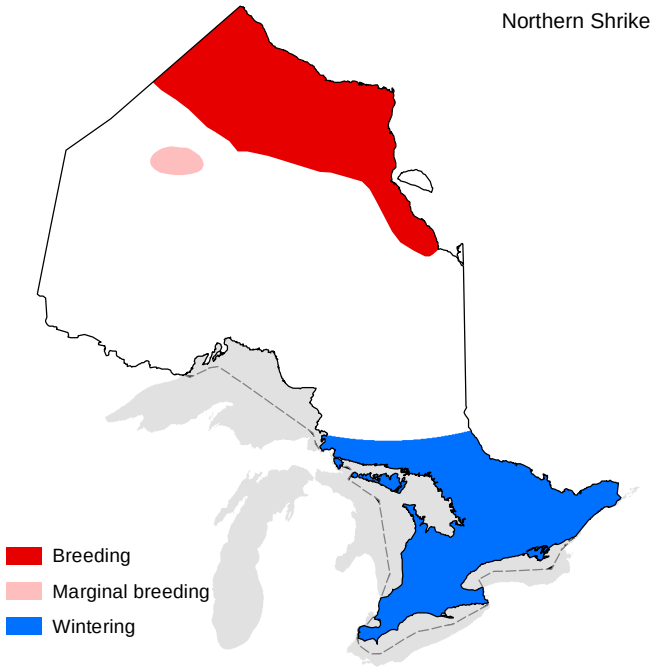
Lanius borealis



BREEDING SEASON

Habitat Requirements

The Northern Shrike breeds in the Hudson Bay Lowland and Tundra Region in Ontario, mostly in tundra habitat or large, open fens with scattered shrubs or trees. The first confirmed breeding record was in a large sedge fen with scattered tamarack and dwarf birch (Cadman in Cadman et al. 1987; James 1981; Peck and James 1987). Sutherland (in Cadman et al. 2007) described its preferred breeding habitat as sparsely treed open muskeg, spruce-lichen woodland patches within open peatlands, extensive regenerating burns, and willow and alder riparian thickets. In northeastern Manitoba and northwestern Ontario, McLaren and McLaren (1981) observed it in coniferous forests with understorey and in coniferous shrub habitats. In boreal Canada, Erskine (1977) described it as characteristic of tundra habitat.



In Alaska, breeding habitat includes tundra and coniferous forest, but continuous stands of conifers are avoided. The Northern Shrike nests either on the edge of coniferous forests or in open-canopied forests with a strong preference for forest edge. Other habitats it uses include spruce-birch forests near openings such as rivers, lakes, burned areas, muskegs, or black spruce bogs. It prefers semi-open landscapes and shrub-like vegetation, so it may nest in clumps of willows 1.3-5 m tall north of the treeline (Cade 1967).

No nests have been found in Ontario and few have been described from North America. The Northern Shrike nests both in coniferous and deciduous trees as well as in shrubs. In the southern part of its range and south of the treeline, it typically nests in spruce trees, but may nest in poplars and willows. Dense spruce trees appear to be preferred where available, and nests are well concealed, usually on a branch near the trunk. It possibly also nests in witches'-brooms and old Canada Jay nests. Old nests are rarely reused, with a new lining provided for the cup. Nests are often in the same tree or shrub as previously, but not always in consecutive years. Nests have been reported 1-10 m from ground, with most 2-4 m up (Bent 1950; Campbell et al. 1997; Paruk et al. 2020).

The Northern Shrike is territorial, but limited information on territory size is available. In Alaska, the closest nesting pairs were 1.6 km apart and other shrikes were attacked if they came within 1 km. This suggests the territory size may be in the order of 300 ha; 3 Alaska territories were approximately 145 ha in size. Most hunting is done within an area of 130-260 ha, so this is probably representative of the core territory size. Nesting birds are widely spaced and may not remain within a defined territory. Birds have been observed regularly flying as far as 3.2 km from the nest, so home ranges may be at least as large as 32 km² (Cade 1967). In Alaska, nearest-neighbour distance between nests averaged 2,333 m (range 700-4,230 m). In another area of Alaska, nests were 2-8 km apart, with high variations in numbers and density year to year. Males apparently do not defend their territory year round in North America (Paruk et al. 2020).

No information is available on natal site philopatry. Adult site fidelity appears low to moderate. In Alaska, a male nested 1.2 km from his previous nest site. Of 12 nesting areas examined 7 years, 1 was used 5 times, 3 4 times, 4 twice, and 4 once. Also in Alaska, 9 of 21 willow stands were used for nesting 19 times in a 5-year period. Although the Northern Shrike is somewhat migratory in North America, some individuals overwinter in the breeding range (Cade 1967).

Limiting Factors

Although no data are available, it is likely that most clutches in Ontario occur in June (Peck and James 1987). In Labrador, a replacement nest took 7 days to build. Most often, eggs are laid at the rate of 1 a day. The onset of incubation has been recorded twice: once after laying of the second egg, and once after laying of the seventh and last egg. Size of nestlings in Alaska nests suggested incubation began with laying of the first egg (1 case), second egg (4 cases), third egg (6 cases), and seventh egg (1 case). The incubation period is 17-21 days, and hatching is asynchronous over a 3-4-day period. Young fledge when they are 18-20 days old, but may leave the nest at 15 days if disturbed (Cade 1967; Paruk et al. 2020).

A single brood is raised annually, but renesting may occur if the first clutch is lost. No information on Ontario clutch sizes is available, but fledgling numbers have been documented. Four juveniles were observed on the Sutton Ridges, 5 at North Point north of Moosonee, and a female collected near Moosonee had 6 enlarged ova. Overall, clutch sizes of 2-9 eggs have been reported. Clutches with fewer than 4 eggs are probably incomplete. Clutches of 4-6 eggs are probably typical, but most clutches in Alaska contained 8 eggs and some 9-egg clutches occurred. There may be significant differences in clutch sizes between eastern and western populations, but insufficient data are available (Bent 1950; Cade 1967; James 1981; Manning 1981; Paruk et al. 2020; Schueler et al. 1974).

The age at first breeding is 1 year. Most birds are monogamous and it is probable that extra-pair copulations occur (Paruk et al. 2020).

The Northern Shrike prefers to hunt by perching atop one of the tallest trees in its territory. It prefers perches 3-10 m high a minimum of 25 m apart, but perch height is dependent upon the trees and shrubs that are available. It has extremely acute vision; it can see a bumble bee 100 m away, a mouse at 200 m, and another shrike at 1 km. An area of about 130 ha around the nest is used regularly for hunting, but birds occasionally range out to cover an area of about 260 ha. One was observed killing a longspur and flying 400 m with it to the nest. Once prey is observed from a perch, the shrike flies off in pursuit. Insects are snapped up in the beak in mid-air. It may pursue birds in the air for several hundred metres, but is seldom successful in capturing them in flight. It has been documented catching swallows and bats in mid-air. The feet are usually used to capture birds but occasionally they are struck by the beak. To kill rodents, it jumps and dances around the prey then strikes it with the beak. It usually kills vertebrates by severing the vertebrae in the neck with the beak. It has other hunting techniques that are used infrequently and usually with low success. It may move quickly on the ground or among shrubs and trees in an attempt to flush prey. Sometimes it hovers over a spot where prey has been seen and attacks if it is observed again. Rarely, it hunts in large sweeps 900 m back and forth, flying as high as 60-100 m. In Alaska, immature birds have been observed hunting cooperatively. Two young worked together to flush American Tree Sparrows from dense cover into the open, where they were pursued. Cooperative hunting may improve success of inexperienced birds. Once captured, it carries all vertebrates and most large invertebrates to a tree or shrub and impales them on a thorn or sharp twig or hangs them in the fork of a branch. During the breeding season, larders of impaled prey may be maintained, but not always. In Alaska, prey was hung at heights from ground level to 3.6 m, mostly 1-2.3 m from ground. Larders may attract foxes

and other predators, so are usually 40-200 m from the nest. When larders are maintained, the female may feed from them during breaks and take food back to nestlings (Cade 1967; Yosef 1994a).

When adults first arrive in April or May in Alaska, they eat mostly adult passerines and occasional voles. Once the snow begins to melt, more voles are exposed, and they make up the bulk of the diet. By late May, bumble bees emerge and they dominate and are critical to the diet. After the peak courtship of passerines is over in mid-June, the number of birds in the diet decreases rapidly; at the same time, young voles appear and become important prey. In the first week of July, fledglings of other bird species become important in the adult but not juvenile diet. In autumn, both adults and juveniles feed mostly on migrating birds. There were very few species in the diet: 4 species of birds (Savannah Sparrow, Lapland Longspur, Snow Bunting, and Redpoll), 4 species of mammals (voles and shrews), and only 6 invertebrate taxa (spiders, bumble bees, wasps, grasshoppers, ground beetles, and other beetles). Over a 1-year period, birds constituted 21% of the total weight of food eaten, young voles 22%, adult voles 52%, bumble bees 3.5%, and other insects less than 1%. Further south in northern British Columbia and Labrador, the diet is more varied. In addition to the species consumed in Alaska, it has eaten young ptarmigan, shorebirds, Downy Woodpeckers, Horned Larks, young Canada Jays, Black-capped Chickadees, Golden-crowned Kinglets, American Robins, Bohemian Waxwings, Yellow-rumped Warblers, White-crowned Sparrows, Fox Sparrows, Dark-eyed Juncos, Red and White-winged crossbills, Evening Grosbeaks, Pine Grosbeaks, red-backed voles, and meadow voles. Near Churchill, it fed on young shorebirds and longspurs captured in a nearby fen. It rarely attacks larger birds such as Mallards, Sharp-tailed Grouse, and ptarmigan. Other invertebrates consumed include caterpillars, ants, and millipedes (Bent 1950; Cade 1967; Campbell et al. 1997; Paruk et al. 2020). It is likely that Ontario breeding birds prey on most of the above species when they are available.

Food may be a significant limiting factor on the breeding grounds. In Alaska, shrikes eradicated the entire population of bumble bees and wasps in their territory, eliminated all nesting birds within 200 m of the shrike nest, and removed about 14% of the vole population. The last 2 hatchlings often die before fledging, probably because they do not get enough food. In cold, wet weather when prey is scarce, adults may cannibalize young just to stay alive (Cade 1967; Yosef 1994a).

In Wisconsin, 2 Northern Shrikes had mean feather mercury concentrations of 7.7 µg and 9.1 µg per gram. Mercury concentrations higher than 7 µg per gram may cause a 40% reduction in nesting success. Spiders have been found to have high concentrations of mercury, so it is possible that a diet high in spiders could have caused these elevated concentrations (Paruk et al. 2020).

Status

McIlwraith (1894) concluded that the Northern Shrike probably bred in the northern portion of the province. Schueler et al. (1974) provided the first breeding evidence when they collected a female with enlarged ova near Moosonee on 26 May 1972. Other sightings or specimens have been taken from Moose Factory, Winisk, Severn River, Severn House, York Factory, Akimiski Island, and the Twin Islands, and it was reported to be fairly common on the west side of Hudson Bay (Manning 1952, 1981; Schueler et al. 1974). Breeding was confirmed on 12 July 1981 when a pair was observed feeding recently fledged young at the Sutton Ridges (James 1981). Although not reported until later, Manning (1981) saw a group of 5 young at North Point, just north of Moosonee on 23 June 1975.

During the first atlas, breeding was confirmed near the Fawn River in 1983 and near the Sachigo River in 1984. Cadman (in Cadman et al. 1987) concluded that the Northern Shrike was widespread in the Hudson Bay Lowland, but at low densities. McLaren and McLaren (1981) estimated it bred at densities of 1 or less than 1 pair per km² in the Hudson Bay Lowland. James (1991) considered it a rare breeder in the Hudson Bay Lowland south and east to Moosonee.

The second atlas indicated no change in the breeding distribution or abundance of the Northern Shrike. A shift in the areas where breeding evidence was obtained between atlases was probably due to changes in coverage rather than an actual distributional change. No nests were found during the second atlas but breeding was confirmed along the Winisk River north of Peawanuk and near Shegogau Creek, 30 km north of Moosonee (Sutherland in Cadman et al. 2007).

POSTFLEDGING PERIOD

Young remain in the nest tree or one nearby for a few days after leaving the nest, staying quiet and still for the first week except when adults bring food. They gradually become more active and move away from the nest tree. The brood remains together in a loose group for more than 30 days, and the adults split the brood and continue to feed them during this period (Paruk et al. 2020).

Fledglings begin feeding themselves by attacking small arthropods while they search on the ground. These include ground beetles, flies, mosquitoes, and spiders. By 7-10 days out of the nest, they hunt from perches and begin to capture juvenile voles and shrews. By 20 days out of the nest, they are capable of wedging and impaling prey in trees and begin attacking insects and small birds in the air. They soon start to feed on bumble bees, wasps, and grasshoppers. At the end of the summer, they start taking mice and switch to birds a little later (Paruk et al. 2020).

Groups of independent juveniles may occur away from the nesting areas from July to early September. These are probably siblings and they may migrate together (Paruk et al. 2020).

MIGRATION

The Northern Shrike is an irregular, short-distance migrant, with movements occurring only during the day. It probably follows major river valleys out of the Boreal Forest Region and has been observed following ridge lines, coursing just above the treetops. Some years, most birds stay on or near the breeding grounds; other years there are large southward emigrations. During invasions, 2-5 times as many individuals migrate than in non-cyclic years. From 1900 to approximately 1950, it migrated in regular cycles, but the frequency of abundance became random thereafter. Peaks in numbers occurred approximately every 4 years in the first half of the 20th century, usually coinciding with Snowy Owl and arctic fox abundance. Prior to 1893, the interval between peaks was usually 3 years. By the 1940s, owl and shrike emigrations began to diverge, indicating that the reasons for the 2 species migrating were not the same. By the 1970s, there was no consistent pattern to emigrations, although they still occur. In Ontario, numbers counted on Christmas Bird Counts (CBC) peaked at intervals of 3-7 years with an average of 4 years until the 1970s. In Toronto in the 1930s, peaks occurred at intervals of 3-6 years, usually 4 or 5. Reasons for emigration are unclear, but they may be tied to low vole abundance on the breeding grounds. When there is a year of unusually high survival of fledglings during low vole abundance, there may be insufficient prey and many individuals may

be forced south (Cade 1967; Davis 1937, 1949, 1960a, 1974; Davis and Morrison 1988; Freedman and Riley 1980; Graber et al. 1973; Miller 1931; Paruk et al. 2020; Root 1988; Speirs 1939).

In southern Ontario, the Northern Shrike usually arrives in mid- to late October and leaves in mid- to late March, or early April in Algonquin Park (Curry 2006; Mills 1981; Tozer 2012).

Habitat used during migration is similar to that of the breeding season. The Northern Shrike may also occur on rural residential lots and in urban parks where there is a concentration of small birds or other suitable prey.

In Ottawa, a bird banded on 9 November 1985 was retrapped on 13 April 1986 suggesting that this shrike may exhibit site fidelity during migration (Rimmer and Darmstadt 1996).

The Northern Shrike is a rare migrant in Ontario (James 1991).

WINTER

The Northern Shrike prefers open habitats in winter, including grasslands, pastures, old fields, clear-cuts, burns, fencerows in agricultural areas, treed roadsides, shrublands, margins of wetlands and streams, and edges of sparse forests. It may be attracted to rural residential areas where bird feeders offer potential prey (Campbell et al. 1997; Hernández 1995; McIlwraith 1894; Weir 2008). In Idaho, shrike territories contained 4 habitat types: shrubland, grassland, agricultural land, and mesic habitat. Grasslands were used significantly more than expected. Each territory included 2 or 3 types of linear habitat such as rimrocks, roads, and riparian areas. Territories contained significantly greater lengths of roads and riparian corridors than occurred in general (Atkinson 1993). In Minnesota, 81% of shrikes were observed in wetlands with the remainder in upland areas including grasslands and woodlands. Of birds observed in wetlands, 38% were in thicket swamps and 31% each in marshes and mixed thicket swamps and marshes (Lee et al. 1992).

Shrikes used night roosts in their territories and stayed at individual roosts several times, although not necessarily on successive nights. All roosts were in deciduous trees or shrubs, particularly willow. Perches were on twigs an average of 1.5 m from ground, halfway between the trunk and edge of the canopy, regardless of tree height. All twigs used were surrounded by many stems that may have provided shelter from the wind. Roosts may also be used during day to escape from predators (Atkinson 1993).

Shrikes that move south for the winter maintain territories that may be occupied and defended for 4 months. In Idaho, territories averaged 216 ha, with core areas slightly larger than 50 ha. Territories were widely spaced and separated by an average of 1.4 territory diameters (Atkinson 1993). In Minnesota, home ranges in extensive areas of grassland and suitable habitat were about 1.25 km^2, and twice as large in less than ideal habitat (Lee et al. 1992). In northern Wisconsin, winter territories averaged 554.7 ha (range 289-889 ha) in a colder winter and 53.0 ha (range 18-93 ha) in the following winter, which was warmer (Paruk et al. 2020).

Limited data suggest that some birds may exhibit site fidelity to wintering areas. The information is based on band recoveries that are typically reported as 10' blocks. A bird recovered in the same block may have occurred at the same site as previously, or as far away as 37 km. Of 17 birds recovered the following year, 71% were in the same block. One Ontario bird was recovered in the adjacent

block (Rimmer and Darmstadt 1996). The study demonstrated that birds may return to the same general wintering area. To date, there is no evidence that individual birds home to the same wintering sites. In Idaho, the same winter territories were occupied each year, but no banded birds returned to the same territory. Further studies in Idaho revealed that some individuals used the same area for as many as 6 winters (Paruk et al. 2020). When a bird died, its territory was soon reoccupied, suggesting high demand for good quality habitat (Atkinson 1993). Paruk et al. (2020) stated that some winter territories were occupied traditionally, but it is unknown if the same birds were involved. Some territories are used frequently, but not every winter. Apparently some birds switch territories over the winter, depending on weather, food availability, and opportunity to acquire a better territory if 1 bird disappears. Some birds do not establish territories and wander throughout the winter.

In winter, the primary hunting technique is still sitting on a perch watching for prey. Due to limited food resources, the Northern Shrike uses additional methods in winter. It may be more successful and determined in aerial pursuit of birds. It may chase small birds in air until they tire and are overcome. In Ontario, it has been seen scavenging a recently killed red squirrel and eating a bat that may have either been captured or was carrion. It has been documented eating carrion and suet in winter (Bent 1950; DiLabio 1996; James and Harrison 1987; Pittaway et al. 1992; Stronks and Stronks 2020). In Utah, A. Smith (1991) observed that the same impaling sites may be reused.

The winter diet is about one third small mammals with birds comprising most of the food. In the south, meadow voles are preferred, but the Northern Shrike may alos consume white-footed, house, and deer mice. House Sparrows, juncos, and tree sparrows are staples of the winter diet. Other birds present in Ontario in winter that it may eat are Downy Woodpecker, Hairy Woodpecker, Rock Pigeon, Mourning Dove, Canada Jay, Blue Jay, Horned Lark, Black-capped Chickadee, Tufted Titmouse, kinglets, waxwings, European Starling, Snow Bunting, Lapland Longspur, Northern Cardinal, Pine Siskin, Redpoll, crossbills, Pine Grosbeak, Evening Grosbeak, and American Goldfinch (Atkinson and Cade 1993; Bent 1950; Cade 1967; Paruk et al. 2020; Graber et al. 1973; Kinch 2006; Paruk et al. 2020; Weir 2008). Where they are available, the Northern Shrike may feed on invertebrates, including caterpillars, orthopteran nymphs, beetles (especially ground beetles), ants, wasps, bees, flies, and spiders (Paruk et al. 2020).

Cade (1967) concluded that winter food might be the main limiting factor to Northern Shrikes in Alaska. Nesting success was very high, yet populations remained low. In winter, no insects are available, small mammals are protected by snow cover, and small bird populations are low.

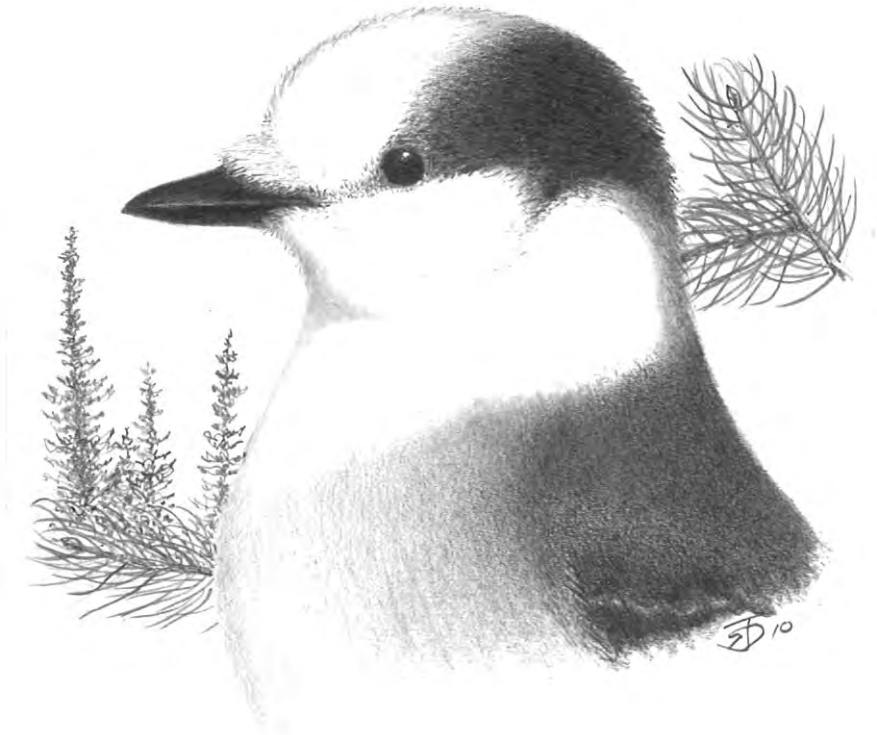
There may have been a reduction in the amount of suitable wintering habitat for the Northern Shrike. Forest regeneration, urbanization, and intensive agriculture have reduced the amount of early successional habitat (Paruk et al. 2020).

Historically, the Northern Shrike was frequently destroyed because it fed on birds and impaled its prey; it was known as the butcher bird. In the 1870s, the City of Boston hired people to shoot them to protect House Sparrows and 50 were shot in 1 year. In the 1920s, most bird banders killed them instead of banding and releasing them (Bent 1950; Davis 1937). Human destruction is no longer a significant problem.

The Northern Shrike is rare in winter (James 1991). Freedman and Riley (1980) suggested it had increased in abundance on CBCs since 1952, but this may have been an artifact of better coverage by observers. The CBC has no current trends for this species (National Audubon Society 2022).

Canada Jay

Perisoreus canadensis

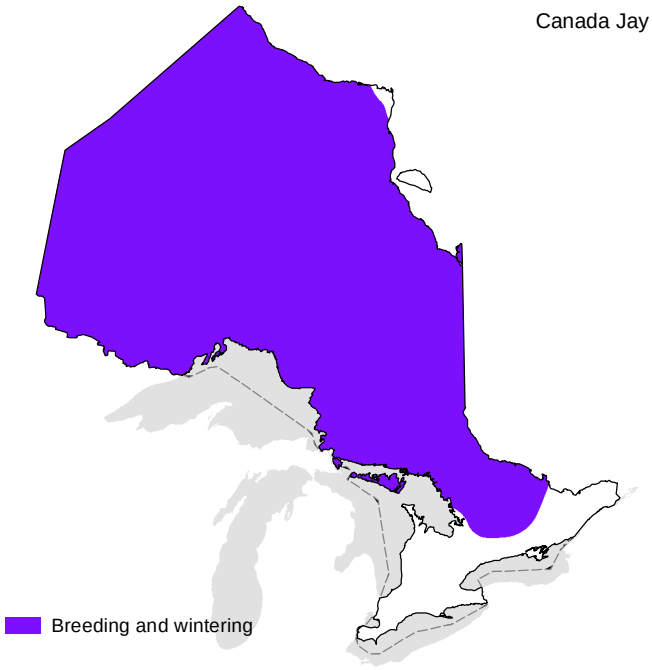


BREEDING SEASON

Habitat Requirements

In Ontario, the Canada Jay breeds most frequently in coniferous (47.3% of nests) and mixed (45.5%) woods, seldom in deciduous forests (7.3%). It commonly nests near water and in spruce bogs, but nests are almost as common in dry areas. Presence of favoured nest-tree species appears to be the dominant factor in selecting nesting habitat. It prefers open situations such as forest edges, shorelines, clearings, bogs, beaver meadows and ponds, and roadsides over dense, closed woodlands (Peck and James 1987).

In the Boreal Forest Region near Pickle Lake, the Canada Jay occurred in predominantly coniferous forests, and was representative of spruce forests (James 1980; McLaren and McLaren 1981). Near White River, it occurred most frequently in clear-cuts 18-20 years old, but was not significantly more abundant in these stands than clear-cuts 3-15 or 23-25 years old or mature stands



40-100 years old (Venier and Pearce 2005). In the Clay Belt, it was abundant in a variety of stands, including those dominated by black spruce, jack pine, and trembling aspen. It occurred over a wide moisture gradient, from very wet to dry and in sites that were poor to rich in nutrients (Welsh and Lougheed 1996).

In the Great Lakes–St. Lawrence Forest Region in the Canadian Shield, the Canada Jay was uncommon in jack pine stands near Parry Sound and Gogama. It may not have nested in pines, but occasionally foraged in them with nesting occurring in adjacent spruce swamps (James 1979a; James and Peck 1995a). In Algonquin Park, preferred habitat is coniferous forest, particularly spruce and spruce-tamarack stands with small- to medium-sized trees. Black spruce bogs are used most consistently. Upland mixed forests of trembling aspen, white birch, balsam fir, and white spruce are inhabited, but less favoured. It may forage in pure hardwoods, but most territories contain at least 50% conifers. It avoids areas dominated by sugar maple unless they contain corridors of spruce (Rutter 1969; Strickland and Ouellet 2020). Sugar maple stands were abandoned as breeding habitat in Algonquin Park in the 1970s-90s (Strickland and Ouellet 2020). In Mer Bleue, breeding occurred in a large, open bog with small isolated clumps of black spruce and tamarack (Ouellet et al. 1976).

The Canada Jay is characteristic of the Boreal Forest Region and is strongly associated with spruce stands and spruce bogs. In Alberta, it was equally abundant in young, mature, and old-growth aspen stands, many of which contained balsam fir. In Quebec, it was equally abundant in young clear-cuts and burns and forests 120 years old. It occurs in a wide range of forest ages, from very young to mature, with a tendency to prefer older stands. Fir stands are used frequently, with lesser use of tamarack and white cedar forests. In Saskatchewan and Michigan, it also nests in jack pine stands. Although most breeding is in coniferous or mixed forests, a few occur in rural areas of British Columbia, where it prefers edges of extensive forests, avoiding dense forest. Where conifers are scarce on the prairies or in the north, it may nest among aspens and willows (Bent 1946; Campbell et al. 1997; Dawson 1979; Erskine 1977; Imbeau et al. 1999; Kirk et al. 1996; Manning and MacPherson 1952; Niemi and Pfannmuller 1979; Schieck et al. 1995; Strickland in Gauthier and Aubry 1996; Strickland and Ouellet 2020; Thompson et al. 1999). In Newfoundland, 62% of captures of Canada Jays were in areas where openings were natural features, such as peatlands, compared with 38% in areas where openings were clear-cuts (Whitaker et al. 2008). Also in Newfoundland, it was most abundant on forest edges created by roads or clear-cuts. It was less than half as abundant in forest interior as on edges, and was absent in riparian forests. Although it was absent in undisturbed

riparian forest, it occurred in low numbers in 20-50-m-wide riparian buffer strips left between aquatic habitat and clear-cuts. The forest cover was dominated by balsam fir 50-100 years old (Whitaker and Montevecchi 1997, 1999). In coniferous forests in British Columbia, it exhibited no significant distribution relationships to riparian habitat. It tended to avoid riparian habitat in winter and spring, which includes the breeding season, and to be attracted to riparian habitat in summer and autumn (Wiebe and Martin 1998).

In Algonquin Park, habitat quality is related to the proportion of coniferous trees within territories because of their superior ability to preserve cached food over deciduous trees (Strickland et al. 2011). Canada Jays have higher reproductive success on territories with more conifers. Juveniles that recruited into the study area were more likely to disperse to territories with similar abundance of conifers as on their natal area. The exception was for juveniles born in low-conifer areas, who were more likely to disperse to areas with a higher proportion of conifers. When adults dispersed, they moved to territories with higher proportions of conifers (Norris et al. 2013).

Ralston et al. (2019) surveyed for the Canada Jay in 20 plots in boreal forest habitat in New York, Vermont, Maine, Nova Scotia, and Newfoundland. It occurred at 10 of the sites, indicating broader habitat preferences than many species and an ability to use multiple boreal forest habitat types. It was associated with peatlands, black spruce, tamarack, and taller canopy cover.

The Canada Jay roosts close to the trunk of a well-foliaged spruce or balsam fir at night (Strickland and Ouellet 2020).

All nests reported to the Ontario Nest Records Scheme were in live coniferous trees: 48.4% in black spruce, 25% each in white spruce and balsam fir, and 1.6% in hemlock. Of 652 nests in Algonquin Park, 57.4% were in black spruce, 28.4% in balsam fir, and 13.5% in white spruce. Two nests were in hemlock and 1 was in a white pine. Both large and small trees were used for nesting. Most nests were against the tree trunk in crotches of lateral branches (77.8%). The remainder were 1-4.6 m from the trunk on horizontal branches. In Algonquin Park, 96% of nests were touching the tree trunk or separated from it by less than 1 nest diameter; the rest were well out on horizontal branches, usually in white spruce. Nests were 1.2-15 m from the ground, mostly 2.4-6.1 m up. The average height of nests in Algonquin Park was 6.0 m with a range of 1.6-25 m (Peck and James 1987; Strickland and Ouellet 2020).

Nests are very often at an edge, such as a bog, beaver pond or meadow, forest clearing, road, or building. Nests tend to be on the northern side of openings, 1 or 2 trees in from the edge. They are usually well concealed, but on the southern side of the tree where there is sufficient clearance to allow the late winter sun to reach the nest and give birds a free flight path. Almost all nests are in conifers, especially spruce, but western birds occasionally nest in willows and trembling aspen. Nests have been found 0-31 m from the ground, usually 1-6 m up. Snow depth may be as great as 1 m when nesting is initiated, so some nests are very close to the snow's surface. A new nest is almost always built. One pair relined a 3-year-old nest that had held eggs but not nestlings. Nests abandoned during construction or incubation are stripped of most soft materials for use in replacement nests. Nests in early phases of construction are occasionally abandoned; 1 of these was

used the following year (Bent 1946; Campbell et al. 1997; Lawrence 1947, 1968; Ouellet et al. 1976; Parmelee 1988; Rutter 1969; Strickland and Ouellet 2020; Walley 1987).

The Canada Jay defends a year-round, permanent territory. Its territory size is considerably larger than expected based on its body size. This may be due to the necessity of having sufficient food caches to ensure winter survival at a density low enough to avoid high losses due to cache predators. Average territory size was 129 ha in Algonquin Park, where territories may not be contiguous due to intervening marginal or unsuitable habitat. Other reported average territory sizes are 69 ha in La Vérendrye Park in Quebec, 65 ha in Manitoba, 23.2-41 ha in the Yukon, 27 ha on Anticosti Island, and 80 ha in another Quebec area. Birds tend to remain in core areas that are less than half the territory size (about 40-70 ha in Algonquin Park), but the entire territory is vigorously defended. Territorial boundaries remain constant year to year and successive nests are placed within 100-200 m of each other in the core area. Annual internest distance averaged 1,260 m in Algonquin Park, 890 m in La Vérendrye Park, 600 m in Alberta, and 1 km in Alaska (Desrocher 2000; Parmelee 1988; Rutter 1969; Shank 1986; Strickland 1992; Strickland and Ouellet 2020).

Occasionally juveniles breed on the natal territory, but only if both parents have disappeared. Usually they acquire a territory by moving from territory to territory until they can fill a breeding vacancy. Young have acquired territories as far as 11 km from their natal area. In Colorado, where mortality was high, dispersal was almost nonexistent because there were always unoccupied territories. Mean maximum dispersal distances were 208 m for juveniles and 265 m for adults (Ha and Lehner 1990; Strickland 1991, 1992, 2002, 2003; Strickland and Ouellet 2020; Strickland and Waite 2001).

Adult site fidelity is extremely high, with most birds spending their entire life on the same territory. Successive nests are placed in the core of the territory within 100-200 m of each other. One male occupied the same territory for 6 years despite losing 2 mates. Occasionally widowed birds move as far as 10 km to fill breeding vacancies elsewhere due to lack of replacement birds. Rarely, established birds may be displaced or switch territories. One male in Algonquin Park occupied a territory for 4 years with 2 different females, but was displaced to an adjacent marginal territory the following year. Three pairs moved into newly vacant neighbouring territories (Rutter 1969; Strickland 1992; Strickland and Ouellet 2020).

Limiting Factors

The Canada Jay is one of the earliest nesting birds. Eggs have been reported in Ontario nests from the second week of March until the first week of May, with most present from the last week of March until mid-April (Peck and James 1987). In Algonquin Park, nests are under construction from late February to early April, eggs are present mainly from late March to mid-April with extreme dates from late February to mid-May, and nestlings typically occur from mid-April to early May but may be present from mid-March to early June (Tozer 2012). In Algonquin Park, fledging dates of nestlings were from 17 April to 26 May (mean 1 May; Fuirst et al. 2024).

Both sexes build the nest, which typically takes 2-3 weeks and occasionally as long as 4 weeks; nests may rarely be built in 1 week. Several days usually elapse between nest completion and laying of the first egg. Eggs are laid at the rate of 1 a day. The mean date of the first egg at 581 Algonquin

Park nests was 23 March and also 23 March at La Vérendrye Park. Incubation begins with laying of the first egg, but effective incubation starts with laying of the last or penultimate egg; all eggs hatch on the same day. The incubation period is 16-20 days, and appears to be 18.5 days in Algonquin Park. Young leave the nest when they are 22-24 days old. Reports of young leaving the nest at age 17-20 days may have been due to regular handling of the birds (Bent 1946; Campbell et al. 1997; Lawrence 1947; Madge and Burn 1994; Ouellet et al. 1976; Peck and James 1987; Rutter 1969; Strickland and Ouellet 2020).

A single brood is raised annually. Replacement clutches may be laid if the loss occurs before 10 April; a new nest may be built and egg laying initiated within a week. In Algonquin Park, 1 pair that had access to a feeder successfully raised 4 young on the third attempt. Clutches of 1-5 eggs have been reported in Ontario, with most containing 3 eggs. The 1-egg clutch was produced by a yearling female that had moved into an unfamiliar territory and was breeding for the first time. Mean clutch sizes were 3.0 eggs in Algonquin Park and 3.2 in La Vérendrye. Elsewhere, clutches of 1-6 eggs have been documented. The normal clutch is 2-4 eggs, with 3 eggs most frequent (Bent 1946; Campbell et al. 1997; Lawrence 1947; Madge and Burn 1994; Ouellet et al. 1976; Peck and James 1987; Rutter 1969; Strickland in Gauthier and Aubry 1996; Strickland and Ouellet 2020).

Both sexes can breed when they are 1 year old, but most males do not have the opportunity until they are 2 years old. In Algonquin Park, 1-year-old males may attract a mate and breed in unoccupied, marginal habitat, but most yearling males do not breed in good, saturated habitat. Mean age of first breeders at Algonquin Park was 1.76 years for males and 1.5 years for females. Three percent of males did not breed until they were 3 years old. Nonbreeding birds, usually males, may accompany pairs during the breeding season; typically only 1 per pair. Although they are excluded from the nest area during nest building, incubation, and the nestling period, they often feed fledglings. These birds are often young of the adults from the previous year that have been unsuccessful in acquiring a territory. The Canada Jay is monogamous, and pairs remain together year round and remain mated as long as both are alive. Members of a pair are rarely apart. There are some exceptions. One Ontario male, whose mate was incubating, built a nest with another female that had moved into his territory; both nests failed. Three cases of divorce have been documented. If a mate is lost, the survivor remates (Ha and Lehner 1990; Strickland 1991, 1992, 2002, 2003; Strickland and Ouellet 2020; Waite and Strickland 1997).

The Canada Jay forages by scanning from perches. When potential prey is seen, it flies to a nearby branch, tree trunk, the ground, or shallow water before seizing it. Forest edges less than 30 m wide are prime foraging locations because it is a nest predator. In Quebec, groups of Canada Jays were closely associated with forest edges in summer. This association occurred regardless of the amount of forest within their home range, which varied from 20-94%. Jays with the most forest cover in their home range were more strongly associated with edge. Seventy-six percent of jay locations were less than 30 m from edge, although only 46% of forest was within 30 m of edge. Jays travelled more slowly along edges where foraging success was presumably greater than away from edges. In the Mackenzie District of the Northwest Territories, 97.4% of foraging occurred in conifers at an average height of 6.9 m. The Canada Jay may land on the backs of live moose to get engorged winter ticks, and snap up flying insects flycatcher-like. Occasionally, it tears up wasp nests to eat the

contents. It usually ignores small birds, but occasionally chases after them, usually unsuccessfully. It has extremely large saliva glands that secrete mucous. Food that is not consumed immediately is coated in mucous to create a bolus, which is then hidden. Caches are deposited singly in trees behind flakes of bark, under tufts of lichen, in coniferous foliage, or in tree forks, typically 3-15 m from the ground. Most food storage occurs in the territory, but occasionally in neighbours' territories. In Alaska, it may make more than 1,000 caches per day, but fewer are made in the south of its range. Caching is done any time when a surplus of food is acquired. These stores are essential to winter survival. In Minnesota, caching began in August and continued until early May. No caching was observed from early May until the end of July during leaf-out and the peak of insect activity. The early breeding season may be an adaptation to allow enough time to store food for the upcoming winter (Barnard 1996; Bock 1961; Desrochers 2000; Dow 1965; Greenberg et al. 1999; Ibarzabal and Desrochers 2004; Lawrence 1968; Rogers 2005; Rutter 1969; Strickland 2003; Strickland and Ouellet 2020; Tozer and Allen 2004; Waite 1988).

The Canada Jay is an opportunistic omnivore, but feeds extensively on insects during the breeding season, especially lepidopterans. Grasshoppers may form a considerable portion of the diet. Food brought to nestlings is a dark, viscous paste coated with saliva. It is mostly arthropods. The stomach of 1 nestling contained remains of 75 spiders and insects including larvae of geometer and owlet moths, flies (flower, crane, and horse flies), and beetles (weevils and predaceous diving and ground beetles). Aquatic invertebrates or those inhabiting damp soils were most frequent in nestlings' diets. Nestlings may be fed from caches as emergency food during late winter snowstorms. Of 67 stomachs of fledglings and adults, 31% contained fur or bone from small mammals (shrews and red-backed voles), 76% contained berry seeds, and 82% contained arthropods. In Algonquin Park, fecal samples from nestlings contained 2% vertebrates (wood frog and masked shrew), 74% arthropods, and 24% plants. Spiders and lepidopterans represented the majority of food items but the most common food items were blueberries. Twenty-eight percent of nestling food items were likely from winter caches. The most common invertebrates eaten by adults were beetles, hymenopterans, bugs, lepidopterans, flies, grasshoppers, spiders, and centipedes. In Alaska, it consumed 2.5 times more invertebrates in spring than in autumn and 5.5 times more vertebrate flesh and 2 times more berries in autumn than in spring. In Maine, 15% of food items within stomachs were spruce budworm larvae and pupae during a budworm outbreak. It takes winter ticks from infested moose and engorged ticks that have fallen off. It takes eggs and nestlings from a wide variety of species, to those as large as thrushes and grouse chicks, and there are 2 records of it killing and eating independent juvenile Magnolia Warblers. Recently fledged birds may be more important to the diet than observed. Although seldom recorded, the Canada Jay kills and consumes small rodents and this may be an important component of the diet. It also eats frogs, toads, and snakes. In Oregon, it fed on salamander larvae in small woodland pools. It has been observed attacking a wounded Green-winged Teal and a blood-stained weasel and wresting a nursing hoary bat from its roosting mother. It eats a wide variety of berries, especially those of false solomon's-seal, Canada mayflower, blueberries, elderberries, bearberry, sumac, viburnums, juneberries, and mountain-ash. Fungi and lichens are eaten and fungi are commonly stored, including slime moulds. Spruce seeds are not extracted from cones, but are eaten if found on the ground. Carrion is vital to its survival, especially when other food sources are scarce. It may eat or

store carcasses of fish, birds, bears, seals, caribou, deer, moose, and small mammals, and also consumes maggots on carcasses. There is often interspecific territoriality at large carcasses. The Canada Jay displaces the Blue Jay, but is displaced by the Common Raven. The Canada Jay is well known for taking table scraps and other food from humans. It drinks water when it is available and also eats snow. In New Brunswick, abundance of the Canada Jay was unrelated to abundance of the spruce budworm (Addison et al. 1989; Barnard 1996; Bowers and Farley 1990; Derbyshire et al. 2019; Gilmore 1996; Madge and Burn 1994; McIlwraith 1894; Mitchell 1952; Morris et al. 1958; Murray et al. 2005; Ouellet 1970; Rutter 1969; Strickland 1996; Strickland and Ouellet 2020; Sutton et al. 2024; Swift et al. 2022).

Habitat loss may be a factor at the southern extent of the range. Through natural succession, coniferous stands gradually are replaced by deciduous species, making habitat marginal or unsuitable.

Vanderwel et al. (2007, 2009) summarized studies that examined the effects of partial timber harvesting in the Boreal Forest Region on the Canada Jay with particular reference to Ontario. They reported no change in its abundance when 30%, 50%, or 70% of trees were removed. In the Boreal Forest Region of Alberta, it increased significantly compared with control plots when 50% of trees were removed from stands dominated by white spruce (Harrison et al. 2005). In Oregon, Douglas-fir forests were thinned from more than 650 trees per ha to 180 trees per ha. The Canada Jay increased after thinning and had higher populations for 7 years after thinning. By 12 years after thinning, populations were similar to pre-management conditions (Hagar et al. 2024). In Ontario, there was no difference in its abundance between burned and clear-cut stands in early successional or mid-successional forests. There was no difference in its abundance in mature and early successional stands, but it was significantly more abundant in mid-successional than mature stands (Zimmerling et al. 2017).

In Algonquin Park, survival rates of Canada Jays were consistently lower on territories adjacent to highways. Several carcasses of birds were recovered beside the highway that runs through it, indicating collisions with vehicles. During spring and summer, survival on highway territories was 4% lower than on territories distant from the highway for both adults and juveniles. During autumn and winter, mortality increased by 6% for juveniles and 2% for adults on territories adjacent to the highway. Jays exhibited no tendencies for directional dispersal away from the highway. Highways may act as an ecological trap for the Canada Jay (Norris et al. 2013).

There is evidence that the Canada Jay is declining at the southern edge of its range, possibly due to climate change. Warmer temperatures may result in degradation of the perishable food items that are used during late-winter nesting (Strickland 1992, 2014; Strickland and Ouellet 2020). In Algonquin Park, females began gaining weight 9 days prior to egg laying and the rate of weight gain was best explained by the percent coverage by conifers in the territories. The weight gain was due to consuming food that had been cached 4 or more months previously. This provides support for previous studies demonstrating that coniferous trees are better at preserving cached foods. Preservation time of food items placed on trees by researchers was longer on black spruce than on sugar maple. Food stored at Cochrane, several hundred kilometres north of Algonquin Park, lasted significantly longer under the cooler temperatures experienced there (Sechley et al. 2014, 2015;

Strickland 2014). In Alaska, cached food was recovered within 4 weeks. Jays responded to a record-breaking warm spring by foraging on emerging insects rather than caches. It may be better adapted to changes in cache integrity and food availability than previously thought (Swift et al. 2022). Warmer temperatures may favour growth of deciduous trees over conifers. In the Boreal Forest Region of eastern Quebec and Labrador, the Canada Jay was associated with forest stands with relatively low temperatures (DesGranges and LeBlanc 2012).

In Newfoundland, annual survivorship of the Canada Jay was slightly lower in forested landscapes where openings were clear-cuts than in forests where openings were peatlands and other natural features (Whitaker et al. 2008).

Walker and Marzluff (2015) examined the response of the Canada Jay to factors associated with human recreation in Washington. Its probability of detection increased in forests with at least some canopy cover compared with open sites with little or no canopy. Detection rates were greater at quiet sites compared with those with at least moderate noise. The probability of an area being used increased with greater patch richness within 5 km and it was most likely to use areas with high percent forest cover within 5 km. Probability of use was greatest in trail zones and least in day-use areas compared with backcountry areas and it was 118% more likely to use areas with greater numbers of visitors. Usage increased with distance to the nearest campground. It commonly used areas where food subsidy was available and the odds of use increased with the availability of anthropogenic food. In general, it used areas with food subsidy in high-elevation forests away from most recreational infrastructure. Food availability may allow for local increases in its presence.

In Alberta, the Canada Jay was significantly more abundant at seismic lines than in adjacent forest interior. There was no difference in its abundance at pipelines and well pads than in forest interior adjacent to these features. There were no differences in its abundance near noisy compressor stations and quiet well pads (Bayne et al. 2008, 2016).

The Canada Jay is extremely vulnerable to being caught in traps set for furbearers. New baits are being devised to help alleviate this problem (Manning and MacPherson 1952; Porsild 1943; Strickland and Ouellet 2020).

Status

McIlwraith (1894) considered the Canada Jay a common resident in Muskoka District. Baillie and Harrington (1937) stated that it bred from Algonquin Park north to Severn River and Cape Henrietta Maria, and west to Kenora. James (1991) considered it an uncommon to common permanent resident in the north, becoming rare in the Canadian Shield south to Parry Sound and central Peterborough County. There are breeding records from Mer Bleue in Ottawa and southern Peterborough County, and there is a breeding population on Manitoulin Island (Ouellet et al. 1976; Peck and James 1997; Strickland in Cadman et al. 1987).

The second atlas demonstrated that there had been no change in the Canada Jay's distribution since the first atlas. Its probability of observation increased significantly province-wide, in the Boreal Forest Region, and in the Hudson Bay Lowland. There was no significant change in the Great Lakes–St. Lawrence Forest Region in the Canadian Shield, although there was considerable turnover in the squares where breeding evidence was reported. The atlas results are contrary to more detailed

studies in Algonquin Park that indicated a 60% decline in territory occupancy. Highest abundance occurred in the northern portion of the Boreal Forest Region and in the Hudson Bay Lowland (Strickland in Cadman et al. 2007).

Since the 1980s, the Canada Jay has disappeared from many formerly occupied territories in Algonquin Park and southern Quebec. This may be a reflection of the marginal deciduous habitat or unknown pressures on a species at the extreme south of its breeding range, such as climate warming (Strickland and Ouellet 2020). Forty-three territories have been surveyed annually in Algonquin Park since 1964 and only 19 (44.2%) were occupied in 2014. Some are now dominated by hardwood tree species, but many unoccupied territories still contain much coniferous cover (Strickland 2014).

Long-term (1970-2021) population trends indicated by the Breeding Bird Survey were annual decreases of 0.367% in Canada and 0.284% in Ontario. The short-term (2011-21) trends were annual decreases of 0.22% in Canada and 0.417% in Ontario. The data were of medium reliability for the short-term Canadian results; the other results were of low reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Young start climbing out on branches 1-2 days prior to fledging. They can fly 10-30 m in level or ascending flight when they leave the nest. Recently fledged birds are mostly inactive and usually huddle close together along a branch close to the trunk of a conifer. Occasionally, the group flies 50-100 m to another similar site where they huddle together again. The family begins to travel as a group 18-21 days after the young fledge (at age 42-45 days). Partial dispersal of fledglings occurs when they are 55-65 days old. Once fledglings are that old, they start to fight among themselves until one becomes dominant and expels its siblings from the territory. About two thirds of dominant siblings are male. Expelled birds may attach themselves to a pair that was unsuccessful in fledging young. Fledglings that are unsuccessful in joining a pair have very low survival potential because there is usually insufficient time to store enough food for the winter. Dominant fledglings remain with the parents until early March when they are expelled at the beginning of the breeding season. They subsist over winter chiefly on food that the adults have cached. Juveniles use the natal or adopted territory to prospect for their own territory (Strickland and Ouellet 2020). In Algonquin Park, dominant juveniles had an 80% chance of reaching adulthood compared with 47% of expelled juveniles. Dominant juveniles produced more fledglings over their lifetime than expelled juveniles (Fuirst et al. 2023).

During the postbreeding period in Algonquin Park, adults strongly preferred forest-wetland edges and exhibited a weak preference for coniferous forests. They used mixed forests and wetlands in proportion to their availability and exhibited a weak avoidance of tolerant hardwood forests. The mean home range size of 12 adults was 84 ha with a range of 35-201 ha (Fuirst et al. 2022). The mean home range of fledglings that remained on the natal territory was 48 ha with a range of 10-140 ha (Fuirst et al. 2024).

AUTUMN

The Canada Jay is essentially non-migratory, with no reports of breeding territories being vacated in winter. Nonetheless, there are occasional wanderings and major incursions to the south some years;

reasons for this are unknown. A large invasion occurred in southern Ontario the winter of 1839-40. Birds appeared in the Toronto area in 31 years from 1825 to 2022, with multiple birds observed in 21 of these years. When flights to the south occur, birds typically arrive in October through to late January and depart in March. Incursions may result in isolated breeding records far south of the normal breeding range, as occurred at Mer Bleue after the winter of 1972-73. Large numbers were seen in southern Ontario in the winter of 1905-06, and this occurred about once every 20 years thereafter (Coady 2023; Fleming 1907; Ouellet et al. 1976; Saunders 1930a; Strickland and Ouellet 2020; Weir 2008). During an autumn flight in 2010, at least 90 of 120 birds (75.0%) were hatch-year birds (Strickland and Ouellet 2020). Major flights have occurred outside of Ontario. In southern Minnesota, major flights occurred in the winters of 1929-30, 1974-75, 1976-77, 1985-86, and 1986-87 (Janssen 1987), and there was a major flight near Godbout, Quebec in September 1884 (Bent 1946). Campbell (1965) reported thousands in the Moisie Bay area of Quebec with the flight lasting from mid-August until late October, with as many as 250 per hour passing by. Flights occurred every autumn there, originating in northeastern Quebec and Labrador, moving south to the coast, then westward and finally northwestward, possibly returning to the same area. Birds may congregate along the north shore of Lake Superior from mid-September to late November. There are 2 reports of northward spring migration from mid-May to early June at Whitefish Bay on the south shore of Lake Superior (Strickland and Ouellet 2020).

During autumn, the Canada Jay is attracted to areas where humans are present and provide a potential source of food, such as ski resorts, campgrounds, bush camps, and traplines (Campbell et al. 1997). It regularly visits hunt camps in search of handouts. Fat and entrails from big game that has been shot is an important food source. Fruit, such as chokecherries, is collected and stored at this time (Rutter 1969).

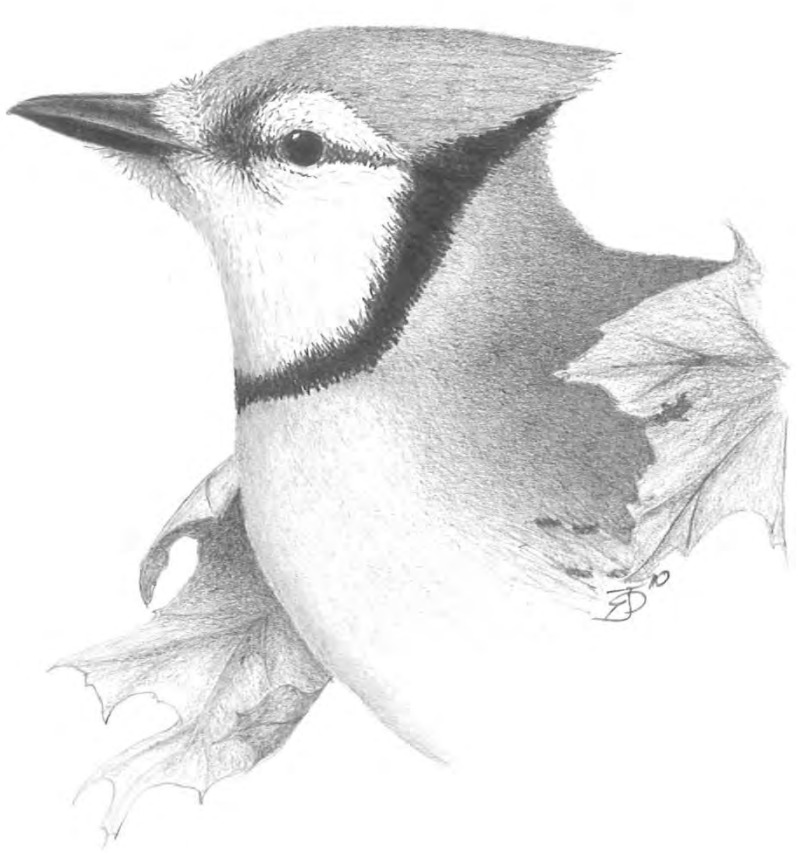
WINTER

In winter, carrion and stored food are the mainstays. In remote areas, wolf kills of deer, caribou, and moose are important to the Canada Jay as are road-kills. It readily comes to winter bird feeders and may cross 2 territories to reach them. It eats a wide variety of food at feeders and prefers suet, bread, meat scraps, cheese, baked beans, oatmeal, and peanut butter mixes. Occasionally it eats sunflower seeds, nuts, mixed seeds, and raisins. Lichens may be consumed in winter, but may be subsistence food (Bent 1946; Dow 1965; Dunn and Tessaglia-Hymes 1999; Rutter 1969; Strickland and Ouellet 2020; Whittam and Francis 2000).

Data from Project FeederWatch counts indicate that the percentage of feeders visited by Canada Jays has been declining since the peak in 1999 when 13% of feeders Canada-wide were visited (Wilcox 2006). Christmas Bird Count data indicated annual decreases in Ontario of 0.95% 1970-2021 and 2009-21 (National Audubon Society 2022).

Blue Jay

Cyanocitta cristata

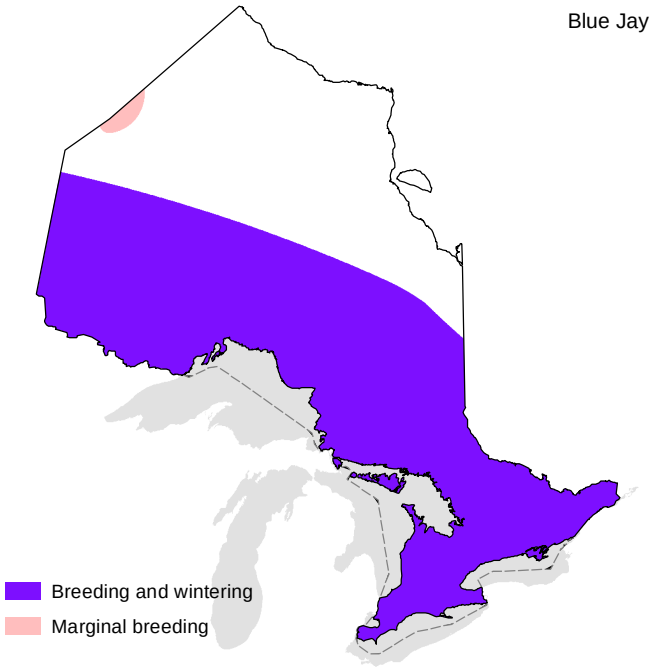


BREEDING SEASON

Habitat Requirements

Ontario Blue Jay nests were in and at edges of treed areas, with 24.7% of nests in mixed, 15.2% in deciduous, 7.4% in coniferous, and 12.4% in unspecified woodlands. Other nests were in urban and rural gardens, parks, and schoolyards (24.1%); in old fields and fencerows (10.6%); at edges of marshes, rivers, and lakes (2.8%); in orchards (2.1%); and along roadsides (0.4%). Although the Blue Jay occasionally nested in swamps, most nests were in upland areas (Peck and James 1987).

In the Boreal Forest Region, the Blue Jay nests in upland mixed forests and may occur in clear-cuts that are only 5 or 6 years old as well as in mature forest (Kendeigh 1947; Venier et al. 2009; Welsh and Fillman 1980).



In the Great Lakes–St. Lawrence Forest Region in the Canadian Shield, the Blue Jay commonly nests in mature and old-growth stands of white pine (Kirk et al. 2012). In jack pine stands near Gogama, it was uncommon and seen mostly in deciduous portions of mixed woods. It occasionally foraged in pines, but did not appear to nest in them. Breeding could have occurred in any mixed forest 15-20 or more years old (James and Peck 1995a). Of 5 plots of jack pine stands in Parry Sound District, it was absent in 4 and occurred at low density in an open, 5-8-m tall jack pine stand mixed with trembling aspen, white birch, white pine, and sugar maple (James 1979a). In Algonquin Park, it was absent in bogs, black spruce–white cedar woods, and pure hemlock forests. It occasionally occurred in black spruce, balsam fir–spruce, birch-poplar, and pure hardwood forests, but may not have been a breeding species. It occurred regularly in birch-poplar-fir-spruce and fir-spruce stands (Martin 1960).

In the Great Lakes–St. Lawrence Forest Region south of the Shield in Durham Region, it occurred in all forested plots, including mixed and deciduous stands, black spruce bog, upland and lowland forest, and disturbed, open stands to closed mature stands. Greater densities occurred in drier stands and in young, disturbed stands. It was a mid-succession species (Speirs and Orenstein 1975). In the Kingston area, it occurred in every square that contained trees during the atlases. It nested within most cities and towns, especially within conservation authority lands (Weir 2008). The Blue Jay is a habitat generalist and may be found in most forested areas within the Great Lakes–St. Lawrence and Carolinian forest regions, including those in urban areas.

In southern Ontario there was no difference in the Blue Jay's abundance on organic and conventional farms. Its presence was significantly associated with corridors such as roads, railways, and power line rights-of-way and the number of large, isolated trees (Kirk et al. 2011).

Habitat reported elsewhere is similar to that in Ontario. Until the early 20th century, the Blue Jay nested predominantly in forests and orchards, but numbers in residential areas are now frequently higher than in mature forests and orchards are rarely used. Although it is almost ubiquitous within its core range, it exhibits some habitat preferences. It prefers mixed to deciduous forests. Pure coniferous forests and plantations are seldom used, or it is present in these habitats in low numbers. It prefers forest edges to interior, and prefers stands with widely spaced trees. In Wisconsin, it is one of the most abundant species in pine and oak barrens, and occurs regularly at edges of moderately open barrens. It is characteristic of savannahs in that state. Most studies determined that it prefers younger forests to mature stands. Near Manitouwadge, however, it was equally abundant in young

clear-cuts, intermediate-aged stands and mature and old-growth stands. In Alberta aspen stands, it was equally abundant in stands of all ages. In Wisconsin, it was most common in pioneer stands. When it occurred in mature stands, they tended to be more open-canopied, with second-generation trees in the subcanopy. In the Pennsylvania Appalachians, it was negatively associated with old-growth forests. In forests, it selects areas with a dense understorey, or nests in undergrowth at edges of forests. After agricultural land is abandoned or forest clear-cutting occurs, it becomes established 10-20 years later once there is some shrub and sapling cover, reaches greatest abundance at 40 years then declines. It inhabits forests over the full range of moisture regimes, but greatly prefers and reaches its highest density in upland xeric stands. These forests are most likely to contain favoured mast-producing trees such as oaks, beech, and hickories. In suburban areas, best habitat occurs in areas with mature trees, especially oaks. Ornamental coniferous trees may provide suitable nest sites and lawns may be important for storing food. In New Hampshire and Maine, abundance of the Blue Jay was positively correlated with the number of coniferous trees 2-10 cm diameter at breast height. It was negatively correlated with canopy closure (Anderson and Shugart 1974; Back 1979; Beals 1960; Bielefeldt and Rosenfield 1994; Bond 1957; Campbell et al. 1997; Capen 1979; DeGraaf et al. 1998; Faanes and Andrew 1983; Graber and Graber 1963; Graber et al. 1987; Haney 1999; Hoffman 1989a; Kirk et al. 1996; Langevin and Dauphin in Gauthier and Aubry 1996; Mossman and Hoffman 1989; Mossman et al. 1991; Samson 1979; Schieck et al. 1995; Stribling et al. 1990; Suthers 1988; Temple et al. 1979; Thomas et al. 1977; Thompson and Capen 1988; Tarvin and Smith 1995; Tarvin and Woolfenden 1999; Tyler in Bent 1946; Venier et al. 2009).

In 400-m landscapes in North Dakota, the probability of occurrence of the Blue Jay increased with increasing tree cover within 100 m in landscapes with less than 30% forest cover. When the landscape was more than 30% wooded, its probability of occurrence initially increased with increasing tree cover, but levelled off and declined somewhat with high tree cover. At high levels of tree cover, it selected more edge-rich areas (Cunningham and Johnson 2016). It preferred landscapes that were 51-75% forested in North Dakota; no areas were more than 75% forested. In New York, it preferred landscapes that were 71-94% forested (Cunningham and Johnson 2019).

The Blue Jay is not an area-sensitive species and benefits from habitat fragmentation. In southern Ontario, its abundance was negatively correlated with woodlot size, amount of forest cover 100 m or more from edge, the amount of forest cover within 2 km, and the amount of regional forest cover, although only the latter parameter was significant (Austen et al. 2001). In Michigan, its abundance was negatively associated with forest size and it was not associated with any landscape variables (Crozier and Niemi 2003). Robbins (1979) concluded that it required 4 ha of forest to maintain a viable population, but Robbins et al. (1989) determined that it was most likely to occur in greatly isolated forests. In Pennsylvania, it was associated with larger woodlots but was more prevalent in fragmented landscapes (Keller and Yahner 2007). In Wisconsin, it was at least 50% more common in smaller woodlots (5-14 ha) than larger forests. Although it showed a slight preference for larger patches in xeric woods, it greatly preferred smaller woodlands in more mesic stands (Bond 1957). In Maryland and Delaware, its probability of detection in woodlands of different widths was greatest at 50 m, declining gradually to 50% at 300 m, and 33% at 800 m (Keller et al. 1993). In South Carolina, its probability of occurrence was 39% in 0.5-ha forests and 76% in 10-ha forests surrounded

by pine forests, and 53% in 0.5-ha forests and 86% in 10-ha forests surrounded by field and shrub habitats (Kilgo et al. 1997). In fragmented North Dakota aspen woodlands, its abundance was correlated with forest size. Probability of detection was 15% in 1-ha woodlots, 20% in 10-ha woodlots, 38% in 100-ha forests, and 52% in 1,000-ha forests. It did occur in very small woodlots (Grant and Berkey 1999). In Saskatchewan, it was randomly distributed within fragmented landscapes and its presence was not correlated with forest type or amount of cover within 5 km (Hobson and Bayne 2000). Stauffer and Best (1980) observed it in riparian strips as narrow as 15 m, and concluded that it would be unaffected if vegetation were reduced to a narrow riparian area.

In Tennessee, the core areas of Blue Jay territories adjacent to an open corridor appeared to be shifted toward the edge but territory density was not significantly higher near the edge than in forest interior. Territories tended to line up in rows parallel to the edge of the corridor (Kroodsma 1984). K.G. Smith et al. (2020) concluded that it was associated more with woodland edges than deep forest.

Most Ontario nests were in live trees and shrubs. Eight were in dead trees; 4 were on a building rafter, a sunporch beam, a shelf under a house eave, and a shelter on the side of a house; 1 was in dead tree roots under an overhanging earthen bank. Coniferous trees were slightly more preferred for nest sites (58%) than deciduous trees, shrubs, and vines. Species most frequently selected were white cedar (58 nests); pines, mostly white pine (53 nests); hawthorns (53 nests); spruces (37 nests); hemlock (19 nests); and maples (19 nests). Nests were more often in small than large trees, and more often near the top than middle and lower portions of the tree. Nests occurred in crotches (56.7%) and on horizontal branches and more were near or against the trunk (78.2%) than away from it. Distances from the trunk for 13 nests were 0.2-6 m, mostly 1.2-3 m. Six nests were between 2 adjacent tree trunks. Most nests are freshly built, but one was used 2 successive years, one was built on an old nest, and one was built on a squirrel drey. Nest height ranged from 0.9 to 20 m, with most 2.4-4.6 m up (Peck and James 1987).

In the east, the Blue Jay appears to prefer conifers for nesting, but in Iowa 94% of nests were in deciduous species. A high proportion of deciduous species were also reported from Illinois: 18.4% of nests were in oaks, 11.6% in hawthorn, 10.8% in apple, 9.6% in Osage orange, 9.2% in Manitoba maple, 4.8% each in cedar and pine, 4.4% each in Norway and blue spruce and elms, 3.6% in willows, 2.4% each in black cherry and chokecherry, 2.0% in grape, 1.6% each in ash, honey locust, and hackberry, 1.2% each in poplar, cottonwood, and honeysuckle, 0.8% in mulberry, and 0.4% each in hickory, lilac, and sycamore. Other species it has nested in include black locust, beech, grey alder, black alder, pitch pine, flowering dogwood, and a variety of fruit trees. Nests may be on or in buildings or other human-made structures, such as cross-members on hydro poles and transformers. Some of these nests are highly exposed and in areas of high human activity. Nests were 1 m to more than 30 m from the ground, but most are 3-8 m up. One yearling female used a nest that her parents had abandoned earlier. There are some records of long-term use of nests, with one in North Carolina used 4 consecutive years; another was used 5 consecutive years, left idle for a year, then used again. It was unknown if the same birds were reusing the nests. One pair appropriated a newly constructed robin nest (Brackbill 1950a; Duyck and McNair 1990; Fitch 1958; Graber et al. 1987; Kilham 1956; Langevin and Dauphin in Gauthier and Aubry 1996; Laskey 1958a;

K.G. Smith et al. 2020; Stauffer and Best 1980; Tarvin and Garvin 2002; Tarvin and Smith 1995; Tyler in Bent 1946).

The Blue Jay does not maintain exclusive territories and may be gregarious even during the breeding season. Occasionally neighbouring males or pairs may engage in contests similar to cock fights. Aggression is usually between adults at the same nesting stage, so that adults with nestlings may tolerate adults with fledglings entering the territory and even landing in the same tree. There is no defence of consistent boundaries. Mated pairs may form flocks and move through their neighbourhood and band together to attack predators. When territorial defence occurs, it is usually within 60 m of the nest. Territory size in Quebec was estimated at 2.61 ha. In Maine spruce forest, territory size was estimated at 4.0 ha. Home range size varies seasonally and home ranges of pairs greatly overlap. In Florida, home ranges were 0.54-6.1 ha. In Kansas, a female often flew 350 m from the nest to join other Blue Jays and food for fledglings was brought from distances of 130-275 m. The home range for this female may have been in the order of 9 to more than 30 ha (Fitch 1958; Graber et al. 1987; Langevin and Dauphin in Gauthier and Aubry 1996; Laskey 1958a; McIlwraith 1894; Morse 1977; K.G. Smith et al. 2020).

In Tennessee, 3 yearlings of a brood from the previous year returned. One of these, a female, fledged 4 young, and one of them returned the next 2 years. Another nest produced 2 fledglings, both of which returned the following year (Laskey 1958a). These data suggest that natal philopatry is fairly high, but no other information is available. In Illinois, 34 of 594 birds (5.7%) banded over 32 years returned, but the age of birds when they were banded was not specified (Graber et al. 1987). Laskey (1958a) and K.G. Smith et al. (2020) determined that most adults remained in the same area year to year in Tennessee and Florida. Adult site fidelity rates are unknown for northern populations that may be partially migratory, although the Tennessee population was mostly migratory.

Limiting Factors

Eggs have been found in Ontario nests from mid-April to mid-July, with most present in the last half of May (Peck and James 1987). In Algonquin Park, nests are under construction from early May to early June, eggs are present from early May to early June, nestlings occur from mid-June to early July, and dependent fledglings have been observed from late June to early August (Tozer 2012).

Nest construction may take as long as 26 days, but 8 or 9 days is typical. It may be some time after nest completion before eggs are laid. One egg is laid per day and daytime incubation appears to begin with laying of the penultimate egg. The incubation period of 10 Ontario nests was 13-18 days. Some of the short incubation periods and variability of incubation periods may be due to incubation starting before the clutch is complete. Elsewhere, the incubation period has been reported as typically 17 or 18 days, with extremes of 15-18 days. Young may leave the nest when they are 15-21 days old, but typically at age 17-21 days. In Illinois, the time for a successful nesting from nest building to fledging was estimated at 48 days for a 5-egg clutch (Graber et al. 1987; Laine 1981; Laskey 1958a; Madge and Burn 1994; Peck and James 1987; K.G. Smith et al. 2020; Tyler in Bent 1946).

One or 2 broods may be raised annually, and there are records of 2 broods in Ontario. The Blue Jay appears to be more productive in suburban and urban habitat, where it is most likely to raise 2

broods. One brood appears more typical in natural habitats. Third broods have been reported in Florida and Tennessee, but the Florida record is uncertain. The Tennessee record was unusual in that young fledged prematurely in the second nest due to disturbance and the young were taken into captivity. The adults may have perceived this as a failed nest with the third nest a renesting attempt. Renesting after a loss is common and may continue into July. Clutches of 2-6 eggs have been reported in Ontario, with most having 4 or 5 eggs; 5-egg clutches are most frequent. Throughout its range, clutches of 2-7 eggs have been reported, typically 4-6 in northern populations and 3 or 4 in the south. Seven-egg clutches are rare (Graber et al. 1987; Laskey 1958a; Madge and Burn 1994; Peck and James 1987, 1997; K.G. Smith et al. 2020; Tyler in Bent 1946).

Both sexes are capable of breeding at 1 year of age, but many do not until they are 2 years old. The proportion of each sex that breeds as yearlings varies regionally and annually. In Florida, 45% of breeding birds were yearlings in a year of high productivity but low population, but only 6% in a year of high population density. The mating system is long-term monogamy. Pairs remain together for several years and typically dissolve only when one dies. In a nonmigratory Florida population, 7% of pairs divorced (Graber et al. 1987; Laskey 1958a; K.G. Smith et al. 2020).

The Blue Jay feeds mostly in trees and shrubs and on the ground, occasionally aerially. It may hawk flying ants, cicadas, and dragonflies from the air. It takes seeds and nuts directly from the tree or shrub; acorns on trees are much preferred to those on the ground. Cached acorns are retrieved from the ground by digging with the beak. It may also raid Canada Jay caches. It has been observed trying to catch live mice, but appears fairly unsuccessful at this (K.G. Smith et al. 2020; Tyler in Bent 1946; Wourms and Wasserman 1985).

Although the Blue Jay is an opportunistic omnivore, it has definite food preferences that vary seasonally. Nestlings have been documented being fed lepidopteran pupae, but they are probably fed a wide variety of invertebrates. Beal (1897a, 1897b) examined 530 stomachs. They contained a large amount of mineral matter that averaged more than 14% of total stomach contents. The real food consisted of 24.3% animal material and 75.7% vegetable matter. The animal food was predominantly insects, with a few spiders, centipedes, millipedes, crustaceans, snails, and small vertebrates such as fish, salamanders, treefrogs, snakes, mice, and birds. Important insects were lepidopteran larvae, grasshoppers, and scarab, ground, and adult and larval click beetles. Although the Blue Jay is much maligned as a nest predator, traces of bird eggs and nestlings were found in only 6 stomachs. A wide variety of vegetable matter was eaten, but hard mast (acorns, beechnuts, chestnuts, hickory nuts, and hazelnuts) were most important and comprised 43% of the overall diet. No hard mast was found in stomachs of birds collected in July and August, but it comprised 67% of the diet from October to March. Grain was important food, especially corn which constituted 17.9% of the annual total diet. Other vegetable matter it consumed included wheat, oats, buckwheat, currants, blackberries, mulberries, blueberries, sumac, knotweed, sheep sorrel, huckleberries, black cherries, chokecherries, wild grapes, juneberries, elderberries, hawthorn fruit, and pokeweed berries. Beal et al. (1916) examined 184 stomachs collected in the southeastern United States. The diet consisted of 31.9% animal food and 68.1% vegetation. Insects comprised 26.5% of the annual diet, predominantly caterpillars and grasshoppers. Scarab beetles and June beetles were common in the diet and comprised 30% of the diet in May. It ate numerous snails, a few toads and frogs, and some

fish. Only 1 stomach contained the egg of a small bird; 13 stomachs contained hens' eggs, but these may have been taken from waste. Corn represented more than 58% of the food in August and was also commonly consumed in July and September. Mast comprised almost 46% of the annual food and was 84% of the diet in January when other food items were scarce. Other vegetable matter reported by other authors in the breeding season diet include green shoots, apples, crabapples, bladdernut blossoms, and sugar maple buds. Additional invertebrates reported in the diet include tent caterpillars and their eggs, linden looper moths, geometer moth larvae, tussock moths, cicadas, and wasp larvae. Vertebrates are a very small proportion of its diet and most of these are birds. In residential areas, nest depredation by the Blue Jay may be more frequent. In some areas, the main predator of Blue Jay nests has been other Blue Jays. It has been documented eating eggs, nestlings, and young fledglings of Rose-breasted Grosbeak, House Sparrow, Mourning Dove, Purple Martin, Northern Cardinal, Swainson's Thrush, and White-winged Crossbill. It appears to be inefficient at capturing more mature small birds and mammals. Rarely, it attacks day-flying bats; an attack on a red bat by a group of Blue Jays was interrupted by humans so the outcome was not determined. Blue Jays captured in idle lobster traps in Maine ate the flesh of other jays that had already starved to death (Atkins 1990; Clay 1959; Cline and Hatt 2011; Graber et al. 1987; Holt 1918; Johnson and Johnson 1976; Langevin and Dauphin in Gauthier and Aubry 1996; Laskey 1958a; Madge and Burn 1994; K.G. Smith et al. 2020; Steinberg and Tozer 2003; Tarvin and Smith 1995; Tozer 2012; Tyler in Bent 1946). In spring in Ontario, it has been observed feeding on icicles created by sugar maple sap (Simpson 2025). In New Brunswick, Morris et al. (1958) found no relationship between the abundance of the Blue Jay and numbers of spruce budworms. Mitchell (1952) examined the contents of 9 stomachs during a spruce budworm outbreak in Maine. By volume, they contained 0 and 2% budworm larvae and pupae.

The Blue Jay caches hard mast beginning in August, but particularly in September and October. Six birds each cached 3,000-5,000 acorns 1 autumn. While caching, 2-5 acorns or as many as 15 beechnuts are taken at once. Initially, it harvests acorns directly from trees, but later takes them from the ground once abcission has occurred. It also caches chestnuts and beaked and American hazel nuts, and occasionally egg shells, a source of calcium. Oak species that it caches acorns from include white, bur, chinquapin, Hill's, black, pin, and red, and it may prefer smaller nuts from beech and pin oak. It cannot subsist entirely on acorns and loses weight if it tries to do so. It was originally thought that it ate acorns infested with acorn weevil larvae to obtain protein supplements in the diet. Subsequent studies demonstrated that it selects healthy acorns and there is no evidence of consumption of acorn weevil larvae by wild birds. It may also cache unshelled peanuts taken from feeders. All caching apparently occurs within the bird's home range. It has been documented flying as far as 4 km for beechnuts and 1.9 km for acorns. It is highly selective about habitats that caching occurs in. In Iowa, most acorns were cached in woodlands, woodland clearings, and woodland edge habitats. Firebreaks and short-grass habitats were used according to availability for caching, and tall-grass areas were avoided. Use of grasslands for caching increased after they were burned and plowed areas may be used. Each nut is buried separately in the ground within a radius of 1-3 m and caches are typically covered with a leaf or pebble. It selects different areas for caching on each trip, and subsequent caching areas may be more than 100 m apart. The Blue Jay rarely caches food above

ground in tree crevices or old bird nests (Dixon et al. 1997a, 1997b; Graber et al. 1987; Henry and Franks 1987; Johnson et al. 1997; Johnson and Webb 1989; K.G. Smith et al. 2020).

Because of its habit of dispersing acorns a long distance, the Blue Jay is a keystone species for oak forest ecosystems and other species that inhabit them. The rapid postglacial dispersal of oaks has been attributed to the Blue Jay. From a single Wisconsin woodlot, approximately 150,000 beechnuts were dispersed by jays, and an estimated 5-6% of an oak crop was dispersed. It selects healthy acorns and caches them in ideal habitat for oaks, thereby enhancing probability of successful dispersal. From a total cache of several thousand nuts, about 150 oak seedlings per ha germinated and survived the first year. In a Virginia oak stand, jays removed an estimated 133,000 of 221,000 acorns (54%). Of the acorns remaining below trees in the woodlot, 43% had been eaten by jays and many of the remaining acorns had fungal or insect infestations, so that the proportion of viable acorns remaining near the trees was small. Distances between collecting trees and caches averaged 1.1 km (range 100 m to 1.9 km). Ninety-one percent of caches were in lawn or bare soil and an acorn was cached in a site unsuitable for germination only once. Most acorns taken were from pin oak; red oak and white oak were not used. White oak may not have been chosen because its acorns had already germinated beneath seed trees and red oak acorns may have been too large to swallow. In a laboratory study, the preference of Blue Jays for acorns of white oak, pin oak, black oak, and red oak, and shagbark hickory nuts was tested. They showed a clear preference for pin oak and strong avoidance of red oak acorns when alternative foods were available. White oak and black oak acorns were selected intermediately; shagbark hickory nuts were never used. Preference was negatively correlated with acorn size and the proportion of the seed consisting of a hard seed coat. When other food was unavailable, it readily took small red oak acorns. The large red oak acorns were mostly avoided but still used by some birds. In another study, acorns of bur and red oak were avoided due to their large size unless no other food was available. Pin oak was preferred over black and white oaks (Darley-Hill and Johnson 1981; Johnson and Webb 1989; Johnson et al. 1977; Moore and Swihart 2006; Richardson et al. 2013).

Cowbird parasitism of the Blue Jay is rare, with only 3 or 4 records; parasitism has not been documented in Ontario. In 25 experimentally parasitized nests, all eggs were rejected, 23 by ejecting eggs from the nest and 2 by abandoning the nest (Rothstein 1975; K.G. Smith et al. 2020). Because it is an egg rejecter, parasitism rates may be higher than reported.

Habitat loss and degradation do not appear to be problems due to the high diversity of habitats used. Extensive urbanization or deforestation may reduce or extirpate local populations (K.G. Smith et al. 2020). In many areas, the Blue Jay may be more abundant in towns than in rural areas (K.G. Smith et al. 2020). Graber et al. (1987) concluded that declines between 1907 and 1957 may have been due to conversion of edge habitats to blocks of habitat. In Pennsylvania, Rohnke and Yahner (2008) conducted bird surveys in a forest 16 years apart. In the interim, density of tall shrubs increased, but density of canopy and subcanopy trees and short shrubs declined. During this period, the Blue Jay increased by 219%. In New York, Brooks and Bonter (2010) surveyed the number of territories over a 35-year period in a field that was allowed to regenerate, a forest, and a managed Christmas tree plantation. There were significant increases in the number of territories in the

regenerating area and plantation, but no change in the forest. Although the plantation was maintained in early succession stage over the study period, the trees were allowed to grow taller.

The West Nile virus killed large numbers of Blue Jays. McCracken (2003a) predicted that its population would initially decline significantly, but that it should be able to recover. Kilpatrick et al. (2007) identified the Blue Jay as the species most compatible for accepting the virus and concluded that the virus had had significant effects on populations. The Blue Jay is a common resident in urban areas where it is most likely to encounter the vector. Evidence of range-wide population recovery was evident by 2005 (K.G. Smith et al. 2020).

It has been suggested that nest success is greatest in suburban areas due to fewer nest predators, and that nests closer to houses are more successful because humans may deter predators. This may not be the case in Ontario, where major nest predators such as raccoons, domestic cats, and gray squirrels are abundant in urban areas and have little fear of humans. Predation rates in suburban areas of Arkansas were not affected by nest-tree species or nest location within trees. Nest success was higher when the nest was in a patch containing several nest trees of the same species, size, and vine cover. This suggested that the more complex the habitat and the more similar the nest site was to the surrounding area, the less likely that predation would occur. This relationship did not hold true in Florida (Tarvin and Garvin 2002; Tarvin and Smith 1995).

Densities in forests appear to be unaffected by selective and diameter-limit logging, and densities may be higher in logged than unlogged areas. Forest thinning that retains snags results in higher densities than management that removes snags (Webb et al. 1977). Tozer et al. (2010) studied the effects of group-selection harvesting in tolerant hardwoods in Algonquin Park. Typical harvests affected about 5% of the stand area; intensive harvests affected about 20% of the stand. The Blue Jay increased significantly in response to intensive group selection in the first or second year after harvesting. Jobes et al. (2004) reported similar results for single-tree selection. The Blue Jay was significantly more abundant in stands that had been logged recently than in control stands and those that had been logged 15-20 years previously. In the Carolinian Forest Region of Ontario, its abundance was negatively associated with basal area, and it was more abundant in harvested than uncut woodlots (Holmes et al. 2004). In the Canadian Shield of Ontario, there was no difference in its abundance in early and mid-successional clear-cuts and burns in the same seral stages. It was equally abundant in early successional, mid-successional, and mature stands (Zimmerling et al. 2017). In Vermont, Blue Jay territories occurred both in clear-cuts and adjacent northern hardwood forests (Lent and Capen 1995). In Minnesota, it decreased in an area when riparian buffers were partially harvested but rebounded quickly in subsequent years. In another area in Minnesota, it responded positively to partial harvest of riparian buffer strips (Hanowski et al. 2002, 2005).

Farwell et al. (2019) examined the response of the Blue Jay to shale gas infrastructure (well pads, access roads, and pipelines) in contiguous forest in West Virginia. It was significantly less abundant close to these features than distant from them.

Schneider and Miller (2014) examined the effects of invasive shrubs on the Blue Jay in the Chicago area. It was negatively correlated with invasive shrub stem density, most likely related to

presence of common buckthorn, because it was positively correlated with abundance of nonnative honeysuckle species.

In North Carolina pine-oak forests, the Blue Jay responded favourably to fire (Rose and Simons 2016).

In New Jersey and Pennsylvania over a 15-year period, hemlock declined from representing 56% of the total basal area to 46% due to the hemlock woolly adelgid; the amount of deciduous understorey increased. The Blue Jay responded favourably to hemlock decline and increased in abundance (Toenies et al. 2018).

In North Carolina, abundance of the Blue Jay was significantly correlated with temperature, suggesting that it might benefit from climate change. This area was in the Appalachian Mountains where temperatures are lower than other areas at the same latitude (Lumpkin and Pearson 2013).

Status

The Blue Jay has always been common in Ontario. McIlwraith (1894) considered it common and Baillie and Harrington (1937) concluded that it was a fairly common summer resident north to at least southern Kenora District and the Missinabi River. They stated that it was much more common in southern Ontario, breeding commonly north to central Sudbury District and Thunder Bay. In the Kingston area, it was considered common in 1864, and it still is (Weir 2008). James (1991) considered it common in the south, becoming uncommon in the north to Red Lake and Kapuskasing.

The second atlas indicated that there had been no change in the distribution of the Blue Jay since the first atlas. It was common in the Carolinian and Great Lakes–St. Lawrence forest regions where breeding evidence was documented in almost every square. It was less abundant in the Boreal Forest Region, where it occurred only in the southern portion from about Sioux Lookout east to Fraserdale. There was no difference in its probability of observation province-wide or in any region except the Boreal Forest Region, where a significant increase was documented. It was most abundant in the southern Canadian Shield and south of the Shield in the Great Lakes–St. Lawrence Forest Region. Urban areas with mature trees, such as Toronto, Hamilton, Ottawa, and Kingston supported high densities as did the orchards in Grey County and Niagara Region (Coady in Cadman et al. 2007).

In other areas, Blue Jay populations are increasing in suburban habitats and rural woodlots, but declining in larger forest blocks (Graber et al. 1987; K.G. Smith et al. 2020). Long-term (1970-2021) population trends determined by the Breeding Bird Survey indicate annual increases of 1.06% in Canada and 0.826% in Ontario. The short-term (2011-21) trends were annual increases of 1.87% in Canada and 1.27% in Ontario. All results were highly reliable (A.C. Smith et al. 2023).

Most surveys reflect only relatively recent trends, but Graber and Graber (1963) compared populations between 1907 and 1957 in Illinois. Although the Blue Jay was still very common in the latter period, the population declined 50-80% with declines in all habitats except suburban areas.

POSTFLEDGING PERIOD

Fledglings move en together away from the nest, and are usually 25-100 m distant on the second day. Although fledglings are capable of feeding themselves at age 3 weeks, they follow the adults

for another 1 or 2 months to be fed. Some disperse as soon as they are independent; others may wait until autumn or winter (K.G. Smith et al. 2020).

MIGRATION

The nature of the Blue Jay's migration is poorly understood. Two patterns are evident: at least some birds remain year-round throughout the range, even in the extreme north; and at least some depart in autumn from all areas except Florida and the Gulf Coast. Birds that depart in autumn are replaced by those from further north, so that most winter populations are a combination of permanent residents and migrants. The distance travelled by migrants is highly variable and, in most areas, many jays are resident. The proportion of birds that migrate is probably not more than 20% even in northern portions of the range. Individuals may respond differently year to year, being resident some years and migratory in others. An adult that bred at 1 location may summer substantially south in subsequent years, or return to the same area after an absence of 1 or more years (Graber et al. 1997; Nunneley 1964; Smith 1986a; K.G. Smith et al. 2020).

The factors that trigger migration are uncertain, but may be related to food supplies. Some authors contend that most migrants are young birds that may be forced to migrate by more dominant resident adults. Most authors demonstrated that there is no difference in propensity to migrate among sexes or age classes. Fluctuations in abundance of mast may affect the likelihood of birds migrating, but studies report mixed results. Peak autumn flights in Ontario are associated with poor crops of acorns, beechnuts, and hazelnuts. No relationship between number of migrants or overwintering birds and mast production was observed in Wisconsin, a small insignificant correlation was evident in Missouri, and numbers were highly related to amount of mast in Pennsylvania and Iowa. The number of birds migrating has declined, and this has been attributed to increased numbers of bird feeders (Bock and Lepthien 1976a; Carpentier 2010; Hickey and Brittingham 1991; Johnson et al. 1997; Langevin and Dauphin in Gauthier and Aubry 1996; Overlease and Overlease 1987; Smith 1986b; Smith and Scarlett 1987; K.G. Smith et al. 2020).

At Holiday Beach, the most favourable conditions during the first and mid-portions of the autumn flight appear to involve light winds from a northerly or easterly direction, with cold or cool overnight temperatures followed by warm daytime temperatures. Persistent rain and sustained winds in excess of 15-20 km per hour greatly hinder or halt migration. Later in the season, winds from almost any direction do not appear to influence migration (Carpentier 2010).

Migration appears to be strictly diurnal. Flights usually start shortly after dawn, decrease by mid-morning, and cease by noon. During heavy flights, passage may continue until 1500-1700 hours, but with considerably fewer birds later in the day. Occasionally flights cease at noon, but resume for a while later in the afternoon. In New Jersey, 61.2% of birds passed through in the first 2 hours of daylight; morning fogs delayed flights (Graber et al. 1987; K.G. Smith et al. 2020; Yunick 1995a). Although it migrates over a broad front, the Blue Jay also follows landmarks such as rivers and shorelines. In autumn, migration is more concentrated along rivers, but cross-country flights are still evident. Spring destinations of birds are unknown in the Kingston area, but some may move along the St. Lawrence River into Quebec. During autumn, it is very obvious, travelling southwest along the lakeshore from Ivy Lea to Prince Edward Point. Although a few cross Lake Ontario at Prince Edward Point, most continue westward along the shoreline. Birds banded along the northern shore

of Lake Ontario have been recovered along Lake Erie and in Detroit, Kentucky, and Louisiana, suggesting that they move down the Mississippi Flyway. Flocks observed leaving Point Pelee in autumn flew directly over the lake to Ohio without stopping at Pelee Island. Many birds cross over at Sault Ste. Marie into Michigan and then Illinois. There is 1 record of a Blue Jay banded in Ontario in winter being recovered in Tennessee 2 winters later. There are numerous examples of birds spending the winter in geographically disparate areas in Canada and the United States, suggesting that irregular migration is a response to changes in natural food supplies (Brewer et al. 2018; Graber et al. 1987; Smith 1986a; K.G. Smith et al. 2020; Tyler in Bent 1946; Weir 1989).

Canadian banding records indicate that more than 50% of juveniles were recovered in a different state or province than where they were banded compared with 30% of adults. Hatch-year birds tended to travel further than adults. Fifty-one percent of hatch-year birds moved more than 100 km and 32% moved more than 500 km compared with 30% and 14% respectively for adults (Brewer et al. 2018).

Spring migration throughout the Blue Jay's range is concentrated from mid-April to late May, and from mid-September to late October in autumn (Graber et al. 1987; K.G. Smith et al. 2020). Autumn migration in Ontario occurs throughout September and October, with peaks from mid-September until mid-October and greatest numbers in late September and early October (Carpentier 2010; Curry 2006; Tozer 2012; Weir 2008).

Graber et al. (1987) summarized habitat preferences during migration in Illinois. Spring densities were highest in forest edge and shrub habitats, and the Blue Jay preferred upland habitat to lowlands. In autumn, densities were also greatest in forest edge and shrubs, and least in pines. In Pennsylvania, it was associated with more fragmented landscapes during spring migration and with larger woodlands in autumn (Keller and Yahner 2007). During spring migration in Minnesota and Wisconsin, it was significantly more abundant in upland than riparian forests (Kirsch et al. 2013).

James (2010) studied the behaviour of autumn-migrating Blue Jays in relation to tree cover and wind turbines near Port Burwell. Large numbers of jays moved along the shoreline of Lake Erie, but they also occurred as far inland as 2 km. Where they were forced to decide whether to fly across an untreed opening or follow treed fence lines or other vegetation, 45.8% continued to fly across the gap and 54.2% went out of their way to follow trees (n = 4,380 jays). They followed cover at other locations such as treed watercourses and wooded ravines. Birds frequently moved in a zigzag pattern that more than doubled the distance travelled during their westward migration. In areas along the shoreline where there were no gaps in tree cover, 86.3% of 8,160 jays continued to fly along a direct route. The avoidance of open areas by many jays may have been an antipredator tactic because Sharp-shinned Hawks, Cooper's Hawks, and American Kestrels were migrating at the same time. The jays did not demonstrate any avoidance reaction to the wind turbines and they appeared to have no appreciable effect on the migration of Blue Jays.

Loss et al. (2014) analyzed bird collisions with buildings throughout the United States. The Blue Jay was among the most vulnerable species for striking residences 1-3 stories tall, where it was 26.5 times more likely to suffer a collision than average. It was not on the lists of the 20 most vulnerable species for striking low-rises or high-rises.

In Pennsylvania, an invasion by the viburnum leaf beetle resulted in almost complete mortality of the southern arrowwood, formerly the third most abundant shrub. After the infestation, the number of spring migrating Blue Jays declined significantly (Smith and Hatch 2017).

The Blue Jay is common to locally abundant during migration, and more numerous in autumn. Counts indicate that there is a 2-year cycle, with lower counts in even-numbered years. There may also be a longer-term trend of 7-10 years between high and low points in the cycle (Chartier 2005; Curry 2006; Weir 2008). Numbers from Holiday Beach covering a 28-year period indicate an average of 292,126 jays per year. Most followed the Lake Erie shoreline with few deviating further south. Largest numbers occur in southwestern Ontario in autumn as birds coming from the east join those coming from the north and those in the west (Carpentier 2010).

WINTER

Winter habitat preferences are similar to those of summer, with the principal areas being forests, forest edges, shrublands, and suburban or rural areas with bird feeders. In Ohio, the Blue Jay's presence in forest fragments was correlated with an increase in edge, and its density increased with shrub cover. In forest cover, it appears to prefer lowland deciduous forests; pine forests are least favoured (Bock and Lepthien 1976a; Doherty and Grubb 2000; Graber and Graber 1963; Graber et al. 1987). In Arkansas, Kentucky, and Mississippi, it was equally abundant in row-crop fields with and without buffers of native grasses and forbs (Evans et al. 2015).

In Maryland, 2-5 birds roosted in a front yard in several small oaks that retained their leaves until spring. Branches used as perches were 1.2-6.0 m from the ground (Turner 1965).

The Blue Jay is nonterritorial in winter and tolerates large numbers of its species while feeding. There is a dominance hierarchy, with only one feeding from a perch at a feeder and being replaced when it is finished. Perches on an experimental feeder were large enough to support 4 jays, but typically only one used it at a time; when 2 were present, they were usually birds that had previously nested together. The relative rank of a jay present in successive winters does not change much (Racine and Thompson 1983; Whittam and Francis 2000).

Wintering jays form groups that share a common home range, often resting together during the day and roosting together at night. Individuals may move by themselves within this home range or with their former nesting partner, or the group may move as a unit. A winter group in Kansas consisted of 8 pairs that tended to move as a unit within a home range of approximately 55 ha. In Massachusetts, group sizes remained fairly constant over the course of each winter, and consisted of 14, 18, and 49 individuals over 3 years. This group focused its activity on 1 feeder, and members rarely, if ever, visited other feeders approximately 600 m away. Many jays were not observed every week, but reappeared later. Some appeared irregularly and were not really part of the social group. Most birds that survived rejoined the group the following year. Offspring of birds that had been part of the group often joined, and occasionally birds that had been casual visitors to the group previous years joined. Although many birds form groups around food resources, others spend the winter singly or with their former mate (Fitch 1958; Racine and Thompson 1983; K.G. Smith et al. 2020).

The Blue Jay is an opportunistic feeder in winter. In the southern portion of its range, cached mast is not eaten in winter but is eaten in spring, used in courtship feeding, or fed to incubating

females. Cached food is an important food source in the winter in the north. In Algonquin Park, it fed on insects in cocoons obtained by stripping bark off decaying trees. It may feed on dead adult and larvae bald-faced hornets taken directly from the nest, and also eats paper wasps. When food is abundant in winter, it continues to cache; it has been observed caching dead white-footed mice in snow. It occasionally consumes carrion in winter, and dog food, bread, and table scraps (Graber et al. 1987; Martin 1960; Smith 1986b; K.G. Smith et al. 2020; Tozer 2002a; Whitford 1996).

The Blue Jay is a widespread user of winter bird feeders, visiting virtually all feeders in its winter range regardless of habitat. Numbers seen at rural feeders are more than twice as high as those at urban ones, and jays are more likely to visit rural feeders all winter. Numbers are higher at northern than southern feeders, but northern populations are not higher in the north, suggesting greater dependence on feeders. At feeders, it prefers foods with shells, facilitating caching and delaying spoilage. Favourite feeder foods are striped sunflowers, unshelled peanuts, mixed seeds, black oil sunflowers, cracked or whole corn, hulled peanuts, pet food, meat scraps, baked goods, and water. Occasionally it eats millet, canary seed, hulled sunflowers, safflower, milo, wheat, peanut hearts, suet, peanut butter mixes, bird puddings, fresh or dried fruit, sugar water, and popped corn (Dunn and Tessaglia-Hymes 1999). Other foods it has taken at feeders include cracked butternuts and walnuts, and cheese (Graber et al. 1987). Horn et al. (2014) provided participants in Canada and the United States with 10 different types of seeds and 3 types of feeders. A total of 24,072 feeding observations were made for the Blue Jay. It preferred whole peanuts and platform feeders.

Based on Christmas Bird Count (CBC) data, Smith (1986a) concluded that the Blue Jay was unaffected by severe winter weather. In Pennsylvania, Overlease and Overlease (1987) found that numbers declined in severe weather and concluded that it may be vulnerable to depth and duration of snow cover, especially when accompanied by low temperatures. In Illinois, Graber and Graber (1979) did not detect an overall decline in numbers as a result of prolonged severe winter weather. There was a significant shift in habitat use, with jays moving from lowland forests to urban residential areas. They found 4 carcasses, indicating that the storm caused some direct mortality.

The Blue Jay is a common winter resident in the south and uncommon in the north to Thunder Bay (James 1991). Mills (1981) reported that it was virtually absent some winters in Muskoka and Parry Sound and abundant in others. CBC data indicate an annual population increase of 1.74% for Ontario for 1970-2021 and 2.12% for 2009-21 (National Audubon Society 2022). Winter numbers in the west, east, and northeastern parts of its range increased dramatically whereas southern densities declined. It was postulated that the overall increase in numbers and change in winter distribution patterns was due to an increase in bird feeding (Bock and Lepthien 1976a). Winter increases observed in Wisconsin, the eastern states, and Missouri were also attributed to bird feeders (Hickey and Brittingham 1991; Smith 1986a, 1986b). In Illinois, winter populations declined 30-45% between 1907 and 1957, but populations in urban residential habitat increased during this period (Graber et al. 1987).

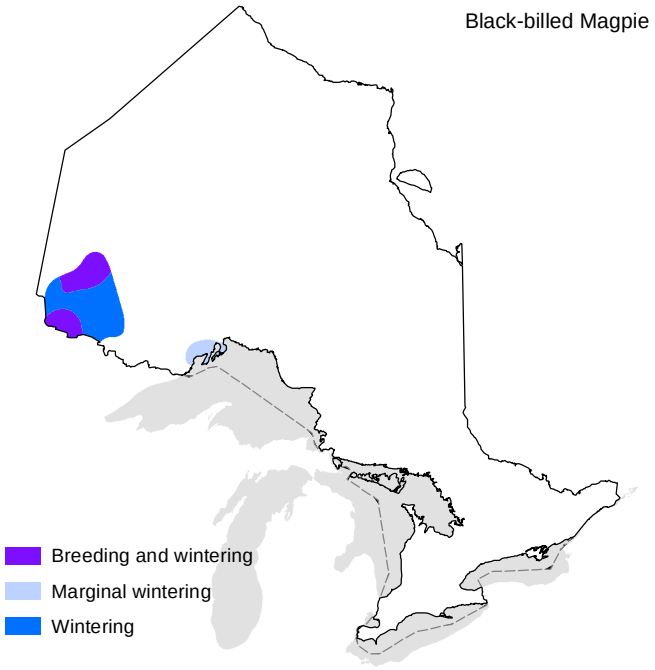
Black-billed Magpie

Pica hudsonia

BREEDING SEASON

Habitat Requirements

In Ontario, the Black-billed Magpie breeds only near Dryden, between Rainy River and Fort Frances, and at Ear Falls. Habitat in Rainy River District consists of relatively open areas dominated by agricultural lands. Most nests there were in dense shrub areas at edges of agricultural fields and marshes. Habitat near Ear Falls consisted of open woodland dominated by white birch, black spruce, and balsam fir, with scattered tall white pines. Magpies used the interface between this woodland and the headpond of a hydro generation station (Elder 1986, 2006; James 2014; Peck and James 1987, 1997).



The Black-billed Magpie is associated with open, human-altered landscapes; it avoids extensively treed areas. Habitat is characterized by linear strips of riparian vegetation and open meadows and grasslands with scattered trees and shrubs. In Kansas, magpies started nesting at a military base after habitat changed from open grassland to grassland containing savannahs of nonnative shrubs and trees. Nesting often occurs in clumps of trees and shrubs near sources of food and water, such as picnic areas and highways where road-kills are common. It also nests at forest edges and in forest clearings and old barns. It colonized the City of Edmonton in urban areas where there are many mature deciduous and coniferous trees interspersed on lawns and in gardens. Presence of water near the nest appears to be important in many areas (Andrén 1992; Bailey 2003; Buitron 1988; Campbell et al. 1997; Dhindsa and Boag 1992; Evenden 1947; Linsdale 1937; Madge and Burn 1994; Sinclair et al. 2003; Trost 2020; Winter et al. 2000). In Utah, it nested more in shelterbelts, riparian areas, and orchards than expected; monotypic hawthorn stands were used less than their availability. Underused areas had less total cover (10.1% compared with 16.6%), lower canopy closure (11.3% compared with 18.2%), and smaller patches of trees (45.1 m^2 compared with 87.4 m^2; Reese and Kadlec 1985).

In Nevada, magpies roosted together during the breeding season in tall willow clumps at the edge of a slough (Linsdale 1937). Breeding birds roost in trees within the territory, or in the nest if eggs or young are present.

Most Ontario nests were in willow trees at edges of farm fields or marshes. One was in a trembling aspen in an aspen woodlot, one was in a spruce tree, and one was in an open hay shed. Nests in trees were 2-8 m from the ground; the nest in the shed was 5 m up (James 2014; Peck and James 1987, 1997).

Many authors stated that nest-tree species are used according to availability. Others found that the magpie prefers thorny trees, or that tree or shrub structure is more important with most nests among dense growths of twigs and branches. In Edmonton, conifers were used 1.8 times their availability in urban areas and 12 times their availability in suburban areas. In British Columbia and the Yukon, most nests were in deciduous species. It has nested in Russian olive, willow, Siberian elm, Manitoba maple, hawthorn, alder, aspen, birch, cottonwood, fir, juniper, spruce, pine, elm, mountain-ash, and ash. Some magpies build nests over water where they are less accessible to snakes and humans. It frequently nests on utility poles; in Colorado several nests were supported by 3 wires well out from the poles. Occasionally it nests in barns or deserted buildings, or rarely on the

ground where there is a scarcity of trees and shrubs. One nest was on a railroad bridge under a rail and between 2 ties, and at least 1 train a day passed over it. A Wood Duck box was used in Alberta in 2 consecutive years. This appears to be the first record of a magpie nesting in a confined cavity. Nest heights of 0-19 m have been reported; most are 2-5 m up. Nest height may be influenced by the structure of available trees and by disturbance. An undisturbed population in Edmonton nested at an average height of 5.0 m compared with 9.0 m and 9.9 m by populations frequently disturbed by humans. Selection of nest height may be a compromise between exposing high nests to wind and cold and exposing lower nests to predation. Usually a new nest is built each year, but old nests are occasionally refurbished and some have been used 3-6 years. Often domes are taken from old nests and used in new ones (Buitron 1988; Campbell et al. 1997; Dhindsa et al. 1989; Erpino 1968; Linsdale 1937; Linsdale in Bent 1946; Reese and Kadlec 1985; Sinclair et al. 2003; Stauffer and Johnson 2011; Stone and Trost 1991; Trost 2020). Nests may be closely associated with raptor nests and may be in the side or bottom of raptor nests such as Ferruginous Hawk, Prairie Falcon, Bald Eagle, and Osprey. Magpies benefit by feeding on the remains of the raptor kills (Linsdale 1937).

The magpie has highly variable territorial behaviour, depending to a large degree on habitat and food availability. In Wyoming, no signs of aggression were observed and there were 6 active nests in a 0.48-ha woodlot. When it is territorial, an area around the nest is defended, but foraging may occur 300-400 m from the nest. Foraging areas are undefended and 2 or more pairs may feed side by side. Neighbouring birds do not forage near other nests. In Utah, when intruders approached within 30 m of the nest, they were chased away about half the time, but only to a distance of 40 or 50 m. Territory size was estimated at 0.5 ha. Some nests were only 10 m apart, but visually isolated. In South Dakota, nesting birds expelled intruders within 30 m of the nest, but dominated other birds in an area of 3 ha. At road-kills, the pair whose nest was closest dominated other magpies and, within a pair, the male dominated the female. In Edmonton, nests tended to be regularly spaced, with mean distances between nests ranging from 117 to 150 m over 6 years. The nearest nests were 50 m apart, but they were visually isolated. Territories ranged from 1.1 to 1.7 ha over the years (average 1.5 ha). Territories were contiguous or slightly overlapping. They were defended from before egg laying until late incubation. In many areas, nests are clustered and nesting appears to be colonial. In the Yukon, nests were usually 50-200 m apart in loose colonies; only 2 of 29 nests were isolated. In some areas, the magpie nests in clusters with groups of nests often separated by unsuitable habitat. The territorial system varies depending on food resources. When there is a sudden increase in food, nests may be clustered and territoriality abandoned. When a rich supply of food disappears, territoriality may be initiated. These responses have been observed when a steer carcass became available, fish hatcheries closed, and an abattoir was present. No information is available on home range size. In South Dakota, males regularly fed 0.5 km from the nest (Birkhead 1991; Buitron 1988; Dhindsa and Boag 1992; Erpino 1968; Knight 1988; Linsdale in Bent 1946; Reese and Kadlec 1985; Sinclair et al. 2003; Stone and Trost 1991; Trost 2020).

Natal philopatry is fairly high in dominant males. Young disperse after the breeding season, but return the following year in an attempt to inherit the territory. They typically have to wait for the parents to die or move on before the territory can be acquired. More submissive siblings and females disperse further and establish a territory if they can find a reliable source of food. In South Dakota,

only 1 male and 2 females of 126 fledglings (2.4%) returned to breed the following year and another 2 males returned the subsequent year. Two fledglings were found 6-9 km from the natal site the following year; one was found dead 200 km away. Adult site fidelity is high, with most Idaho pairs breeding in the same territory all their lives. In South Dakota, pairs nested in the same area year after year, moving an average of 280 m from the previous nest (range 0-790 m). There was no correlation between distance moved and breeding success the previous year or whether mates had changed. In Edmonton, 72% of males and 70% of females nested in the same territory as the previous year, with 69% of pairs retaining the same territory. Distance moved from the previous nest averaged 144 m (range 0-527 m). Of 8 that changed territories, 5 moved to the adjacent territory, 1 moved 2 territories away, and 2 moved 3 territories away (Birkhead 1991; Buitron 1988; Dhindsa and Boag 1992; Trost 2020; Trost and Webb 1997; Wang and Trost 2001).

Limiting Factors

Eggs are most likely to be in Ontario nests from late April until the end of May (Peck and James 1987). Well-built nests may take longer than 3 months to construct; a shoddy one may be put together within a week. In Wyoming, nests took an average of 43 days to build. Five to 7 weeks appears typical for building a nest; birds that return to territories earliest take the longest time. In Alberta, juveniles took an average of 67.3 days to complete a nest compared with 37.5 days for adults. Eleven days to 3 weeks may elapse between nest completion and initiation of egg laying. Eggs are laid at the rate of 1 a day, with occasional 1-2-day interruptions. The incubation period is difficult to ascertain as it is uncertain when it begins. Approximately 23% of time is spent incubating on the first day compared with 90-95% by day 7 of laying. Eggs hatch in about 18 days, (range 16-21 days). Hatching is asynchronous and occurs over 2-3 days in clutches larger than 6 eggs. Young fledge at age 19-32 days, but usually when they are 26-28 days old (Birkhead 1991; Buitron 1988; Campbell et al. 1997; Erpino 1968; Komers and Boag 1988; Linsdale in Bent 1946; Trost 2020; Trost and Webb 1997).

A single brood is raised annually. Renesting may occur once or rarely twice after loss of a clutch. Renesting occurs 13-16 days after loss, occasionally in the same tree but more often within the territory in a different tree an average of 90-135 m away. Some birds move out of their territory to renest. Clutches of 1-11 eggs and 13 eggs have been reported, but 5-8 eggs is the typical clutch size. Mean clutch sizes were 6.5 eggs in Utah, 6.2 in South Dakota, 6.1 in Wyoming, 7.0 in Idaho, and 6.6 in Alberta. Early nesting birds have larger clutches (6.6 eggs compared with 5.3 eggs), adult females have larger clutches than yearlings (6.3 eggs compared with 5.2 eggs), females paired with their previous mate have larger clutches than females with a new mate, pairs with an adult male have larger clutches than those with a juvenile male (6.3 eggs compared with 5.0 eggs), and first nests have larger clutches than replacement clutches (6.5 eggs compared with 5.8 eggs). Food is often limited for nestlings, so brood reduction is common due to starvation, siblicide, and possibly infanticide. Usually only 2-4 young fledge (Buitron 1988; Campbell et al. 1997; Dhindsa and Boag 1992; Dhindsa et al. 1989; Erpino 1968; Linsdale in Bent 1946; Reese and Kadlec 1985; Reynolds 1996; Trost 2020; Trost and Webb 1997).

Both sexes are capable of breeding at age 1 year, but more yearling females breed than males. Of 7 males in Alberta, 1 nested the first year, 5 at age 2 years, and 1 at age 3 years; all 4 known-age females nested their first year. In South Dakota, 9% of breeding birds were yearlings. In Utah, first-

year birds constituted 20-47% of the breeding population. Yearlings were 40% of known-age females and 47% of males. The mating system is monogamous. Some pairs mate for life and long-term fidelity is common, but divorce also occurs. In South Dakota, 8% of pairs divorced between seasons and 4% split up within a breeding season during nest building. In Edmonton, 50% of males and 62.5% of females switched mates at least once. Divorce was not related to previous reproductive success. Mate switching by males was associated with changes in territory, usually to a better breeding territory. Lost mates are frequently replaced within 24 hours, with the new mate assisting with the breeding cycle regardless of what phase it is in (Buitron 1988; Dhindsa and Boag 1992; Linsdale 1937; Reese and Kadlec 1985; Trost 2020).

The magpie is an opportunistic forager and scavenger. Most foraging occurs on the ground in the open where there is vegetation 0-20 cm tall. It tends to avoid areas of bare soil (except recently plowed fields where invertebrates are exposed) and tall vegetation. It rarely forages in trees. It often feeds near water or where the water table is high and invertebrates are near the surface. Ground litter and other potential cover for prey, including cow dung, is flipped over with the bill and feet. It has a symbiotic relationship with large ungulates such as deer, elk, moose, and domestic livestock. It frequently lands on them to feed on ectoparasites, particularly winter ticks on moose. It visits roadsides, picnic areas, and landfills for road-kills and human scraps. It often steals food from domestic animals and may singly or cooperatively kleptoparasitize gulls, Northern Shrikes, eagles, coyotes, and red foxes. It may perch close to birds of prey to feed on leftovers of their kills. It also captures small mammals. Aerial capture of bats occurs rarely and flying insects are occasionally taken. It caches food, but only for short periods of time. Most cached food is perishable and retrieved within 1 or 2 days. It caches food in the ground by creating a hole with the bill, then covering the cache with grass, or a stone, twig, or leaf. Caches are spread throughout the territory or home range, with daily caches clumped together and individual caches spaced about 13 m apart. Within a few hours, original caches are usually moved closer to the nest. Magpies appear to remember where food was cached and are capable of smelling caches, so kleptoparasitism occurs (Birkhead 1991; Buitron and Nuechterlein 1985; Genov et al. 1998; Halliday 1992; Hochachka and Scharf 1986; Linsdale in Bent 1946; Madge and Burn 1994; Sarno 1989; Sinclair et al. 2003; Trost 2020).

The magpie eats mostly ground-dwelling invertebrates, seeds, and carrion, especially insects. It is more insectivorous than any North American corvid. Both parents feed the nestlings, predominantly insects and carrion. The average length of food brought to nestlings is 7 mm; grasshoppers are important in their diet. Food delivered to nestlings differs considerably from food eaten by adults. More than 94% of nestlings' food consisted of animal matter compared with 82% for parents. Most of nestlings' food consisted of insects (18% caterpillars, 11% grasshoppers, and 11% flies). During the breeding season, ground beetles, caterpillars, grasshoppers, and carrion are important foods for adults as are insects associated with carrion. In some areas, earthworms are frequently consumed. All carrion, maggots, and other invertebrates are eaten as well as meat. Ticks and moose carcasses are critical sources of food in winter and early spring. It eats bird eggs, nestlings, and small birds. The magpie may attack small- to medium-sized mammals such as ground squirrels and cottontails. In the case of larger prey, it prefers those that are already weakened or may attack them cooperatively. It has been reported pecking into sores of livestock and eating their flesh and

subsequently killing some. It is usually initially attracted by a wound or sore, but tends to make it much larger, feeding on the flesh of the live animal. Mammals may constitute about 10% of the diet. Occasionally it kills frogs, fish, crayfish, lizards, and snakes. Near Ear Falls, fish offal was an important source of food. Some vegetable matter may be consumed, usually wild fruits in late summer or autumn, but these appear to be consumed only when animal foods are lacking (Birkhead 1991; Buitron 1988; Goulden 1975; James 2014; Knight 1988; Licht and Johnson 1992; Linsdale 1937; Trost 2020).

Food availability may be a limiting factor, especially early in the breeding season and other critical times such as winter. Food abundance may influence timing of nesting as well as success and productivity rates. Breeding populations increase where food is abundant (fish hatcheries, cattle feedlots, landfills, etc.) or crash when food becomes scarce. Populations increased 1 year when a steer carcass became available early in spring, and nesting occurred earlier. Populations and timing of breeding reverted to normal the following year. Similar results have been found where magpies were fed dog food. After a late-winter storm in Alberta, 71% of nests with access to dog food survived compared with 15% of nests without supplemental food (Hochachka and Boag 1987; Knight 1988; Trost 2020).

Presence of both adults is essential to successful breeding. From the first day of laying until young hatch, the male provides the female with all her food. If the male is lost during this period, the female abandons the nest unless a replacement male is found quickly. Males do not incubate or brood, so if the female is lost before the clutch hatches or young are close to fledging, the nest fails. If either sex dies after the young hatch, a new mate may help rear the young, then nest with the same mate the following year. Occasionally, a single parent may successfully raise fledglings if a mate is lost after the young fledge. In these cases, the bird had to greatly increase provisioning rates. Of 28 nests where males were removed in Edmonton, a replacement male assisted at 32% of nests and these nests produced as many young as nests where the pair remained intact. The nests without replacement males did not produce any young. Of 5 males and 4 females whose mates were lost in South Dakota, 2 males obtained mates within a day, 2 females had mates within a month, and the remaining 5 birds did not acquire mates that breeding season (Buitron 1988; Dunn and Hannon 1989; Reese and Kadlec 1985; Trost 2020).

Spring weather may affect nesting success, with nesting occurring earlier in warm springs and later in cold springs. Early nests produce more fledglings but these nests are also at risk from late storms. Cold or rainy weather can significantly decrease success. The risk of death of nestlings due to rain is high, and is 2 times greater if rain falls on day 1 after hatching versus day 5. Probability of nestling death on any day increases by 1.3 if it is windy. Heavy rain and snow in May in Edmonton resulted in the loss of 72% of nests (Dhindsa and Boag 1992; Erpino 1968; Gerstell and Trost 1997; Reynolds 1996).

The magpie's distribution appears to be regulated by climate, corresponding to the cold-type dry-steppe climatic region. It appears to be unable to tolerate high temperatures and humidity. Death may occur when temperatures reach 36-41°C. In the east, it does not breed where more than 61 cm of rainfall occurs annually (Linsdale in Bent 1946; Root 1988; Trost 2020; Winter et al. 2000). It may shift habitat to avoid temperature extremes. In California, summer midday temperatures at

ground level exceeded its upper critical temperature, so more time was spent on fence posts and in shade. Open ground was used more in winter, because temperatures there were warmer. The winter roost was selected to avoid heat loss (Mugaas and King 1981).

Several die-offs have occurred as a result of toxic chemicals. Organophosphates are still painted on backs of cattle to control fly larvae. Magpies are highly vulnerable to this because they routinely land on cattle to glean ectoparasites (Trost 2020).

The Black-billed Magpie is highly vulnerable to human disturbance during the nesting season. Disturbance may cause extreme reactions such as females eating their eggs or small young or moving eggs to another magpie's nest. In response to disturbance, adults reduce feeding rates resulting in brood reduction. Young may also fledge prematurely, increasing risk of predation. When populations are studied intensively over several years, the number of nesting pairs frequently declines steadily (Erpino 1968; Trost 2020). Magpies that experienced nest disturbance attempted to minimize further disturbance by placing subsequent nests higher above the ground (Dhindsa et al. 1989; Knight and Fitzner 1985).

The magpie has been widely persecuted by humans. It was considered vermin because it picked at sores on livestock and was frequently shot. Some western states and provinces paid a bounty for it in the 1920s and 1930s. In 1933, 1,033 were killed in the Okanagan Valley by 2 teams of bounty hunters and an estimated 5,000 were shot in southcentral Washington in the winter of 1920-21. Although the rate of shooting has declined, it still continues. Some western urban areas still have active eradication programs. Poison bait was widely used to kill coyotes in the west. Poison grain was put out first to kill birds so that they did not take the bait; thousands of magpies were reported killed in a single county (Bailey 2003; Campbell et al. 1997; Linsdale 1937; Reebs 1986; Trost 2020).

Status

Nesting was first confirmed in the province near Rainy River on 4 May 1980. The Black-billed Magpie continues to be a rare breeder in western Rainy River District. Prior to that, the magpie was a rare autumn and winter vagrant in the province, and it still rarely occurs east of the breeding range in these seasons (Elder 1986; James 1991; McIlwraith 1894; Peck and James 1997).

The second atlas revealed that the probability of observation of the Black-billed Magpie had increased significantly since the first atlas. Breeding evidence was obtained in 39 squares during the second atlas compared with 6 during the first. Breeding is still confined to the general area of Lake of the Woods. It appears that the Ontario population experienced a 10-fold increase since the first atlas, with an estimated population of 200-250 breeding pairs (Coady in Cadman et al. 2007). James (2014) reported a small population at Ear Falls that has probably existed since the 1980s.

Elder (2006) concluded that the magpie would not move much further east than Rainy River District in Ontario. He considered it dependent upon agricultural and anthropogenic habitat and the area to the east is predominantly forested. James (2014) noted that there was no agricultural land in the vicinity of Ear Falls, but that there was considerable open habitat that may provide suitable habitat. These include clear-cuts, wide grassy hydro corridors, bedrock outcrops in forests, and grassy openings around homes and cottages. If the magpie can adapt to these habitats and

overcome any limitations posed by summer temperatures, it may be able to extend its range eastward along the trans-Canada highway.

North American populations have fluctuated considerably. The magpie disappeared from much of its range with the demise of the bison in the 1880s and to later human persecution. Numbers started to increase in the 1910s and 1920s, and it now probably occupies all of its former range. It is unknown how present-day populations compare with presettlement populations. Long-term (1970-2021) Breeding Bird Survey results indicated an annual decrease of 0.836% in Canada and an increase of 16.7% in Ontario. Short-term (2011-21) trends were annual decreases of 1.26% in Canada and 3.31% in Ontario. Results for Canada were highly reliable; Ontario results were of low reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Fledglings remain near the nest for 1-4 weeks after which families begin wandering widely. Groups of 2-8 families may join together in areas near food and water. Adults continue to feed fledglings until they are 6-8 weeks old (Trost 2020).

Postbreeding dispersal begins in mid-July and most movements are local. Many young birds, especially males, remain within 3.5-4 km of the natal site. Females moved further from the nest than males in Idaho (1,034 m compared with 560 m), and dominant males from a brood remain closer than their subordinate siblings. Young females may move 15-25 km from the natal nest, and there are several records of long-term dispersal. At least 40 reports were received from north-central Ontario from Sioux Lookout and Nakina south to Atikokan and Terrace Bay in 1972. Two Saskatchewan juveniles moved 580 km and 151 km southeast and a Wyoming bird moved 354 km. Large flocks rarely occur: 50 were reported in Idaho in October and 1,500 in Death Valley, California in October 1919 where it had never been seen before (Buitron 1988; Speirs 1985; Trost 2020; Trost and Webb 1997).

The magpie is less specific in its habitat requirements outside the breeding season, but is still strongly associated with human-altered landscapes. It avoids forested areas, except for roost sites, and favours open habitats. Its slow flight makes it vulnerable to raptors, so it seldom strays far from cover. Near habitation, it frequents livestock feedlots, barnyards, landfills, sewage lagoons, rural and suburban parks and gardens, and urban gardens. In natural habitats, it prefers riparian thickets, wet meadows, open forests, shrubby gullies in grassland areas, lakeshores, and beaver ponds (Campbell et al. 1997; Trost 2020).

Communal roosts are important in the nonbreeding season, and they are used traditionally. Prior to winter, their main function appears to be related to pair formation and establishment of dominance among yearlings. Even during the breeding season, breeding adults may join nonbreeders more than 1 km from the nest except during incubation and when young nestlings are being brooded. Once young have fledged, they begin following their parents to roosts, as far as 4 km from the nest. A large proportion of a local population may gather at a single roost. Roosts tend to be in dense thickets of trees or shrubs near major food sources (Buitron 1988; Campbell et al. 1997; Trost 2020). Reebs (1987) characterized 12 Alberta roosts. Two were in stands of deciduous trees and the rest were in conifers. All were sheltered in a river valley, except for one in a spruce

hedgerow in an urban area. One deciduous roost was a dense thicket of trembling aspen. The other was dense trembling aspen, white birch, and shrubs. Tree density in these roosts was 14,511 and 10,873 per ha, with average tree heights of 6.1 m and 5.9 m and average diameter at breast height of 5.2 cm and 5.9 cm. Coniferous roosts were typically tall, slim white spruce where crown coverage was more than 50%. The lower halves of trees within the stand were completely defoliated leaving dead limbs where birds could perch. Tree density in coniferous roosts was 2,200-14,900 per ha, but mostly 3,000-5,000. Birds consistently roosted on the side of trees with longer and more numerous branches. Although most birds roosted communally, some roosted singly. Within a roost, there was only 1 bird per tree, and others were prevented from roosting in adjacent trees. Roosts were typically 3-8 m from ground on branches 0.5-1.5 cm in diameter. In conifers, birds usually roosted next to the trunk on the lowest branch with needles. Some perches were used repeatedly over several nights.

Shortly after leaving the nesting area, grasshoppers are very important in the diet and the magpie may feed on them almost exclusively. Later in autumn, grain and fruit are important foods. It may eat fruits of hawthorn, mountain-ash, elderberries, dogwoods, and grapes. It follows roads and hunters to look for carcasses, and visits landfills (Birkhead 1991; Buitron 1988; Campbell et al. 1997).

AUTUMN

The magpie does not appear to be a regular migrant, and most movements may be considered dispersal or wandering. In mountainous areas, there may be seasonal elevational changes and north-south movements have been documented in some areas, including British Columbia. It is not known to migrate in the Yukon (Campbell et al. 1997; Linsdale in Bent 1946; Sinclair et al. 2003; Trost 2020).

WINTER

In winter, the Black-billed Magpie inhabits areas similar to those used during the postbreeding period, but may be more dependent on anthropogenic areas with abundant food. In western Canada, large numbers congregate near feedlots, barnyards, sewage lagoons, railway loading yards, and grain elevators. These habitats are essential to winter survival in the north. In some areas, all winter records are from landfills (Campbell et al. 1997). In Colorado, the magpie was positively correlated with the density of housing within 500 m, percent canopy cover, and percent cover by understorey vegetation. It was negatively affected by the height of understorey vegetation. Although it is known to be human-adapted, it is important to maintain some canopy cover for wintering birds (Miller et al. 2017).

The magpie selects winter roosts to provide shelter from the elements. In Alberta, deciduous roosts were abandoned a few days after permanent snow occurred on the ground. Wind speed in 1 coniferous roost was less than 10% of that in the adjacent open field. In winter, the magpie has roosted in nests and in a cattle shed, where birds rested on the backs of cattle overnight (Erpino 1968; Linsdale in Bent 1946; Reebs 1987).

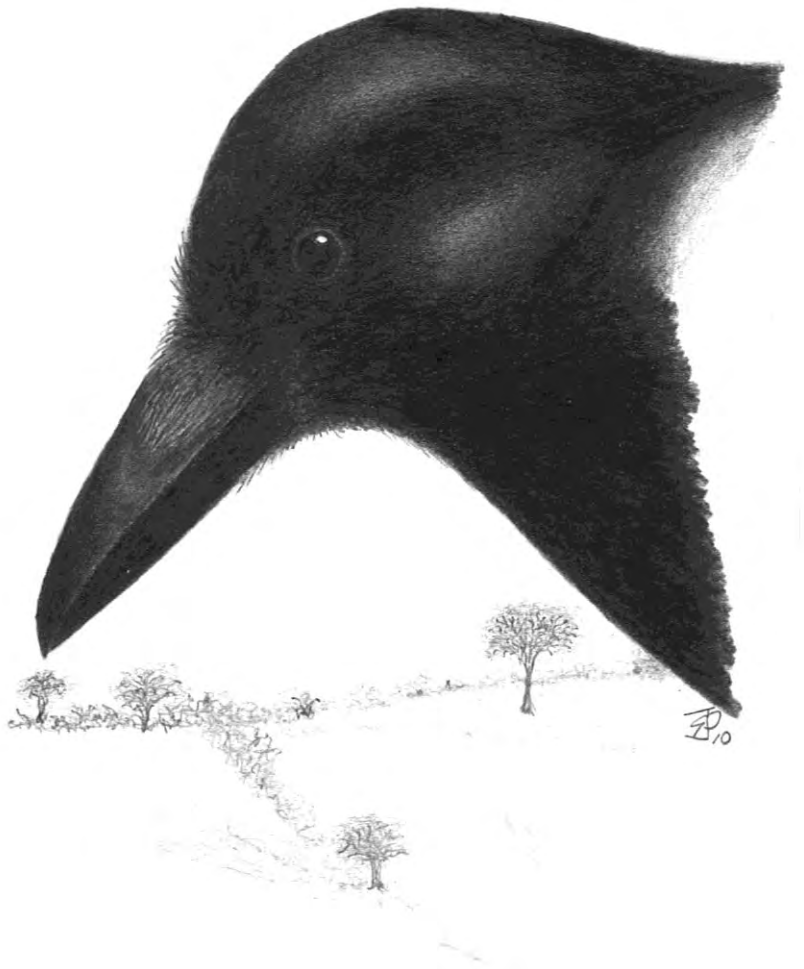
The winter diet is highly variable depending on food sources that birds elect to congregate around. In Alberta, 92% of the diet consisted of decomposed vegetation, primarily oats and wheat. Some seeds of chokecherry and pin cherry were consumed. Other food included meadow voles,

eggs, forest tent caterpillar egg masses, and garbage. Reebs and Boag (1987) concluded that waste grain, meadow voles, and garbage were the most important foods. In Colorado, the magpie is part of an avian scavenging guild that includes Bald Eagles and ravens. Because it is subordinate to these species, it often feeds in flocks at carcasses (McKinstry and Knight 1993). Linsdale (1937) concluded that grain was an important winter food, but that it was eaten out of necessity rather than preference. Grain is avoided as food in July and August when it is abundant; animal food is consumed then. Road-kills on highways are an important source of winter food (Linsdale 1937).

The magpie may visit winter bird feeders, and in Ontario it visits feeders from Rainy River District east to Thunder Bay. Preferred food at feeders is meat and suet, as well as peanuts in the shell and peanut butter mixes. It infrequently eats millet, sunflowers, cracked and whole corn, bird puddings, milo, hulled peanuts, oats, and fresh fruit (Dunn and Tessaglia-Hymes 1999).

American Crow

Corvus brachyrhynchos



BREEDING SEASON

Habitat Requirements

The American Crow breeds in almost every habitat in the province except treeless tundra, although it tends to avoid large, dense forested areas. It breeds in deciduous (18.8% of nests), mixed (10.4%), and coniferous (18.8%) woodlands, including plantations, and in unspecified woodland types (5.8%); in fencerows (13.3%); in overgrown fields or those with isolated trees (11.3%); in urban cemeteries, gardens, parks, and other residential and industrial areas (10.4%); in strips of trees along shorelines (4.6%); on islands (2.9%); in orchards (2.5%); and on treed sand dunes (1.3%; Peck and James 1987). Near Pickle Lake and Parry Sound, it was associated with forest openings near small towns, roads, railways, or buildings (James 1980; James and Peck 1995a).

In southern Ontario, the American Crow was equally abundant on organic and conventional farms. It was positively associated with spring grain, row crops, number of treatments applied to fields, farmsteads, and amount of riparian and upland woods. It was negatively associated with the number of large isolated trees, field size, number of tills, habitat heterogeneity, and road, railway, and hydro rights-of-way (Kirk et al. 2011).

In Quebec, the American Crow was much more abundant in agricultural and densely populated areas than in large forests. In heavily forested areas, it was associated mainly with water bodies, clearings, and openings created by logging and road construction (Pelletier in Gauthier and Aubrey 1996). In Illinois, Graber et al. (1987) considered it a highly generalized forest-edge species, a dominant species of black oak forest, and a common species of prairies and prairie thickets. Densities were higher in bottomland than upland forest and it shunned forest interiors. In an intensively cultivated area, 45% of nests were associated with trees in open fields, 34% were in woodlands, 14% in sparsely wooded pastures, and 7% in orchards, cemeteries, abandoned farm yards, tree plantations, and thickets. Also in Illinois, it preferred low- to medium-density habitat and avoided forested habitat. Within home ranges, there was a preference for agricultural land; high-density urban areas were avoided (Yaremych et al. 2004). In California, it was associated with urban areas and areas distant from extensive forest (Kalinowski and Johnson 2010). In British Columbia, preferred natural habitat is open to semi-open coniferous forests and adjacent grasslands, riparian woodlands, valley bottoms, and lakeshores. It is most abundant in agricultural fields among woodlands and near communities where it inhabits landfills, barnyards, parks, residential areas, orchards, railways, and road corridors. Forty-nine percent of nest sites were associated with cultivated farmland or pasture and rangeland; 12% with riparian areas; 11% with deciduous forest; 10% with urban, suburban, or industrial land; and 9% with coniferous forest (Campbell et al. 1997). In the Appalachians, it occurred in 18.2% of old-growth forests compared with 97.8% of forests statewide and 96.4% of forests on the Appalachian Plateau (Haney 1999). This crow has 2 important habitat requirements: openness for ground feeding and presence of scattered trees, woodlots, windbreaks, and forest edges for safety, loafing, nesting, and roosting. It uses a wide range of natural and human-made habitats such as logged areas, agricultural fields, cities, villages, farmland, pastures, landfills, city parks, cemeteries, golf courses, residential yards, road rights-of-way, feedlots, and shorelines. Areas of extensive grassland without trees and extensive forests are avoided. It may occur in openings in extensive forests where rivers or highways provide an access corridor (Verbeek and Caffrey 2020).

At the landscape scale, the American Crow preferred areas with 44-58% forest cover in New York (Cunningham and Johnson 2019). In Seattle, its abundance was negatively correlated with percent forest cover at the 1-km^2 scale (Marzluff et al. 2007).

In Missouri, Hayden et al. (1985) stated that the American Crow required a minimum forest size of 4.6 ha, and considered it area sensitive because it typically occurred in forests larger than its territory size. They acknowledged that the minimum forest size required in New Jersey was only 0.2 ha. Robbins et al. (1989) stated it was area sensitive in the mid-Atlantic states, with its probability of detection 100% in 10-ha forests (the smallest-sized forest for all species they considered area sensitive). Probability of detection declined to 50% in 0.2-ha woodlots. Its presence was positively associated with forest size, but negatively associated with the amount of forest cover within 2 km. In North Dakota, its probability of observation increased with forest size. Probability of occurrence was approximately 52% in 1-ha aspen groves, 80% in 10-ha stands, 90% in 100-ha stands, and 100% in 1,000-ha woodlands (Grant and Berkey 1999). Other studies found no correlation between crow presence and forest size, but confirmed that it is more likely to be present in fragmented habitat where there is a small percentage of forest cover in the landscape (Hobson and Bayne 2000; Keller and Yahner 2007; Kilgo et al. 1997). There is no evidence of it being area sensitive in Ontario. In southern Ontario, its probability of observation was negatively correlated with the amount of forest 100 m or more from edge, woodlot size, amount of forest within 2 km, and amount of regional forest cover. Only the first and last relationships were significant (Austen et al. 2001). In southern Ontario, it frequently nests in hedgerows in agricultural landscapes (Reaume 2013).

Smith (2004) examined the distribution of predators in 2 forested habitats in Michigan. The American Crow was the only species that showed a preference for forest edge over forest interior.

Communal nocturnal roosts are important to crows year round. Ontario roosts were predominantly in deciduous woodlands, often in areas subject to considerable disturbance. In Thunder Bay, a roost in a woodlot was close to high human activity including a major highway, airport, railway, and industrial and residential areas. The Chatham roost was in deciduous trees along the Thames River. The St. Catharines roost was in a willow-aspen-maple woodlot along a slope of the Niagara Escarpment in the city. This roost is used consistently, but its location shifts as much as 0.5-7.5 km along the escarpment within seasons. In Essex, a deciduous woodlot is used for roosting. In this roost, roost trees were all deciduous and included ash, elm, oak, basswood, hawthorn, maple, and hickory. Trees smaller than 3 cm diameter at breast height (DBH) and dead trees with no remaining limbs did not appear to be used for roosting. Large oaks (44-70 cm DBH) were preferred; crows settled into them first. The lowest that crows roosted was 2 m. Most Ontario crows roost in larger deciduous trees; in downtown Hamilton, some roosted in planted pines. The Niagara gorge was used historically for roosting, especially on the steep slopes between the falls and Queenston. This roost shifted to a deciduous woodlot in the mid-1920s and was subsequently abandoned. In Hamilton, crows roosted along the forested Niagara Escarpment and also near city hall in urban habitat. In British Columbia, roosts are in mature deciduous or coniferous trees distant from disturbance, typically in tall trees along rivers. New Jersey roosts were in secondary forests dominated by red maple 3-8 m tall, and were associated with superabundant food sources. In California, nesting birds roosted together in a cluster of about 40 trees within an area of high nest

density, and several nests were within the roost. Trees used for roosting were taller than random, had a greater DBH, a larger crown, and greater crown volume. During winter, ambient light levels and interior canopy temperatures were higher in roost than non-roost trees. In Illinois, roosts occurred in upland deciduous stands, particularly oaks, and in willow-cottonwood bottomland forests, plantations, hedgerows, and evergreen plantings. In New York, crows preferred to roost near water below 300 m altitude. Many other roosts are near water. Roosts tend to be traditional and may be used for decades or over a century (Campbell et al. 1997; Dobos 1985; Emlen 1940, 1942; Graber et al. 1987; Knapton and Maturi 1984; Reaume 1985, 2013; Sheppard et al. 1936; Stouffer and Caccamise 1991; Verbeek and Caffrey 2020; Weseloh 1983). Roost use varies seasonally. During the breeding season, roosts are often in the territory and near the nest. Adults, helpers, other yearlings, and fledglings may roost in the territory. Breeding males sometimes leave their territories to join the local communal roost. Numbers of roosts begin to increase in September and they are well established by mid- to late October. Maximum numbers in roosts tend to occur in late November or early December, particularly where resident birds are joined by migrants. Numbers decline again in late winter and early spring. In winter, some New Jersey birds roosted exclusively at the communal roost; others alternated between the territory and communal roost. By mid-April, most stopped using the communal roost or made individual trips to it after several nights of remaining on territory (Caccamise et al. 1997; Graber et al. 1987; Sullivan and Dinsmore 1992; Verbeek and Caffrey 2020). Foraging areas may be 7.5-80 km from the roost, with birds moving at least 34 km from the Chatham roost. Birds using the Essex roost spread over the entire county during the day, an area of about 1,925 km^2. The area used around New York roosts ranged from 130 km^2 to 1,800 km^2. Resident birds may be faithful to foraging areas within their territories. Migrants show no fidelity to foraging areas. Cooperative groups and flocks break up when returning to the roost, with individuals staging at pre-roost areas away from other members of the group. They also roost independently of each other and may attend different roosts. Pre-roosting areas are used when the birds move towards the roost in late afternoon. These tend to be fields that are bare or have very short grasses. In St. Catharines, pre-roosting occasionally occurs in trees. In California, the same fields were used day after day with similar nearby fields rarely used. Birds grouped together tightly within a field with only a small percentage of it used; locations used within the field often changed day to day. Although some foraging occurs at pre-roosts, their main function appears to be to minimize predation. Some pre-roosts were on rooftops where foraging was not possible (Caccamise et al. 1997; Dobos 1985; Emlen 1940; Graber et al. 1987; Knapton and Maturi 1984; Moore and Switzer 1998; Reaume 1985, 2013; Stouffer and Caccamise 1991; Verbeek and Caffrey 2020).

All Ontario nests were above ground, mostly in live trees or shrubs, although 3 were in dead trees, 2 were on top of dead stubs, and 1 was 15 m up in a crevice on a cliff face. Coniferous trees of 7 species supported 54.0% of nests compared with 46.0% in 16 species of deciduous trees. Tree species most frequently chosen were pines (74 nests), spruces (45), white cedar (36), oaks (24), maples (20), willows (17), and beech (16). Nests were well concealed in crotches or on horizontal limbs and most often at or near the trunk. Some nests were 0.5-6 m from the main trunk. Most were in the upper third of the supporting tree or shrub. One nest was repaired and used the following year. Nests were 0.6-26 m from ground, with most 5.5-10.7 m up. The lowest nest was on an island where only short trees were available (Peck and James 1987). In southern Ontario, rural crows favour

nesting in deciduous trees; urban crows prefer conifers (Reaume 1987a, 2013). A nest was reported on an upper ledge of the Royal Ontario Museum building, 21 m from ground. This appears to be one of very few records of crows nesting on a building. Most of these were from the prairies on abandoned buildings where there are few trees for nesting. Another nest was on a wooden ledge along a lock gate at Jones Falls (Peck 2002).

In Maine, almost all nests were in conifers; most were in deciduous species in Pennsylvania, Delaware, and New Jersey; all at Cape Cod were in conifers; it appeared to prefer oaks in Ohio; most Illinois nests were in deciduous trees and it may have preferred oaks and elms; and 50% of British Columbia nests were in deciduous species. Nest height reflects the average height of available trees. Nests are typically in the top quarter to third of trees or shrubs. Where woody vegetation is absent, the American Crow rarely nests on the ground. Nests have been reported 0-23 m from ground, but mostly 4-11 m up. A new nest is typically built each year, but old ones are occasionally used as a base, or rarely refurbished and reused. One nest was used in 3 consecutive years and another was used for at least 3 years. Nests tend to be built very near the previous year's nest and occasionally in the same tree. It has nested in old hawk nests, in cavities in trees, on hydro poles, in bulrushes above water, on top of old magpie nests, and on chimneys. In Illinois, nests in dense forests were within 36.6 m of edge. In a California walnut plantation, early nests built before leaf-out averaged 12.2 trees from edge; later nests averaged 8.8 trees from edge (Campbell et al. 1997; Chamberlain-Auger et al. 1990; Emlen 1942; Graber et al. 1987; Gross in Bent 1946; Reaume 2013; Verbeek and Caffrey 2020).

The American Crow may be nonterritorial, defend a small area around the nest or female, nest colonially, or defend large exclusive home ranges. In some cases, only core areas around nests are defended and birds feed communally in undefended areas, or foraging areas may be included in the defended area. Alternatively, territorial disputes may be intense with birds violently locking together and falling through the air. Understanding territoriality is further confounded by the fact that some nests have helpers, leading some authors to conclude that the nest site is not defended. Territories are maintained year round in Massachusetts, New Jersey, California, Oklahoma, Florida, and New York, but apparently not in Ohio or northern portions of its range (Reaume 2013; Verbeek and Caffery 2002). Nonbreeding birds may move about various territories, visit their parents, or move in with nearby groups; group sizes may change hourly to annually (Reaume 2013). Emlen (1942) described a nesting colony in California where about 60 pairs nested in a 93.7-ha walnut plantation. The spacing of nests suggested territoriality, with nests relatively uniformly distributed and averaging about 75 m apart, although 7 were only 24-27 m apart. On a California golf course, core areas averaged 1.25 ha but did not appear to be defended. Overlap of core areas occurred, especially in peripheral territories where almost complete overlap occasionally occurred; some even nested in the same tree. Neighbours regularly trespassed on other core areas, and groups from different core areas fed together without strife. When a new pair wished to establish a territory, it simply squeezed in and neighbours adjusted territories without conflict (Caffrey 1992). In Illinois, territoriality was confined to the nest tree or female, and defence of the nest appeared rare (Graber et al. 1987). Fitch (1958) concluded that crows were nonterritorial in Kansas. Kilham (1989) studied crow territoriality in Florida and New Hampshire and realized that pairs frequently had helpers. He observed 2 groups of crows in Florida that maintained distinct territories with typical territorial disputes along

boundaries. Each group had territory sizes of approximately 90 ha. One year, birds in 1 group split into 3 subgroups, all nesting in a portion of the original territory. Two subgroups had territories of 40 ha and the other's size could not be determined. These subgroups defended territorial boundaries against members of their former group. Male territorial behaviour was strongest from prior to nest building until early incubation. Females became increasingly territorial as incubation progressed. In New Hampshire, groups maintained territorial boundaries through summer and autumn, and the same boundaries were maintained for 3 years. In Massachusetts, territories were all purpose and defended year round. Mean territory size was 42.1 ha (range 9.4-104.0 ha). Mean distance from neighbouring nests was 0.86 km. Mean distance of subsequent nests in territories maintained year round averaged 0.2 km (range 0-0.6 km; Chamberlain-Auger et al. 1990). In New Jersey, birds bred cooperatively and each individual of the group maintained a small activity centre. Conflicts between neighbouring groups were infrequent and occurred primarily in early stages of breeding. Birds sometimes all left their territories to feed communally at a landfill (Caccamise et al. 1997). In Oklahoma, Knopf and Knopf (1983) observed territorial behaviour by groups of birds. In Manitoba, crows maintained non-overlapping home ranges or territories that averaged 2.6 km^2 (range 0.8-6.0 km^2). The mean foraging flight distance was 382 m (range 16-2,078 m; Sullivan and Dinsmore 1992). Overall, territory sizes have been reported as 0.72-278 ha. In urban areas of New York, crows defended territories averaging 8.7 ha (range 0.8-28.3 ha) compared with 37.7 ha (range 12.6-95.0 ha) in rural areas. Oklahoma families occupied non-overlapping to slightly overlapping territories of 50-150 ha (average 94 ha; Verbeek and Caffrey 2020). Yaramych et al. (2004) radio-tracked 45 American Crows from late spring to early autumn in Illinois. Home range averaged 9.6, 6.7, and 6.4 km^2 for hatch-year, subadult, and adult crows, respectively. In Guelph, home ranges of families averaged 15 ha with extremes of 8-20 ha (Reaume 2013). Territories or home ranges of 1-3,500 ha have been reported elsewhere. Urban birds tend to have smaller home ranges than rural birds due to greater abundance of food. In Manitoba, the average home range size during the breeding season was 260 ha. Other home range sizes include 50 ha in Florida, 67 ha in Maryland, 59 ha in Illinois, 94 ha in Oklahoma, 31 ha in suburbs and 67 ha in rural New York, 25-49 ha in New Jersey, 20 ha in Philadelphia, and 42 ha in Massachusetts with a range of 9.4-104 ha (Reaume 2013).

No information is available on natal site fidelity for migratory populations. In Illinois, homing to nesting areas was not documented, but juveniles were recovered after a year near the nesting area (Graber et al. 1987). In New York, dispersal from natal to breeding sites ranged from 0 to 60 km and averaged 3.2 km in urban areas and 3.3 km in rural areas. Of 49 crows raised in urban areas, only 2 nested in rural areas. None of the birds raised in rural areas nested in urban areas. Three urban-raised females moved to other cities to breed (Verbeek and Caffrey 2020).

In resident populations, juveniles often remain in the natal territory and become helpers at their parents' nest. In California, 75% of young known to be alive were still on the natal territory with their parents the following season. Yearlings that were not helpers often remained on the natal territory, but might join the resident nonbreeding flock or trespass on core areas of other breeding pairs. In Massachusetts, over 94% of breeding was cooperative, with offspring remaining in the family unit throughout the year. In all cases when a pair raised young unassisted, these young remained and assisted the following year. Each breeding group consisted of the breeding pair and offspring aged

1 to several years old. All surviving young remained on the natal territory and acted as helpers. In California, significantly more females (100%) remained in the natal territory to help than males (64.3%). Some remained with their adults an additional 1-3 years. In all cases, these individuals helped some years but not in others. In this population, 18% of juveniles dispersed from the natal area in autumn and either joined the nonbreeding flock or left the general area; half returned to the natal area the following spring. In the Seattle area, 27% of 56 juveniles dispersed more than 2 km from their natal territory and 32% remained within 1.5 km. Dispersing crows moved a median distance of 10.4 km (average 9.1 km, range 2.1-22.2 km). Birds that remained locally moved a median distance of 0.6 km (average 0.7 km, range 0.2-1.5 km). Twenty-three percent of urban juveniles helped their parents and 21% of suburban and rural young helped. Females were more likely to disperse, and males were more likely to be helpers (Withey and Marzluff 2005). In New Jersey, fidelity of individuals to core areas was 54-96% over 2 years and did not differ between adults and juveniles. Some birds remained in the same group and area for at least 3 years. Individuals were sometimes absent from the group for days or weeks, then returned without resistance from other group members. Although helpers feed nestlings and fledglings, feed the incubating and brooding female, and attend to nest sanitation, their presence does not improve productivity, so they are not helpful from an ecological perspective (Caccamise et al. 1997; Caffrey 1992, 1999; Chamberlain-Auger et al. 1990; Verbeek and Caffrey 2020).

In resident populations, adults maintain permanent all-purpose territories (Caffrey 1992). No information is available on adult site fidelity for migratory populations. In Ontario, it is unknown if the wintering population consists of permanent residents maintaining territories, if they are migrants from further north, or a combination of residents and migrants.

Limiting Factors

Eggs have been found in Ontario nests from the beginning of March until the third week of June, mostly in the last week of April and first week of May (Peck and James 1987). In Algonquin Park, nests are under construction from late March to late April, eggs are present from late April to early May, nestlings are present from mid- to late June, and dependent fledglings have been observed from mid-June to mid-August (Tozer 2012). In Guelph, nest building began on 10 March, the first egg was laid on 24 March, incubation began on 26 March, the first egg hatched on 13 April, the first nestlings fledged on 16 May, and the last nestlings fledged on 16 June (Reaume 2013).

Depending upon weather, nest construction may take 1-3 weeks, but duration of nest building also depends on whether there are helpers. California nests took 10-17 days to complete without helpers and 5-9 days with helpers; second nests are built in 5-10 days. In Saskatchewan, an average of 4.8 days elapsed between nest completion and clutch initiation; the interval was 6-16 days in Florida. In California, egg laying started before some nests were complete. Usually 1 egg is laid a day, or occasionally 1-2 days may be skipped before the last egg is laid. Incubation usually begins with the laying of the third egg, with eggs hatching over a 2-3-day period. The incubation period is 16-21 days, but mostly 17-19 days. Reported incubation periods of 14-33 days with an average of 23.2 days in Massachusetts are considered suspect by some authors. Young fledge when they are 24-43 days old, but mostly about 30-32 days. In Illinois, it was estimated that 53-59 days were required from the onset of nesting to fledging of young (Campbell et al. 1997; Chamberlain-Auger et al. 1990;

Emlen 1942; Graber et al. 1987; Gross in Bent 1946; Ignatiuk and Clark 1991; Kilham 1989; Reaume 2013; Verbeek and Caffrey 2020).

One brood is raised, but the American Crow is a persistent renester that may lay as many as 4 clutches in an attempt to raise young. Usually a new nest is built when renesting, but occasionally the old one is used. Clutches of 2-8 eggs have been reported in Ontario, with most containing 4 or 5 eggs. The 8-egg clutch appeared to be laid by 2 females because there were 2 groups of 4 eggs with different colour patterns. Overall, clutches of 2-10 eggs have been reported. Normal clutches contain 3-7 eggs, with 5 eggs most frequent. Average clutch sizes were 4.5 in California, 4.8 in Saskatchewan, and 4.7 in Pennsylvania and New York. Clutch size may increase northward. Brood reduction may occur due to siblicide (Campbell et al. 1997; Emlen 1942; Graber et al. 1987; Gross in Bent 1946; Ignatiuk and Clark 1991; Kilham 1986; Peck and James 1987; Verbeek and Caffrey 2020).

Although many birds breed when they are 2 years old, 25-65% may not breed until later. Some may not breed until they are 3 or more years old. Breeding may not occur every year. In California, 1 male that had bred for 3 years joined the nonbreeding flock when he was 7 years old. A widowed female that was at least 5 years old and had bred the previous year joined another pair to help (Caffrey 1992; Kilham 1989; Verbeek and Caffrey 2020).

The mating system is monogamous. Long-term pair bonding has been reported in resident populations, but it is unknown if this occurs in migratory populations. In more than 100 pairs monitored in California and Oklahoma, only 1 case of divorce was observed. Some California pairs remained together for at least 9 years. In New York, females resisted extra-pair copulations, but 19% of young within 23 of 71 broods (32%) were sired by extra-pair males. Extra-pair males included birds both within and outside the family group (Townsend 2009; Verbeek and Caffrey 2020).

The American Crow forages in open habitats and usually does not feed in forested areas. In Manitoba, it foraged often in cropland but this was the only open habitat used less than its availability. Wetlands were used for foraging slightly more than availability; other habitats were used proportionately. Some pairs made extensive use of a particular habitat; others made little use of the same habitat. Vegetation taller than the crows was not used for foraging. Foraging occurred in hayfields until vegetation was too tall, then resumed after cutting. In southern Ontario, most feeding occurred in hay or alfalfa fields (25%), on lawns (13%), and in small grain stubble (13%). Other substrates used for foraging included 9% in gravel, 9% in pastures, 6% in landfills, 5% in weedy fields, 4% in corn stubble, 3% in plowed fields, 2% in small grains 15 cm or less in height, 2% in corn of similar height, and 2% in recently planted fields that were still bare earth. Hayfields were used much more than their availability. It obtains most food by walking on the ground, but takes some fruit from trees and shrubs. It takes food from the surface of the ground or on vegetation, but may dig with its bill and turn over cow dung and other debris to find food. It may catch flying insects or pounce from a perch onto prey and occasionally captures small birds in flight. Amphibians and small fish may be captured in water. It was observed waiting for cooperatively feeding Common Mergansers to drive fish into shallow pools, where crows captured some of them. Kleptoparasitism of other birds and river otters occurs, and it may rob other birds' stores. Occasionally the crow walks on the backs of pigs and cattle and removes and eats ticks and lice from them. It may walk beside the heads of rooting pigs to obtain invertebrates. In Florida, it took salamanders in front of an

advancing line of White Ibises and occasionally kleptoparasitized them and Great Egrets. One or 2 birds occasionally shook leaves and branches in trees while the remainder of the group waited for invertebrates, frogs, and snakes to fall down. In Michigan, crows captured and ate little brown bats emerging from a mine. On 3 occasions, a crow descended into the mine shaft and returned with a bat. There are accounts of apparent cooperative hunting to kill a bat near Ottawa and a single crow capturing a little brown bat in flight. This crow often drops hard prey such as nuts and small turtles on pavement or other hard surfaces to break them open. Observations of tool use include modifying a piece of wood and using it to probe a hole for a spider, and a captive bird using a plastic cup to add water to dry mash (Caffrey 2000, 2001; Flaspohler 2017; Hernández et al. 2007; Hulse and Atkeson 1953; Kilham 1989; Lefevre 2005; Putnam 1992; Reaume 2013; Sullivan and Dinsmore 1992; Verbeek and Caffrey 2020; Walley 1993).

Short-term food caching occurs on the territory when food is abundant. Hard food, such as nuts, is typically cached in the ground by hammering it in with the bill. Caches are covered with grass or leaves. The American Crow may carry food as far as 2 km prior to caching it. Corn may be stored in the ground or in shallow water. Soft or more perishable foods may be stored in trees or in long grass where it may be covered with grass clippings; in winter suet may be stored under snow. During the breeding season in Guelph, 46% of caches were in lawns, 41% were in weedy areas, 8% were on or among used machinery, and 5% were in coniferous trees. Other food items the crow has cached include noodles, bird eggs, fish, clams, frogs, snakes, mice, young rabbits, and otter dung. The male occasionally feeds cached food to the female on the nest. Cached food may be stolen by other crows, and crows may raid the caches of woodpeckers (Conner and Williamson 1984; George and Kimmel 1977; Kilham 1989; C. Long and C.A. Long 1990; Reaume 2013; Verbeek and Caffrey 2020).

The diet of nestlings is essentially the same as that of adults, except that the relative percentages of individual food items vary. When they are very young, nestlings are fed readily digestible food such as spiders and caterpillars. By the time they fledge, the diet differs only slightly from that of the adults, and includes beetles, crustaceans, small mammals and grain. Food consumed by 778 nestlings consisted of 17.4% scarab beetles, 3.9% ground beetles, 2.6% other beetles, 14.6% grasshoppers, 2.6% bugs, 5.3% caterpillars, 1.9% miscellaneous insects, 9.7% spiders and centipedes, 1.8% crayfish, 0.7% fish and molluscs, 7.0% amphibians and reptiles, 1.6% wild birds and their eggs, 1.6% poultry and their eggs, 6.2% rodents, 2.6% other mammals, 4.0% carrion, 11.9% corn, and 4.6% miscellaneous vegetable matter (Kalmbach 1918).

Adults are opportunistic omnivores that quickly respond to insect outbreaks or other abundance of food. Earthworms may be an important food; crows in Guelph selectively fed on the anterior of common earthworms and left the remainder. In Florida, it fed on tapeworms passed by cattle and on their placenta. It may follow plows to feed on uncovered June beetle grubs, and may dig them up in lawns and pastures. In some areas, it is an important predator of waterfowl and heron eggs but in other areas these food items are rarely exploited. It commonly eats nestlings of other bird species but not at rates formerly reported. Mock Common Nighthawk nests were provided in rural and urban settings and on roofs in Wyoming. Predation rates were higher in urban areas where crows were more abundant, and all identified predators were crows. It may be contributing to the decline of urban nighthawk populations. Most mammals it attacks are mouse-sized, but there is 1

record of it killing a live eastern chipmunk. It occasionally attacks larger mammals such as young pigs, raccoons, and deer, but only if they are in a weakened state. Congregations have been observed at garter snake hibernacula, feeding on the concentration of snakes. It commonly scavenges on road-kills and other carcasses where it is subordinate to Turkey Vultures and ravens, but dominant to Blue Jays. In urban areas, this crow readily feeds on human garbage and discarded food. In Toronto, crows routinely foraged on small injured or dead passerines that had collided with windows of an office building (Bent 1946; Giles et al. 2015; Graber et al. 1987; Gross in Bent 1946; Kilham 1985a, 1989; Latta and Latta 2015; Nocera 2000; Reaume 1987b, 2013; Sullivan and Dinsmore 1992; Verbeek and Caffrey 2020; Walley 1993). Watermolen (1996) reported crows eating sand which may aid in the digestion of grains and acorns.

Kalmbach (1918) examined 2,118 stomachs throughout the American Crow's range. The adult diet consisted of 28.1% animal matter and 71.9% was vegetable material. Most (52.4%) animal food was consumed in May with a uniform decrease through June (47.0%), July (44.3%), and August, but even as late as September animals constituted about a third of the diet. Lower percentages of animals (11.0-18.4%) by month were eaten from October through April. Beetles represented 7.6% of the yearly food, including 4.3% adult and larval scarab beetles, 1.6% ground beetles, 0.6% weevils, and 1.0% miscellaneous beetles. Grasshoppers, crickets, and katydids comprised 7.3% of the diet with most taken in July, August, and September. Other animal food included 1.6% caterpillars; 0.6% bugs, including cicadas, leafhoppers, and stink and leaf-footed bugs; less than 0.5% flies; 0.7% hymenopterans; 0.5% spiders; 0.7% miscellaneous insects such as caddisflies, dragonflies, mayflies, and dobsonflies; 1.2% crustaceans, (mostly crayfish); 0.3% aquatic and terrestrial molluscs; 0.6% fish remains; 1.4% reptiles (turtles, snakes, and lizards) and amphibians (toads, frogs, and salamanders); 0.3% wild birds and their eggs, 0.6% poultry and their eggs; 1.6% small mammals (young cottontails, voles, white-footed mice, house mice, rats, shrews, moles, weasels, and bats); and 2.6% carrion. May was the month when the least (47.6%) amount of vegetation was consumed. Highest consumption occurred from October through February. Corn is a staple and constituted 38.4% of the annual diet with peak consumption from October through February. Other grain constituted 12.7% of the diet, including wheat, oats, and buckwheat in order of abundance. It may also eat cultivated plants including fleshy fruits (apples, pears, and plums), the rind and pulp of melons, the meat of nuts, frozen waste pumpkins, turnips, blackberries, mulberries, grapes, strawberries, potatoes, peanuts, beans, peas, and cherries. Wild fruit comprised 14.0% of the annual diet, with peak consumption in September and October. This was mostly mast in the forms of acorns and chestnuts, but it also ate fruits of sumac, poison ivy, greenbrier, grapes, Virginia creeper, black gum, dogwoods, wild cherries, plums, strawberries, mulberries, raspberries, juneberries, blueberries, red cedar, beech, hackberry, barberry, currants, hawthorns, and huckleberries. It occasionally eats mushrooms. Weed seeds constituted less than 0.5% of the diet and included those of knotweeds, foxtails, ragweed, amaranths, and pokeweed. In the southeastern United States, the diet was comprised of 31% animal food and 69% vegetable matter. Insects comprised almost 20% of the diet, with June beetle adults and larvae, weevils, grasshoppers, and caterpillars dominating. Crustaceans, predominantly terrestrial crayfish, were an important food item (7.4%). It also fed in aquatic habitats with molluscs, amphibians, and fish comprising 4% of the diet. Corn and wild fruits were the dominant vegetable matter in the diet. Corn constituted about 25% of the diet and about a third of the crow's food was

fruit of black gum, sumacs, pokeweed, blackberries, and greenbriers. Some grain and cultivated fruits were also taken. It caused some damage to watermelon, pea, strawberry, and peanut crops (Beal et al. 1916). Other miscellaneous vegetation that it may consume includes soybeans, squash, sunflowers, elderberries, nightshade, winterberry, and yellow flatsedge tubers (Verbeek and Caffrey 2020).

Peck and James (1987) reported a punctured Brown-headed Cowbird egg in a crow nest, but it was uncertain if the egg had been laid in the nest or carried to it by a crow. Three cases of cowbird parasitism of the crow have been reported in North America (Verbeek and Caffrey 2020), but chances of successful parasitism are nil.

The American Crow is highly vulnerable to West Nile virus and a high proportion of birds that contract it die. In 2000, 1,095 of 1,105 birds (99.1%) testing positive for the virus in Ontario were crows; 1,122 of 1,125 (99.7%) in New Jersey were crows (McCracken 2003a; Verbeek and Caffrey 2020). In 2002, more than 2,700 dead crows were found in Burlington south of the Queen Elizabeth Way (Mike Cadman, personal communication). It was scarce in urban Burlington in 2003 and less common throughout the entire Hamilton area, but appeared to make a quick rebound from this setback (Curry 2006). On the 2003 Christmas Bird Count (CBC) held in the Oakville/Mississauga area, a 90% decline in crow numbers was observed, possibly due to West Nile virus. This virus arrived in Quebec in 2002 with major fluctuations in crow numbers in 2003 and smaller fluctuations in 2004 and 2005. Thereafter, the crow population stabilized (Reaume 2013). In Illinois, 68% of 45 crows died and tested positive for West Nile virus. This crow's preferences for low- and medium-density housing habitat exposes it to the primary sector for West Nile virus, and its large home range results in it potentially spreading the virus over a large area (Yaremych et al. 2004). Kilpatrick et al. (2007) stated that significant effects on its population occurred due to the virus. In California, the crow was one of the most vulnerable species to West Nile virus (Smallwood and Nakamoto 2009; Wheeler et al. 2009). Caffrey et al. (2005) estimated that 65% of an Oklahoma crow population died as a result of West Nile virus. Reaume (2013) provided an in-depth account of the relationships between the American Crow and West Nile virus.

Humans have a long history of persecuting crows. In the 1920s and 1930s, it was common practice to dynamite roosts. From 1934 to 1939, the kill from shooting in Illinois was estimated at 300,000 and an additional 630,000 were dynamited between 1934 and 1945; 127 roosts were dynamited in Oklahoma killing 3.8 million crows. Eighty thousand were killed 1 night in Texas. Poison has also been used to control numbers. The crow was regularly shot and some provinces and states paid bounties for dead crows. In the 1940s, most nest losses occurred before foliage developed sufficiently to conceal the nest, and shooting was the major cause of loss. In Illinois, 94% of band recoveries were birds that had been shot or trapped. In the 1920s, a roost in Niagara Region was abandoned due to logging and shooting. Although the incidence of shooting has declined, crow hunting is still a popular sport. In the United States, the crow is partially protected, with hunting seasons not to exceed 124 days and they must exclude the breeding season. In Ontario and most of Canada, it is unprotected. Some Canadian towns and cities have initiated eradication programs, and controlled crow hunts have been held in Chatham. Beginning in the 1950s, crows recognized that they were safe from shooting in urban areas and started nesting in them. Urban and rural crows

exhibit different nest defence behaviours based on their relative wariness of humans. Urban crows are habituated to humans. In rural areas, crows stay outside of gun range and fly from the nest at distances that would give a human few clues in finding the nest (Bailey 2003; Campbell et al. 1997; Erskine 1998; Graber et al. 1987; Gross in Bent 1946; Houston 1977; Knight et al. 1987; Pelletier in Gauthier and Aubry 1996; Sheppard et al. 1936; Verbeek and Caffrey 2020).

Habitat changes have been mostly beneficial for crows. Clearing and fragmentation of forests, tree planting in urban centres and around homesteads, planting coniferous plantations, and tilling of agricultural land have been beneficial. Corn is planted much more frequently and over a larger proportion of southern Ontario than previously, and this is a major source of food. More roads and higher traffic volumes produce more carrion for foraging crows. In a Pennsylvania woodland where the density of tall shrubs increased over a long period, and densities of canopy and subcanopy trees and short shrubs declined, the crow population increased by 733%. In intensively farmed areas, numbers may decline (Graber et al. 1987; Rohnke and Yahner 2008; Verbeek and Caffrey 2020). Along the Michigan shoreline of Lake Superior, the crow was significantly more abundant where cottage development had occurred than in forested habitat on the other side of the road (Ford and Flaspohler 2010).

In the Carolinian Forest Region of Ontario, there were no differences in the abundance of the American Crow in unharvested forests, woodlots where standard thinning had occurred, or those in which diameter-limit cuts had been made (Holmes et al. 2004). In the Canadian Shield of Ontario there was no significant difference in its abundance in early and mid-successional clear-cuts and burns in the same seral stages. It was equally abundant in early successional, mid-successional, and mature stands (Zimmerling et al. 2017). In New York woodlands, selective logging was beneficial for crows. Crows occurred on 32% of unmanaged forests and in 42%, 53%, 78%, and 70% of forests where 25%, 50%, 75%, and 100%, respectively, of legal diameter trees were harvested (Webb et al. 1977).

The American Crow can contract rabies by feeding on rabid, dead vertebrates. It may also be infected by other crows that have the disease (Verbeek and Caffrey 2020).

Status

The American Crow is probably much more abundant now than it was before European settlement and forest clearing (Verbeek and Caffrey 2020). McIlwraith (1894) noted that it preferred cultivated areas and increased as Ontario became settled. Fleming (1907) considered it an abundant summer resident in Toronto. Baillie and Harrington (1937) concluded that it was one of the most common residents and that it bred throughout the province. It was known to breed north to southern Kenora District and range rarely north to Hudson Bay. In the Niagara area, it was formerly abundant in the breeding season, but only fairly common in 1936 due to abandonment of a major roost (Sheppard et al. 1936). It was very common in eastern Ontario in the 19th century, and numbers in the Kingston area are gradually increasing (Weir 2008). James (1991) considered it a common resident north to Kenora and Cochrane, and rare and local north to Hudson Bay.

The second atlas demonstrated that there had been little change in the distribution of the crow since the first atlas. It was found in a few more locations in the Boreal Forest Region and the Hudson

Bay Lowland, but this may have been due to better coverage. Its probability of observation increased significantly province-wide and in the Boreal Forest Region between atlases. Trends in other regions of the province were positive or stable. It was most abundant south of the Canadian Shield, including on eastern Manitoulin Island, although it was relatively scarce in Essex County where it may be limited by the low number of trees. Even Metro Toronto supported a higher density of crows than Essex. In the north, there were nodes of higher abundance around urban areas such as Kenora, Dryden, Thunder Bay, Sault Ste. Marie, and Sudbury, and in the agricultural and more open areas of Rainy River and the Clay Belt. Crows tended to be concentrated along major highways in the north, but were absent from adjacent forested areas. Highways provide a source of carrion as well as openings in the forest that are suitable for nesting (Sandilands in Cadman et al. 2007).

Graber and Graber (1963) compared Illinois crow populations in 1906-09 and 1956-58. Populations in most habitats were much higher in the earlier period than later. They concluded that breeding populations had declined by 72% and wintering populations by 71%. Habitat changes between the 2 survey periods should have been beneficial and they had no explanations for the decline. Given that the wintering population decreased significantly, this appeared to be a wide-scale decline because the Illinois winter population consists of residents as well as migrants from Ontario, Michigan, and Wisconsin.

Long-term (1970-2021) Breeding Bird Survey results indicated annual decreases of 0.569% in Canada and 0.308% in Ontario. The short-term (2011-21) trends were annual decreases of 1.65% in Canada and 2.74% in Ontario. All results were highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Fledglings may spend about 10 days in the canopy near the nest before coming to the ground. If they fall before then, they usually cannot get off the ground and are preyed upon. Adults feed the young for at least 2 weeks after fledging, and young may be fully independent 1 or 2 months after fledging (Verbeek and Caffrey 2020).

MIGRATION

The American Crow withdraws from the northern portion of its Ontario breeding range. It is unknown if wintering birds are residents, migrants from further north, or a combination of these. Some birds well within the resident range migrate south. In the eastern states, half of banded crows between latitudes 38°N and 43°N were residents, and Illinois birds that breed south of latitude 43°N are mostly sedentary. In Quebec, most birds migrate, although those south of latitude 51°N are considered resident (Graber et al. 1987; Pelletier in Gauthier and Aubry 1996; Verbeek and Caffrey 2020). In wintering roosts in New York and California, it was a partial migrant. Some birds migrated and others were resident. Individual birds were consistent in their migratory behaviour across years and site fidelity was high, with birds generally returning to the same wintering areas each year (Townsend et al. 2018).

Migration appears to be diurnal except for a record of a nocturnal flock flying north over Saskatchewan. The American Crow migrates in flocks of 30-200 birds, occasionally in flocks as large as 500-1,000, rarely over 2,000; some individuals migrate singly. Three birds roosted at the same communal roost along the way in each of 3 years and 3 other crows roosted in different roosts in 2

different years. Some Ontario birds migrate southwestward to Illinois, Arkansas, Tennessee and North Carolina. A crow banded in Ontario in May was recovered in Arkansas the following January (Brewer et al. 2018; Graber et al. 1987; Morrison 1995; Reaume 2013; Verbeek and Caffrey 2020).

In southern Ontario, arrival is in late February or early March, occasionally in early February, and continues into mid-April in the southern Shield. Southward migration may begin in September and peaks in mid-October; movement continues until mid-November (Curry 2006; Mills 1981; Morrison 1995; Tozer 2012; Weir 2008).

The American Crow uses similar habitat during migration as in the breeding season. Agricultural landscapes are preferred and suburban and urban areas are used. Natural habitats frequented include open woodlands and small woodlots, forest edges, treed riparian areas, and marshes. In British Columbia, large areas of coniferous forest act as a barrier to the American Crow. In Illinois, bottomland forest, forest edges, and shrubby areas were favoured in spring and autumn (Campbell et al. 1997; Graber et al. 1987). In Pennsylvania, it preferred larger woodlands during spring migration and fragmented landscapes during autumn migration (Keller and Yahner 2007).

The American Crow is a common to locally abundant migrant (James 1991). Over an 8-hour period in mid-October, Morrison (1995) estimated that 3,000 passed along Georgian Bay northwest of Parry Sound. In mid- to late October, 3,000-5,000 birds may be counted daily along the Elgin County Lake Erie shoreline and flocks of 2,000 are common inland (Lancaster et al. 2004). In 2010, more than 343,000 were counted during autumn migration at 2 raptor counting stations along Lake Erie (Woodliffe 2011).

WINTER

Root (1988) concluded that the American Crow was absent where the average minimum January temperature is below –18°C. Ontario CBC results demonstrated that most counts south of latitude 47°N recorded crows every year, except for Manitoulin Island and the southern Shield south of North Bay. North of 47°N, only the Thunder Bay CBC recorded crows annually. Central Ontario was the northern limit of early winter distribution (Weseloh 1985).

In winter, this crow is strongly associated with anthropogenic habitats and its local distribution is influenced by food abundance. Corn fields are favoured habitat until they become snow covered. Congregations may occur at landfills, cattle feedlots, and slaughterhouses, with lesser numbers at bird feeders. Roads are frequented for road-kills. In more northern areas, it may be almost completely dependent upon landfills (Campbell et al. 1997; Knapton and Maturi 1984; Pelletier in Gauthier and Aubry 1996; Reaume 1985; Weir 2008). In Pennsylvania, wintering crows were associated with larger woodlands within fragmented landscapes (Keller and Yahner 2007).

Shoemaker and Phillips (2011) observed wintering crows roosting on the ground in urban areas in Ohio. Birds roosted on the roof of a building, in nearby trees, and on parking lots that had been cleared of snow. Ground roosting may have provided shelter from the wind and heat conductance from the pavement. Reaume (2013) observed the entire crow population roosting on the ground in Essex twice. Ground-roosting appeared to be unrelated to weather conditions. Crows normally roost in trees in winter and radiate out to foraging areas in the morning along a series of flight lanes. Large increases in the number of crows using a particular flight lane may occur if a food patch is discovered

along it, such as grain spilled from a railcar or an unharvested sunflower field. Langley (2014) established artificial food plots directly in the path of flight lanes at least 10 km from a roost. The number of crows using flight lanes closest to food patches increased but numbers using adjacent flight lands remained constant or declined. Some crows flew from an adjacent flight lane to one that supported a food patch. Roosts may function as information centres with crows learning about food availability.

Some birds or groups of birds may be territorial in winter; others in the same location are not. In New Jersey, wintering crows had territories of 26-49 ha. Territories of 2 groups overlapped slightly, and territorial disputes occasionally occurred in this area. Vagrants that occasionally foraged in the same fields were tolerated by territorial birds. Territoriality is nonexistent in roosts and densities may be as high as 3.7-5.4 crows per m^2 (Stouffer and Caccamise 1991; Verbeek and Caffrey 2020).

Graber et al. (1987) analyzed 1,214 pellets and 718 stomachs of crows wintering in Illinois. Corn comprised 94.7% of pellet and 93.1% of stomach contents. Other vegetation it ate included seeds of smooth sumac, poison ivy, hemp, hackberry, linden, and giant ragweed, and sedge tubers. Grit comprised 20.5% of the volume of pellets and stomachs. Small mammals constituted 1.4-3.0% of the diet, with deer mice most frequent followed by voles and shrews. Miscellaneous food items included insects, crayfish, and snail shells. Near Essex, crows often pecked at bases of cornstalks. Gizzards of 17 of 18 crows contained European corn borer larvae. At least 4% of all cornstalks within 25 km of the roost had been perforated by crows and over 85% within 2 km were perforated. Crow predation resulted in a 50% reduction in the number of larvae that successfully overwintered. The corn borer was an important winter food. Other items crows had eaten included large quantities of fish, unidentified meat, corn kernels, and garbage (Quiring and Timmins 1988). The crow may feed on the fruit of sumac in winter in southern Ontario (Reaume 2013).

This crow is readily attracted to carrion, and supplemental feeding by placing out carcasses increases local wintering populations. When a large carcass is found within the territory of a group, numbers in the immediate area only increase slightly (Heinrich 1988; Knight and Anderson 1990).

The American Crow frequently comes to bird feeders. Favourite foods at feeders are meat scraps, cracked and whole corn, peanuts in the shell, pet food, baked goods, and popped corn. Less frequently, it eats mixed seeds, canary seed, millet, sunflowers, milo, hulled peanuts or hearts, suet, bird puddings, fresh or dried fruit, and oats (Dunn and Tessaglia-Hymes 1999). At a southern Ontario feeder, a crow attacked and killed an American Goldfinch that was snow bathing. The crow flew with it to a nearby tree and completely consumed it within 8 minutes (Sandilands 1992).

Reaume (2013) reported that numerous crows died at the Essex roost due to an ice-storm. Hailstorms have killed roosting crows at other locations. It is vulnerable to severe weather events because large concentrations of birds occur in small areas.

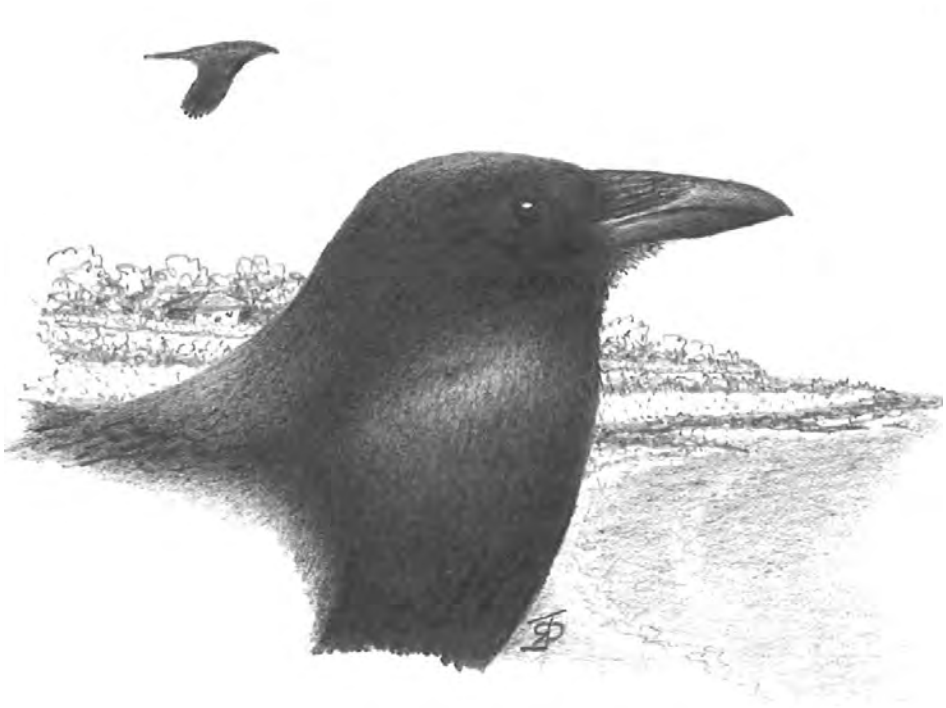
The American Crow was formerly rare to uncommon during winter in southern Ontario. McIlwraith (1894) stated that most left for winter, but that it suddenly reappeared if a carcass became available, suggesting it typically avoided areas near human habitation. Fleming (1907) reported that only a few overwintered near Toronto. In the 19th century, a few remained all winter along the St. Lawrence River and still only a few overwinter in the Kingston area (Weir 2008). In the Hamilton area,

crows were scarce during winter in the 1950s, but thousands have been present since the early 1980s (Curry 2006). Weseloh (1985) reviewed results from 77 Ontario CBCs from 1975 to 1983. Highest concentrations were in Thunder Bay, Essex, south Lambton, in a strip around Lake Ontario in Niagara, and in Toronto. There were also large numbers in the rest of southwestern Ontario, excluding the Bruce Peninsula, and in eastern Ontario off the Shield. Freedman and Riley (1980) examined CBC trends in southern Ontario from 1929 to 1977. Peak numbers occurred 1929-35 and 1964-77, with low numbers in between. They thought numbers recorded might reflect changes in roost sites. Sheppard et al. (1936) confirmed that roost locations affected local abundance. They considered it abundant in the Niagara area until a roost was abandoned, after which few were seen in winter. Woodliffe (2011) summarized more recent CBC counts. Between 1986 and 1990, there was an average of 7.8 crows counted per party-hour in all counts reporting the species. The average increased to 31 between 1999 and 2004 but dropped to 16 from 2005 to 2010. The reasons for the decline were uncertain. Many Ontario CBCs recorded their highest numbers in the 2000s. Trends determined by CBC data indicate annual increases in Ontario of 5.75% 1970-2021 and 0.43% 2009-21 (National Audubon Society 2022). James (1991) considered the crow a common to locally abundant winter resident in the Carolinian Forest Region, rare to locally uncommon elsewhere in the south and in the north at Thunder Bay, and occasional and rare elsewhere in the north to Atikokan and Moosonee.

There are several large winter roosts in the province. Weseloh (1983) estimated 50,000-75,000 crows at the Essex roost; Quiring and Timmins (1988) stated that numbers had swelled there to 90,000, with a peak of 96,669 (Woodliffe 2011). Reaume (2013) monitored this roost and determined that crows using it spread throughout Essex County during the day, an area of about 1,900 km^2. The St. Catharines roost was estimated at 6,000-7,000 crows (Knapton and Maturi 1984). At the Hamilton roost, 4,200-5,000 crows have been documented (Curry 2006); Reaume (1985) estimated 3,500-4,000 at the Chatham roost. The Chatham roost now surpasses the Essex roost for numbers with an all-time high of 159,860 reported on the 2000 CBC. This count does not record all the birds. A bird control company hired to discourage crows from roosting in the city estimated that there may be 250,000-500,000 crows present between late October and mid-November when there is a mix of migrants and birds intending to overwinter (Woodliffe 2011). At Thunder Bay, about 500 crows congregate in the roost. Weseloh (1985) reported a substantial roost of undetermined size near Port Hope–Cobourg. Reaume (2013) reported a winter roost of about 50,000 crows in the southeastern end of Woodstock. Ontario supports the largest crow roosts in Canada, but some roosts in Oklahoma and Kansas support as many as 6,000,000 wintering crows (Reaume 2013).

Fish Crow

Corvus ossifragus



BREEDING SEASON

Habitat Requirements

A single pair of Fish Crows nested in Mississauga in 2018. The habitat consisted of suburban residential and park areas, all close to the shoreline of Lake Ontario (Fazio 2019).

The Fish Crow breeds predominantly in coastal areas along beaches, marshes, and estuaries and into adjacent pine woods and riverine forests. It is usually found near water, including large rivers and lakes as well as saltwater areas. It often nests in heronries which may be in swamps. Islands in saltwater marshes that are forested with red cedar and pitch pine are favoured in some locations. Into the early 20th century, it was strictly coastal and occurred along major rivers upstream to the extent of tidewater influence. It has since adapted to inhabit more inland areas, including agricultural lands, urban and suburban residential areas, and commercial areas. It breeds in farmland as far as 160 km inland in Pennsylvania and Maryland, but occurs less in agricultural lands than the American Crow. It is now common in urban areas, although urban nesting was known as early as the 19th century. In upstate New York, it prefers urban parks, golf courses, and wooded residential areas over rural or heavily forested areas. It also nests in wooded cemeteries (Bent 1946; McGowan 2020).

The Ontario pair built 3 nests before successfully fledging young. One was in a spruce and the final nest was in the tallest white pine in the area (Fazio 2019). The Fish Crow typically nests in trees and occasionally in shrubs; there is 1 record of it nesting on a building. The nest is frequently in the uppermost crotch of a tree. It nests in both deciduous and coniferous species, showing a slight preference for conifers, especially pines. It has nested in junipers, red cedar, black oak, holly trees, beech, gum, sycamore, wild cherry, and maples. One nest was in the tallest shrub within a Green Heron colony. Nests were 1.7-45.7 m from the ground, with the highest nests in large sycamores. Average nest height tends to be 5-10 m above ground and is dependent upon the size of the nest tree. Nests are not used again in subsequent years but new nests may be built in the same tree even when the old one is still present. Several nests may be started before one is completed and used (Bent 1946; McGowan 2020).

Fish Crow nests may be close to each other and it has been suggested that it forms small colonies (Bent 1946; Madge and Burn 1994). It does not have multiple nests in the same tree or in adjacent trees, so it is not truly colonial. Nests may be clumped in areas where suitable nest sites are limited. Two pairs with nests approximately 100 m apart in a small woodlot simultaneously defended the woodlot from passing conspecifics. The nest and area around it are defended chiefly by the male. No information is available on the area that is defended around the nest. Chases of other Fish Crows are frequent. The area immediately around the nest is defended from the American Crow, but the 2 species may nest within 50 m of each other. Adults may forage 0.5 km or further from the nest, so the home range is a minimum of 79 ha but is probably much larger (McGowan 2020).

No information is available on natal philopatry or adult site fidelity rates. Young from previous years do not appear to return to their natal area but no studies have been done to test this theory. It is uncertain whether the Fish Crow is a true migrant. Even if it is a resident in much of its range, it may move to different habitats during the nonbreeding seasons and not necessarily return to the same breeding location (McGowan 2020).

Limiting Factors

No information is available on how long it takes to build the nest, whether time elapses between completion of the nest and egg laying, the egg-laying rate, or when incubation begins. Construction of the first Ontario nest was initiated on 23 April, but it was abandoned 3 days later. A second nest was initiated and quickly abandoned and the third and final nest was initiated on 1 May. The

incubation period is 16-19 days, mostly 18-19 days. The nestling period is approximately 5 weeks. Young in 5 Florida nests fledged at ages of 32-40 days; young fledged from the Ontario nest on 13 July. Young may fly from the nest and return before finally leaving (Bent 1946; Fazio 2019; Madge and Burn 1994; McGowan 2020).

The Fish Crow raises a single brood in a season but renests if nest loss occurs early in the season. The Ontario pair built 3 nests but these did not appear to represent replacement nests because it is unlikely that any eggs were laid in the first 2 nests. This appeared to be more typical of the species' habit of starting several nests before completing one to raise a brood. Clutches of 2-6 eggs have been reported, with most containing 4 or 5 eggs. Mean clutch sizes of 4.5 and 4.6 eggs have been reported. The clutch size of the Ontario nest was unknown, but 2 young fledged from it. The number of young produced is typically lower than the average clutch size, indicating that brood reduction is common (Bent 1946; Fazio 2019; Madge and Burn 1994; McGowan 2020).

The age at first breeding is unknown, but the Fish Crow probably does not breed until it is 2 or more years old. The mating system is monogamous. The duration of the pair bond is unknown but is likely to be long term. A third bird often attends nests, occasionally during nest building, and it may feed the nestlings. These appear to be adults rather than yearlings and are probably unrelated nonbreeders. These birds are probably not true helpers and the pair spends much time driving them away. The third bird is probably trying to establish a bond with the female and may attempt to copulate with her while she is incubating (McGowan 2020).

The Fish Crow is an omnivore that uses a variety of foraging techniques. It frequently robs heron nests of eggs and young nestlings, and it may breed in or congregate in heronries where they may significantly affect heron populations. It takes eggs and nestlings of a wide variety of waterbirds and passerines. It often feeds on the seashore and in marshes and other water bodies, wading in shallow water. It patrols low over water to pick up floating items such as dead fish and has been reported catching small fish and lizards from the surface of the water with its feet. It is an important predator of turtle eggs, digging them up and eating them. It often forages on the ground, on the edge of water, and in trees for bird nests. In urban areas, it frequents dumpsters, parking lots, and landfills in search of waste and offal. It spends less time on the ground foraging than the American Crow, but may follow plows in fields to pick up grubs and other arthropods. It may land on the backs of cattle to prey on ticks. It kleptoparasitizes other Fish Crows, American Crows, gulls, ibises, and Ospreys to obtain prey. The Fish Crow hops from a perch to catch terrestrial insects, picks small spiders from their webs, and sallies from the ground or an elevated perch to catch flying insects. It scavenges migratory birds killed at communication towers. It may spread its bill tips to open balls of dirt and dig in dirt or litter with a sideways swipe of the bill (Bent 1946; Madge and Burn 1994; McGowan 2020).

The Fish Crow has perches where it regularly brings food to eat (Bent 1946; McGowan 2020). It frequently stores food for later use, often at the perch. Caches may be in grass, Spanish moss, or tree bark. Those in grass may be covered by another object such as a leaf. Caches near the nest are used by both pair members to feed the nestlings (McGowan 2020).

The male feeds the female while she is incubating; the female may also leave the nest to obtain her own food. At the Ontario nest, the male brought the female Mourning Dove eggs and nestlings of House Sparrows, Baltimore Orioles, Red-winged Blackbirds, and Common Grackles (Fazio 2019). Adults may dunk food in water before giving it to the nestlings, or take water directly to them. Food supplied to nestlings in 1 area included chicken bones, young swallows and Blue Jays, bread, and other refuse (McGowan 2020).

In the core of the Fish Crow's range, adults specialize on preying on eggs and nestlings of colonial waterbirds such as herons, cormorants, gulls, and terns. It eats eggs and nestlings of a wide variety of birds including shorebirds, rails, chickens, ibises, waterfowl, pigeons, grackles, Blue Jays, Northern Mockingbirds, Brown Thrashers, House Sparrows, and Red-winged Blackbirds. It may be a locally important predator on turtle eggs. On beaches and in salt marshes, it consumes small crabs, shrimps, crayfish, dead and live fish, amphibians, carrion, and offal. It also eats ants and grasshoppers. It consumes a wide variety of vegetable matter, including seeds, fruits, and grain. It eats seeds of locusts, flowering dogwood, wild rice, and hackberry and fruits of pokeweed, mulberries, huckleberries, red cedar, black gum, magnolias, hollies, pawpaw, greenbrier, mistletoes, pears, oranges, tomatoes, and acorns. The grain that is consumed is mostly corn and oats and appears to be mostly waste grain. In Virginia, it inflicts considerable damage on peanut crops (Bent 1946; Madge and Burn 1994; McGowan 2020).

Habitat loss is not a significant limiting factor for the Fish Crow, particularly now that it is adapting to urban life. In South Carolina, it decreased when natural succession was allowed to proceed in abandoned farmlands, but it increased in other habitats (McGowan 2020).

The Fish Crow died in large numbers in 1999 during an outbreak of West Nile virus in New York and New Jersey but populations have rebounded. Occasionally it is struck by vehicles; young birds in their first summer are usually the victims (McGowan 2020).

The Fish Crow is highly tolerant of human activity near the nest. At the Ontario nest, it was oblivious to pedestrians, wedding parties, and trail construction. It readily abandons the nest if a human climbs up to it and may abandon nests with young as old as 2 weeks (Fazio 2019; McGowan 2020).

Hunting may be a major source of mortality and may be the most significant limiting factor. In most states, the Fish Crow is unprotected by legislation and is widely shot. Some states have closed seasons on it, but no bag limits when the season is open (McGowan 2020). Crows are not protected by a closed season in Ontario.

Status

James (1991) considered the Fish Crow a vagrant to Ontario, with 3 documented records at that time, all at Point Pelee: on 15 May 1978, 21 April 1982 (James 1983), and 20 May 1983 (James 1984a). Several occurred in the province in 2012, with 2 seen on 14 March to 29 July at Bronte, 2 from 26 March to 13 April in Guelph, 1 on 4 and 5 May at Thickson Point in Durham Region, 1 on 7 May at Turkey Point, and at least 5 at Fort Erie from 15 January to 26 February. By the end of 2012, the Ontario Bird Records Committee (OBRC) had accepted 22 records, some of which represented multiple birds (Cranford 2013). In 2014, 3 more records from Guelph, Hamilton, and Fort Erie were

accepted by the OBRC and there were many more records for which no documentation was submitted. It continued to spread into the province through the Niagara Peninsula and the west end of Lake Ontario. It was still considered very rare, with a total of 33 records accepted by the OBRC (Burrell and Charlton 2015). It is probable that some Fish Crows go undetected because of the difficulty in distinguishing them from the American Crow. In 2015, the OBRC accepted more records from Fort Erie, Waterloo, St. Catharines, Camelot in Niagara Region, Rondeau, Point Pelee, Stoney Creek, and Chatham-Kent. By then, there were 42 accepted records (Burrell and Charlton 2016). In 2018, a record of 4 birds in Mississauga was accepted by the OBRC. Burrell et al. (2019) concluded that within a decade it had gone from being a vagrant with 1 or 2 records per year to a regular and now breeding component of the Ontario avifauna. By then, there were records for every month of the year. Fazio (2019) reported that breeding behaviour was seen in Oakville in 2012 and Port Weller in 2016, but there was no evidence of successful nesting. At least 55 were seen in Niagara Falls on 4 August 2017, including a pair of recently fledged young, but it was possible that these fledglings were not produced in Ontario. A pair was seen in Mississauga calling and interacting with each other in April 2016 and this is where the first successful nesting occurred in the province. Fazio (2019) predicted that it would eventually nest in most municipalities on or near the shore of Lake Ontario and other lakes in the region.

The Fish Crow has greatly expanded its range in the last few decades and its population is increasing. In the 19th century, it occurred from southern Connecticut to Louisiana as well as up the Hudson River and casually into Massachusetts. At that time, it was strictly coastal and occurred up major rivers to the extent of tidewater influences. It expanded inland along major rivers in the late 20th century, and northward along the Atlantic Coast. It generally colonizes in a leapfrog fashion, establishing new breeding areas long distances from its previously known range, despite the presence of suitable breeding habitat in between. A population near Ithaca, New York, was established 200 km from its former breeding range. All newly established New York colonies were at least 55 km from the nearest known range limit at the time. Colonies were also established by leapfrogging in Maine and Virginia, and the Ontario nest is another example of this behaviour. The expansion of the Fish Crow's range in the United States may have followed the expansions of heron and Common Grackle colonies which are both major sources of food. The increase in its population in the core of its range may have fuelled the range expansion. Its more recent adaptation of nesting in urban areas may promote its establishment in new areas (McGowan 2020; Wells and McGowan 1991).

Results from the Breeding Bird Survey (BBS) for 1966-98 indicated that the Fish Crow increased at a rate of 1.6% annually throughout its range. Most of the increase occurred 1966-79 when it increased at a rate of 6.0% per year. It did not exhibit any significant trends 1980-96, with a modest increase of 0.8% per year (McGowan 2020). There are no BBS data for Ontario.

POSTFLEDGING PERIOD

Young can fly short distances when they fledge. Fledglings stay in trees for several weeks after leaving the nest until they are proficient at flying. They then follow their parents to the ground and begin foraging for themselves. Young remain with the adults for 1 month or more after fledging and continue to be fed until they are about 70 days old (McGowan 2020). At the Ontario nest, the

single fledgling stayed close to the female for its first week out of the nest. It was fed by the female, with the male absent most of the time. The last time the female and fledgling were seen together was 5 October (Fazio 2019).

The Fish Crow is highly gregarious during the postfledging period and other nonbreeding seasons. It may congregate in foraging flocks of hundreds of birds that include juveniles, adults that bred, and nonbreeders. These flocks are often mixed with the American Crow (Bent 1946; Madge and Burn 1994; McGowan 2020).

Communal roosts are an important habitat component in nonbreeding seasons, and some limited use of communal roosts may be made while breeding. Roosts tend to support large numbers of birds, with more than 45,000 Fish Crows reported at some roosts. It often roosts with the American Crow and also with herons and egrets. Roosts tend to be distant from the favoured foraging area. A Florida roost in pine trees was 48-64 km from the feeding areas. The Fish Crow typically roosts in trees but has been reported roosting in willows along lakeshores and in rushes in marshes. In the core of its range, it prefers to roost in isolated rural areas and on offshore islands (Bent 1946; Madge and Burn 1994; McGowan 2020).

MIGRATION

It is uncertain whether the Fish Crow is a permanent resident within its range or a short-distance migrant. Some are found year-round even in the northernmost portions of its range. Individuals may simply withdraw from areas where they nested and move to locations with a plentiful food source in winter. Seven birds banded in winter along the Louisiana coast were shot in central Arkansas in spring, suggesting that migration had taken place. All other recoveries were within 300 km of the banding site. Observations of flights of several hundred per day in autumn in New York are suggestive of migration. All movement appears to occur during the day (McGowan 2020). Longer movements may possibly represent juvenile dispersal.

WINTER

Winter habitat is similar to breeding habitat but the Fish Crow congregates near abundant food sources such as estuaries, landfills, feedlots, and shopping centres in winter. In Maine, it wintered at an inland landfill and moved to the coast for the breeding season. Overwintering at landfills near rivers or other aquatic habitats is becoming more common. It exhibits no territoriality in winter and continues to roost communally at night (Madge and Burn 1994; McGowan 2020).

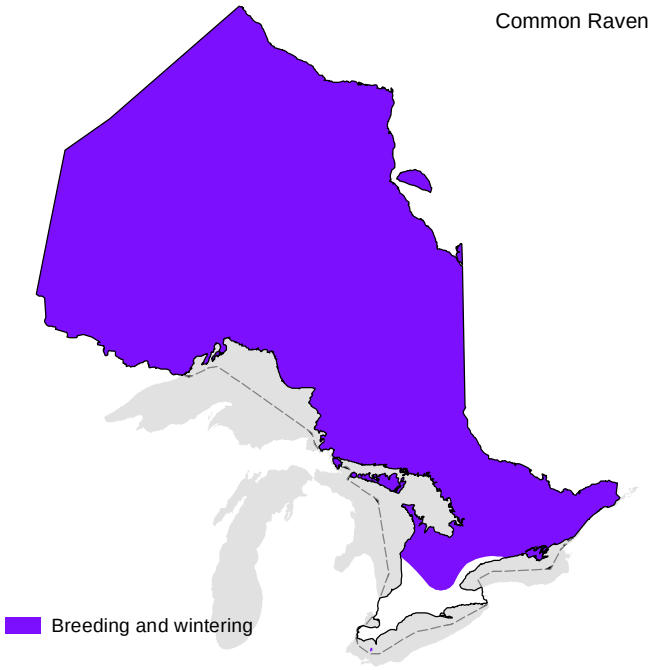
Common Raven

Corvus corax

BREEDING SEASON

Habitat Requirements

In Ontario, the Common Raven nests in forested areas, open grasslands and shrubby areas, near buildings and hydro rights-of-way, and in tundra. It prefers mixed woodlands over deciduous or coniferous forests. Most nest sites overlook vistas, even in forests, and nests are near water (Peck and James 1987). In the Gogama area, it nested in groves of mature pines and foraged in recently cut, planted, or burned forests and along roads (James and Peck 1995a). Near Kingston, it nested in the Canadian Shield and was associated with rock faces and outcroppings in mature, undisturbed forest (Weir 2008). In Ottawa, it nested in an active quarry (DiLabio and Martin 1959) and it has nested 43 m below ground level in an open-pit mine at Sudbury (Blomme in Cadman et al. 1987). It also nested in an active quarry in Halton Region (personal observation). In Ontario, it is associated with landscapes that are predominantly forested, but is becoming increasingly common in the



agricultural south. Near Elora, it apparently nested for several years in Norway spruce around a farmstead (Grant Egerdee, personal communication).

The raven prefers areas with considerable topographical relief, such as cliffs, because they provide thermals for long-distance foraging flights, and areas with cliffs, trees, or human structures that provide nest sites. In the north, it prefers wilderness and often avoids areas with human activities. Where food resources are scarce, it adapts to human presence (Boarman and Heinrich 2020). Erskine (1977) considered the raven more characteristic of coniferous than deciduous forests in the Boreal Forest Region, but it was a wide-ranging species not confined to 1 community or forest type. In Quebec, it inhabits mixed and coniferous forests, mountainous regions, tundra, seacoasts, and, more recently, urban areas. In the south, it prefers mountainous areas and extensive mixed and coniferous forest. Distribution is patchy in southwestern Quebec where the low relief, scant forest cover, and intense human activity probably discourage it from nesting (Roy and Bombardier in Gauthier and Aubry 1996). In British Columbia, 40% of nests were in forested habitat, at a 3:1 ratio of mature to second-growth forests; 36% were associated with cliffs; and 7% with industrial sites. The remaining nests were in residential areas, parks, burns, and miscellaneous habitats. Fifty-six percent of nests were in forested areas and 35% were in human-altered areas (Campbell et al. 1997). In Michigan, the raven nested in bogs treed with spruce (Parmelee 1988). In Wyoming, it nested in isolated stands or on edges of large stands (Dunk et al. 1997), but was unaffected by distance from edge in California (Brand and George 2001). In Saskatchewan, it was randomly distributed within fragmented landscapes. Forest size, amount of forest within 5 km, and forest type had no significant effect on its distribution (Hobson and Bayne 2000). In the Appalachians, it had neutral affinity to old-growth forests, occurring in them at equal frequency to other ages of forests (Haney 1999). Cities had the highest density of ravens in Wyoming where the dominant habitats were sagebrush steppe and grasslands with interspersed human settlements. All other habitats had low densities; of the linear habitats, occupancy was greater along roads than in riparian habitat. Edge habitats had the lowest level of occupancy. Ravens were consistently present in cities and along roads. Nest sites, food, and water may have been scarce outside cities (Bui et al. 2010). In open habitat in Idaho, it was significantly associated with anthropogenic features. There was a 31% decrease in its probability nesting for every 1 km increase in distance from a transmission line. Ravens were most likely to nest near edges of cover types that were associated with direct human disturbance or fire (Howe et al. 2014). Presence of suitable nest sites and adequate food supply may be more critical than habitat types. In Ontario, it is

predominantly associated with extensively forested landscapes with minimal human disturbance, but is beginning to encroach into areas with more human activity.

In Wyoming, nest sites had 51.4% cover compared with 30.4% at random sites, the basal area at nest sites was 0.79 m^2 compared with 0.52 m^2, nest sites had 3.1 snags compared with 1.9, ground cover at nest sites was 72.1% compared with 65.3%, and slope at nest sites was 16.3% compared with 12.4% at random sites (Dunk et al. 1997).

Raven roosts have not been reported in Ontario, but have been documented in several areas. They are unlikely to occur in areas of low nesting density, but even in these areas temporary roosts may be established around abundant food sources outside the breeding season. Roost characteristics are variable, with roosts reported in white pine groves, hard-stemmed bulrush marshes, on cliffs, on telephone and hydro poles and wires, on high-tension power lines, in abandoned buildings, in birch woodlands, on oil tanks, and on the ground. A large roost on new high-tension towers in Idaho occurred where birds formerly roosted on rock outcrops, scattered clumps of low trees, and smaller transmission lines. Use of roosts varies seasonally. In Massachusetts, roosts were used July through September. In Oregon, roosts formed in mid-October, with peak numbers in January and abandonment in mid-March. In Idaho, highest numbers occurred from July to September and lowest numbers were from January to March. Use of roosts for 10-15 years has been documented, but most roosts are transitional. Some are present for 2 or 3 months never to be used again; some congregations occur for only a week or single night. One area in California that had never been used previously was used by 1,500 birds for 36 nights then abandoned. Within traditional roosting areas, the roost site varies considerably and may move a few hundred metres or even kilometres in response to weather conditions, disturbance, and unknown factors. In Idaho, radio-tracking over 209 days demonstrated that some individuals remained at a single roost during this period; another changed roosts 19 times. Movement occurred between all roosts, including those 63 km apart. In some areas, pre-roosts are used. These are typically unvegetated or sparsely vegetated areas. The number of birds at roosts is usually 10 to less than 100 birds, but large roosts in excess of 2,000 occasionally occur. The primary function of roosts appears to be as an information centre for food. Strangers are readily accepted and led to food sources. Roosts used mostly in late summer are dominated by juveniles but all age classes may be present at winter roosts. At Churchill, numbers at a winter roost increased with windchill (Boarman and Heinrich 2020; Cotterman and Heinrich 1993; Engel et al. 1992; Flanagan 1993; Heinrich 1988; Stiehl 1981).

In Ontario, the raven has nested on natural and human-made substrates. These included ledges and crevices of cliffs (55.5%), trees (27.0%), bridge beams (4.8%), hydro towers (4.8%), grain elevators (3.2%), small sheds (1.6%), lumberyard incinerators (2.4%), and radar-dish girders (0.8%). Human structures that have supported nests include towers for hydro, radar, and navigation; active or abandoned buildings, silos, and grain elevators; bridges and canal locks; racetrack light platforms; and water towers. One nest was on a moving power crane. Tree nests were in living trees, both in deciduous (54.5%) and coniferous (45.5%) species. Poplars were preferred over spruce and pine. Nests were typically near the top of the tree in crotches near the tree trunk. Nests on cliffs and human-made structures faced all directions, but more frequently towards the southwest. Nests are frequently reused and the raven has used old Bald Eagle nests in the province. Some cliff nests were

abandoned Peregrine Falcon nests. Nests on cliffs were 1.8-152 m from ground, with most 12-24 m up. Tree nests were 3-30 m from ground, with most 10.5-15 m up. Nests on human-made features were 3-35 m from ground, with most 7.5-18 m up (Peck 2005a; Peck and James 1987, 1997). The 70 nests found in southern Ontario since 1980 showed more use of human structures than occurred historically. Forty-nine percent were on cliffs and rocky ledges (mostly on the Niagara Escarpment); 20% were in trees; and 31% were in or on buildings, towers, or other human-made structures (Peck 2005a). At Cape Henrietta Maria, the raven was apparently scarce due to rarity of nesting sites until the radar stations were erected in the 1950s. Subsequently, it nested on the radar screens and on a cable tower support attached to a cabin (Peck 1972). In Algonquin Park, it nested on a sawdust burner (Tozer 2012).

Throughout its range, the raven nests either on cliffs, in trees, or on human-made objects. Human substrates are usually used only in areas with limited tree growth and topographical relief. In such an area in Idaho, 73.2% of nests were on anthropogenic features; 53.0% were on electrical transmission towers. Natural nest sites included 6.2% on rock ledges and 20.6% in a variety of native and cultivated tree species. In some areas, it strongly selects cliffs despite the abundance of suitable nest trees; in other areas the reverse is true. In Virginia, only 3 of 57 nests were in trees. Individuals use the same nest-type for their life. Nestlings may become imprinted to nest substrates, possibly explaining why certain populations prefer cliffs over trees or vice versa. In Washington, canopy closure at nests was 85% and denser than surrounding areas. Seventy-four percent of nest trees were the tallest trees within the plot. Other authors noted that the raven tends to select tall trees and nest near the top of them. Nesting in tall trees or at edges probably improves accessibility. Although nests may be near treetops, they are in dense canopy; shading of the nest appears important. In British Columbia, some nests on cliffs were in trees. It appears to prefer coniferous trees for nesting, particularly in the west. It has nested in black and white spruce, balsam poplar, trembling aspen, hemlock, white pine, cottonwood, willow, white oak, and Manitoba maple (Bent 1946; Boarman and Heinrich 2020; Campbell et al. 1997; Fleming and Speich 1988; Sinclair et al. 2003; Tyrrell 1945). In Virginia, cliffs of particular rock types were used in proportion to availability; nest success was unrelated to cliff height. Nests on cliffs faced all directions, but mostly south and west, and most nest cliffs were at the end of ridges or where water formed a gap in the cliff. All nests on cliffs were sheltered by overhanging ledges of 2-600 cm, and most were sheltered by rock buttresses on 1 or both sides. Nests may be in cavities in cliffs or wedged into crevices. Mean width of nest ledges was 61.3 cm (range 41-91 cm). Cliffs were undercut below the nest ledge at 63.2% of sites and nearly vertical at 31.6%. Ledges often sloped away from the cliff; occasionally a small shrub helped hold the nest in place. The most important factors in cliff nest-site selection appeared to be a suitable ledge with an overhang above and steep rock face below. Proximity of other active nests also appeared important. Similar characteristics have been reported for cliff nests elsewhere. Cliff height appears secondary, but it seldom uses cliffs that are less than 15 m tall. In lieu of cliffs, the raven may nest in active or abandoned quarries and on steep road cuts (Bent 1946; Boarman and Heinrich 2020; Bowles and Decker 1930; Coates et al. 2014; Conner 1985; DiLabio and Martin 1989; Flanagan 1993; Harlow 1922; Hooper 1977; Hooper et al. 1975; Knight 1984; Peck and James 1987; Roy and Bombardier in Gauthier and Aubry 1996; Stiehl 1985). The raven has nested on or in a variety of human-made structures. These include windmills, abandoned and occupied buildings, barns, oil

derricks, high-tension towers, hydro poles, railway and highway bridges, grain elevators, church steeples and bell towers, billboards, communication towers, abandoned cars, a barbecue in an abandoned railway car, the top of a chimney, a window opening in an old lighthouse, and water towers. It typically nests on beams or other structures within abandoned buildings, but occasionally on a porch or other exterior structure. One nest on the beam of a railway bridge was only 60 cm below the tracks, and the adult remained on the nest while trains passed over (Booth 1996; Boarman and Heinrich 2020; Campbell et al. 1997; Bowles and Decker 1930; Coates et al. 2014; Congdon 1948; Dunk et al. 1997; Knight 1984; Kozij 1986; Kuyt 1992; White and Tanner-White 1988). The raven has nested in old Red-tailed Hawk, Golden Eagle, and Bald Eagle nests, and a nest used the previous year by a Great Horned Owl. It also nested on an island in a Great Blue Heron colony, but it was unknown if it nested in an old heron nest or one that it constructed (Bent 1946; Boarman and Heinrich 2020; Bowles and Decker 1930; Conner 1985; Flanagan 1993; Fleming and Speich 1988; Kuyt 1992; Stiehl 1985).

Territorial defence is greatest during the breeding season, but may occur at other times of the year. Birds usually defend their territory against other individuals or small groups and stay out of sight when a flock encroaches. Intruders may be chased for several kilometres or, when resources are plentiful, only a small area around the nest may be defended. Home range sizes vary greatly depending on availability of food and nest sites. Average home range was 40.5 km^2 (range 27.3-195 km^2) for 9 birds, but another 13 were so nomadic that home ranges could not be estimated, covering minimum areas averaging 1,252 km^2; some of these were nonadults. In coastal California, average home range for 12 breeders was 1.2 km^2 (range 0.3-4.4 km^2) and the average for nonbreeders was 8.2 km^2 (range 2.2-45.8 km^2). In spring, average home ranges were 19.5 km^2 for nonbreeders, 1.8 km^2 for breeding males, and 0.8 km^2 for breeding females. In Wyoming, 3 pairs had home ranges averaging 9.4 km^2. In the Yukon, birds were evenly spaced throughout the Boreal Forest Region with a pair every 50 km^2. In Washington, mean home ranges were 15.34 km^2 for males, 12.75 km^2 for females, 8.59 km^2 for adults, and 19.50 km^2 for nonbreeders. Median distances moved were 4.5 km for males, 7.6 km for females, 1.3 km for adults, and 14.5 km for nonbreeders. Mean maximum distances moved were 19.5 km for males, 17.7 km for females, 5.5 km for adults, and 42.4 km for nonbreeders. Not all birds demonstrate clear home ranges, and there may be overlap of home ranges. In Maine, nonbreeders wandered widely over more than 1,800 km^2. Mean internest distances also vary considerably and may be hundreds of kilometres in tundra or other places where nest sites are scarce. Normally, internest distances vary from 300 m to 9.6 km. In a high-density population in Wyoming, the mean internest distance was 1.6 km (range 0.5-2.45 km). In Virginia, the mean internest distance was 4.3 km and the closest nests were 2.2 km apart in 1 area. In another area of Virginia, mean internest distances were 4.8-5.1 km over 2 years, with a mean home range size of 38 km^2. At a third Virginia site, mean internest distance was 2.9 km with a mean home range size of 30.2 km^2. There are 2 reports of nesting colonies from British Columbia. There were 9 nests on a small, eroded cliff face and this site was used for several years before it was abandoned. At a second colony, 2 or 3 pairs nested for several years on a lakeshore cliff face (Boarman and Heinrich 2020; Campbell et al. 1997; Craighead and Craighead 1956; Dunk et al. 1994; Hooper 1977; Hooper et al. 1975; Linz et al. 1992; Madge and Burn 1994; Sinclair et al. 2003; Webb et al. 2012).

In Idaho, 4 of 163 nestlings (2.5%) returned to the natal area to breed. In Washington, juveniles left their natal territory between early July and late September, with a median date of 9 August. Sixteen of 22 juveniles (72.7%) did not return to their natal territory; the other 6 returned on and off for an additional 5-26 days. Following independence, 55% of juveniles returned at least once to their parents' home ranges, but only as members of large groups attracted to abundant food resources. Some pairs build 2 or 3 nests a year and alternate between nest sites. Most adults tend to nest within 0.5 km of the previous year's nest, but successive nests may be as far apart as 12 km. In Virginia, 4 of 12 pairs (33.3%) used the same nest the next year, 33.3% moved 0.01-0.8 km, 16.7% moved 0.81-1.6 km; 8.3% moved 1.61-2.4 km; and 8.3% moved 2.41-3.2 km. Another pair used the same nest in 3 years, even though there were at least 10 potential nest sites within 0.8 km. Ninety-one percent of birds nesting on hydro towers nested on the same tower or within 2 towers of the previous nest. In Washington, breeders displayed strong site fidelity, except in autumn and winter or after death of a mate, when some breeding ravens moved extensively. Two Algonquin Park nest sites were used 20 and 21 years. Some cliffs are thought to have been used for centuries, so it is thought that adults have high nest-site tenacity. Few studies have determined if the same birds were involved in long-term occupancy of nest sites. Of 10 nests reused in California, 2 were used by the same pair, 4 by 1 member of the previous year's pair, and 4 by different birds (Boarman and Heinrich 2020; Booth 1996; Congdon 1948; Flanagan 1993; Hooper 1977; Hooper et al. 1975; Peck 2005a; Roy and Bombardier in Gauthier and Aubry 1996; Webb et al. 2012). In Algonquin Park, ravens nested on 1 cliff most years from 1963 to 2000 (38 years) and a nest site on another cliff was occupied from 1970 to 1999 (Tozer 2012).

Limiting Factors

Eggs have been found in Ontario nests from the second week of March until mid-May, with most present from the last week of March until mid-April (Peck and James 1997). In Algonquin Park, nests are under construction from late February to early April, eggs are present from mid-March to mid-April, nestlings are present from early April to early June, and dependent fledglings have been observed from mid-May until mid-June (Tozer 2012).

Experienced birds start nesting 2 or 3 weeks earlier than inexperienced birds. Weather conditions may also influence timing of nesting. Nest construction took 9 days in Wyoming; Pennsylvania nests took 14-18 days to complete. In Pennsylvania, egg laying started 3-7 days after the nest was complete. Eggs are laid at the rate of 1 a day. Incubation may begin with laying of the first or second egg, or the female may just cover the eggs for the first few days and not incubate. The incubation period at 4 Ontario nests was 20-21 days. Elsewhere, incubation periods of 17-25 days have been reported. Eggs hatch asynchronously, typically a day apart. Fledging occurs at age 35-49 days (Boarman and Heinrich 2020; Bowles and Decker 1930; Campbell et al. 1997; Conner 1985; Engel et al. 1992; Flanagan 1993; Harlow 1922; Kilham 1989; Madge and Burn 1934; Peck 2005a; Stiehl 1985).

One brood is raised annually. Renesting may occur if a clutch is lost, either in the same or a new nest. Some pairs laid 3 clutches in attempts to raise young; many pairs do not renest. One Ontario pair renested in Timiskaming District in a second nest 183 m from the original nest. In Oregon, a male renested after the female and brood died. He remated and another clutch was laid in the same

nest. In Washington, a pair renested successfully after losing a brood. Replacement clutches may be laid 11-22 days after loss, and frequently contain 1 less egg than the first clutch. In Idaho, replacement clutches had significantly fewer eggs (5.6 compared with 4.9) and were not always successful. In Pennsylvania, ravens typically laid another clutch 3 weeks after the first one was collected. Clutches of 2-7 eggs have been reported in Ontario, but 2-egg clutches were incomplete. Most clutches contained 4 or 5 eggs. Most North American clutches have 3-7 eggs, with 8-egg clutches rare; most contain 4 or 5 eggs. Based on 200 nests from 6 studies, the average North American clutch is 5.3 eggs: 4.6 in Ontario, 6.0 in Oregon, 5.6 in Idaho, 5.4 in Utah, 5.4 in California, and 4.6 in Wyoming. It has been suggested that clutch size increases with latitude, with typical clutches of 6-8 eggs in the far north. In some areas, clutch size varies significantly annually; in others it is stable. Stable clutch sizes are most likely in populations with consistently abundant food resources and where late spring snowstorms rarely occur. Even where clutch size is consistent, there may be large annual variations in numbers of fledglings produced (Bent 1946; Boarman and Heinrich 2020; Bowles and Decker 1930; Congdon 1948; Dunk et al. 1997; Harlow 1922; Peck and James 1997; Stiehl 1985).

The age of first breeding is largely unknown. In Washington, 1 male bred unsuccessfully in his fourth year and successfully fledged young in his fifth year. In captivity, successful breeding occurs at 3 or 4 years of age; 2-year-olds make unsuccessful attempts. Once breeding is initiated, most birds breed annually, but older birds may occasionally skip a year. The mating system is considered monogamous, but few data are available. Pair members usually remain together year round and may mate for life. In Washington, pair bonds were broken only by the death of a mate; the survivor remated when this occurred (Boarman and Heinrich 2020; Ellis et al. 1994).

The raven forages mostly on the ground but also aerially, and uses several unusual techniques to secure food. Most feeding is on the ground on carrion and live vertebrates and invertebrates. It may follow plows and harvesting equipment in fields or dig in soil with its bill to obtain invertebrates. One pair regularly walked a shoreline to search for dead fish. Birds as large as Rock Pigeons and eiders may be struck down in midair and the raven has been observed aerially kleptoparasitizing Northern Harriers and Merlins; American Crows and Great Egrets have been kleptoparasitized on the ground. In Nevada, it kleptoparasitized a Golden Eagle nest, feeding on 9 of 30 prey items delivered to the nest during the chick-rearing period. It also scavenged a dead nestling. In some areas, the raven regularly patrols highways to search for road-kills. It has an important commensal relationship with large carnivores, following them to forage on their leftovers. Its relationship with the gray wolf is particularly important, especially in winter. It also follows polar bears, coyotes, lynx, and human hunters. It cannot open body cavities of mammals larger than raccoons, so may purposefully attract large carnivores to carcasses so they will open them up. Cooperative foraging by groups of ravens is common to capture larger or potentially dangerous prey, or to kleptoparasitize cats and dogs. Teams of ravens have killed roosting kittiwakes, a Common Loon, a young porcupine, caribou fawns, seals, and hares. A group of birds may distract dogs by pulling their tails, while another raven steals its food. Foraging at landfills is common. Some birds spend much time at landfills; others never visit them. Colonies of gulls, terns, cormorants, and other seabirds are particularly attractive to ravens, where they feed on eggs and nestlings. Depredation by ravens at some Ring-billed and Herring gull

colonies was so intense that it resulted in colony abandonment. It may follow traplines to pick at animals caught in traps. In the far north in winter, it follows dogs and eats their fresh dung. In Oregon, it dug female crabs from the sand during low tide, flipped them over, and ate the egg masses they were carrying, but did not eat the crabs (Bent 1946; Boarman and Heinrich 2020; Conner and Adkisson 1976; Flanagan 1993; Gehring 1993; Harlow et al. 1975; Heinrich 1988; Hendricks and Hendricks 2011; Hendricks and Schlang 1998; Hooper 1977; Irwin et al. 2003; James 1980; Jehl and Smith 1970; Kilham 1985b; Ling et al. 1992; Maguire 2000; Parmelee and Parmelee 1988; Porsild 1943; Proctor 1995; Roy and Bombardier in Gauthier and Aubry 1996; Simes et al. 2017). The raven is attracted by the sound of gunshots; this may signal the presence of a downed ungulate. Predator calls blown to imitate a dying rabbit or young deer also attract ravens (Frame 2010).

The raven is an opportunistic omnivore, but a high proportion of its diet is carrion, mammals, and birds and their eggs. In early spring at the beginning of the nesting season, carrion may be a significant component of the diet. It feeds on carcasses of large mammals brought down by carnivores and road-killed frogs, toads, and mammals. As spring progresses, it relies less on carrion, although it may still visit landfills and patrol roads. The diet shifts at this time and is dominated by small mammals, particularly juvenile rabbits, but also voles, mice, shrews, muskrats, flying squirrels, gray squirrels, and chipmunks. Bird eggs become important in the diet at this time. Eggs of any species except large raptors may be taken, from small and medium-sized passerines to loons, herons and egrets, waterfowl, gulls, terns, and cranes. Some populations may focus on preying on certain birds, such as waterfowl, Sandhill Cranes, and Whimbrel. Local populations may decline in years when these prey species are affected by drought or other factors. As the nesting season progresses, nestlings and adult birds replace eggs in the diet. The raven has been observed pulling flickers and American Kestrels out of nesting cavities, and it frequently catches and consumes Rock Pigeons. In late spring, summer, and early autumn, insects may be important food. In Oregon, insects were second to mammals in importance in summer, comprising 48.6% of adult and 29.4% of nestling food. The order of importance of insects was bugs, flies, hymenopterans, beetles, lepidopterans, and grasshoppers. Cicadas were the most important bugs, representing 18.7% of all food items and 56% of insects consumed. They constituted 21.1% of the nestling diet and 10.0% of the adult diet. Hymenopterans were the third most important insect group, particularly sawflies. Most flies were flesh fly larvae and pupae that may have been ingested incidentally with carrion, but some were probably picked off carrion. Other flies consumed were soldier fly larvae. Beetles were the most frequently occurring insects in the diet, but in small numbers and volumes. Darkling beetles were most frequent, but weevils and scarab, skin, ground, and carrion beetles were also consumed. In August in Oregon, large flocks gathered in cultivated fields as far as 100 km from nesting areas to feed on grasshoppers. The amount of vegetation eaten is highly variable; in most populations, it is a minor component of the diet, but plant material predominates in some areas. In Idaho, vegetation comprised 73.5% of food eaten and 69.3% was cereal grains (corn, oats, wheat, and barley). The remainder was Russian olive seeds and unidentified vegetable matter. In Ungava Bay, the raven ate large quantities of unspecified berries. It has eaten stems, leaves, and roots of various grasses and forbs, holly berries, hemlock seeds, spruce cones, and mountain-ash berries. Although it will eat almost anything given the opportunity, mammals are most important in the diet. Populations are highest where there are large mammals present whose carcasses provide occasional bonanzas of

food. These may be large ungulates such as deer, moose, elk, caribou, or livestock. A population in the Mackenzie delta initially survived mainly on hares. Other items it has eaten include clams (which it may drop on rocks to open them), lizards, snakes, turtles, skunks, fish, snails, grouse, garbage, crayfish, tadpoles and frogs, chickens, opossums, bobcats, dogs, squirrels, cats, woodchucks, rats, and bats (Alvo and Blancher 2001; Bent 1946; Boarman and Heinrich 2020; Bowles and Decker 1930; Engel and Young 1989; Flanagan 1993; Harlow et al. 1975; Jehl and Smith 1970; Kelly et al. 2005; Kilham 1989; Littlefield and Thompson 1985; Maguire 2000; Murray 1945; Nelson 1934; Porsild 1943; Simes et al. 2017; Sinclair et al. 2003; Stiehl 1985; Stiehl and Trautwein 1991). Occasionally, it attempts to prey upon porcupines. In 1 case, the raven was killed by quills (Katzner et al. 2015).

Food storing occurs, mostly in autumn and winter, but also during the nesting season when food is abundant. Birds may fly several kilometres from a carcass to store food. The more ravens that are present at a carcass, the further individuals fly to cache food. All types of items may be cached including meat, bones, pine nutlets, bread, and bird eggs and nestlings. Each cache is in a different location, generally in snow or on the ground covered with material such as leaves, sod, and soil. In New Hampshire, 1 pair cached food on the cliff where the nest was situated. Birds can remember cache sites for about 2 weeks, and they also remember where other birds have caches (Boarman and Heinrich 2020; Heinrich 1988; Kilham 1989).

The Common Raven requires water for drinking and uses a variety of natural and artificial sources of water. One bird learned how to turn on a faucet in a California campground and drink from it (Hanks et al. 2009).

Habitat loss may have contributed to the raven's initial extirpation in southern Ontario, but is no longer a problem. It is now extending its range southward, possibly due to a combination of abandonment of farmland, tree planting, greater tolerance of human activity, and decreased persecution by humans. In California where nest sites and food resources were scarce, fledging success was greater nearer anthropogenic resources such as residences, artificial wetlands, sewage lagoons, livestock feedlots, shopping malls, agricultural fields, and golf courses. In this area, it increased in abundance with increasing human disturbance of natural habitat (Webb et al. 2004).

In the Canadian Shield of Ontario, the raven was equally abundant in early successional and mid-successional stands created by fire and clear-cutting, and in early successional, mid-successional, and mature stands (Zimmerling et al. 2014). The results may be questionable because it is likely that ravens documented in early successional and possibly mid-successional stands represented foraging birds rather than breeders.

In the 19th and early 20th centuries, the raven was greatly maligned and persecuted by humans. It may be an agricultural pest, pecking at eyes of livestock, so was widely shot. It also frequently damaged hides of furbearers caught in traps. Poison baits were frequently set out throughout Canada to control wolves. Ravens commonly ate the baits and also the flesh of poisoned wolves, resulting in widespread declines in areas of remaining suitable habitat. The decline in wolf numbers also reduced numbers of carcasses for ravens to scavenge. These practices were discontinued, although there may still be isolated incidents of shooting (Bent 1946; Boarman and Heinrich 2020; Flanagan 1993; Houston 1977; MacLulich 1938). With large increases in western populations of the

raven, there are concerns about its depredation effects on species of conservation concern and on livestock. In California, raven eggs were oiled, resulting in a decrease in predation on Black-crowned Night-Heron eggs and chicks. Brussee and Coates (2018) concluded that oiling raven eggs can be a viable localized method to reduce raven predation of sensitive avian species. In Wyoming, a toxicant called DRC-1339 is widely used to treat ravens that are causing problems related to human health, livestock, and species of conservation concern. The toxicant is often injected into chicken eggs or sprayed on dog food; it causes death 1-3 days after ingestion (Peebles and Conover 2016).

The raven's range initially shrunk due to avoidance of humans. Now it is reoccupying previously inhabited areas, and has initiated nesting in cities in Saskatchewan and Quebec. In the Yukon and British Columbia, as well as many other northern areas, it is more frequent near settlements. In these areas, landfills provide essential food sources in the winter. In addition, more roads and increased traffic provide carrion. In British Columbia, it became more abundant along the Alaska highway when construction camps were active (Campbell et al. 1997; Flanagan 1993; Houston 1977; Jehl and Smith 1970; Kuyt 1992; Sinclair et al. 2003).

The reaction of nesting ravens to human activity varies. Those nesting in remote areas that have little contact with humans are more easily disturbed. Those that choose to nest in populated areas may be highly tolerant of disturbance. This relationship may be reversed if birds are persecuted in populated areas. In Ottawa, a pair nested in an active quarry where heavy machinery worked and dynamite blasting occurred (DiLabio and Martin 1989), and it has nested in other active quarries (personal observation). In Washington, Knight (1984) monitored responses of nesting ravens to humans in rangelands where human activity was rare and in agricultural areas with moderate levels of human activity. Rangeland nests were significantly further from highways (1,373 m compared with 53 m) and dwellings (2,404 m compared with 1,562 m) than those in agricultural lands. In rangeland there were several unused cliffs and abandoned buildings suggesting an avoidance of humans. In farmland, there were no cliffs or abandoned buildings, so ravens nested on human-made structures, but not necessarily close to occupied houses. Ravens nesting in agricultural land flushed at greater distances (456 m compared with 91 m). Nests in agricultural areas were subject to human persecution, with 42% of nests destroyed compared with none in rangeland. In Virginia, it nested close to human activity and probably relied on humans for a substantial portion of its food. Nest success was not related to cliff height or distance from a road or dwellings; those closer were slightly more successful. Response of individual birds was variable. One pair subjected to high activity of people frequently standing below the nest ledge and weekly checking of the nest was successful as was one on a 10-m cliff only 40 m from a road. Another nest 150 m from a popular stream for fishing failed in 3 years because the adults left the nest whenever humans were present. Hooper (1977) concluded that a few might be adversely affected by humans within 200 m of the nest, but that most would not. He determined that pedestrians should not be permitted within 200 m of the nest if visible to the birds, or within 100 m if hidden from view. Vehicles within 100 m of a nest would be acceptable, but parking areas should not be within 200 m. Walker and Marzluff (2015) studied the response of the raven to recreation and associated facilities in Mount Rainier National Park in Washington. It was most likely to use areas with frequent nearby edges but where there was a high percentage of forest cover within 5 km. It was less likely to use areas with complex or very complex

forests compared with simply structured forests. It was most likely to use areas with abundant nearby roads but its probability of use decreased with the number of human visitors. It was more likely to use areas where anthropogenic food was available despite avoiding areas heavily used by humans. It was correlated with edge, road length, and forest cover.

In Alberta, the raven was significantly less abundant along seismic lines than in adjacent forest interior and significantly more abundant along pipelines than in adjacent forest interior; it was equally abundant at well pads and in adjacent forest interior (Bayne et al. 2016).

Long winters may delay nesting by 2 weeks or more. Timing of egg laying is strongly influenced by the cumulative winter snowfall, with eggs laid later after winters with the most snow. Later nests produce fewer fledglings. Severe snowstorms may result in death of nestlings, even those that are fairly old (Boarman and Heinrich 2020; Dunk et al. 1997; Kozij 1986).

DesGranges and Morneau (2010) concluded that the raven was not very sensitive to climate change.

Status

Prior to European settlement, the raven inhabited all of Ontario. McIlwraith (1894) quoted Wilson who travelled along the shores of Lakes Erie and Ontario in the early 1800s and observed ravens daily; crows were absent to rare. By McIlwraith's time, ravens were gone in southern Ontario, but common in Muskoka District. Baillie and Harrington (1937) considered it a rare inhabitant in the north from Ottawa to Hudson Bay west to Manitoba. They assumed it nested throughout this area, but had nesting records from only 5 areas. In Algonquin Park, where it is now common, it was rare in the wilder parts of the park (MacLulich 1938). The rarity of the raven during this period in ideal habitat was probably related to intensive poisoning programs with direct impacts on ravens and indirect effects due to loss of wolves and the essential carrion they provided. It is uncertain when populations began to recover, but it was probably before the mid-20th century. It was rare in the early 1900s in Muskoka and Parry Sound, reduced from its former abundance by scavenging on poisoned wolf bait. It began to increase in this area in the 1950s, but was still scarce in the 1970s and early 1980s (Mills 1981). James et al. (1976) considered it a common permanent resident throughout the province, but rare south of Algonquin Park. In the Ottawa area, it was a rare resident in 1911 until about 1944 when it became locally extirpated; it returned as a local breeder around 1984 (DiLabio and Martin 1989). In the Kingston area, it was apparently absent in the 1850s, but occasional sightings started in the 1960s (Weir 2008). The raven was common around Niagara Falls in the early 1800s, but southern populations were extirpated by the mid-1800s. In the early 2000s, small numbers began to recolonize the Hamilton area along the Niagara Escarpment and in quarries (Curry 2006). Blomme (in Cadman et al. 1987) stated that the raven reoccupied the Bruce Peninsula in the 1970s, and the first atlas documented an eastward range extension into the Ottawa area. James (1991) considered it common in central Ontario and becoming uncommon to rare in the Hudson Bay Lowland and in southern areas such as the Bruce Peninsula and central Peterborough and Leeds counties. By 2004, it had been confirmed breeding south as far as York, Durham, and Halton regions (Hofmann 2005), and was confirmed breeding in the Rouge Park in Toronto in 2012 (Worthington 2012).

The second atlas confirmed that the raven had extended its range significantly south of the Canadian Shield since the first atlas. Although there was no change in its probability of observation province-wide, it increased significantly in the Great Lakes–St. Lawrence Forest Region, particularly south of the Shield, and in the Hudson Bay Lowland. It was most abundant in the Hudson Bay Lowland, generally decreasing southward and uncommon south of the Shield. The largest areas of high density were along the western portion of the Hudson Bay coast and in the Boreal Forest Region in northwestern Ontario (Peck in Cadman et al. 2007).

The decline with European settlement was widespread in North America. Mayfield (1988) considered the main reason for the raven's disappearance in the Lake Erie area to be the disruptive influence of humans, and replacement of it by the American Crow. The disappearance of ravens in southern Ontario was much more complicated than this. Forest clearing eliminated suitable breeding habitat and favoured the crow; replacement of the raven by crows was an effect and not a cause. Most importantly, the clearing of forests had significant impacts on large carnivores and mammals. Temporary loss of the raven in the west has been attributed to the decimation of bison and the carrion they provided (Bent 1946; Boarman and Heinrich 2020; Houston 1977). Prior to European settlement, gray wolves occurred throughout southern Ontario. With clearing, their habitat disappeared. Some of the large mammals that formerly occurred in the south also disappeared. The moose formerly ranged all along the northern shoreline of Lake Ontario, and elk were present in southern Ontario but became extirpated before 1830 (Banfield 1974). The loss of these large ungulates and their primary predator was undoubtedly a major factor in the extirpation of the raven in southern Ontario.

Long-term (1970-2021) population trends determined by the Breeding Bird Survey indicated annual increases of 2.92% in Canada and 1.94% in Ontario. The short-term (2011-21) trends were annual increases of 0.925% in Canada and 1.2% in Ontario. All results were of medium reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Some fledglings leave the nest area almost immediately to join a communal roost. Although many join the nearest roost, some joined roosts 50-60 km from the nest site in Idaho. Most fledglings remain near the nest site for 1-6 weeks; in Virginia young remained with their parents all winter. Young become independent of adults by July or August. Inexperienced late nesters may still be feeding young in August (Boarman and Heinrich 2020).

The raven is a year-round resident throughout its range. In autumn and winter, it may wander widely, especially where food resources are scarce and patchy. In the Yukon and many other areas, there are local movements into human settlements in late autumn with a return to natural habitats in early spring (Boarman and Heinrich 2020; Campbell et al. 1997; Sinclair et al. 2003).

WINTER

During winter, the raven may congregate near populated areas or remain in more remote breeding areas. All natural and anthropogenic habitats may be used in winter. Although it may be locally common at some landfills, it may frequent farm fields, feedlots and barnyards, highways, railways,

mine sites, ski resorts, bush camps, and urban and suburban areas. In the Yukon, it is most common around towns in winter (Campbell et al. 1987; Sinclair et al. 2003).

The most critical limiting factor for raven populations is presence of adequate food in winter. Although it is widely distributed, there are large areas where there is insufficient winter food to support any birds. Access to carcasses or other clumped, unpredictable food supplies is essential. Away from habitation, it is heavily dependent on wolves that provide carcasses of large animals. Highways are heavily patrolled in winter, as many ungulates are killed during this period. The raven also feeds on Pine Siskins, crossbills, and Evening Grosbeaks that were killed while eating road salt (Boarman and Heinrich 2020; Campbell et al. 1997).

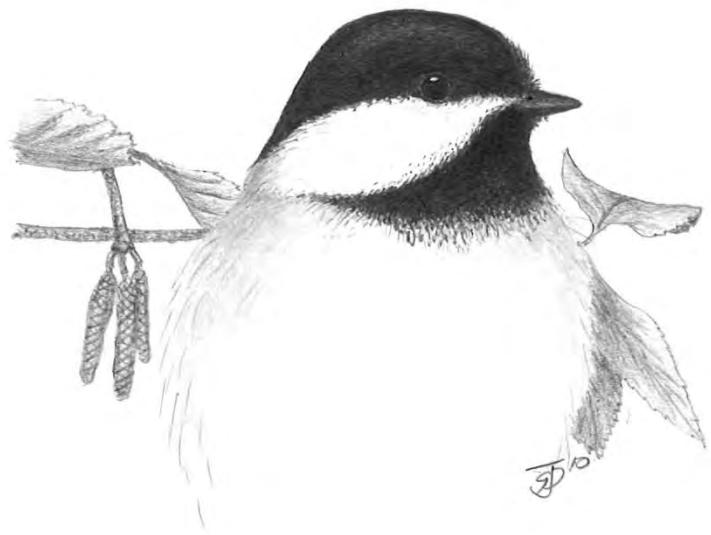
Heinrich (1988, 1994) placed carcasses out for ravens in winter in Maine and Vermont. Sheep and deer carcasses were completely consumed in 2 days; as many as 90 fed simultaneously at a carcass. There were large congregations at carcasses, but ravens were rare when no carcasses were put out for them. Resident pairs were quiet around a carcass and did not advertise its presence; they made regular and punctual visits. Nonresidents gave a yell call at carcasses that attracted large groups that attracted additional birds. Groups of birds appeared irregularly and were absent for months or years at a time. Groups were mostly subadults and juveniles (90%) and the composition of the group changed daily. Of 61 marked birds, 36 were never seen again after 6 days, 29 were seen a month later at a newly established bait, and only 1 was seen 6 weeks later at the original bait. Some showed up at baits more than 50 km away. Of 71,000 raven sightings, only 2 were of the 54 birds marked the previous winter. Some travelled at least 90 km per day to feed at known food resources; daily flights to search for food are probably even greater. Individuals did not stay at a feeding site even though the food remained abundant. Birds wander widely and may visit several roosts in succession.

Addison et al. (1989) kept moose in pens in Algonquin Park and infected them with winter ticks. Ravens visited the pen with infected moose, but ignored the other pen. They ate engorged ticks that had fallen off moose, but did not take ticks from moose. They also ate oats that had fallen from the moose feeder or were present within moose feces.

The raven is an infrequent visitor at bird feeders, possibly because few people provide its preferred food of meat scraps. Suet is readily taken, and it frequently cuts smaller pieces off and probably caches them. In the absence of meat, baked goods are preferred. Other foods infrequently eaten are mixed seeds, sunflowers, corn, cracked corn, popped corn, pet food, and peanut butter mixes (Dunn and Tessaglia-Hymes 1999; Heinrich 1999).

Black-capped Chickadee

Poecile atricapillus

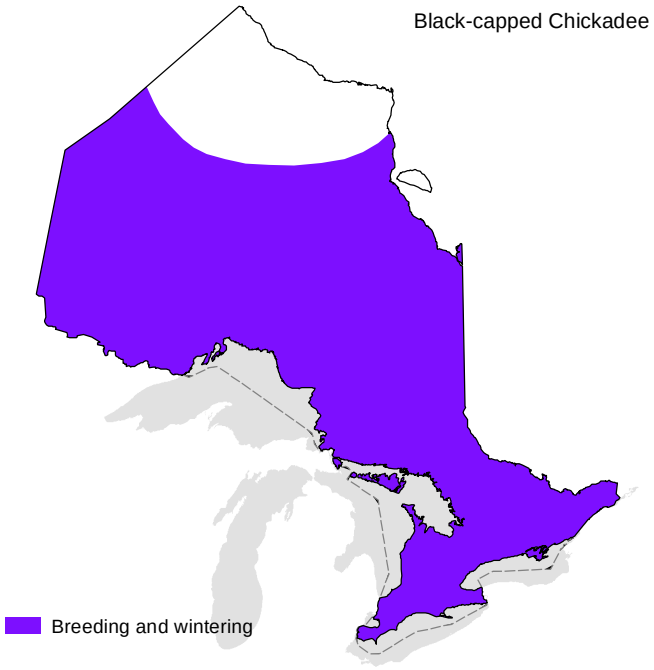


BREEDING SEASON

Habitat Requirements

In Ontario, the Black-capped Chickadee nests mostly in open forests and woodland edges (60.4% of nests), with mixed woods (37.2%) selected over deciduous (17.2%) and coniferous (6.0%) woods. It also breeds in agricultural areas, including overgrown fields and pastures, hedgerows, floodplains, and orchards (22.0% of nests); in beaver ponds, bogs, and marshes (4.0%); in park and cottage areas (2.4%); in sand-dune areas (2.0%); and burns (0.4%). Most nests were beside roads and water bodies. Breeding occurred more often in wet habitats, probably due to the greater abundance of dead trees in these areas (Peck and James 1987).

In the Boreal Forest Region, Erskine (1977) considered the Black-capped Chickadee typical of poplar and birch stands, and reported it in white pine, red pine, pitch pine, and hemlock stands in Ontario. Where their ranges overlap, the Black-capped Chickadee replaces the Boreal Chickadee in hemlock stands. Boreal Chickadees replace Black-capped Chickadees in balsam fir stands. Near White River, the Black-capped Chickadee was significantly more abundant in clear-cuts 23-25 years old than in younger clear-cuts or in mature forests (Venier and Pearce 2005). Near Hearst, Welsh and



Fillman (1980) observed it in clear-cuts in upland mixed forests 9-14 years old. Venier et al. (2009) observed it in clear-cuts, young forests, and mature and old-growth forests near Manitouwadge.

In the Great Lakes–St. Lawrence Forest Region in the Canadian Shield, the Black-capped Chickadee is common in mature and old-growth white pine stands (Kirk et al. 2012). In jack pine stands near Gogama, it was common in the deciduous portions of mixed forests. It was absent in new-growth jack pine, present sporadically in younger stands, and present in low density in mature stands (James and Peck 1995a). In jack pine stands in Parry Sound District, it occurred in low densities in some open canopy stands with mixed deciduous trees (James 1979a). In Algonquin Park, it occurred in black spruce, black spruce–white cedar, birch-poplar, birch-poplar–balsam fir–spruce, balsam fir–spruce, immature white pine, balsam fir–spruce-hardwood, hardwood, and hemlock forests. It was most abundant in hemlock stands and was the second-most abundant species in immature white pine stands. It was absent in bogs (Martin 1960).

In the Kingston area in the Great Lakes–St. Lawrence Forest Region south of the Shield, the Black-capped Chickadee nested in urban, agricultural, and woodland habitat, but was most abundant in forested areas (Weir 2008). Near Kingston, only 1 of 27 habitat characteristics Ramsay et al. (1999) measured differed significantly between control and nest sites. There were significantly more trees with a diameter at breast height (DBH) greater than 32 cm at nest sites than control sites. In Durham Region, it occurred in a variety of deciduous and mixed stands as well as in a black spruce bog, and was present in a wide range of canopy closure, from open growth to closed canopy (Speirs and Orenstein 1975).

In southern Ontario, there was no difference in abundance of this chickadee on organic and conventional farms. It was significantly correlated with hedgerows and the amount of riparian and upland woods, and had positive but nonsignificant relations with habitat heterogeneity. It was negatively associated with road, railway, and hydro rights-of-way, but not significantly (Kirk et al. 2011).

Throughout its range, the Black-capped Chickadee nests in a variety of habitats, including urban areas, small woodlots, rural residential lots, wooded fence lines and roads, wooded riparian strips in agricultural areas, and in almost all forest types. It is a habitat generalist, with presence of a suitable nest site being the most important habitat requirement. Often the nest is in an open area, with adults foraging nearby in wooded habitat. Territories often contain 2 distinct habitats such as

second-growth and mature forest, or open areas with scattered trees and forest. Even when nesting occurs in forest, the nest tends to be in open portions. In Ohio, there were 406 trees per ha at nest sites compared with 1,472 for unused areas. Several authors concluded that it prefers to nest at forest edge. Nesting occurs in the interior, but often where tree density is low. Low tree density promotes growth of saplings and seedlings; it is associated with thickets and high density of woody understorey in wooded areas. Mixed forests are highly preferred, followed by deciduous woods; coniferous stands are used sparingly. In Saskatchewan, it occurred in almost equal density in trembling aspen, mixed, and white spruce stands. In the mid-Atlantic states, its presence was negatively correlated with mean canopy height, the number of standing dead trees larger than 3 cm diameter at breast height (DBH) per ha, density of foliage 0.3-1.0 m tall, and percent cover of forest within 2 km. Some studies concluded that it is more abundant in wetland than upland forests: others concluded the opposite. It has been reported preferring pioneer, mid-succession, and mature stands. In the Clay Belt of Ontario, it occurred in all ages of stands. In Pennsylvania, it occurred in 100% of old-growth forests, 84.2% of all forests in the state, and 97.0% of forests on the Appalachian Plateau. It was considered to have neutral old-growth affinity. In Alberta trembling aspen forests, it was equally abundant in young, mature, and old-growth stands. Some habitat ordinations have failed to put the Black-capped Chickadee into any group, indicating a true habitat generalist. Others considered it associated with an intermediate canopy and dense understorey, mature deciduous or coniferous uplands with a shrub layer, yellow birch, or small woodland openings. In Washington, it preferred the deciduous component of woodlands and was associated with a high volume of trees and shrubs and the mid-canopy level. In Vermont, its abundance was correlated with increasing successional age, high percentages of conifers, and sites with approximately the average number of dead trees. It is not significantly associated with density of snags in woodlands, possibly because it also nests in dead limbs that are not typically inventoried during these types of studies. Being a weak-billed primary excavator, it requires softer types of wood for cavity construction, explaining why poplar and birch are the most common nest-tree species (Back 1979; Beals 1960; Bond 1957; Brewer 1963a; Campbell et al. 1997; Capen 1979; Desrochers in Gauthier and Aubry 1996; Evans and Conner 1979; Graber and Graber 1963; Haney 1999; Hobson and Bayne 2000; Kirk et al. 1996; Kluyver 1961; Lent and Capen 1995; Mossman et al. 1991; Niemi and Pfannmuller 1979; Odum 1941a; Robbins et al. 1989; Rumble and Gobeille 1998; Schieck et al. 1995; Schroeder 1982a, 1990; Sedgwick and Knopf 1990; Sinclair et al. 2003; Stauffer and Best 1980; Sturman 1968a; Taylor and Taylor 1979; Temple et al. 1979; Thomas et al. 1977; Thompson and Capen 1988; Welsh 1993).

In North Dakota 400-m landscapes with less than 30% tree cover, the probability of occurrence of the Black-capped Chickadee increased significantly with tree cover within 100 m but there was no correlation between its occurrence and tree cover within landscapes with more than 30% tree cover (Cunningham and Johnson 2016). It preferred landscapes that were 51-75% forested in North Dakota and 71-98% forested in New York. There were no areas with more than 75% forest cover in North Dakota (Cunningham and Johnson 2019).

The important microhabitat requirements appear to be presence of soft wood or snags for cavity excavation and some larger trees, but in low enough density that there is a rich woody understorey. In urban areas, the important variables appear to be volume of coniferous and

deciduous trees and deciduous shrubs. In New Hampshire and Maine, its abundance was positively correlated with the number of deciduous trees 2-10 cm DBH and the number of woody stems per ha. It was negatively correlated with canopy closure and the total volume of foliage of both deciduous and coniferous trees 2-10 cm DBH (Foote et al. 2020; DeGraaf et al. 1998).

Some authors considered the Black-capped Chickadee an area-sensitive species; others found no relationship between its presence and forest size. In southern Ontario, its abundance was negatively correlated with the amount of forest 100 m or more from edge, woodland size, the amount of forest cover within 2 km, and the amount of regional forest cover, although these relationships were not significant (Austen et al. 2001). In Saskatchewan, forest size was a significant predictor of its presence, and it was more common in large forest fragments. Despite this, it was randomly distributed among forests and forest types, and within fragmented landscapes (Hobson and Bayne 2000). Keller and Yahner (2007) reported similar results in Pennsylvania. In Illinois, its presence was significantly correlated with woodlot area (Blake and Karr 1987). In North Dakota aspen stands, its presence was associated with forest size. It was predicted that it would reach 50% occurrence in woodlots 8-20 ha in size and that it would almost always be found in larger woodlands. Its probability of observation in 1-ha woodlots was 30%. It was also more likely to occur in stands with a greater proportion of trees larger than 23 cm DBH (Grant and Berkey 1999). Schroeder (1990) concluded that it did not require any minimum forest size. Robbins et al. (1989) concluded that the Black-capped Chickadee was not area sensitive. In Iowa, Stauffer and Best (1980) considered it restricted by habitat patch size based on their literature review. The minimum width of riparian strip they found it in was 15 m. They predicted that its numbers would be reduced but not eliminated if cover was reduced to a narrow strip. Foote et al. (2020) reported that it was an edge species most often found within 75 m of edge. All evidence suggests that the Black-capped Chickadee is not area sensitive in Ontario, and it also nests in non-forested habitat in the province.

During the breeding season, both adults use night roosts but do not roost together. They are often not in the same tree and may roost as far apart as 50 m. The female spends the night in the nesting cavity from the time of nest building until the nestlings are several days old. At 1 New York nest, the male roosted 20 m away among the leaves of a small maple tree. Later in the nesting season, both sexes roost on sheltered branches or in vines (Brewer 1963a; Odum 1941b, 1942).

All Ontario nests were in cavities, including those excavated by the chickadees, old woodpecker nests, and nest boxes. Nests were in standing tree stumps (61.7% of nests), trunks and branches of complete trees (19.7%), bird boxes (9.7%), wooden fence posts (6.9%), fallen tree branches and trunks (1.4%), and standing iron posts (0.6%). All nest trees were dead except for 7: 3 with dead branches, 2 with dead tops, 1 with a rotted centre, and 1 with a natural cavity. Of nests in tree stumps, 68.8% were in cavities in the side of the stump and the remainder were in a hollow exposed cavity at the top of the stump. Most nest cavities were excavated by the chickadees with lesser numbers of natural and old woodpecker cavities used. Deciduous trees were preferred for nesting; 90.1% of nests occurred in 15 species of deciduous trees compared with 9.9% of nests in 5 species of conifers. The most common nest-tree species were birches (49.7% of nests), poplars (22.4%), elms (12.1%), maples (9.1%), and white cedar (6.7%). The DBH of trees and stumps used for nesting ranged from 7.5 to 61 cm, mostly 10-18 cm. Nest height ranged from 0 to 15 m from ground, with most 0.9-3.7

m up. Two nests had cavity entrances at ground level, and in one of these the nest was 11.4 cm below ground (Peck and James 1987). Near Kingston, 35.6% of nests were in white birch; 11.1% were in sugar maple. Two thirds of nests were in dead trees. Nest trees averaged 8.7 m in height and 20.5 cm DBH. Cavity entrances averaged 5.3 m from ground (Ramsay et al. 1999). Straus et al. (2011) characterized the mean microhabitat features of 138 nests in the Carolinian Forest Region of Ontario. Average nest height was 1.7 m, DBH of nest trees averaged 12.2 cm, there were 7.1 additional cavities in the nest tree, canopy closure was 65.1%, nests averaged 166.4 m from a hard edge, 94.7% of nest trees were dead, 5.3% of nest trees were declining, 0.0% of nest trees were healthy, 5.4% of nests were in sugar maple, 18.9% were in red maple, 2.7% were in ash, 29.7% were in beech and birch, 8.1% were in fruit and nut trees, and 35.2% were in unidentified tree species.

Throughout its range, the Black-capped Chickadee nests in dead, decaying, or hollow trees and stumps. Hardness of the wood is a critical factor, as it can only excavate in soft or decaying wood. Therefore, poplars, birches, willows, cherries, and apple are often selected. In New England, gray birch is preferred, and it has also nested in beech, red oak, white oak, and basswood. Most excavated cavities are in dead tree trunks, dead or diseased branches, in rotten stumps, in knotholes, and in boles. In the Seattle area, it nested in snags that were more decayed than average and nested more in broken-top snags than expected. It is one of few species that will nest in upward-facing cavities and it shows no preference for cavity-opening orientation. It frequently nests in fallen, leaning limbs and occasionally in natural or old woodpecker cavities. Most nests are in trees with a DBH of 10-20 cm. It uses nest boxes. In urban areas, nest boxes may provide nest sites in areas where natural nesting locations are rare or absent. Artificial snags built from polyvinyl chloride tubes and filled with wood shavings are preferred to nest boxes. It has nested in a hollow steel post, and there is 1 record of it nesting in an old, unusually deep robin's nest. Nest height may range from ground level to more than 20 m but most nests are within 3.4 m of ground (Bender et al. 2016; Blewett and Marzluff 2005; Brawn et al. 1984; Brewer 1963a; Campbell et al. 1997; Cooper and Bonter 2008; Fitch 1958; Kluyver 1961; Odum 1941a, 1941b; Schroeder 1982a; Sedgwick and Knopf 1990; S.M. Smith 1967a, 1974, 1991; Stauffer and Best 1980, 1982; Tyler in Bent 1946).

Territorial defence begins in early spring when pairs start to disassociate themselves from winter flocks, usually between late March and mid-April. Most breeding territories are within the winter-flock territory. Territoriality is most intense in the 2 weeks following breakup of the winter flock. Initially the male defends an area around the female, but soon the pair defends a space. Once the female selects a nest site, territory boundaries become fixed and defence is intense until the nest is built. Territoriality wanes during egg laying and territory size shrinks at this point. The territory increases again during the nestling phase, but it is still considerably smaller than during nest building. Territoriality ceases once young leave the nest. In Utah, territories were 0.3-5.1 ha during nest building (averages 2.0 ha and 2.7 ha over 2 years), 0.2-2.1 ha during egg laying (averages 0.6 ha and 1.2 ha), 0.1-0.7 ha during incubation (averages 0.1 ha and 0.3 ha), and 0.1-1.2 ha during the nestling period (averages 0.3 ha and 0.7 ha). During the nesting cycle, the original territory may be used as a home range, but the outer limits are seldom visited as nesting progresses. Territory size varies depending on status of the male, quality of habitat, population density, and whether adjacent habitat is occupied. Dominant males have larger territories; in Utah, territories of dominant males

averaged 0.7 ha larger than beta males. Territories in wooded habitat are superior and much smaller than those in more open areas or in a mix of open and wooded habitat. If all habitat is occupied, territory sizes decrease to accommodate the additional breeding pairs. Territorial boundaries are more flexible when adjacent areas are unoccupied, and these territories may be larger. Mean territory size reported from several North American studies is 1.5 ha (means 0.07-8.8 ha). In Alberta, there was no consistent relationship between territory size and stage of breeding cycle; only 21% of territories decreased in size as the breeding season progressed. Territories averaged 7.8 and 8.8 ha over 2 years. Sizes of home ranges have been reported as 0.04-17.2 ha. In Algonquin Park, average territory size was 0.5 ha (range 0.07-1.6 ha). In birch-poplar–balsam fir–spruce stands, chickadees remained mostly in shrubs and lower branches of conifers, but ranged from the ground to treetops in fir-spruce stands. Nests are usually at the edge of the territory, and active nests have been found within 10 m of each other. Some populations may have nonbreeding floaters that have home ranges that cover 3-5 nesting territories (Brewer 1963a; Butts 1931a; Fitch 1958; Hill and Lein 1989; Martin 1960; Odum 1941a; Schroeder 1982a; S.M. Smith 1967a, 1974, 1976, 1989, 1991; Stefanski 1967). Near Quebec City, there was no aggregation of territories and singing males were more evenly distributed than by chance. There was no tendency toward colonial nesting (Bourque and Desrochers 2006).

Natal site fidelity is low. Fledglings disperse rapidly from their parents' territory and form flocks that may travel widely until they join wintering flocks. These birds may establish their first breeding territory in the vicinity of the winter territory, or move again in spring before breeding. In British Columbia, most young left the study area by September, and only one returned to breed over 2 years. In Wisconsin, most of 88 nestlings disappeared from the study area immediately after family breakup. Fourteen of these were subsequently found in winter, 12 0.5-2.4 km from the natal nest, 1 at 5.5 km, and another 11.2 km from the nest. Distances from natal sites to first breeding sites were 0.4, 0.8, 0.9, 1.3, 1.8, and 11 km (median 1.1 km). Adult site fidelity is very high. Most chickadees remain near their initial breeding site the rest of their lives (Butts 1931a; Foote et al. 2020; Odum 1942; S.M. Smith 1967a, 1991; Weise and Meyer 1979).

Limiting Factors

Eggs have been reported in Ontario nests from the last week of April until the third week of July, mostly in the last half of May (Peck and James 1987, 1997). In Algonquin Park, nests are under construction from mid-April to mid-June, eggs occur from late May to late June, nestlings are present from late May to mid-July, and dependent fledglings have been documented from late June until late July (Tozer 2012).

Usually 5-14 days elapse after pair formation before initiation of cavity excavation, with longer periods for early pairs. The female may several cavities before selecting one for nesting. Two cavities may be fully excavated before one is chosen. Cavity excavation takes 4-10 days. The female builds the nest in 2-4 days. There is often a delay of 1-2 days between completion of nest construction and egg laying; occasionally there is no delay. One egg is laid a day, but occasionally a day is skipped. Incubation usually starts with laying of the penultimate egg, or earlier in replacement or second clutches. Incubation periods of 11-17 days have been reported in Ontario, with most eggs hatching in 12 or 13 days. Overall, incubation periods of 11-20 days have been documented, with 12-13 days

typical. All eggs in a clutch usually hatch on the same day. Most young fledge when they are 16 days old, with a range of 16-20 days (Fitch 1958; Foote et al. 2020; Holleback 1974; Kluyver 1961; MacKenzie 1996; Odum 1941a, 1941b; Peck and James 1997; S.M. Smith 1991; Tyler in Bent 1946; Weise and Meyer 1979).

Usually 1 brood is raised, but occasionally 2 broods are raised. Three double broods have been reported from Ontario. True double broods are rare and possibly more frequent in low-density populations. Second clutches are started well before the first brood has dispersed and may be initiated within a few days of the young leaving the first nest. Renesting occurs if loss does not occur too late in the breeding season. Replacement nests are often 100-300 m from the original nest but occasionally nearby or even in the same nest if nest sites are scarce. Replacement clutches may be initiated 4-11 days after loss. Clutches of 3-11 eggs have been reported in Ontario, with 6 and 7 eggs most frequent. In southwestern Ontario, the mean size of 29 clutches was 5.59 eggs. Clutches of 1-13 eggs have been reported in North America, with 80% of clutches having 6-8 eggs. In British Columbia, 66% of clutches had 5-7 eggs. Overall average clutch size is 6.64 eggs. Northern clutches tend to be larger, older females tend to have larger clutches, and nests later in the season have smaller clutches. The clutch size is usually larger and eggs are laid earlier if an old nesting cavity is used (Butts 1931a; Campbell et al. 1997; Clemmons 1994; Foote et al. 2020; Kluyver 1961; Odum 1941a, 1941b; Peck and James 1997; S.M. Smith 1967a, 1991; Straus et al. 2011; Tyler in Bent 1946).

Most birds first breed when they are 1 year old. Those that do not are the lowest ranking in the winter flock and are unable to find a mate or defend a territory. These birds remain as floaters within the breeding population. Some are chased by dominant birds and may end up as far as 20 km away. Some floaters manage to breed their first year by filling in when a pair loses one of its members. Those that are unsuccessful in gaining a territory the first year join the winter flock again. They rejoin with a higher status than the previous winter and are usually successful in obtaining a mate and territory their second year. Some individuals do not breed until they are 3 years old. There are typically no more than 1 or 2 nonbreeding floaters in a subpopulation; many years there are none. There are frequently no floaters present to replace lost mates, but 1 female raised 2 broods 2 years in a row with 4 different mates (Butts 1931a; Desrochers et al. 1988; Foote et al. 2020; Odum 1941b; S.M. Smith 1967a, 1989, 1991).

Almost all Black-capped Chickadees are monogamous and maintain a life-long pair-bond. Polygyny occasionally occurs, usually when 2 females construct nests within a male's territory. When this occurs, the territory is divided in half by the females. One case of polyandry was reported from Alberta, when a mated male bred with the female of a pair in an adjacent territory. Two other cases of polyandry have been documented, including one in Ontario; in all cases, the neighbouring male had lost his mate (Clemmons 1994; Dixon 1986; Odum 1941a; Otter et al. 1994; S.M. Smith 1967b, 1991; Waterman et al. 1989). In Massachusetts, 15 cases of divorce occurred over 10 years but 84% of pairs remained intact. Near Kingston, divorce occurred in 13 of 144 partnerships (9.0%) over 8 years. Divorce may rarely be related to unsuccessful nesting, but is almost always related to social climbing. Most divorces are initiated by females, and the potential for this starts early in the breeding season. Near Kingston, nest-site selection was influenced by the range and status of the neighbouring male, and not by habitat, prey abundance, or previous nesting experience. Females

that are mated to a low-ranked male often nest within 10-15 m of the territory boundary of a superior male. Females actively sought extra-pair copulations from adjacent dominant males and 37.5% of nests had extra-pair young. Extra-pair young account for 9-17% of nestlings and occur in 29-38% of nests. Females that divorced were significantly more likely to have mixed paternity broods prior to divorce, and all moved up on the social scale. Divorce may also occur when a dominant male loses his mate. Females mated with a lower-ranking male may leave him to mate with the alpha male. All males that divorced were elevated from beta to alpha males (Foote et al. 2020; Otter et al. 1994; Ramsay et al. 1999, 2001; S.M. Smith 1974, 1988, 1991, 1992).

The Black-capped Chickadee forages predominantly on dead, damaged, or curled leaves; on twig tips; or on tree boles. In New Hampshire, it was the only species that hung upside down to uncurl leaves to pluck prey from a leaf, or uncurl a leaf rolled by a caterpillar or spider. Prey-capturing techniques were 57.0% gleaning, 28.7% hanging, 8.8% hovering, 3.5% probing, and 2.4% hawking. Of attacks on arthropods, 58.0% were on bark and 38.2% were on leaves. In Ontario, 48.3% of foraging occurred while hanging upside down; 66% of foraging occurred in deciduous species and 34% in conifers. In Ohio, 45% of feeding was below 3 m and 75% was below 10 m; plant use depended primarily on availability. It hovers near sap at woodpecker borings where it may feed on insects attracted to or trapped in the sap. In Washington, 70% of foraging was done by hanging. In early spring, it fed more often on buds and catkins than later in the season. Most foraging occurred in hardwoods, but it also fed in conifers. This chickadee fed from trunk and branch bark 73% of the time in hardwoods and 81% in conifers. Foraging occurred mostly in the subcanopy of trees, the area occupied by branches with little to no living foliage. In British Columbia, it preferred to forage within 1.5 m of the ground (Brewer 1963a; Greenberg et al. 1999; Odum 1942; Robinson and Holmes 1982; Schroeder 1982a; Sturman 1968b). During the breeding season in central Ontario, it foraged at heights of 2-13 m compared with 5-14 m in autumn. These differences were minor and nonsignificant. Foraging techniques were top-gleaning, clinging, and probing. During the breeding season, top-gleaning was the prevalent foraging method, with clinging and probing becoming more common later in the breeding season and in autumn. Early in the breeding season, all tree species were used for foraging, particularly white birch. In mid-season, foraging was concentrated in early successional hardwoods, including white birch. In autumn, greater use was made of conifers but white birch continued to be important (Mills 2007). In savannahs and oak woodlands in Illinois, it foraged throughout the foliage layers, but 63% of foraging occurred in the lower canopy (11-15 m) and canopy layers (above 16 m). In savannahs, it exhibited no preference for tree species while foraging. In closed-canopy forests, it foraged in oaks more than expected based on availability and in sugar maple and red elm less than expected (Grundel and Pavlovic 2007b).

Males bring food to females early in the nesting season to keep their energy up during the egg-laying, incubation, and brooding periods. Of 65 food items brought to nestlings in Massachusetts, 13 were large caterpillars weighing 200-300 mg, 22 were small caterpillars averaging 120 mg, 11 were spiders, 6 were termites, 6 were small unidentified larvae, 4 were small red larvae, 1 was a white butterfly or moth, 1 was a pupa, and 1 was a fly. Caterpillars and sawflies were the main items fed to nestlings; caterpillars smaller than 8 mm were rarely brought to young. Chickadees in Massachusetts concentrated where caterpillars were most abundant, but had a marked preference for clumps of

red and white pine. Most remained almost entirely in red pine until the end of June but occasionally forayed into oaks. In Michigan, young were fed predominantly spruce budworm and spring cankerworm caterpillars. During the breeding season, chickadees feed mostly on invertebrates and most frequently on caterpillars and spiders. In New Hampshire, food items consisted of 75.9% caterpillars, 13.8% spiders, 6.9% beetles, and 3.4% adult lepidopterans. The most important caterpillars were those of prominent, geometer, and sphinx moths. It occasionally eats hairy caterpillars such as gypsy moth and eastern and forest tent caterpillars. The Black-capped Chickadee has been observed probing in cattail heads in Ontario, presumably foraging on cattail borer moth larvae. It eats a wide variety of other insects such as beetles, true bugs, sawflies, ants, honey bees, and other lepidopterans, as well as small snails, slugs, and centipedes. Cicadas may be avidly consumed when they are abundant. It has been observed pecking bird eggs in Ontario and partially drinking the contents. In early spring, it regularly drinks sap from sugar maples and eats sap icicles. As the breeding season progresses, It eats some seeds and fruit, especially those of common and giant ragweed, staghorn sumac, blackberries, honeysuckles, and blueberries (Brewer 1963a; Dance et al. 2012; Dobos 1986; Foote et al. 2020; Kluyver 1961; Odum 1941b, 1942; Picman and Belles-Isles 1988a; Pribil and Picman 1994; Robinson and Holmes 1982; Simpson 2025; S.M. Smith 1991; Tyler in Bent 1946). It eats spruce budworms even when they are present in low density, but populations do not increase with increasing budworm numbers (Crawford and Jennings 1989; Venier et al. 2009; Morris et al. 1958). In Maine during a spruce budworm outbreak, its diet was composed of 44% and 37% spruce budworm larvae and pupae in 2 years (Mitchell 1952).

The Black-capped Chickadee is rarely parasitized by the Brown-headed Cowbird. Some authors stated that only 7 incidences of parasitism have been documented. There is 1 record of chickadees successfully rearing both cowbird and chickadee fledglings (Campbell et al. 1997; Lowther 1985, 1997; S.M. Smith 1991; Tyler in Bent 1946). The highest reported rate of parasitism appears to be in Ontario; 6 of 247 nests (2.4%) were parasitized (Peck and James 1997).

The Northern House Wren competes with the Black-capped Chickadee for nest sites. In addition to taking over nests, wrens frequently break or remove chickadee eggs. In Massachusetts, 20% of chickadee clutches were destroyed by wrens (Brewer 1963a; Kluyver 1961). The Tufted Titmouse may outcompete this chickadee, especially when titmice expand their populations. One chickadee population declined significantly when titmice became established; chickadees experienced a reduction in survival rates and numbers of recruits. This effect lasted only 1 year and there was no long-term effect on population size. After the population stabilized, there was still a significant decrease in survival rate but a significant increase in recruits. The population remained stable, but was comprised of a higher proportion of juveniles (Dhondt 1989). In Connecticut, there was evidence of lower average long-term survival rates, especially in winter, following establishment by the Tufted Titmouse (Loery et al. 1997).

Habitat loss and degradation do not appear to be significant limiting factors for the Black-capped Chickadee. It is predominantly an edge species, so forest fragmentation may be beneficial, providing more edge habitat for nesting. Excessive forest clearing may be detrimental. It is absent from portions of Essex County where forest cover has been significantly reduced.

It has been suggested that managed woodlots where dead trees are removed are less suitable for nesting, but this may not be the case because chickadees frequently nest in dead limbs of live trees. In the Boreal Forest Region with particular reference to Ontario, the abundance of the Black-capped Chickadee was unaffected when 30%, 50%, or 70% of trees were removed. In the North Bay area, there were no significant differences in its reproductive success in healthy sugar maple forests and those that were declining due to acid precipitation. The only difference was that chickadees in the healthy forest spent more time foraging in the canopy. Birds at the declining site spent equal time foraging in the upper and mid-canopies. Lower foraging at the declining site may have been a response to canopy dieback and lower quantity of food resources in the upper canopy. In the Carolinian Forest Region of Ontario, there were no differences in its density in control woodlots or those that had been logged. Clear-cutting removes habitat in the short term, but may be beneficial in the long term due to regeneration by birch and poplar. In Pennsylvania, there were no significant differences in its numbers in clear-cuts where snags were removed or retained. In Vermont, it nested in clear-cuts as well as adjacent uncut forest. In British Columbia, chickadees breeding in forest regenerating after clear-cutting had significantly lower breeding success than those nesting in adjacent mature, mixed-wood forest. Canopy height was significantly associated with nest success, and was significantly lower in clear-cut areas. Good quality nest sites and breeding territories may have been more limited in disturbed habitat. In New York clear-cuts, it was in a guild of species that was positively correlated with the total leaf area 0-7 m from the ground. The species in this guild attained their highest abundance 7-10 years after cutting. In New York, it was unaffected when 0%, 25%, 50%, 75%, and 100% of merchantable timber was removed from stands. This silvicultural technique left the smaller diameter trees that are preferred for nesting by the Black-capped Chickadee. No significant effects due to partial harvest were observed in the Boreal Forest Region of Alberta. In Minnesota, it responded positively to partial timber harvesting, but was not significantly more abundant in cut than uncut forests (Desrochers in Gauthier and Aubry 1996; Foote et al. 2020; Fort and Otter 2004; Lent and Capen 1995; Hanowski et al. 2003, 2005; Harrison et al. 2005; Holmes et al. 2004; Keller et al. 2003; Mahony et al. 1997; Straus et al. 2011; Stribling et al. 1990; Vanderwel et al. 2009; Webb et al. 1977). In the Canadian Shield of Ontario, it was equally abundant in early successional clear-cuts and burns, but was significantly less abundant in mid-successional clear-cuts than in mid-successional burns. It was significantly less abundant in early successional than mature stands but equally abundant in mid-successional and mature stands (Zimmerling et al. 2017).

Blewett and Marzluff (2005) studied the effects of urban sprawl on the Black-capped Chickadee in the Seattle area. Higher densities were associated with high interspersion of habitats at the landscape scale. There was no difference in breeding densities in urban forests and more extensive forests. In Colorado, it was more abundant in undeveloped landscapes than in areas with low or high density of homes. Abundance was negatively correlated with distance to houses, suggesting sensitivity to humans (Foote et al. 2020).

After forestry applications of fenitrothion, songbirds may experience 50-60% brain cholinesterase E depression. The 50% level is loosely associated with a variety of physiological effects and mortality in many species. Chickadees were able to remember their food caches at this level of contamination, but their physical abilities were visibly impaired (Mineau et al. 1994).

In response to anthropogenic noise, the Black-capped Chickadee sang its notes at higher frequencies when ambient noise levels were higher. Anthropogenic noise did not affect its abundance or health. It is well adapted to noise and its abundance was not correlated with noise levels (Bayne et al. 2008; LaZerte 2014; Proppe et al. 2012, 2013). In New York, Damsky and Gall (2017) played Tufted Titmouse mobbing calls and mobbing calls accompanied by anthropogenic noise, including traffic with occasional airplane and lawnmower noises. The addition of noise resulted in an approximately 80% decrease in the number of chickadees approaching the speakers; there was no effect on feeding behaviour. The decrease in response to the mobbing call as a result of noise was considered a concern. These calls are given in response to a threatening stimulus. If birds are slow to respond to the warnings, they may be unable to take advantage of them.

In Edmonton, this chickadee was equally abundant near roads and in undisturbed habitats. There were no differences in hematological measures of stress or physical condition of birds residing near or distant from roads. Proppe et al. (2013) concluded that roads did not affect its abundance, health, or physical condition. Bayne et al. (2016) compared its abundance near energy sector disturbances and adjacent forest interior. It was more abundant near pipelines and well pads than in adjacent forest interior. There was no difference in its abundance in forest interior and near seismic lines.

In Minnesota, blowdown of spruce-fir forest resulted in an 80% decline in canopy cover and a 100% increase in shrub cover. The Black-capped Chickadee bred in the control plots but was only a visitor to blowdown areas (Burris and Haney 2005).

In New Jersey and Pennsylvania over a 15-year period, hemlock declined from representing 56% of the total basal area to 46% due to the hemlock woolly adelgid; the amount of deciduous understorey increased. The Black-capped Chickadee responded favourably to hemlock decline and increased (Toenies et al. 2018).

In New York, Brooks and Bonter (2010) surveyed territories over 35 years in a field that had been allowed to regenerate, in forest, and in a managed Christmas tree plantation. Over this time, the number of Black-capped Chickadee territories in regenerating areas increased significantly. There was no change in numbers in forest habitat; it was absent in the Christmas tree plantation.

Cold spring weather does not appear to be a significant limiting factor. In Massachusetts, cold weather delayed clutch initiation, but did not affect clutch size (Kluyver 1961). Severe spring storms may cause death of fledglings (Smith 1967a).

In southwestern Ontario, daily survival rates were negatively correlated with nest height, canopy closure, tree DBH, and arthropod biomass. Areas with lower canopy closure tend to develop dense sapling layers which may provide nest concealment (Straus et al. 2011). In New York, the most important factor influencing nest success from predators was thickness of the cavity wall, with less predation of thicker-walled cavities. Lower rates of predation were associated with harder wood at the nest site and larger tree circumference at the nest. Nest height did not affect success (Christman and Dhondt 1997).

Price (2004) predicted that the range of the Black-capped Chickadee could contract in southern Ontario if the average summer temperature increased by 2°C.

Status

The Black-capped Chickadee has always been a common breeding bird in Ontario. McIlwraith (1894) concluded that it was distributed throughout the province. Baillie and Harrington (1937) considered it a fairly common breeding species from the southern border north to Fort Albany and west to Lake of the Woods, and probably northward along the Manitoba border. Historical populations did not vary significantly from present in Elgin County (Lancaster et al. 2004) and the Kingston region (Weir 2008), and probably throughout the province. James (1991) considered it a common permanent resident north to Big Trout Lake and Moosonee, and rare to Little Sachigo Lake and Attawapiskat.

The second atlas revealed that the probability of observation of the Black-capped Chickadee had not changed significantly province-wide, although the trend was positive. Significant increases occurred in the Carolinian and Boreal forest regions. The increase in the Carolinian Forest Region was mostly in Essex County, but it was also observed in several new squares in adjacent Chatham-Kent and Lambton. It was most abundant in the Great Lakes–St. Lawrence Forest Region, although it was notably less abundant west of a line between the western base of the Bruce Peninsula to about the Cambridge area. It was relatively uncommon in the Carolinian and Boreal forest regions and in the southern portion of the Hudson Bay Lowland (Cheskey in Cadman et al. 2007).

Long-term (1970-2021) population trends determined by the Breeding Bird Survey were annual increases of 0.78% in Canada and 2.05% in Ontario. Short-term (2011-21) trends were annual decreases of 0.49% in Canada and 0.466% in Ontario. The long-term results for Canada were of medium reliability; the other estimates were highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Once all young have fledged, they begin to move away from the nest. Young can usually capture prey 10 days after fledging, and parents begin to ignore begging 8-10 days after fledging. Breakup of the family occurs about 3 weeks after the young fledge (Foote et al. 2020).

Juvenile dispersal begins shortly after fledging and occurs in random directions. This dispersal may partially explain why the Black-capped Chickadee occasionally occurs south of its normal range during winter. In Wisconsin, 3 weeks after attaining independence, juveniles were seen 180-760 m from their nest sites and 50-590 m from the nearest location where they had been last seen with their parents. Within 30 minutes, 1 juvenile travelled 500 m through 3 territories, and then another 200 m before it was lost from view. These rapid dispersals are typical. Juveniles are not accosted by adults who remain on their territories at this time. Dispersal lasts only a few weeks and is usually complete by mid- to late July. In 1 area, juvenile females dispersed an average of 2.3 km compared with 1.3 km for males. Most years, juveniles band together to form flocks from July to mid-August. These flocks are often joined by woodpeckers, vireos, kinglets, and warblers. Flocks of juveniles disband later in autumn, but at that time they are joined by adults who form the nucleus of winter flocks. Most juveniles winter and subsequently breed in the area where they settled after dispersal (Butts 1931a; Odum 1941b, 1942; S.M. Smith 1991; Weise and Meyer 1979).

During the autumn dispersal and flocking periods, the Black-capped Chickadee prefers wooded areas and forest edges. In British Columbia, preferred habitat includes deciduous, mixed, and open coniferous forests; shrub thickets; riparian woodlands; and willow, aspen, and birch stands with a shrub understorey. In coniferous forests, it prefers edges and openings along beaver ponds, lakeshores, river banks, bogs, meadows, and other human-made clearings. In Pennsylvania during autumn, it was most abundant in forest edge, followed by forest interior, shrub-sapling-stage forest, forest-agricultural edge, pole-size forest, and suburban forest. In New York, late-summer flocks usually remained in woods; October flocks were seen in all parts of the study area, including weedy fields (Campbell et al. 1997; Foote et al. 2020; Odum 1942; Rodewald and Brittingham 2002).

During the postbreeding period, juveniles were equally likely to occur in riparian (59% of birds) and upland (41%) forests (Akresh et al. 2009). In Minnesota, Streby et al. (2011b) captured only 1 chickadee in clear-cuts during the breeding season, but caught 42 adults and 25 fledglings during the postbreeding period. This suggested that they moved to areas with dense shrub cover in the postbreeding period. In Pennsylvania, Stoleson (2013) captured 78 adults and 61 juveniles in clear-cuts and 3 adults and 5 juveniles in mature forest.

After fledging, the family roosts wherever it happens to be. Once flocks form, birds tend to roost solitarily but in the same general area of forest or group of trees, and the same area is used every night, particularly in winter. Birds roost near the ends of limbs in dense foliage, often in low conifers such as in pine plantations (Odum 1942).

During autumn at Prince Edward Point, 27% of foraging occurred on outer leaves, 15% on outer branches, 8% in inner branches, 17% on tree trunks, 10% on sapling foliage, 14% on sapling branches, 6% on shrubs, and 3% on the ground. Foraging occurred at heights of 0-12 m, with peaks at 3 and 10 m (Keast 1980).

In late summer and autumn, the Black-capped Chickadee's diet changes from being dominated by invertebrates to a mix of animal and vegetable matter. Invertebrate food consists predominantly of insect and spider eggs and pupae. As fruit becomes available, it feeds on fruit of staghorn sumac, common buckthorn, yew, hawthorn, winterberry holly, pin cherry, poison ivy, yellow birch, tree-of-heaven, sweet gale, blueberries, and blackberries. It also feeds on seeds of giant ragweed, early goldenrod, flat-topped goldenrod, and other members of the aster family. In late autumn and winter, hemlock seeds are highly preferred (Barnea and Nottebohm 1995; Fitch 1958; Foote et al. 2020; Mudrzynski and Norment 2013; Odum 1942; S.M. Smith 1991; Tyler in Bent 1946).

The onset of shorter days stimulates the Black-capped Chickadee to store food. This starts in mid-October. In some areas, this only lasts through November. In other areas, including Ontario, food storage may occur throughout winter and can potentially occur at any time of the year. Most items cached are seeds, although insect and spider eggs and pupae may be cached, as well as suet from feeders in winter. Each item is cached separately, usually 15-20 m or less from the food source, occasionally as far away as 70 m. Most individuals cached food in a certain orientation from a food source every day, but this orientation may vary daily and there is no favoured cache location within the home range. Most caches are retrieved within a few days. Although initial cache sites are used briefly, food may be cached at a secondary site for as long as a month before recovery. In Ohio, 48%

of seeds were stored on branches, 25% on twigs, and 21% on small trunks less than 2.5 cm DBH. More than 85% of storage substrates were less than 8 cm in diameter. It showed a strong preference for caching on the underside of branches and also cached in dead leaves that were still hanging from trees. Mean height of caches was 7.0 m. Although most food is stored in small cracks and crevices in trees, it occasionally caches on the ground or under snow, or rarely under shingles, in eavestroughs, or in drain pipes (Barnea and Nottebohm 1995; Foote et al. 2020; Kilham 1975; Odum 1942; Petit et al. 1989; Shettleworth et al. 1995; S.M. Smith 1991).

MIGRATION

The Black-capped Chickadee is typically a permanent resident that remains year round in its breeding range, even in the north. Several types of movement may occur; some occur regularly, others are more sporadic. Autumn dispersal of juveniles occurs regularly and, in some areas with significant altitudinal gradients, birds may move down in autumn and back up in spring. In some areas, there is evidence of a slight southward movement in late autumn or winter. In New York and Illinois, the Black-capped Chickadee occurred further south in winter than in the rest of the year. In the Yukon, it persists in winter at the northern extent of its range, but many disappear during cold spells suggesting sporadic seasonal movements or mortality. Most noteworthy are massive and irregular autumn movements southward. These are best termed irruptions rather than true migration and appear to be a response to low cone crops in the north. During irruptions, birds may move 50-500 km and 1 bird moved more than 2,000 km. Irruptions are usually followed by a spring return of lesser numbers that usually occurs in April and May. It is unknown if birds involved in irruptions return to their area of origin. Most birds involved in irruptions are juveniles, but some adult movement may occur. Short-distance movements during non-irruption years are rather aimless and these may represent dispersal rather than migration. All movement is during the day and chickadees may move singly, often in ragged groups, or occasionally in large flocks, especially along lake shorelines. Movements may terminate when chickadees reach the shoreline of a large lake, but flocks have been observed flying across the Great Lakes from Point Pelee and Presqu'ile Provincial Park (Brewer et al. 2018; Brooks 1991a; Butts 1931a; Foote et al. 2020; Graber and Graber 1963; Hussell 1996; Lawrence 1958; Odum 1942; Sinclair et al. 2003; S.M. Smith 1991; Weir 2008).

After a major irruption southward in October 1961, there was a pronounced spring migration at Long Point. Between 20 April and 3 June 1962, 505 Black-capped Chickadees were banded. The major influx was between 10 and 20 May, with numbers considerably reduced after 20 May. Some stayed in the area 24-25 days (mean 6.7 days). Spring invasions at Long Point are infrequent, with an average of less than 1 chickadee a day recorded most years. Only 1964 came close to the 1962 results with an average of 42.3 per day. Average number of birds in spring was correlated with average numbers occurring the previous autumn. During spring migration years, peaks at Long Point tend to be from 26 April to 20 May. Some of these birds may be paired; 2 chickadees banded at Point Pelee were recaptured together at Long Point 20 days later (Hussell 1991d, 1996; Hussell and Stamp 1965). At Pimisi Bay, there were few, if any arrivals from the south, and peak numbers occurred in March. This appeared to represent the return of wintering birds back to the breeding areas (Lawrence 1958).

Near Guelph, a regular influx of chickadees occurred in October and March suggesting that regular migration was taking place. Recoveries of birds also suggested migration. One banded in Fergus was recaptured in Guelph, 1 banded in Eramosa was recaptured in Ottawa, and 1 banded in Toronto was recaptured in Eramosa. Salvadori et al. (2002) concluded that large-scale migration occurs in the Black-capped Chickadee, but that a large number wander around in no specific direction. Of 60,000 Canadian banding records, 90% of chickadees exhibited no movement (Foote et al. 2020).

In New York, only 32 of 1,378 chickadees (2.3%) were re-encountered more than 16 km from the banding location. Most moved northeastward and the average distance travelled was 119 km over 50 days, about 1.6 km a day (Brooks 1989, 1991b). Due to the late migration of spring migrants, probably most do not return to their area of origin to breed (Hussell and Stamp 1965).

Autumn irruptions are irregular and may occur across a wide geographic area or be more localized. At Long Point, large flights occurred in 1961, 1965, 1972, 1973, 1980, 1983, and 1993, with lesser influxes in 1963, 1969, 1980, and 1990. The 1961 flight was massive and covered much of the east. In 1985, an irruption occurred that appeared to be restricted to western Ontario and western Pennsylvania. In New York, some birds moved more than 320 km during an autumn irruption. At Point Pelee from 1909 to 1920, autumn migration was very irregular. On most days, there were no migrating chickadees, but occasionally 300-400 would be present for several days; flocks were occasionally observed flying across the lake. In the Kingston area, irruptions were documented in 1961, 1968, 1972, 1975, 1981, 1983, and 1986. During autumn irruptions, movement is leisurely and generally in a southwest direction (Brooks 1991a, 1991b; Hussell 1996; Tyler in Bent 1946; Weir 2008).

Migration is not fully understood. Juvenile dispersal occurs in July and autumn irruptions occur in October and November, with spring return in May. In non-irruption years, there may be high and low winter populations suggesting some short-distance movements in response to mast abundance. At Pimisi Bay, there were 3 peaks in abundance over 5 winters that occurred in November, January, and March, along with a fourth peak of juveniles in September (Lawrence 1958; Smith 1986a).

During irruptions, Black-capped Chickadees use the same habitats as regular autumn flocks, but also may be found in urban and more disturbed areas (Foote et al. 2020; Weir 2008).

The Black-capped Chickadee is highly vulnerable to striking residences 1-3 storeys tall. It was 14.9 times more likely to suffer a collision than on average for birds. It was not on the lists of the 20 most vulnerable species for striking low-rises or high-rises (Loss et al. 2014).

During irruptions, the Black-capped Chickadee may be abundant locally or occur over a widespread area. In the Kingston area, as many as 2,000 have been seen in a day (Weir 2008). In Elgin County, more than 1,500 were observed on 21 October (Lancaster et al. 2004). In 1954, 31,000 were reported along the New York shoreline of Lake Ontario, and more than 36,000 were seen in the same place in October 1961 (S.M. Smith 1991).

WINTER

Winter flocks begin to assemble in September or October or even as early as August. Flocks have mostly stabilized by mid-September to early October in British Columbia and by late October in Alberta. Flocks remain stable until nesting territoriality begins in spring. Flock sizes range from 3 to 16 birds. Winter flocks are comprised of 1 or occasionally 2 adult pairs and a small number of juveniles. Sex ratios in flocks are typically 1:1, and juvenile birds form pair bonds over the winter and breed in the vicinity in spring. Within each flock, there is a well-defined dominance hierarchy. Males typically dominate females, although the reverse is occasionally true, and adults always dominate young of the same sex. Usually the hierarchy is adult male, juvenile male, adult female, and juvenile female. Once established, dominance relationships continue for 7-8 months. Dominance is very important because dominant birds obtain superior breeding territories and have better access to food and cover from predators. At feeders, dominant birds may make fewer visits, but have access to the feeder all the time; subdominants have to wait until the feeder is not occupied by a superior bird (Barnea and Nottebohm 1995; Desrochers 1989; Desrochers and Hannon 1989; Desrochers et al. 1988; Ekman 1989; Ficken et al. 1990; Hogstad 1989; Odum 1941a; S.M. Smith 1967a, 1976, 1991).

In winter, the Black-capped Chickadee is a snow-associated species. Important predictors of its presence include a long snow season and lack of frozen ground without snow (Keyser et al. 2022). Winter habitat is similar to that used in autumn, although there may be more usage of urban, suburban, and rural residential areas where bird feeders are provided. In suburban areas of California, its winter distribution was closely associated with the presence of feeders (Kalinowski and Johnson 2010). Prior to the era of bird feeding, McIlwraith (1894) stated that it was most frequently found in tamarack swamps during severe winter weather. Bush camps may be visited in autumn and winter where it feeds on human food scraps and meat and fat from carcasses and hides (Campbell et al. 1997). In an area of New York without feeders, flocks remained primarily in woods, orchards, shade trees, hedgerows, and shrubbery. Birds crossed open spaces at the narrowest point; the widest opening they were observed to cross was 175 m (Butts 1931a). Chickadees feeding on goldenrod gall flies in southwestern Ontario preferred open fields to forest edge (Schlicter 1978). Some portions of the winter home range may be used more than others if there is a rich food source such as a feeder, hemlock trees with numerous cones, or a temporary bonanza such as an animal carcass. It winters in areas with an average of more than 51 cm of snow a year and where the average minimum January temperature is −7 to −12°C (Odum 1942; Root 1988). In Missouri, its detectability increased with tree stocking and was lowest in savannah habitat, intermediate in woodlands, and highest in forests (Kendrick and Thompson 2013).

Roosts are a more important habitat requirement in winter. Roosts may be in dense vegetation, but more frequently in cavities. When roosting externally, flocks usually roost loosely together in the same area of a woodlot. Often conifers are selected for roosting, especially hemlock, pine, and spruce. Many of the cavities used are excavated by the chickadees. Winter roost cavities are much smaller than nesting cavities, presumably to conserve heat. Winter roosts have been documented in beech, oak, and ash, but probably a variety of species are used. Winter roosts may be in old woodpecker cavities or nests of other species such as House Sparrow. Almost all records of roosts are of a single bird in a cavity, but at least 5 were found roosting together in a stump in British

Columbia (Brewer 1963a; Campbell et al. 1997; Foote et al. 2020; Odum 1942; Schroeder 1982a; S.M. Smith 1991; Tyler in Bent 1946).

Winter flocks occupy well-defined home ranges 7.7-22.6 ha in size that average 8-10 ha. Individuals may have winter home ranges of 1.2-38.9 ha. Birds with the largest home ranges are either floaters or dominant wanderers; smallest home ranges occur near feeders. Birds in flocks usually remain in the central portion of the home range all winter, but occasionally leave and commute to rich food resources such as feeders. In New York, the greatest distance a flock travelled outside its normal range was 0.8 km. Flocks may be territorial, but flock winter ranges often overlap considerably. When this occurs, flocks tend to avoid each other. Most flocks share food resources such as feeders, but there may be agonistic interactions between flocks. When flocks encounter each other or intermingle, usually the flock that is closest to the centre of its home range is dominant. In these cases, even the most subordinate member of the dominant flock is dominant to the alpha bird of the other flock (Barnea and Nottebohm 1995; Brittingham and Temple 1992; Desrochers and Hannon 1989; Butts 1931a; Fitch 1958; Foote et al. 2020; Mueller 1973; Odum 1941a, 1942; S.M. Smith 1991).

Individuals are highly faithful to their flock through the winter; inter-flock exchange is rare. In Maine, only 19 of 3,976 visits (0.48%) to a feeder were at sites other than where the bird was banded. This occurs even where feeders are close together. In New York, birds moved freely between feeders 220 m apart, but not between those 550 m apart. In Alberta, only 0.6% of 683 individuals switched flocks regularly and permanent changes of membership from 1 flock to another occurred twice. In Wisconsin, birds banded at feeders 2 km apart were never seen at the other feeder. Connecticut birds captured at 1 feeder and moved to another 2.4 km away returned within 24 hours. The rare wanderers that move among flocks include floaters that are low-ranked juveniles, high-ranked former breeders that have a large home range, and visiting migrants (Brittingham and Temple 1988; Butts 1931a; Desrochers et al. 1988; Loery et al. 1987; Mueller 1973; S.M. Smith 1967a, 1976, 1991; Wilson 2001).

When foraging, flocks move continuously from patch to patch and rarely remain in 1 place for more than a few minutes. In Algonquin Park, much foraging occurred in the foliage of conifers and on the twigs and loose bark of deciduous trees. Ground feeding also occurred as patches of ground became clear of snow. In the Gogama area, the Black-capped Chickadee frequently fed in jack pines in winter. Ground foraging on hemlock seeds was common in New Hampshire. Dominance hierarchies affect where chickadees forage. In Alberta, males foraged lower and closer to the trunk than females and used trunks and main branches for foraging more often. Females foraged high and on the outermost tree parts. When males were removed, females foraged where males typically searched for prey. It is readily attracted to winter feeders, especially those that are established early in the season. In Ontario, more than 90% of feeders are visited by Black-capped Chickadees, with lower utilization of feeders at the northern extent of its range. Urban and rural feeders are visited at equal rates, but rural flocks are about twice as large. Flock sizes are also slightly larger in the north, suggesting greater dependence on feeders (Brittingham and Temple 1992; Desrochers 1989; Dunn and Tessaglia-Hymes 1999; James and Peck 1995a; Kilham 1975; Martin 1960; Wilson 2001).

In Michigan, Black-capped and Boreal chickadees often forage together in mixed-species flocks. The Black-capped Chickadee foraged in 6 conifer and 3 deciduous tree species; the Boreal Chickadee restricted its foraging to 3 species of conifers. The Black-capped Chickadee spent 4.5% of its time foraging at the top of trees compared with 36.5% for the Boreal Chickadee, but the 2 species foraged at similar rates in other vertical zones. The niche overlap of the 2 species was 67.6%, higher than expected. The 2 chickadee species eat similar foods but competition is reduced due to the abundance of food resources, the fact that foraging overlaps in only 3 species of conifers, and that Black-capped Chickadees use the crowns of these conifers significantly less than Boreal Chickadees (Gayk and Lindsay 2012).

In Connecticut, Correia and Halkin (2018) compared the winter habitat and foraging niches of the Tufted Titmouse and Black-capped Chickadee. Chickadees spent 83% of their foraging time in the upper and middle canopy and in shrubs. They spent a much greater percentage of their time in the outer-upper canopy (26.7%) and shrubs (25.0%) than titmice (9.1% and 9.9% respectively). From the ground up, there was a steady increase in the amount of time that chickadees spent foraging at each successive level. Titmice spent less time in the upper canopy than at lower levels. Compared with chickadees, titmice used canopy foraging locations more evenly, spent less time in shrubs, and spent much more time on the ground. Chickadees spent significantly more time in the outer-upper canopy and shrubs than titmice, and titmice spent significantly more time on the ground than chickadees. The 2 species had different preferences at feeders. Chickadees selected sunflower seeds without shells on 61% of visits; titmice selected safflower on 54% of visits. At feeders, titmice won all challenges against chickadees. The significant differences found in the 2 species' foraging behaviours and seed preferences may mitigate competition.

Natural winter food of the Black-capped Chickadee includes insect eggs and larvae, mites and other arthropods, and seeds. Most winter food consists of seeds of conifers; hemlock is highly favoured. It may also eat buds and scales of other plants. It eats animal fat if it finds a carcass; flocks have fed on the fat of a dead skunk and dead fish. In southern Ontario, it actively feeds on the larvae of the gall fly in galls on Canada goldenrod. Predation of gall flies declines by the third week of December at forest edges, because 80.5% of galls have been attacked by this time. In open fields, about 60% of galls are preyed upon by the end of January (Brittingham and Temple 1988; Kilham 1975; Schlicter 1978; S.M. Smith 1991; Tyler in Bent 1946). In western North America, gall flies have been introduced in an attempt to control the invasive spotted knapweed. The Black-capped Chickadee actively selects seedheads of knapweeds that support high densities of gall fly larvae for foraging in winter (Templeton 2011).

In Pennsylvania, Nastase and Linville (1995) provided a feeder with trays at heights of 2, 4, and 6 m. Chickadees fed 41.4% of the time on the ground, more than the other 6 species they studied. Rates of foraging at other heights were 32.7% at 2 m, 14.6% at 4 m, and 11.3% at 6 m. They showed an overwhelming preference for sunflower seeds, taking them on 98.1% of visits. Other foods taken were niger seeds on 0.8% of visits, canary seed on 0.6%, corn on 0.3%, and millet on 0.2%.

At feeders, the Black-capped Chickadee's favourite food is sunflowers of any type, but especially striped and black oil sunflowers. Other favoured feeder foods are safflower, hulled peanuts, suet, peanut butter mixes, bird puddings, and water. Foods eaten infrequently include mixed seeds,

millet, canary seed, cracked corn, milo, niger, peanuts in the shell or peanut hearts, oats, canola, pet food, fresh or dried fruit, meat scraps, baked goods, and popped corn (Dunn and Tessaglia-Hymes 1999). A total of 79,570 feeding observations were made for the Black-capped Chickadee. It preferred black oil sunflowers and preferred hopper feeders to tube or platform feeders. It was least abundant at feeders filled with sorghum (Horn et al. 2014). It selects the largest and heaviest sunflower seeds available (Wysinger et al. 2022).

Winter food availability may be a significant limiting factor in the northern and even central portions of the Black-capped Chickadee's range. It stores fat, but only enough to survive less than 24 hours without feeding. In Wisconsin, chickadees obtained about 21% of their daily energy requirements from feeders. Winter survival rates were significantly lower in areas without feeders in Pennsylvania. During all months of the year, survival rates in Pennsylvania were higher in areas with supplemental food. The difference was most pronounced in October and March with 60% survival under natural conditions and 90% where food was supplied. In the north where there are no feeders, winter starvation is likely a regular and potentially significant source of mortality (Brittingham and Temple 1988, 1992; Desrochers et al. 1988; Egan and Brittingham 1994; S.M. Smith 1991).

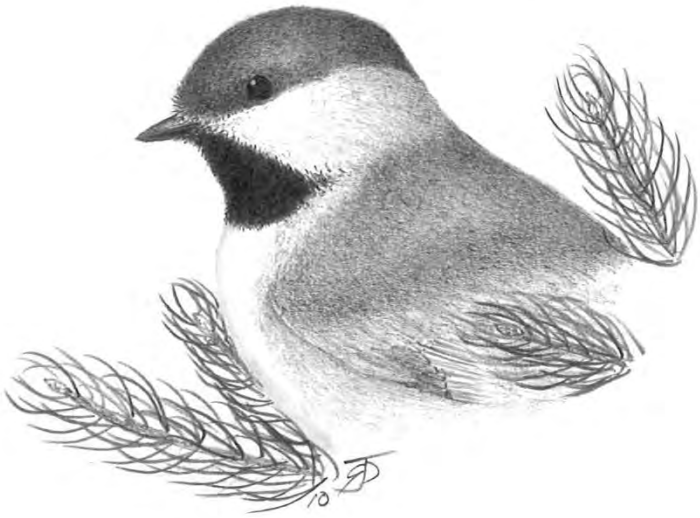
Survival rates of the Black-capped Chickadee are affected by cold weather, particularly where feeders are not available. In Wisconsin, birds that had access to supplemental food continued to feed during very cold weather. Those without a supplied source of food reduced energy expenditure by sitting motionless with the feathers fluffed out. Birds had higher survival rates in winters with 5 or fewer days with temperatures below –18°C than in winters with more days at these temperatures. In winter, it conserves heat at night by dropping its body temperature through controlled hypothermia. Summer abundance has declined occasionally in the eastern states following severe winters (Brittingham and Temple 1988; Holmes and Sherry 2001; Holmes and Sturges 1975; S.M. Smith 1986, 1991).

During winter in Alberta and Quebec, the Black-capped Chickadee was as likely to travel in corridors as narrow as hedgerows as in continuous forest, but less likely to cross gaps. Birds were unwilling to cross gaps wider than 50 m when they had forested alternative routes, even if the distance was much longer. They sometimes crossed gaps as wide as 200 m when there was no alternative route. Chickadees were 4 times more likely to travel 200 m in a forest and 3.5 times more likely to travel that far in a corridor than they were to cross a similar-sized gap. It preferred to remain close to forest cover (St. Clair et al. 1998). In British Columbia, gaps in forest habitat ranged from 10 to 84 m. Birds made significantly fewer movements between feeders on the opposite side of a gap (31.8%) than between feeders on the same side of the gap (68.2%). Birds were 1.8 times less likely to cross gaps as gap distance increased from 10 to 40 m, and 3.7 times less likely to cross as gap distance increased to 70 m. Birds were more likely to cross gaps as the amount of vegetation 1-2 m tall increased. For each 5% increase in vegetation density at 1-2 m, crossing likelihood increased by 1.7 times. Bailey et al. (2018) concluded that gaps in forest canopy impede movements of this chickadee, but this may be partially mitigated by the presence of shrubby vegetation 1-2 m tall.

The Black-capped Chickadee is common in winter. Christmas Bird Count data indicate that it decreased annually in Ontario by 0.25% 1970-2021 and by 0.10% 2009-21 (National Audubon Society 2022).

Boreal Chickadee

Poecile hudsonicus



BREEDING SEASON

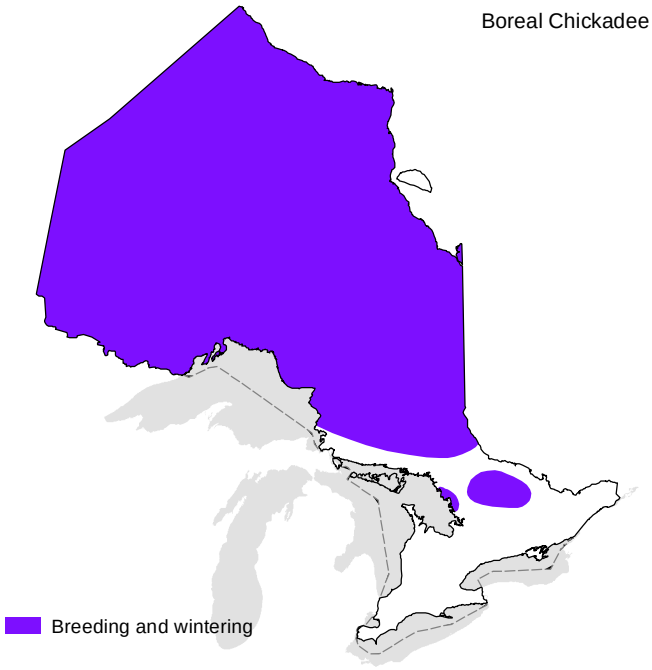
Habitat Requirements

In Ontario, the Boreal Chickadee nests primarily in closed and open coniferous and mixed forests and black spruce bogs. There are single reports of nests in an open field and an open wooded marsh. Some nests were at forest edges, near shorelines, and near a railway right-of-way. Wet habitats were selected more frequently than dry areas (Peck and James 1987).

Along the coasts of Hudson Bay and James Bay, the Black-capped Chickadee nested in dry spruce stands. This habitat was scarce except near the major rivers (Manning 1952).

In the Boreal Forest Region at Pickle Lake, James (1980) observed the Boreal Chickadee regularly in coniferous forests, especially those that were open and disturbed. On the north shore of Lake Superior, Baillie and Hope (1943) found it mostly in or adjacent to black spruce bogs. It also occurred in open, park-like stands of jack pine adjacent to spruce bogs. Near White River, it was significantly more common in clear-cuts 18-20 years old than in younger or older cuts or in mature forests (Venier and Pearce 2005). In the Clay Belt, it was associated with wet areas in forests that were moderate to rich in nutrients (Welsh and Lougheed 1996).

In the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region in Quetico Park, the Boreal Chickadee was most abundant in intermediate-aged stands (67-73 years), but occurred in all age classes (Apfelbaum and Haney 1985). Near Gogama, it occurred only where jack pine was



the dominant tree type. It was absent from very young stands; pines were 4-6 m tall before they were inhabited. Densities were highest where pines were about 10 m tall, and declined somewhat as forests matured. Nest boxes were used more frequently in 20-year-old than 40-year-old stands. Older stands would have more potential nest sites. In most nesting areas, canopy closure was greater than 75% and often approached 100%. It occasionally nested among well-spaced pines with canopy closure only slightly greater than 50%. Tall shrubs were absent or scarce in nesting areas and appeared unnecessary because foraging occurred only in pines (James and Peck 1995a). In Algonquin Park, it occurred chiefly at or near spruce bogs (MacLulich 1938), and in black spruce–balsam fir forests with considerable interspersion by white spruce, trembling aspen, and white birch (McLaren 1976).

The Boreal Chickadee is a permanent resident of the Boreal Forest Region. It occurs in both young and mature coniferous forests and in mixed forests, rarely in deciduous stands. It is most frequently associated with spruce, but also with jack pine and balsam fir. Its preference for spruce and fir forests partially explains its spotty distribution in the south. In the south, it is replaced by the Black-capped Chickadee in hemlock stands and in pines other than jack pine. The Boreal Chickadee displaces the Black-capped Chickadee in fir stands. The Boreal Chickadee occurs in Quebec wherever there are large expanses of coniferous forest. Densities are higher in open spruce-lichen woodlands and taiga than in the more southern black spruce–moss forests. In Quebec black spruce forests, it breeds in clear-cuts and recent burns, and was equally abundant in all habitats that it occupied. In British Columbia, it occurs in open stands or at edges of closed stands. It was considered a forest-interior species in 1 Saskatchewan study. In this area, it was randomly distributed within fragmented landscapes. Its presence was not associated with forest size, the amount of forest cover within 5 km, nor forest type. Nesting in Saskatchewan occurred in tamarack, mixed, and white spruce forests. In Newfoundland, it was more common in 40-60-year-old stands than those 80 years or older. It is in a guild of 34 species that are predominantly associated with conifers. In the Yukon and Alaska, it is a dominant species in spruce forests. The northern extent of its range coincides with that of spruce. In the Yukon, it is a habitat specialist in mature white spruce along rivers and rarely occurs in the deciduous shrub habitats favoured by Black-capped Chickadees. In northern Maine, both chickadee species are present in the same spruce–balsam fir stands. The Boreal Chickadee is more abundant in the lowland flats; the Black-capped Chickadee is more abundant on ridges. In Algonquin Park, both chickadee species are present, but no interactions appear to occur between them. In New Hampshire, the Boreal Chickadee occurred in high-altitude conifers dominated by

taiga or boreal spruce forest. Mean canopy height where it occurred was 8.8 m, mean canopy closure was 63%, and the average diameter at breast height (DBH) of trees was 11 cm. In some areas, it occurs in forests dominated by white cedar (Bent 1946; Campbell et al. 1997; Desrochers in Gauthier and Aubry 1996; Erskine 1977; Ficken et al. 2020; Gage et al. 1970; Hobson and Bayne 2000; Imbeau et al. 1999; Kirk et al. 1996; McLaren 1976; Niemi and Pfannmuller 1979; Sabo 1980; Sinclair et al. 2003; Thompson et al. 1999).

In Minnesota, the Boreal Chickadee was positively correlated with the amount of coniferous cover within 200 m and the density of streams. It used black spruce stands and avoided tamarack forests (Zlonis et al. 2017). In New York, Vermont, Maine, Nova Scotia, and Newfoundland, it occurred at 11 of 20 sites indicating broader habitat preferences than many species and an ability to use multiple boreal forest habitats. It preferred young, dense spruce-fir forests (Ralston et al. 2019).

The female roosts in the nest cavity beginning with laying of the first egg. No information is available on where males roost, or where roosting occurs outside the breeding season (Ficken et al. 2020).

Ontario nests in natural areas were in cavities in standing tree stumps (61.9% of nests), in tree trunks and branches (33.3%), and in an uprooted stump (9.8%). Most nest stumps and trees were dead, but 3 (14.3%) were living or partly alive. Most nests were excavated or natural cavities in the side of stumps or trees (72.2%); the remainder were in cavities at the top of broken stumps. Twelve cavities were excavated or enlarged by the chickadees, but 3 were not; an old woodpecker cavity was used once. Six nests were in birches, 4 in poplars, 2 in balsam fir, 2 in black spruce, 2 in white cedar, and 2 in pines. Nests were 0.3-10.5 m from ground, with most 0.9-4.3 m up. Two nests in hollow stumps were at ground level (Peck and James 1987). In the Sudbury and Gogama areas and elsewhere in the province, the Boreal Chickadee readily accepts nest boxes (Peck and James 1997). In Algonquin Park, tree species were not important in nest-site selection. Chickadees selected trees based on the softness of the heartwood. All nests were in trees or stumps where the heartwood was soft from rotting, but the outer layers and bark were still hard. About 40% of cavity entrances were at the top of stumps; in any given population, approximately 20-40% of nest entrances face upwards (McLaren 1975). In Algonquin Park, nest holes were 0.1-10.5 m above ground, but seldom higher than 3 m (Ficken et al. 2020). Along the north shore of Lake Superior, Baillie and Hope (1943) found 2 nests 1.8 m and 2.4 m up in black spruce stubs in bogs and another was in an old woodpecker cavity 1.5 m up in a dead jack pine (James and Peck 1995a). Nest cavities do not appear to be reused in subsequent years, but nest boxes were occasionally reused (Ficken et al. 2020; McLaren 1975).

Nests reported elsewhere are similar to those found in Ontario. The Boreal Chickadee has nested in white birch stubs in a beaver pond, in spruce and tamarack stubs and stumps, in cedar stumps, in knotholes and splits in live black spruce and trembling aspen, in willow, and in an old Hairy Woodpecker nest. Nest heights in British Columbia were 1.0-8.0 m, with most 1.2-5.5 m up. Optimum stump or snag size appears to be about 10 cm, but larger ones may be used (Bent 1946; Campbell et al. 1997; Evans and Conner 1979; Sinclair et al. 2003; Walkinshaw 1948a).

Pairs break away from the winter flock in early spring and establish a territory. In Algonquin Park, territories were larger than 5 ha. They were not advertized vocally, so considerable trespassing

occurred and it is possible that territories overlap. When intruders are detected, they are vocalized at and chased away. Territoriality may continue until shortly after the young fledge (McLaren 1975). In subalpine areas of New Hampshire, territory sizes averaged 1.2 ha (Sabo 1980).

Essentially nothing is known about natal philopatry and juvenile dispersal. Ficken et al. (2020) reported that no young from 3 broods seen in winter flocks were found later on their natal territory, and it was unknown where they first nested. In Algonquin Park, McLaren (1975) observed 1 pair on the same territory in 2 consecutive years. It is likely that pairs mate for life and remain in the same area for their entire life.

Limiting Factors

Eggs have been reported in Ontario nests from the third week of May until early July, with most present in the last week of May and first week of June (Peck and James 1997). Once pairs split from the winter flock, 2-3 weeks may elapse before nesting behaviour begins (McLaren 1975). In Algonquin Park, nests are under construction from late April to late May, eggs are present from late May to mid-June, nestlings are typically present from early to late June but a nest with young was found on 3 August, and dependent fledglings are present from late June to mid-August (Tozer 2012).

The earliest that nest excavation in Algonquin Park was observed on was 20 April. The time required to excavate a cavity is 1-10 days, depending on the hardness of the heartwood. Several cavities may be examined or excavated before one is selected for nesting. Pairs may spend as long as 5 days excavating a cavity, and then abandon it. Nest construction often starts as soon as the cavity is complete, but may be delayed several days. Egg laying usually begins after 2-3 days of nest building, and always before the nest is complete. One egg is laid per day; incubation begins with the laying of the penultimate or last egg. Incubation periods of 11-16 days have been reported in Ontario, with most eggs hatching in 15 days. In Algonquin Park, eggs in a clutch frequently did not hatch in the same day, and it took 3 days for all eggs to hatch in 1 clutch. Most young leave the nest when they are 18 days old; fledging occurred between 22 June and 3 July in Algonquin Park (Ficken et al. 2020; McLaren 1975; Peck and James 1997).

A single brood is raised annually. It is unknown if renesting occurs if a nest is lost. Clutches of 4-8 eggs have been documented in Ontario, with most containing 6 or 7 eggs. Overall, clutches of 2-9 eggs have been reported, but the clutch sizes reported in Ontario are typical (Bent 1946; Campbell et al. 1997; Ficken et al. 2020; McLaren 1975; Peck and James 1997).

The Boreal Chickadee probably first breeds when it is 1 year old. It is presumed to be monogamous, but data are lacking (Ficken et al. 2020).

In Ontario and the Northwest Territories, foraging occurred in conifers 90.5-96.0% of the time. In the Northwest Territories, 41.5% of foraging was conducted while hanging upside down compared with 20.5% in Ontario (Greenberg et al. 1999). In subalpine New Hampshire, foraging methods included 0.4% aerial flycatching, 39.0% leaf gleaning, 2.6% leaf hawking, 3.7% leaf hovering, 12.5% twig pecking, 15.4% twig gleaning, 3.7% branch pecking, 4.4% branch gleaning, 11.8% bole pecking, and 6.6% bole gleaning. It foraged equally close to (58.6%) and distant (41.4%) from tree trunks. Eighty-two percent of foraging was on coniferous foliage and 11.8% was on deciduous

foliage. Time spent foraging by height was 2.6% at 0.1-2 m, 47.4% at 2-5 m, 31.3% at 5-8 m, and 18.8% above 8 m (Sabo 1980). In Newfoundland, Vasallo and Rice (1982) compared foraging strategies of 2 Boreal Chickadee populations: one where Black-capped Chickadees were present and one without Black-capped Chickadees. Where both chickadee species were present, Boreal Chickadees foraged mostly on conifers and significantly higher than Black-capped Chickadees; Boreal Chickadees foraged on the outer portions of trees and Black-capped Chickadees foraged in the inner portions. Where Black-capped Chickadees were absent, Boreal Chickadees fed mostly in deciduous species and were more generalized in their foraging behaviour, using all portions of trees equally. Bent (1946) also noted that the Boreal Chickadee forages higher than the Black-capped Chickadee, and hangs upside down considerably less than the Black-capped Chickadee. Where the Boreal Chickadee forages within trees is probably a response to competition from other bird species. In New Brunswick, it foraged at the top of trees. In Saskatchewan, it favoured the mid-portions of trees and avoided the canopy and bottom of trees. In Saskatchewan, the mean foraging height was 6.1 m in conifers and 9.1 m in deciduous trees. Foraging occurred in the canopy 36.7% of observations and the remainder were in the subcanopy (Cumming 2004; Gage et al. 1970). In boreal forests in Saskatchewan, it selected balsam fir more for foraging than expected, tended to avoid trembling aspen, and used other tree species in proportion to their availability. In other areas, it is strongly associated with mature spruce and selects mature trees regardless of their height (Cumming 2004; Desrochers in Gauthier and Aubry 1996; Ficken et al. 2020; Matsuoka et al. 2001). In Algonquin Park, pairs foraged closely together in early spring, usually on the ground where melting snow had exposed material that had dropped from trees. Occasionally they fed in the upper third of trees (McLaren 1975). In Saskatchewan, it fed among piles of bark in the snow that were chipped off by woodpeckers. It also landed on tree trunks and pecked in the same locations that woodpeckers had, and followed woodpeckers to continue this foraging technique (Hooper 1988).

The Boreal Chickadee feeds predominantly on insects and spiders, their pupae and eggs, some fruit, and seeds of conifers and birches. Important insect foods include moth and butterfly larvae, aphids, and beetle larvae. It readily consumes budworms, depending on their size. In New Brunswick, no first-instar budworms were eaten even though their density was at a maximum. Consumption increased to a maximum as prey size increased then declined to zero as budworms decreased. In Maine and New Hampshire, it did not consume many budworms and its abundance was not associated with budworm abundance; no response to budworm numbers was observed in New Brunswick. At another Maine site, spruce budworm larvae and pupae constituted 25.3% and 37.0% of the invertebrates consumed in 2 years. It eats ashes from fire pits if ashes have high calcium content. This observation was made in mid-October and suggests that calcium is important in the diet year round (Bent 1946; Crawford and Jennings 1989; Ficken 1989; Ficken et al. 2020; Gage et al. 1970; Mitchell 1952; Morris et al. 1958).

The Boreal Chickadee regularly stores food and this is probably critical to its winter survival. The frequency of storage increases in July and August; as many as 45 items may be stored within an hour. Food may be stored in the same tree where it was found, or transported to another tree an average of 7 m away. It tends to store food at a consistent height, usually lower than foraging height. More than 1 item is usually stored in a cache and most food is stored on dead main branches near

the tree trunk. Seeds are placed closer to the trunk than arthropods. Most stored food is visible from below, thereby increasing chances of finding it when snow covers upper portions of branches. Stored food consists of predominantly moth and butterfly larvae, aphids, some beetle larvae, and spruce seeds. Most invertebrates are stored in bark crevices; aphids are often stored at branch junctions and between conifer needles. Seeds are usually better hidden in bark crevices and under lichens and are secured in place by saliva and sometimes web material from spiders, insect cocoons, or plant down. Cached items are sometimes covered with a small piece of bark, lichen, or spruce needles. Stored items, especially seeds, are sometimes retrieved and moved to another site (Dunn and Tessaglia-Hymes 1999; Ficken et al. 2020; Sherry 1989).

In Ontario, availability of old-growth black spruce may be particularly important for the Boreal Chickadee's survival, particularly in winter. These forest stands are under increased pressure for logging (Ficken et al. 2020). Similar concerns have been raised about mature white spruce stands in the Yukon (Sinclair et al. 2003).

In Minnesota, blowdown of spruce-fir forest resulted in an 80% decrease in canopy cover and a 100% increase in shrubs. The Boreal Chickadee bred in both the blowdown and control areas with no significant differences in abundance (Burris and Haney 2005).

On Anticosti Island, the Boreal Chickadee was unaffected by heavy browsing by high deer populations. Browsing suppressed deciduous regeneration, particularly of white birch, but coniferous regeneration was unaffected. High deer densities may have resulted in better habitat for it (Cardinal et al. 2012).

In Newfoundland, 68% of mist-netted Boreal Chickadees were captured in natural forests and 32% were in clear-cuts. There was no difference in annual survival rates of birds in natural and clear-cut habitats. Whitaker et al. (2008) concluded that it was resilient to a moderate amount of clear-cutting. In Quebec, Hadley and Desrochers (2008a) concluded that increasing the amount of edge due to clear-cutting did not affect its use of remaining mature forests, even under inclement winter conditions. Movements may be restricted in regenerating forests after clear-cutting during adverse weather. In the Boreal Forest Region with particular reference to Ontario, it decreased in abundance when 30%, 50%, or 70% of trees were removed (Vanderwel et al. 2009). In Ontario in the Canadian Shield, there was no difference in its abundance in early and mid-successional clear-cuts compared with similarly aged stands after fire. It was equally abundant in mid-successional and mature stands but significantly less abundant in early successional than mature stands (Zimmerling et al. 2017).

The Black-capped Chickadee does not appear to compete for nest sites but its presence may reduce Boreal Chickadee densities because the 2 species apportion trees and food resources where they coexist. In Newfoundland, the density of Boreal Chickadees on an island without Black-capped Chickadees was significantly greater than the combined density of both chickadee species on the mainland (McLaren 1975; Vasallo and Rice 1981).

In Alberta, the Boreal Chickadee was significantly more abundant at seismic lines than in adjacent forest interior. There was no difference in its abundance at pipelines and well pads than in forest interior adjacent to these facilities (Bayne et al. 2016).

Price (2004) predicted that the Boreal Chickadee might disappear as a breeding species in southern Ontario if the average summer temperature increased by 2°C. DesGranges and Morneau (2010) concluded that it was not very sensitive to climate change in Quebec. In the Boreal Forest Region of Quebec and Labrador, DesGranges and LeBlanc (2012) determined that the Boreal Chickadee was associated with stands having relatively high summer temperatures and high summer precipitation.

Status

The Boreal Chickadee has always been a widespread breeder throughout the Hudson Bay Lowland and the Boreal Forest Region, with an isolated population in Algonquin Park. It is also present in the Great Lakes–St. Lawrence Forest Region north of Lake Superior. McIlwraith (1894) stated that it occurred in the Hudson Bay area and that it might be present in the districts of Muskoka and Parry Sound. Baillie and Harrington (1936) concluded that it was resident from about latitude 46°N to Hudson Bay. The southern limit of the general population was in the central portions of the districts of Algoma, Sudbury, and Timiskaming. Bailey and Hope (1947) found it regularly at Chapleau, but concluded that it was absent in southern Sudbury District. James (1991) considered the Boreal Chickadee an uncommon permanent resident southward to the Sudbury area, and rare to uncommon in the Algonquin Highlands.

The second atlas demonstrated that there had been no change in the range or probability of observation of the Boreal Chickadee since the first atlas. It was most abundant in the northern Boreal Forest Region and southern Hudson Bay Lowland (McLaren in Cadman et al. 2007).

Despite logging and forest fires, distribution of the Boreal Chickadee in northern Ontario is probably similar to presettlement times. Long-term (1970-2021) population trends determined from the Breeding Bird Survey indicated annual decreases of 1.5% in Canada and 1.44% in Ontario. The short-term (2011-21) trends were annual decreases of 0.933% in Canada and 2.64% in Ontario. Results were of low to medium reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

The family remains together in the territory for at least 2 weeks after fledging. Adults feed the young less and less during this period, and fledglings leave the territory 3 weeks after they leave the nest (Ficken et al. 2020).

MIGRATION

The Boreal Chickadee is predominantly a permanent resident that remains on its breeding territory in winter. Short-distance migratory movements occur in some parts of its range. It exhibits regular migration patterns in northern Minnesota, northern Michigan, Saskatchewan, and Alberta. In the Yukon, no significant seasonal movements occur, although there may be withdrawal from the northern portions of its range during extreme cold. In British Columbia, it is nonmigratory even in the north, but populations at high altitudes may move to lower areas in winter. To further confound migration patterns, juveniles form flocks and wander shortly after fledging, and it periodically irrupts considerably south of its normal range. Postbreeding movement appears to occur in the first half of September in the Moosonee area (Bent 1946; Campbell et al. 1997; Dunn and Tessaglia-Hymes 1999; Ficken et al. 2020; Sinclair et al. 2003; Wilson and McRae 1993).

Irruptions occur in autumn and birds may remain south of their breeding range much of the winter or until spring. Southward irruptions are probably a response to low food supplies; most birds that move southward are less than 1 year old. Irruptions between 1964 and 1972 corresponded to irruptions by 8 pine-seed-eating species, suggesting that irruptions may be associated with fluctuations in pine seed crops. Irruptions occur in different areas in different years. All Boreal Chickadee irruptions are associated with Black-capped Chickadee irruptions, but not all Black-capped Chickadee irruptions contain Boreal Chickadees. In New York, irruptions occurred at intervals of 2-7 years, and averaged every 3.8 years from 1950 to 1981. Minor irruptions occurred there at intervals of 2-3 years, while Christmas Bird Count (CBC) data indicate major irruptions every 4-6 years. In some areas, large irruptions occur every 6-8 years. Frequency of irruptions is only about half that of the Black-capped Chickadee (Bent 1946; Dunn and Tessaglia-Hymes 1999; Ficken et al. 2020; Root 1988; Yunick 1984).

In northern Ontario, movements associated with irruptions may start in mid- to late September. On 18 and 25 September 1938, a large southward movement was observed at Moosonee (Manning 1952). On 30 September 1947, a flock of 150-200 was seen moving southward along the Kesogami River near Hannah Bay. None had been seen there the previous 4 days. Several were seen the following week, but only in groups of 2 or 3 (Hewitt 1948). Irrupting birds may appear in southern Ontario from mid- to late October, but the peak is in November; occasionally birds do not appear until December or January. Birds often disappear from the south in January, but many stay much longer, particularly following large irruptions. In most irruption years, numbers start to decline after November. After a large irruption, there may be a weak return flight from mid-April until early May, with occasional stragglers to the end of May (Bent 1946; Ficken et al. 2020; Weir 2008; Yunick 1984).

Resident Boreal Chickadees and those that regularly migrate short distances frequent the same habitat types as they do during the breeding season. Irrupting birds occur in a much wider range of habitats, but still prefer areas with coniferous cover (Campbell et al. 1997; Dunn and Tessaglia-Hymes 1999; Ficken et al. 2020; Yunick 1984).

During the winter of 1951-52, 97 were recorded in the Hamilton area; 118 were observed in the 1972-73 invasion. Extreme dates of occurrence were 1 October to 25 April (Curry 2006).

WINTER

In winter, the Boreal Chickadee (except for irrupting birds) remains mostly in boreal coniferous habitat identical to that used in the breeding season. In Alaska, it has spent the winter in dense willows along a river and in willow and alder copses in addition to spruce–white birch forests (Bent 1946).

In winter near Quebec City, the Boreal Chickadee used mature forests more frequently than regenerating areas or open areas; regenerating areas were used more than open areas. It preferred mature forest stands and avoided young successional forests and open areas, although flocks frequently spent time in regenerating areas. Hadley and Desrochers (2008a) concluded that forestry practices result in substantial reduction of optimal Boreal Chickadee wintering habitat. Declines in its population may be due to loss of high-quality wintering habitat. Flocks showed no response to forest edges in mature forest stands. In regenerating forests 4-7 m tall, flocks mostly used edges near

mature forest and were significantly closer to both open edges (41 m) and mature forest edges (11 m) than would be expected from a lack of response to edges. On the coldest and windiest days, flocks did not avoid exposed edges of mature forest, but avoided edges of regenerating stands and were found disproportionately more along edges between mature and regenerating stands (Hadley and Desrochers 2008b).

Brotons (2000) stated that the Boreal Chickadee exhibited winter territoriality, but provided no explanation. Winter flocks form soon after the young fledge and persist until spring when pairs break off from the flock to breed. In autumn, it forms flocks with Black-capped Chickadees, warblers, Red-breasted Nuthatches, Golden-crowned Kinglets, White-winged Crossbills, and occasionally woodpeckers. The average flock includes 6 Boreal Chickadees (range 4-10). As winter progresses, flocks become composed primarily of Black-capped and Boreal chickadees and Golden-crowned Kinglets, with Black-capped Chickadees more numerous than Boreal Chickadees. One flock that was observed many times over a winter in Algonquin Park had 6-7 Black-capped Chickadees and 2-3 Boreal Chickadees. This indicated flock cohesion and possibly that the flock maintained a winter home range. Birds that irrupt southward exhibit no winter territoriality or site fidelity. These individuals wander widely. Birds that find a feeder seldom stay more than 1 or 2 days, although some become associated with a feeder during winter (Bent 1946; Dunn and Tessaglia-Hymes 1999; Ficken et al. 2020; Yunick 1984).

Near Quebec City, the average size of 85 Boreal Chickadee winter flocks was 4 chickadees (range 3-8). Some flocks contained Black-capped Chickadees or Red-breasted Nuthatches; some contained all 3 species. Boreal Chickadee flocks were cohesive units and occupied a mean home range of 14.7 ha (range 7.9-30.4 ha) with a mean core area of 2.3 ha (range 1.0-5.8 ha). Home range size was not affected by flock size. Home ranges contained 61% mature forest (range 21-94%), 23% regenerating forest (range 0-79%), and 15% open habitat (range 0-43%). Smaller home ranges contained higher proportions of mature forest; flock home range sizes increased with increasing amounts of open habitat. Flocks with larger home ranges had several distinct core areas within the home range. Those with small home ranges used their home range more evenly (Hadley 2006; Hadley and Desrochers 2008a).

Boreal and Black-capped chickadees often forage together in mixed-species flocks. In Michigan, the Boreal Chickadee foraged in only 3 conifer species with 76% of foraging occurring in black spruce and lesser time spent in white spruce and tamarack. The Black-capped Chickadee foraged more widely in 6 conifer and 3 deciduous tree species. The Boreal Chickadee spent 36.5% of its time foraging at the top of trees compared with 4.5% for the Black-capped Chickadee; the 2 species foraged at similar rates in other vertical zones. The niche overlap of the species was 67.6%, higher than expected. The 2 species eat similar foods but competition is reduced due to the abundance of food resources, the fact that foraging overlaps in only 3 species of conifers, and that Boreal Chickadees use the crowns of these conifers significantly more than Black-capped Chickadees (Gayk and Lindsay 2012).

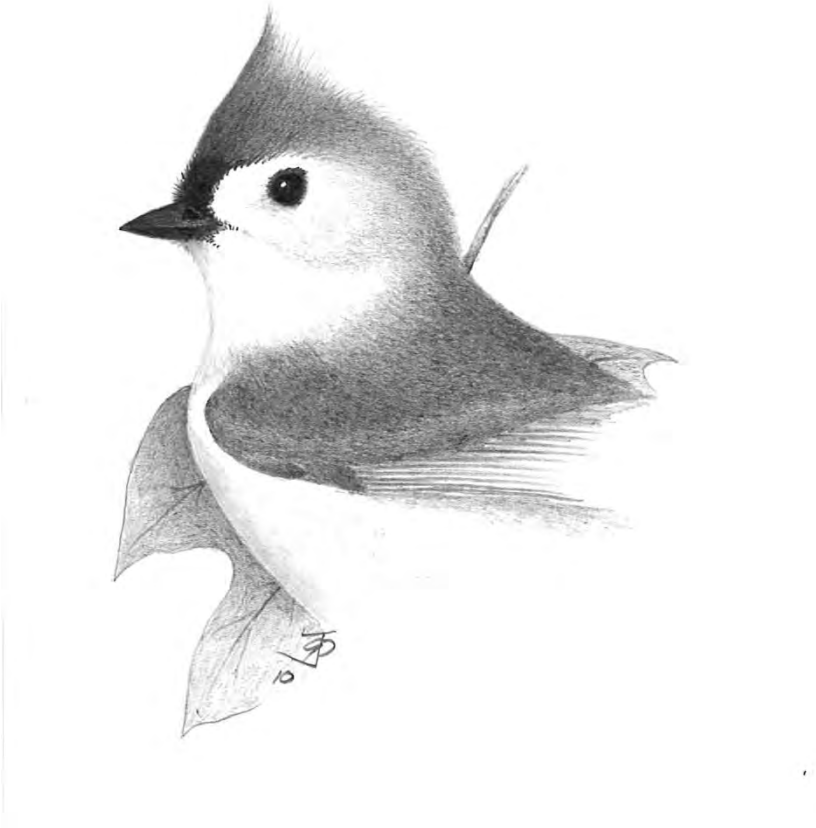
In winter, the diet is dominated by seeds, especially those of conifers, and hibernating insects, pupae, or egg masses. The Boreal Chickadee has been observed feeding on goldenrod and aster stems, on gray birch seed cones, and on red cedar berries in winter. It is a common visitor to winter

bird feeders in Alaska and in the Boreal Forest Region, and visited trappers' cabins for handouts long before winter bird feeding became fashionable. It rarely visits urban feeders, but appears in small flocks of usually 1-3 birds at feeders in rural and natural areas. Favourite foods at feeders include suet, black oil sunflowers, possibly hulled sunflowers, peanut butter mixes, and bird puddings. It occasionally eats sunflowers and baked goods. At 1 Thunder Bay feeder, it fed mostly on doughnuts and raisin bread, although suet and sunflowers were available (Bent 1946; Dunn and Tessaglia-Hymes 1999; Whittam 2000).

CBC data for 1970-2021 indicated that the Boreal Chickadee population decreased annually by 2.24% in Ontario; it decreased by more than 4.40% 2009-21 (National Audubon Society 2022).

Tufted Titmouse

Baeolophus bicolor

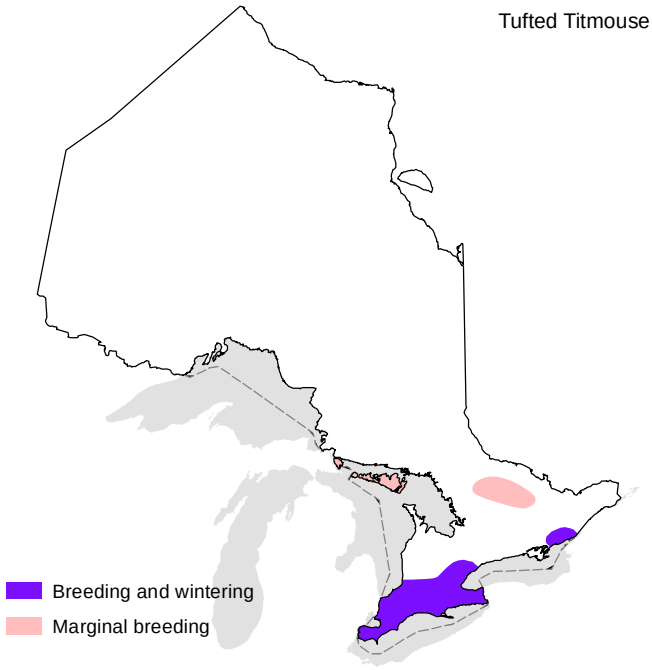


BREEDING SEASON

Habitat Requirements

The Tufted Titmouse has nested in deciduous and mixed woods, on a wooded sand dune, and in a residential garden in Ontario (Peck and James 1987).

It prefers deciduous woodlands, but also nests in mixed woods, and avoids coniferous stands. It occasionally nests in swamps, orchards, parks, on golf courses, and in older urban and suburban areas. Preferred habitats contain tall vegetation with a large number of tree species and a dense canopy. In Pennsylvania, it preferred dense undergrowth near water, but most studies found it in woodlands with little understorey. Occasionally it nests in very open, grassy areas with a few scattered trees. It greatly prefers forest edge to forest interior, and tends to prefer oak-hickory over maple-beech forests. More mature stands are preferred, and it may decline by 50% after forest harvesting. In New Jersey, it preferred second growth, wet disturbed areas, and climax logged areas. It first appeared in fields 40 years after agriculture was abandoned, when they were densely covered with saplings 2-26 cm diameter at breast height (DBH) and the field borders had become densely



wooded (Austen et al. 1994; Bent 1946; Doherty and Grubb 2000; Fitch 1958; Gillespie 1930; Graber and Graber 1963; Noon et al. 1979; Pogue and Carter 1995; Pravosudova et al. 2002; Ritchison et al. 2020; Suthers 1988; Temple et al. 1979).

There are conflicting reports about whether the Tufted Titmouse is a habitat specialist or generalist, or an area-sensitive species. In Tennessee, Anderson and Shugart (1974) could not characterize its habitat requirements with any of the variables they tested and concluded that it was a habitat generalist. In Michigan, Inman et al. (2002) concluded that it was a habitat generalist. In Texas, its abundance was positively correlated with vegetation height, number of tree and shrub species, canopy closure, foliage density at 7 m to above 20 m, percent coverage by hardwoods 5-32 cm DBH, and number of tree stems larger than 32 cm DBH. It was negatively correlated with percent coverage by pines 5-16 cm DBH. It was in a guild that preferred fairly mature pine-hardwood forest (Conner et al. 1983). In the Pennsylvania Appalachians, it was more likely to occur in stands that were not old growth. It occurred in 27.3% of old-growth forests compared with 80.9% of Pennsylvania forests and 64.1% of forests on the Appalachian Plateau (Haney 1999). In the mid-Atlantic states, its presence was positively associated with forest size, percent canopy cover, and canopy height, and negatively associated with slope, percent forest cover within 2 km, presence of coniferous trees, moisture gradient, and the number of standing dead trees larger than 3 cm DBH per ha (Robbins et al. 1989). Its presence was associated with larger woodlands in Pennsylvania (Keller and Yahner 2007). In Indiana, it was most abundant in forests with more than 90% canopy closure but it was not significantly more abundant than in areas of densely regenerating oak saplings. There were no significant differences in its abundance in savannahs, woodlands with 50-90% canopy closure, or regenerating oak areas. It was least abundant in open areas with 20% or less canopy closure. Its abundance increased with tree density. Its probability of occurrence was about 25% when trees were widely scattered compared with 100% at 500-600 trees per ha (Grundel and Pavlovic 2007a, 2007b). In southern and central Illinois, it occurred in a variety of habitats including upland and floodplain forests, savannah, and low-density developed areas. In the northern portion of the state, it was found only in developed areas (Walk et al. 2011).

In a Connecticut woodlot over a 59-year period, there was a progressive shift to larger trees, a sparser shrub layer, and a less diverse tree canopy dominated more by oaks and maples as a result of a severe decline in hemlock. There was no change in the abundance of the Tufted Titmouse (Buchanan et al. 2016).

In Ohio, the titmouse prefers forest fragments, yet the number detected per Breeding Bird Survey (BBS) route increases with increasing forest cover (Pravosudova et al. 1999; Ritchison et al. 2020). In Maryland, its frequency of detection on BBS routes increased with forest size. Robbins (1979) concluded that a minimum of 4 ha was required to maintain a viable population. In the mid-Atlantic states, its maximum probability of detection was in forests 52 ha in area, but the probability of detection did not decline to 50% until woodlot size was only 0.5 ha. It greatly preferred isolated forests (less than 33% forest coverage within 2 km) to moderately isolated forests (33-66% coverage; Robbins et al. (1989). In southern Wisconsin, Mossman and Hoffman (1989) concluded that it required a minimum forest size of 32.4 ha to maintain a population. It was rare there at the time that this study was completed. In Missouri, Hayden et al. (1985) considered it area sensitive and estimated that it required a minimum forest size of 1.2 ha. This suggests that it actually is not area sensitive there. In Ohio farmland habitat, it is uncommon in forest fragments smaller than 2 ha (Ritchison et al. 2020). In South Carolina, it was not area sensitive. It was significantly more abundant in small, fragmented woodlots surrounded by agricultural lands than in same-sized woodlots surrounded by plantations. Probabilities of detection in field-surrounded versus plantation-surrounded woodlots of different sizes were: 0.5 ha, 82% and 47%; 1.0 ha, 87% and 55%; 2.5 ha, 94% and 75%; 5.0 ha, 98% and 92%; and 10 ha, 100% and 99%, respectively. Kilgo et al. (1997) concluded that it was an edge species and that woodlots surrounded by agriculture were all edge and better habitat than those surrounded by plantations. In Ohio, it occurred in 100% of isolated woodlots 3-4 ha in area, in 86% of 2-3-ha woodlots, in 40% of 1-2-ha woodlots, and in 12.5% of woodlots smaller than 1 ha. This study was done in late autumn so results may not have been representative of the breeding season (Ritchison et al. 2020). Keller et al. (1993) found that its probability of detection was unrelated to forested width along rivers. Lindell et al. (2007) reviewed studies that determined edge preferences of the Tufted Titmouse. In 2 studies, it showed no preference for edge or interior; a third study found that it actively exploited edge. In Tennessee, there were significantly more territories close to edge than distant from it (Kroodsma 1984).

In summary, the Tufted Titmouse is a bird of mostly deciduous forests and occasionally mixed forests that prefers forest edge to interior. It may also nest in sparsely treed areas. It is not area sensitive and appears to prefer isolated woodlots rather than those in more forested landscapes. There is a possibility that it prefers larger woodlands at the periphery of its range than in its core range. It preferred areas that were 71-94% forested in New York (Cunningham and Johnson 2019).

One Ontario nest was in a leaning pipe stuck in the ground but the rest were in natural cavities in living trees. Two were in maple trees, one in an oak, and one in an apple tree. Nests in natural cavities were 2-16.8 m from ground, mostly 9-13.5 m up. The nest in the iron pipe was 30 cm below the top of the pipe, which was 1.5 m up (Peck and James 1987). A nest on Manitoulin Island was in a nest box (Peck and James 1997).

The Tufted Titmouse does not appear to excavate its own nest, and relies on cavities excavated by other birds or natural cavities in trees; it occasionally nests in fence posts. It readily uses nest boxes, but prefers tree cavities. Unusual nest locations include cavities in the sides of old large bird nests, in a tin newspaper box at a roadside, in metal pipes, and in Spanish moss. Natural tree cavities are those created by knotholes or lightening strikes, or excavated by woodpeckers. Nests have been

reported in a variety of tree species, mostly deciduous, including beech, red and white oak, sycamore, pine, hemlock, apple, mulberry, red and sugar maple, white ash, chestnut, white elm, dogwood, birch, and black locust. Most nest trees are large with an average DBH of at least 30 cm and occasionally as large as 38 cm. In Missouri, average tree diameter at the nest was 24.8 cm, but in other areas tree diameters were 10-12.5 cm. Preferred cavities are in sound wood with little evidence of decay. The optimum cavity entrance is 4.4-5.6 cm in diameter with a minimum of 3 cm. Nest heights of 0.6-29.6 m have been reported, mostly about 10 m or higher (Bent 1946; Brown et al. 1984; Eshbaugh and Eshbaugh 1979; Evans and Conner 1979; Lancaster et al. 2004; Laskey 1957; Middleton 1949; Pravosuodova et al. 2002; Ritchison et al. 2020; Smith 1985). It readily accepted nest boxes in pine stands in Florida. There was a slight population increase as a result of the addition of nest boxes (Miller 2010).

The female starts roosting in the nest cavity when the first or second egg is laid, and continues to do so until the young are 12-13 days old (Brackbill 1970; Laskey 1957). In autumn and winter, both sexes roost in woodpecker holes and in natural cavities in posts, snags, and trees (Bent 1946).

In Kansas, the average breeding territory was 1.7 ha (Fitch 1958). In Michigan, 14 breeding territories averaged 4.2 ha (range 3.2-5.0 ha). The titmouse may be able to tolerate smaller territories or home ranges in isolated woodlots. In Missouri, 4 dominant pairs had average breeding territories of 3.3 ha (range 2.9-3.6 ha); 4 subordinate pairs had average territories of 3.4 ha (range 3.1-3.8 ha). The mean distance from the centre of the winter flock territory to the centre of dominant pairs' breeding territories averaged 17.8 m (range 12-23 m) compared with 555 m (range 428-675 m) for subordinate pairs (Brawn and Samson 1983).

Natal philopatry is variable and complicated because 1 young frequently remains with the adults over winter and becomes a helper at the nest in the next breeding season. In Tennessee, 1 young helper at a nest returned to the same winter feeder for an additional 6 years, usually returning in late summer with 1 or 2 fledglings; occasionally one of these remained with him over winter. Distances of first nests from the natal area may be in the order of 0.5-1.2 km. Most authors assumed that a winter trio of birds represents a pair and 1 of its offspring. But in small, isolated woodlots in Ohio, only 5 of 12 trios were families. Therefore, studies that report the distance of a bird's first nest from its winter territory may include birds hatched within the area and those that dispersed to the area the previous autumn. Young that dispersed from the vicinity of the natal area travelled a median distance of 75 km in Pennsylvania. Once a bird has bred in an area, it tends to have very high site tenacity. There are records of birds using the same nest box or cavity for 6-7 years. In Missouri, some birds nested and then were absent for 1-5 years before returning to breed again, suggesting that some local movement occurred between nesting seasons. Of 632 bird-years, 49 birds (7%) were missing for a year or more before returning. Forty were absent for 1 year, 4 for 2 years, 2 for 3 years, 2 for 4 years, and 1 for 5 years. Of 112 titmice observed in 3 or more years (making a skip possible), 27% skipped 1 or more years (Brackbill 1970; Brawn and Samson 1983; Davis 1978; Ekman 1989; Elder 1985; Gillespie 1930; Laskey 1957; Middleton 1949; Pravosudova et al. 1999; Ritchison et al. 2020; Tarbell 1983).

Limiting Factors

Eggs are most likely to be present in Ontario nests from mid-May until the third week of June (Peck and James 1987). Pair formation of juveniles may occur as early as the end of July of their first year and continues until January or February. Pairs abandon the winter flock in February or early March and establish a breeding territory. In Oklahoma, about 2 weeks elapsed between the start of nest building and laying. In Maryland, 3 nests took 6-11 days to build and laying began 3 days after they were complete. Eggs are laid at the rate of 1 a day. Incubation starts with laying of the last or penultimate egg. The incubation period is 12-14 days, but mostly 13 days. Young fledge when they are 15-18 days old, but mostly at 17-18 days (Bent 1946; Brackbill 1970; Brawn and Samson 1983; Laskey 1957; Nice 1933; Pogue and Carter 1995; Ritchison et al. 2020; Samson and Lewis 1979).

Usually only 1 brood is raised a year. Circumstantial evidence in Maryland suggested 2 cases of double broods, but these may have been renests. One banded bird in Pennsylvania nested 7 years, and produced 2 broods in 2 of those years. Two Ontario nests contained 3 and 4 eggs, but these probably were not full clutches. Most clutches contain 5-7 eggs. The overall average clutch size is 5.7 eggs, the median is 6, and the range is 3-9 eggs (Bent 1946; Brackbill 1970; Laskey 1957; Middleton 1949; Peck and James 1987; Ritchison et al. 2020).

The age at first breeding is 1 year. The Tufted Titmouse is monogamous and many birds pair for life. Divorce is common and some birds may have 2-5 mates during their lifetime. In 7 Ohio broods, 3 of 29 nestlings (8.8%) were unrelated to their behavioural father. In these cases, the male was a close relative of the female (Brackbill 1970, 1987; Laskey 1957; Provosudova et al. 2002; Ritchison et al. 2020; Short 1933).

The Tufted Titmouse forages by searching bark crevices, exploring dead leaves in hanging clusters or in squirrel nests, and by hammering with the bill to open seeds and acorns. Foraging techniques include 63% gleaning, 21% hanging and gleaning, 3% hovering and gleaning, 8% probing, 2% pecking, 1% scratching and gleaning, and 1% turning leaves. It rarely hawks moths from the air. In Ohio, it foraged 56% of the time on trees, 17% on shrubs, and 27% on the ground. Of tree foraging, 4.4% occurred on the trunk, 12.1% on primary branches, 40.5% on secondary branches, and 43.0% on tertiary branches. In a laboratory experiment, titmice were allowed to forage freely on branches 0.5, 1.0, 2.5, 5.0, 10.0, and 20.0 cm in diameter. All foraging occurred on tops of branches and 2.5-cm diameter branches were used considerably more than expected. Although it occasionally forages at the extremity of a branch or at the trunk, most time is spent between these extremes. Titmice feed mostly in the lower and interior areas of trees, but tend to forage in taller trees in spring and summer. During the breeding season in Illinois, foraging occurred mostly in the shrub (0-5 m) and subcanopy (6-10 m) foliage layers, with 24% of foraging activity at 0-5 m, 52% at 6-10 m, 12% at 11-15 m, and 12% above 16 m. Foraging occurred in hickory more than expected; no foraging occurred in sugar maple and red elm. Tree species preferred for foraging, in order of preference were shellbark hickory, white elm, red maple, silver maple, and bitternut hickory. In order of decreasing avoidance, pumpkin ash, black gum, blue beech, green ash, Manitoba maple, sycamore, and pin oak were used less than their availability. Three preferred species, shellbark hickory, silver maple, and bitternut hickory were uncommon and ranked 11th, 18th, and 19th in abundance, respectively. Pumpkin ash and blue beech were highly avoided yet ranked 2nd and 7th

in abundance (Anderson and Shugart 1974; Bent 1946; Brackbill 1950b; Dickinson 1969; Gabbe et al. 2002; Hartung and Brawn 2005; Pierce and Grubb 1981; Ritchison et al. 2020).

The diet of 186 adults consisted of 66.6% animals and 33.4% vegetable matter. Caterpillars represented over half the animal food, and caterpillars and wasps comprised over half of all food. Ants and other hymenopterans constituted 12.5% of food; beetles totalled 7.1% (mostly weevils). Other animals consumed included stink bugs, treehoppers, scale insects, katydid eggs, cockroach eggs, spiders, and a few snails. It eats soft mast in late summer and early autumn. Hard mast is the principal food item from August until February. It eats some corn, as well as raspberries, blackberries, dogwood berries, Virginia creeper berries, honeysuckle berries, tulip-tree seeds, giant ragweed seeds, grapes, cherries, strawberries, elderberries, hackberries, blueberries, huckleberries, mulberries, juneberries, alder seeds, sumacs, and poison ivy. Acorns and beechnuts comprised 23.4% of the total diet and constituted 95% of the November diet. In late summer and early autumn, juveniles may congregate in oak-hickory woods or stands where beech is common. Beechnuts are a preferred autumn and winter food. In Illinois, acorns from different species of oaks were provided at a feeder. The Tufted Titmouse preferred acorns from white and pin oaks to those of black oak. It was 19.0 and 6.2 times more likely to select pin and white oak acorns, respectively, than black oak acorns. Black oak acorns are intermediate in size but have a harder shell than the other 2 oaks. It caches acorns in areas where they may germinate and may be an important agent for white oak dispersal. In Missouri, a titmouse caught and ate a salamander. One captive bird picked at the carcass of a dead titmouse and ate considerable flesh (Beal et al. 1916; Bent 1946; Dance et al. 2012; Gillespie 1930; Hendricks and Hendricks 1985; Richardson et al. 2013; Ritchison et al. 2020; Stewart 1955).

The Tufted Titmouse is rarely parasitized by the Brown-headed Cowbird. Bent (1946) reported 4 cases of parasitism and Lowther (1997) reported another 2 incidences from Illinois. Clapp (1995) reported a case of parasitism in Virginia. This nest was in a box designed for the Great Crested Flycatcher. Although cowbird eggs have been found in titmouse nests, there appear to be no records of cowbirds successfully fledging.

Cold spring weather may affect nesting success. In Oklahoma, some eggs froze in nest boxes (Pogue and Carter 1995).

Kilpatrick et al. (2007) determined that the Tufted Titmouse was vulnerable to the West Nile virus and that significant effects on populations had been identified due to the virus. The titmouse may be resident in suburban areas where it is most likely to come in contact with the vector. Approximately 80-90% of the Windsor population was decimated in 2002 with an outbreak of this virus (Read in Cadman et al. 2007).

In New Jersey and Pennsylvania over a 15-year period, hemlock declined from 56% of the total basal area to 46% due to the hemlock woolly adelgid; the amount of deciduous understorey increased. The Tufted Titmouse responded favourably to hemlock decline and increased, possibly due to the greater prevalence of snags (Toenies et al. 2018).

Harrison and Kilgo (2004) tested the effects of retaining patches of bottomland hardwood forest within traditional clear-cuts. Titmouse densities were higher in clear-cuts where patches were left.

Robinson and Robinson (1999) created small (0.02-0.4 ha) openings in contiguous forest in Illinois. There was no difference in numbers of titmice in cut and uncut forests.

In Delaware, browsing by white-tailed deer had no effect on the Tufted Titmouse. It was equally abundant in areas of low, moderate, and high deer densities (Tymkiw et al. 2013).

In New York, Damsky and Gall (2017) played Tufted Titmouse mobbing calls and mobbing calls accompanied by anthropogenic noise, including traffic with occasional airplane and lawnmower noise. The addition of noise resulted in an approximately 80% decrease in the number of titmice approaching the speakers; there was no effect on foraging behaviour. The decrease in response to the mobbing call as a result of noise was considered a concern. These calls are given in response to a threatening stimulus. If birds are slow to respond to the warnings, they may be unable to take advantage of them.

Price (2004) predicted that the range of the Tufted Titmouse could expand in southern Ontario if the average summer temperature increased by 2°C.

Status

The Tufted Titmouse is a recent arrival to Ontario. The first provincial record was in May 1914 when one was observed at Point Pelee. The first summer record was at Fisher Glen in Norfolk County in 1932. Adults with young were seen in Hamilton in 1936, and the first undocumented nest was reported from Sarnia in 1953. Nesting was officially confirmed in 1971 when a young bird was photographed leaving a Port Colborne nest. There was an influx of titmice to the Hamilton area in autumn 1961 and it has been a rare resident in that area ever since. Numbers of breeding pairs continued to increase in the province and by the first atlas it was estimated that there were 26-40 pairs. The greatest concentrations occurred in Niagara Region with scattered sightings around Lake Simcoe, Rondeau Provincial Park, Essex County, Sarnia, and Walpole Island (Austen et al. 1994; Baillie 1960; Currie in Cadman et al. 1987; Curry 2006; Peck and James 1987). James (1991) considered it a rare permanent resident in the Carolinian Forest Region with wanderers north to Lake Simcoe. The first Elgin County breeding record was in 1990 and it is now a rare and regular breeder there (Lancaster et al. 2004). A nest in a bird box on Manitoulin Island was the most northern breeding record at the time (Peck and James 1997), but was surpassed by a nest found in Algonquin Provincial Park in 2004 (Peck 2005b).

The second atlas demonstrated that the range of the Tufted Titmouse had expanded since the first atlas. During the second atlas, its range included the Carolinian Forest Region, with numerous gaps in distribution within this area, and a few scattered records in the Great Lakes–St. Lawrence Forest Region south of the Canadian Shield. It was most numerous and widespread in Niagara Region, with other concentrations along the shoreline of Lake Erie, and in Chatham-Kent, Essex, and Lambton, where it was not encountered during the first atlas. There were a few records from eastern Ontario; these birds may have originated from the expanding New York population. Its probability of observation increased almost 5-fold from the first atlas. It was recorded in 21 squares during the first atlas and in 99 during the second. Numbers increased steadily in the Windsor area beginning in the mid-1980s, but 80-90% of the population was killed during the 2002 West Nile virus outbreak.

This population appears to be recovering slowly. The current distribution of the Tufted Titmouse is very close to that of the pin oak in Ontario (Read in Cadman et al. 2007).

The Tufted Titmouse has experienced a widespread northward range expansion. It was first observed in Massachusetts and Maine in the 1950s, but it is now well established in New England. The first records in Wisconsin and Michigan were in the early to mid-1940s and it has since become well established in the southern portions of these states. The northward range expansion appears to be due to a combination of climate warming and an increase in winter bird feeding. It is more likely to visit feeders northward, suggesting that feeders are more important in colder climates (Berger and Dunn 1991; Dunn and Tessaglia-Hymes 1999; Hamilton 1994; Ritchison et al. 2020; Root 1988; Van Tyne 1948; Wilson 1999).

Long-term (1970-2021) population trends determined from BBS results indicate annual increases of 4.19% in Canada and 2.1% in Ontario. The short-term (2011-21) trends were an annual increase of 2.11% in Canada and an annual decrease of 0.0454% in Ontario. All results were of low reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Young may be fed as late as 36 days after fledging but they start feeding themselves 5 days after leaving the nest. They are fully independent at age 6 weeks. From the end of July into August, the Tufted Titmouse is frequently found in feeding flocks, typically in areas with an open understorey and well-developed canopy. These small flocks persist through winter until the following spring. A typical flock consists of a pair of adults and 1 or more juveniles that may include both their own offspring and unrelated young. Young that disperse from the natal area do so in late August and early September (Ritchison et al. 2020).

In Ohio, both adult and particularly juvenile Tufted Titmice used densely regenerating clear-cuts during the post-breeding season. Early successional habitats may be important because they provide dense cover and an abundance of food (Vitz and Rodewald 2006, 2007). In Missouri, Porneluzi et al. (2014) netted birds during the postfledging period in an oak-pine-hickory forest 2-15 years after it was clear-cut. The Tufted Titmouse exhibited a significant curvilinear abundance trend, increasing gradually to a peak 6-9 years after harvesting and declining thereafter. During years of heavy beech or oak mast crops in Ohio, juveniles congregate in pine-oak and beech groves (Ritchison et al. 2020).

AUTUMN

The Tufted Titmouse is a permanent resident that exhibits no regular migratory patterns. Many birds never move much more than 1-2 km from their natal site. In some years, there may be a slight southward movement in autumn, presumably by juveniles. There are 2 classes of birds: adults and juveniles that have been accepted into a winter flock, and nonterritorial juvenile floaters. The floaters exhibit considerable local movement. In Missouri, 80% of birds arriving at a site in December and 67% of January arrivals were absent in February (Berger and Dunn 1991; Elder 1985; Fitch 1958; Gillespie 1930; Graber and Graber 1963; Hogstad 1989; Ritchison et al. 2020; Van Tyne 1948). In West Virginia, 96 were captured in autumn at a banding station over a 21-year period in an area where the species does not breed. This suggested that birds were dispersing but the movement probably

was not true migration. Northward spring movements have been documented in Connecticut, Massachusetts, Vermont, and New Hampshire.

Although the Tufted Titmouse is typically very sedentary, Post (1979) reported the only known irruption of this species. In New York City in 1978, titmice started to arrive in the last week of September and first week of October. The movement peaked between 10 and 23 October, but birds continued to move through until late November. On the local Christmas Bird Count (CBC), 135 were reported compared with the previous high of 17. Higher than normal numbers also occurred in Maine and New Hampshire.

During autumn in Pennsylvania, the Tufted Titmouse was most abundant in mature forest habitats. It was significantly more abundant in suburban forests, followed by forest-agricultural edge, forest edge, shrub-sapling-stage forest, forest interior, and pole-stage forest (Rodewald and Brittingham 2002). It was associated with larger woodlands in spring and autumn in Pennsylvania (Keller and Yahner 2007).

WINTER

Winter habitat is similar to that used the rest of the year, but movements among habitats may occur during severe winter conditions. Portions of the winter flock territory are typically used as a breeding territory by the dominant pair. In Illinois, Tufted Titmice stayed more in woody habitats during winter than chickadees (Graber and Graber 1963). Root (1988) noted that it occurred only in areas receiving more than 61 cm of rain a year, and that it was most common where there was at least 81 cm of rain. It relies heavily on beechnuts and acorns in winter, so it may be most common in oak-hickory woods and forests where beech is abundant.

In Missouri, the Tufted Titmouse increased with increasing tree density and was most abundant in forests, followed by woodlands and savannahs (Kendrick and Thompson 2013). In Michigan, it was more likely to be found in smaller than large woodlots in winter (Ritchison et al. 2020).

Winter flocks form shortly after juvenile dispersal, usually in late July and August, but occasionally as late as September or October. These flocks remain intact and fairly stable until they break up in February at the onset of the breeding season. A typical flock consists of a pair, or occasionally 2 pairs, and their offspring or unrelated juveniles. Once a flock is established, the membership is stable and no new birds are accepted, even if some of the regulars die. Winter flocks usually consist of 2-6 birds and occasionally as many as 8. The sex ratio is usually equal within winter flocks and there is a linear dominance within them. The adult pair is dominant, but all males are dominant to females, and the female mated to the alpha male is the alpha female. Dominance has several advantages: dominant birds arrive at feeders earlier in autumn than subordinates and continue to use feeders longer in spring, dominants may use feeders whenever they wish and obtain more seeds, and dominants select the best area within the winter flock territory for their breeding territory. Occasionally pure juvenile flocks form where there are no survivors from the previous winter. Pairing occurs over the winter and most birds prefer to pair with a bird within the same flock (Brackbill 1970; Brawn and Samson 1983; Condee 1970; Ekman 1989; Fitch 1958; Gillespie 1930; Hogstad 1989; Nice 1933; Ritchison et al. 2020; Samson and Lewis 1979). The Tufted Titmouse is a core species in flocks of other species, and it defines flock movement patterns. It is dominant to

chickadees and affects their foraging behaviour and condition; titmice may steal food from subordinate flock members (Ritchison et al. 2020).

Winter flocks maintain definite home ranges or territories. Birds rarely move out of this area and those that do are usually males that briefly trespass on adjacent winter flocks' territories. In most cases, flocks defend their winter territory and trespassers either retreat themselves or are expelled. Territorial disputes between flocks may be common, especially when food is limited. In 1 area of Pennsylvania where food was abundant, 2 flocks overlapped and showed no signs of aggression. In Ohio, all winter home ranges in 1 area overlapped by 30-50%. Individuals may range throughout the entire flock territory, but many remain in localized areas within the territory. Many shift the portion of the territory that they use from 1 winter to the next; others have very high site fidelity. Flock territories remain fairly constant year to year. Flock territory sizes range from 2.5-17.8 ha, but mostly 5-8 ha. Smallest home ranges were reported from isolated woodlots in Ohio. In these woodlots, pairs accompanied by their first-year offspring occupied larger woodlots (4.5-10.0 ha) than pairs with unrelated juveniles (2.5-5.9 ha; Brackbill 1970; Brawn and Samson 1983; Condee 1970; Ekman 1989; Fitch 1958; Gillespie 1930; Nice 1933; Pravosudova et al. 1999; Ritchison et al. 2020; Samson and Lewis 1979).

In Ohio woodlots, wintering titmice foraged on the ground 27% of the time, 17% of the time in shrubs, and 56% of the time in trees. In trees, 4.4% of foraging occurred on the trunk, 12.1% on primary branches, 40.5% on secondary branches, and 43% in tertiary branches (Ritchison et al. 2020). In winter in Illinois, 45% of foraging time was between 0 and 5 m, 3% at 6-11 m, 16% at 12-17 m, and 40% at 18-23 m. At Pennsylvania feeders at different heights, 32.1% of foraging occurred on the ground, 42.1% at 2 m, 12.4% at 4 m, and 13.4% at 6 m. Foraging at all heights differed significantly from an expected equal distribution (Nastase and Linville 1995).

Favoured natural winter foods are acorns, beechnuts, and lepidopteran cocoons. In New Jersey pine barrens, acorns were the dominant winter food and the Tufted Titmouse was restricted to areas with oaks and acorns (Brush 1989). It is readily attracted to winter bird feeders, where it is slightly less regular and abundant in urban than rural areas. It prefers peanuts and large striped sunflowers at feeders, and usually takes the largest sunflower that is available. Favourite feeder foods include striped and black oil sunflowers, hulled peanuts, hulled sunflowers, safflower, peanut butter mixes, and bird puddings. Infrequent choices include millet, mixed seeds, canary seed, cracked corn, milo, niger, peanuts in the shell or peanut hearts, pet food, raisins, soda crackers, suet, meat scraps, baked goods, and water. At a Pennsylvania feeder, it took sunflowers on 85.6% of visits, corn on 11.8%, and niger on 2.6%. No canary seed or millet was taken (Bent 1946; Berger and Dunn 1991; Dunn and Tessaglia-Hymes 1999; Gillespie 1930; Laskey 1957; Nastase and Linville 1995; Ritchison et al. 2020). Based on 20,246 feeding observations, it preferred black oil sunflowers and whole peanuts in tube or platform feeders (Horn et al. 2014)

About half the items taken from feeders is stored, and around 80% of shelled foods are hulled before storage. Only 1 seed is taken per trip and most are stored within 40 m of the feeder. Height of caches ranged from 0 to 25 m (average 7.8 m). Most seeds (46%) were wedged under loose bark; 15% were placed in furrows, cracks, and rotted areas of trees; 12% in the ground; 12% between 2 branches; and 12% at the end of broken branches and twigs. In trees, seeds were stored on branches

less than 8 cm in diameter and on twigs in trees with diameters greater than 8 cm. In trees, caching occurred equally in the inner, middle, and outer portions of limbs. Seeds were placed more than expected at the tops and sides of branches. Overall, it showed a strong preference for storage on branches, compared with trunks by the White-breasted Nuthatch and twigs by chickadees. Stored food was rarely covered (Laskey 1957; Petit et al. 1989).

In Connecticut, Correia and Halkin (2018) compared the winter habitat and foraging niches of the Tufted Titmouse and Black-capped Chickadee. Compared with chickadees, titmice used canopy foraging locations more evenly, spent less time in shrubs, and spent much more time on the ground (25% of the time for titmice, 1.7% for chickadees). Chickadees spent significantly more time in the outer upper canopy and in shrubs than titmice, and titmice spent significantly more time on the ground than chickadees. In tulip trees, titmice foraged in the outer upper canopy but largely avoided this area in other tree species; seed clusters of the tulip tree tend to be in this area. Both species gleaned small objects on surfaces of all tree species except tulip tree and red pine where feeding was restricted to seeds. Titmice ate pulverized beechnuts and acorns found on forest trails and foraged in conifers much more rarely than chickadees. Titmice actively flipped leaf litter on the forest floor and hopped along decayed logs; no chickadees were observed on the forest floor. The 2 species had different preferences at feeders. Chickadees selected sunflower seeds without shells on 61% of visits; titmice selected safflower on 54% of visits. At feeders, titmice won all challenges against chickadees. The significant differences found in the 2 species' foraging behaviours and seed preferences may mitigate competition.

Cold winds may affect titmouse foraging behaviour and where they occur within small woodlots. In Ohio, titmice were found significantly lower in the canopy as wind velocity increased. As wind increased and the temperature dropped, birds were found significantly further from the windward edges of woodlots. On 62% of visits, titmice were found only in the leeward half of the woodlot. Titmice appeared to be sensitive to winds only when the temperature was below –6°C. On a particularly cold day (–15°C) with a low wind speed of 0.5 m/second, all birds were on the leeward side of the woodlot. Birds may leave very small woodlots when it is cold and windy but dense understorey vegetation near windward edges allows birds to use these areas (Dolby and Grubb 1999).

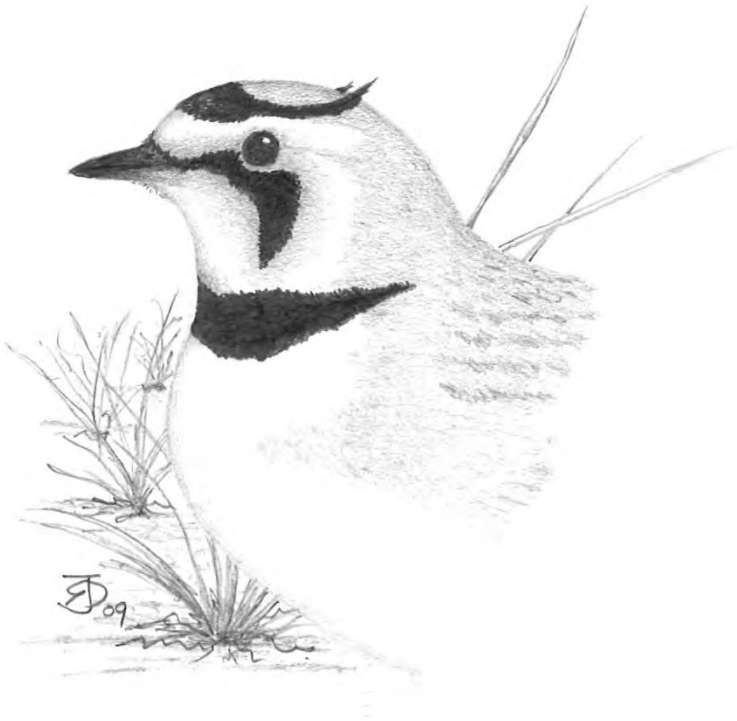
Heavy snow cover may result in changes in habitat use or direct mortality. Because the Tufted Titmouse forages primarily on acorns and beechnuts on the ground, snow cover reduces food availability. Nutritional condition of birds and their survivorship is inversely related to snow coverage. During a severe winter storm in Illinois, titmice appeared to move from bottomland hardwoods to other habitats, especially urban residential areas where none were observed prior to the storm. Numbers in bottomland forests declined by 49.4%; populations in upland forests increased by 6.2%. Some titmice carcasses were observed after the storm (Doherty and Grubb 2003; Graber and Graber 1979).

In Pennsylvania, cycles of abundance were noted, with titmice common some years and scarce others. This was probably due to availability of winter food and the fact that titmice appear to be vulnerable to the depth and length of snow cover, particularly in combination with low temperatures (Gillespie 1930; Overlease and Overlease 1987).

CBC results indicate annual increases in Ontario of more than 12.5% from 1970 to 2019 and 0.25% 2009-19 (National Audubon Society 2022).

Horned Lark

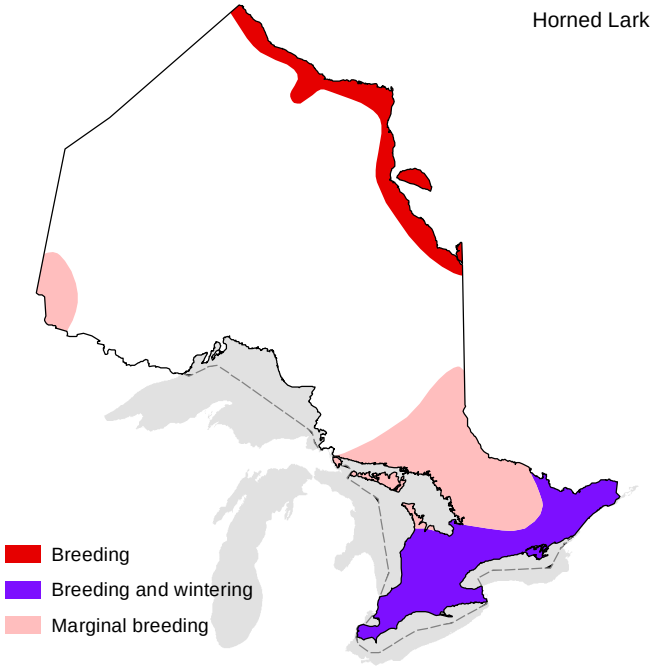
Eremophila alpestris



BREEDING SEASON

Habitat Requirements

In Ontario, the Horned Lark breeds in the tundra along the northern coast in open, treeless areas that are devoid of shrubs and tall forbs. In the south, it breeds predominantly in human-altered areas such as agricultural fields, pastures, large lawns, airports, racetracks, golf courses, gravel pits, landfills, road shoulders, railroad beds, and parking lot edges. Natural areas that may be used for nesting include tundra, short-grass prairies, and sand beaches (Peck and James 1987). In the Kingston area, it occurred mostly in flat agricultural areas and was absent in heavily forested areas (Weir 2008). This is typical of the Prairie subspecies which is found predominantly in agricultural areas in the south. Baillie and Hope (1947) reported a few on a farm in Sudbury District, but did not see it elsewhere, although it previously nested on a golf course in Sudbury. It is seldom found in the Boreal Forest Region because there are few natural areas where there is a permanent lack of trees (Erskine 1977). It is infrequent in northern farmlands, possibly because they are too small. It was almost absent in the heavily forested portions of the province during the first atlas. In forest-dominated landscapes, it is associated mostly with airfields and other large human-made clearings (Hussell in Cadman et al. 1987).



In southern Ontario, the Horned Lark was more abundant on organic than conventional farms, but not significantly. It was significantly associated with spring grain, habitat heterogeneity, row crops, field size, and the number of treatments a field received. Positive nonsignificant associations were with crop biomass and the number of tills in the fields. Negative nonsignificant correlations were with pasture and grassy strips between fields that often supported fences, herbicides, and chemical fertilizers (Kirk et al. 2011).

Elsewhere, the Prairie Horned Lark is largely associated with agricultural lands and other bare habitats. It prefers bare ground, but will nest in very short grasses. In non-agricultural areas, it may nest in shortgrass prairie, bushy flats, deserts, and alpine areas. In agricultural areas, preferred nesting areas are stubble fields, plowed fields, and fall-planted fields. In Iowa, it and the Vesper Sparrow were the only species that nested in fields of row crops. Row crops are excellent habitat in spring and early summer, but become unsuitable later as crops grow. Harvesting of hay and small grains in mid-summer opens up new habitat and it moves to the cut fields. In Illinois, many nested in pastureland in the early 20th century, but by the mid-1950s nesting was confined mostly to crop fields. The former practice of keeping roadsides closely mowed was beneficial to the Horned Lark. By 2000 in Illinois, it nested most frequently in soybean and corn fields, occasionally in grazed grass and mown hay, seldom in wheat and alfalfa, and rarely in idle grass. It nested in Iowa and Illinois cornfields and showed no preference for nesting in the centre of fields or near edges; it avoided edge habitats abutting cornfields. In grazed areas, highest densities are associated with heaviest grazing. In North Dakota, it was more abundant on grassy plots with no shrubs than on shrubby plots, but not significantly. In Washington, it was negatively associated with shrubs and was least abundant in shrubsteppe habitat. It was more abundant in old than new Conservation Reserve Program fields, although the difference was not significant. Other human-made habitats occasionally used for nesting include sod farms, lawns, racetracks, airfields, garden plots, and baseball diamonds. Natural habitats include sand dunes, shorelines with sparse vegetation, shrubsteppe habitats, and shortgrass prairie, which is its native habitat. In grassland, its presence is strongly negatively correlated with vegetation height; it prefers vegetation less than 3 cm tall. Variations in moisture, soil type, elevation, and temperature are tolerated, so vegetation appears to be the controlling factor. Near Churchill, overgrazing by geese created additional breeding habitat (Arnold and Higgins 1986; Beason 2020; Beason and Franks 1973, 1974; Best et al. 1990; Bowles 1900; Campbell et al. 1997; DuBois 1935; Fitch 1958; Graber and Graber 1963; Hurley and Franks 1976; Jehl 2004; Johnson and Gardella 1999; Leighton et al. 2002; Patterson and Best

1996; Pelletier in Gauthier and Aubry 1996; Pickwell in Bent 1942; Rotenberry and Wiens 1980; Skagen et al. 2005; Sutton 1927; Vander Haegen et al. 2015; Verbeek 1967; Walk et al. 2011; Wiens and Dyer 1975; Wiens et al. 1986).

Occupied areas typically have moderate coverage (10-37%) of bare ground. In the Midwest, the Horned Lark's abundance was negatively correlated with percent forb cover, maximum vegetation height, and height of forb and shrub coverage. In Colorado, occupied areas were characterized by 65% coverage by short grasses, 2% coverage by mid-height grasses, 6% sedge coverage, 7% forb coverage, 2% cactus coverage, 0.8% shrub coverage, 17% bare ground, 1% rock coverage, and 7.2 cm mean vegetation height. It was significantly more abundant in upland than lowland grasslands. In North Dakota, it was more abundant in pastures with less than 10% coverage by snowberry and silverberry than in pastures with 30-80% coverage by these shrubs. Highest densities occurred on transects with the lowest height and density of vegetation regardless of the presence or absence of shrubs. Where it was present, maximum vegetation height was taller and the percent coverage by native herbaceous vegetation was greater than where it was absent. Where it was absent, litter depth was greater, cover by shrubs was greater, coverage by aspen within 100 m was greater, and the coverage by Kentucky bluegrass and smooth brome was greater than where it was present. Its presence was strongly tied to the presence of native plants that did not create a deep litter layer. In Saskatchewan, it occupied areas with little or no vegetation or litter. Its occurrence was positively associated with narrow-leaved (less than 5 mm wide) grasses 10 cm or less in height and was negatively associated with vegetation height. Breeding habitat in Missouri cropland consisted of vegetation shorter than 10 cm, no woody stems, and less than 25% coverage by litter that was less than 0.4 cm deep. Areas where cattle and bison created bare ground were also used. In Colorado, it preferred areas with grass shorter than 10 cm but persisted in taller grasses. Its abundance increased with cover of short grasses and litter and decreased with cover of standing dead vegetation, mid-height grasses, and shrubs (Arnold and Higgins 1986; Davis et al. 2021; Dinkins et al. 2002; Grant et al. 2004; Wiens and Rotenberry 1980).

In Saskatchewan prairie habitats, the Horned Lark was not area sensitive. Nonetheless, its abundance increased as the ratio of edge to area decreased. It also increased with increasing distance from the nearest shrub (Davis 2004). In Colorado short-grass prairie habitat, only 6 of 46 nests (13.0%) were found within 50 m of edge. Nest success decreased with increasing patch size. Skagen et al. (2005) concluded that larger patches had a greater suite of predators that resulted in higher predation rates. Ribic et al. (2009) concluded that its occurrence was positively correlated with patch size in South Dakota. In Washington and Oregon, grassland areas used in inland areas were 131-390 ha, but habitat patches as small as 10 ha were used in coastal areas (Beauchesne et al. 2007). In Alberta, its abundance in short-grass prairies increased as distance to crop edge increased. Maximum abundance occurred 2.97 km from crop edges and abundance was 25% of maximum at 0.79 km. It did not avoid roads nor was it attracted to them. Abundance increased with distance to wetlands, indicating that wetlands were avoided. Vegetation density increased near wetlands and croplands and this may have been a factor in their avoidance (Sliwinski and Koper 2012).

The Northern Horned Lark, which nests along the northern coast of Ontario and areas much further north, prefers rocky barrens and sparsely vegetated tundra. It tends to nest in drier upland

areas of tundra, particularly dry sand and gravel ridges which are preferred habitat along the western James Bay coast. Further north, it nests on dry ridges as well as on dry, coastal slopes; on mountain tops, even if they are highly exposed to wind and cold; on old beach lines; in outwash plains; on barren points and islands; in dry meadows; and on areas of bare granite with scattered mosses and lichens. On Bylot Island, it nested in the most exposed areas of uplands that were almost devoid of vegetation. Territories were on hilltops, ridges, old beaches, or frost-heaved areas where most of the surface was gravel. All nests were in the first places that were free of snow in spring. Even in these habitats, it often prefers disturbed areas, nesting near roads through tundra which are used for dusting, roosting, singing, and establishment of territorial boundaries (Bent 1942; Cannings and Threlfall 1981; Drury 1961; Jehl and Smith 1970; Maher 1980; Manning 1952, 1981; Manning and MacPherson 1952; Parmelee et al. 1967; Pelletier in Gauthier and Aubry 1996; Sinclair et al. 2003).

At night, the Horned Lark may dig roost holes and rest in them. In California, this appeared to be a response to cold by desert-nesting birds, with roosts dug at temperatures as high as 10°C. Roosts were often behind vegetation protecting birds from prevailing winds. Roost holes are just large enough (8 x 5 x 4 cm) for a lark to sit with its back almost level with the ground. In areas of soft soil, a new roost may be dug every night but roosts may be used for longer periods in harder soil. Small groups may occasionally roost within a 10-m circle; in 1 instance, there were 5 holes in a 20-cm wide depression (McAtee 1905; Trost 1972).

Ontario nests were on the ground in bare areas, stubble, or short grasses. They were in well-drained, flat areas or on slight slopes or elevations. Most were in depressions dug by the adult, but one was in a horse hoof-track and another was in the centre of a cow chip. Most nests are unconcealed; one was at the base of a tuft of grass, another had a clump of dead grass hanging over it. Some nests were beside a plant, grass clump, shrub, a boulder, driftwood, a person's cap, or a clod of earth. One nest was on a railroad and passed over by a train at least twice a day (Peck and James 1987, 1997).

Other North American nests were similar to those reported in Ontario. The female digs a depression for the nest, usually where the soil is very dry. Occasionally nests are in natural depressions such as cattle hoof-prints, cart ruts, and holes made by dislodged stones. Excavated dirt may be thrown out on 1 side and is often covered with mud pellets, small stones, wheat stubble, cornstalks, corncobs, cow dung, and plant rootlets, apparently in an effort to disguise the diggings. Most nests are protected from the prevailing wind by a tuft of grass, rock, earthen clod, or piece of dead wood. Nests have also been built under stones, large tin cans, boards, and pieces of tarred paper. In Colorado, vegetation offered no protection from wind at many nests and they were almost completely exposed to the sun 55% of the day. Forty percent were adjacent to cow pats and wind velocity within the nest was an order of magnitude less than ambient conditions. High exposure to sun may be beneficial early in the nesting season. At low latitudes, the need for shade results in a preference for northward orientation, mid-latitude nests are oriented predominantly eastward to obtain morning sun and shade in the afternoon, and high altitude nests tend to be oriented southward for maximum warmth all day (Beason 2020; Beason and Franks 1974; Bent 1942; Bowles 1900; Burton 2007; Campbell et al. 1997; Cannings and Threlfall 1981; de Zwaan and Martin 2018; DuBois 1935; Mousley 1916b; Sutton 1927; Verbeek 1967; With and Webb 1993).

Males establish territories upon arrival in spring and defend them until young leave the nest, including the time required to raise more than 1 brood. Birds may occasionally fly outside the territory to feed in neutral areas. Early territories are large then decrease in size as additional birds arrive. When a territorial male disappears and is replaced, territorial disputes heighten for about a week until the newcomer becomes established; final boundaries in these areas are usually similar to initial boundaries. Territory sizes vary depending on habitat type and quality and density of breeding birds. Territory sizes were 0.6-3.1 ha (average 1.6 ha) in Midwest agricultural areas, 0.3-1.4 ha in Colorado shortgrass prairie, 2.3-5.1 ha in heath habitat in Newfoundland (average 3.5 ha), l.5 ha in Wyoming, 0.6-0.8 ha in very disturbed upland tundra at Rankin Inlet and 1.2-2.4 ha in undisturbed tundra, 1.3-2.7 ha in Oregon, 4.9 ha in Kansas, 0.4-1.2 ha on Victoria Island, 0.8 ha in burned grassland in Illinois, and 0.8-6.0 ha in a grain field in New York (Beason 2020; Beason and Franks 1974; Cannings and Threlfall 1981; Fitch 1958; Maher 1980; Parmelee et al. 1967; Pelletier in Gauthier and Aubry 1996; Pickwell in Bent 1942; Verbeek 1967; Wiens et al. 1986).

Camfield et al. (2007) reported that 25% of nestlings banded in British Columbia returned the following year. In Colorado, 6 of 136 juveniles (4.4%) returned to breed (Dinkins et al. 2002).

Adults exhibit strong site tenacity. In Colorado, 65% of a population returned to the same territory, half to the same mate. In British Columbia, 80% of adults returned the following year. Birds on an Illinois golf course continued to nest after it was converted into house lots. They first nested on the stripped lots, then on streetways, then on old sand hazards, and finally on adjacent vegetable gardens until succession crowded them out. A Pennsylvania pair used the same territory several years in a row although road construction for urban expansion reduced its territory to less than 0.4 ha (Beason 2020; Camfield et al. 2007; Pelletier in Gauthier and Aubry 1996; Pickwell in Bent 1942).

Limiting Factors

Eggs have been found in Ontario nests from the last week of March until mid-July, with most present from mid-April until the end of May (Peck and James 1997). Nesting may be initiated when the mean temperature rises above 4.4°C. It takes 1 or 2 days to dig the nest cavity and another 2-4 days to build the nest. The first egg may be laid almost as soon as the nest is complete, or as long as 10-16 days may elapse before the first egg is laid. One female built 2 nests simultaneously. She used one, then finished the other nest and raised her second brood in it. One egg is laid per day, but on Victoria Island, the fifth egg was laid 3 or more days after the fourth. Incubation begins with laying of the last, but occasionally penultimate, egg. The incubation period of Ontario nests was 10-13 days, with 10-14 days reported elsewhere; 11 days appears typical. In most nests, all young hatch in the same day, but hatching may extend over 2 or rarely 3 days when incubation starts with the penultimate egg. Young leave the nest before they can fly at age 8-12 days, mostly 10 or 11 days (Beason 1984; Beason and Franks 1973, 1974; Campbell et al. 1997; Cannings and Threlfall 1981; Drury 1961; DuBois 1935; Maher 1980; Parmelee et al. 1967; Peck and James 1987; Pickwell in Bent 1942; Verbeek 1967; With and Webb 1993).

Egg dates in Ontario and Quebec suggest double brooding, but this has yet to be confirmed. In most locations, the Horned Lark raises 2 broods annually, and possibly 3 in southern areas. Only 1 brood is laid at high altitudes in Wyoming in the north. On Victoria Island, egg dates suggested some double broods; double broods have been documented in the more northern areas of British

Columbia. Renesting is common if a clutch is lost, often within 2 days in the south and in 4-8 days in Newfoundland. In Quebec, the cavity for a second nest was excavated the day after the first clutch was collected. Second clutches are initiated 4-7 days after successful nests. Clutches of 2-6 eggs have been reported in Ontario, mostly 3 or 4 eggs. Clutch sizes may increase northward, with mean clutch size of 2.5 eggs in British Columbia, 3.3 in Newfoundland, and 3.5 in the Northwest Territories. On Victoria Island, almost all clutches had 5 eggs, occasionally 4 or 6. In Washington, almost all clutches contained 2 or 3 eggs, with 4-egg clutches rare. There is 1 record of an 8-egg clutch. Later clutches tend to be larger. In Washington, most early nests contained 2 eggs compared with 3 for later nests. In Newfoundland, mean clutch was 3.0 eggs in nests initiated prior to mid-June and 3.5 for later nests. Of birds that made more than 1 nesting attempt, the first clutch was typically 3 eggs and the second 4 eggs. In Illinois, successive clutches of 1 female contained 3, 3, and 4 eggs. Saskatchewan clutch sizes decreased nonsignificantly as the season progressed (Beason 2020; Beason and Franks 1974; Bent 1942; Bowles 1900; Camfield et al. 2007; Campbell et al. 1997; Cannings and Threlfall 1981; DuBois 1935; Gaudet et al. 2020; Maher 1980; Mousley 1916b; Parmelee et al. 1967; Peck and James 1987, 1997; Pelletier in Gauthier and Aubry 1996; Sutton 1927; Verbeek 1967; With and Webb 1993).

The age at first breeding is 1 year, with nestlings and juveniles returning to breed in British Columbia and Colorado (Camfield et al. 2007; Dinkins et al. 2002). Once a bird has initiated breeding, it nests every year. The Horned Lark is at least seasonally monogamous, and some pairs may reunite in subsequent years. If a mate dies or disappears, a new mate is accepted. If a male dies, the neighbouring male may increase his territory and mate with the widow as well (Beason 2020; Beason and Franks 1974). Camfield et al. (2007) reported a case of a female pairing with a male she had raised the previous year.

The Horned Lark obtains almost all its food by walking in bare agricultural fields and short vegetation. In spring and winter, it may frequent roadsides when fields are snow-covered. Almost 95% of foraging time is in snow-free areas, especially in dry areas (63.7%). In Washington alpine communities, it foraged mostly in snow-free areas that were sparsely vegetated. Occasionally, updrafts from lower elevations deposited arthropods on snow where they were more conspicuous and possibly partially immobilized by colder temperatures. In these circumstances, larks foraged on snow, but usually briefly in the afternoon. It gleans most food from the ground, but may dig up larvae and worms with its beak and pry cutworms out of weed clumps or bases of corn stalks. Occasionally, it perches on a short plant to eat seeds. Adults are skilled at chasing and catching insects as they are flushed in front of the walking bird. Occasionally, it flies after moths and other insects in a manner similar to a flycatcher (Beason 2020; Cannings and Threlfall 1981; McAtee 1905; Norvell and Creighton 1990).

Very early in the season, nestlings may be fed some weed seeds, but most food brought is animal material. The diet of nestlings typically consists of about 80% animals. By May, virtually all food brought to the young is animal matter. Vegetation eaten by nestlings included wheat and seeds of green foxtail, amaranth, and wood-sorrel. Animal foods included beetles (weevils, scarab, leaf, June, and pill beetles, and click and ground beetle larvae), grasshoppers, lepidopteran larvae and pupae, leaf bugs, spiders, ant-lions, and centipedes. About half of nestlings' food in May in

Saskatchewan consisted of lepidopterans, and 77% of these were caterpillars. Later in the nesting season, grasshoppers are the dominant food item. Fledglings are largely vegetarian and eat little animal food (about 10%) August through October when it is most abundant. At the same time, adults feed predominantly on insects. It is probable that fledglings are not sufficiently skilled to catch many insects (Beason 2020; Cannings and Threlfall 1981; McAtee 1905; Pickwell in Bent 1942; Verbeek 1967).

McAtee (1905) examined 1,154 stomachs taken in all seasons, including birds from Ontario. He also reviewed a study that looked at 59 stomachs in 1892. These 2 studies were undertaken in agricultural areas and are not representative of the diet of the Northern Horned Lark. The diet consisted of 20% animal food and 80% vegetable matter, compared with 11% and 90% respectively in 1892. In January and February, animal foods comprised only 1.7% and 31% of the diet, mostly weevils and moth cocoons. Animal food increased to 15.7% and 27.3% in March and April, with increasing numbers of weevils, caterpillars, and bugs consumed, as well as some beetle larvae and leaf beetles. By May, animal food totalled 43.4% with important groups being weevils, June beetles, caterpillars, and grasshoppers. Adult consumption of insects increased from June through August due to the abundance of weevils and grasshoppers but, after August, animal food use declined rapidly to about 1% by December. The animal food was entirely invertebrates and mostly insects. It included beetles, butterflies, moths, grasshoppers, ants, spiders, flies, wasps, millipedes, mites, centipedes, snails, earthworms, termites, bugs, and ant-lions. The stomachs contained 105 plant species, including more than 90 species of grass and weed seeds. Grain comprised 12.2% of food, mainly oats, corn, and wheat. Corn was eaten almost exclusively in winter. The Horned Lark cannot eat entire kernels so depends on livestock or vehicle tires to crush them. Most grains consumed were waste in stubble fields and eaten from September to January. Other grain seeds eaten included those of buckwheat, sorghum, and millet. Weed seeds comprised 63.9% of food items with dominant species being foxtails, smartweeds, amaranths, purslane, ragweed, crabgrass, barnyard grass, and sedges. Grass and sedge seeds comprised 26.2% of the diet. It also consumed seeds of black mustard, wild radish, chickweeds, knapweeds, sunflowers, dandelions, hoary vervain, nightshade, corn cockle, pokeweed, and lamb's-quarters. Miscellaneous plant foods included bits of grass roots and stems, a few flowers, and algae. Fruit constituted only 0.2% of the diet and larks may have consumed only the seeds: blackberries, pears, and cherries. A considerable amount of gravel was consumed, probably to enhance digestion. Beal and McAtee (1912) reported similar findings. In Colorado, it pulled up and ate sprouting crops such as lettuce, wheat, milo, and oats (Beason 2020).

Wiens and Rotenberry (1979) and Rotenberry (1980) determined that the Horned Lark and other grassland species (Upland Sandpiper, Grasshopper Sparrow, Dickcissel, and Eastern and Western meadowlarks) ate much the same things at the same time. The same species collected at different times ate different things. There were no significant differences in the size of food items consumed by the species. The Horned Lark had the broadest diet composition niche of all the species. Food resources were not limiting to these species and individuals and populations exploited the food resources opportunistically without competition. Except in August, all Horned Lark samples collected during the breeding season contained at least 70% arthropods. In autumn, seeds constituted 60-70% of the diet and this proportion increased to 80-100% in winter. Grass seeds

increased in abundance in the diet between February and March and remained at a high level through October. In January, forb seeds constituted almost all the diet. The shift in seeds appeared to be related directly to availability. The major arthropod prey, beetles and especially weevils, were common spring through summer and grasshoppers became abundant in the environment and diet from the warmer parts of the summer into autumn. At some sites, ground beetles and caterpillars were important in the diet. The most important seeds in the diet were those of grasses, followed by those in the goosefoot and mustard families. Hymenopterans, bugs, flies, and neuropterans were also consumed.

Fewer data are available on the diet of northern adults. In Newfoundland, the Horned Lark ate more seeds, berries, and small leaves than nestlings early in the season. Food included small cranberries, crowberries, large ants, moth caterpillars and adults, beetles, crane flies, and spiders (Cannings and Threlfall 1981). In Labrador, the diet consisted of 52% animal matter. Adult and larvae geometer and owlet moths comprised 27.3% of the diet; large ants 7.0%; other hymenopterans, including ichneumonid wasps 5.7%; flies 4.3%; spiders 3.3%; leafhoppers, aphids, and other bugs 2.7%; and 1.7% small molluscs. Of the 48% vegetable diet, fruits and seeds of blueberries totalled 31.7%; the rest was sedge seeds and vegetable debris (Bent 1942). The latter 2 studies are probably characteristic of the diet of birds nesting along the Ontario Hudson and James Bay coasts; the other studies are probably representative of southern Ontario breeders.

The Horned Lark is rarely parasitized by the Brown-headed Cowbird. First clutches are laid well before cowbirds initiate egg laying. Lark eggs hatch as soon or sooner than cowbird eggs and larks develop quicker so that young cowbirds are often left behind in the nest. Successful parasitism does occur. The highest rate of parasitism was in the central prairies where nests may fledge 2 cowbirds. In Kansas, an average of 0.5 cowbird young fledged per parasitized nest. Lark fledging success was 0.7 per nest in parasitized nests compared with 1.4 in unparasitized nests. In Ontario, 4 of 185 nests (2.2%) were parasitized. In North Dakota, 5 of 25 nests (20.0%) were parasitized; in Wyoming, 0 of 140 nests were parasitized; in British Columbia, 0 of 115 nests were parasitized; and 0 of 163 Saskatchewan nests were parasitized. In North Dakota, 50 of 84 nests (59.5%) found after 15 May were parasitized; no nests found before 15 May were parasitized (Beason 2020; Campbell et al. 1997; Dinkins et al. 2002; Igl and Johnson 2007; Leighton et al. 2002; Lowther 1985, 1991, 1997; Mahoney and Chalfoun 2016; Peck and James 1997; Pickwell in Bent 1942).

Habitat loss and degradation is not a problem for birds along the northern coast. Prior to conversion of forested lands to agriculture, the Horned Lark was absent in southern Ontario. Habitat for it is currently declining in the south due to abandonment of farmland and conversion to residential areas. Some agricultural practices may also be detrimental. Modern machinery is able to get on the land earlier in spring so that first nests may be lost. It has been estimated that 138,000 young are killed annually across Canada due to direct effects of agriculture, including approximately 12,000 in Ontario. Mortality rates for the Horned Lark were lower than for other species because it completes its nesting cycle before crops are harvested. Most mortality is associated with tilling and seeding. Until the early 1900s, wheat was sown by broadcasting and larks often ate a high proportion of the seed. In some areas, poisoned wheat was sown first to kill the larks before sowing the final crop. Once seed drilling was initiated, birds could not access the seeds and poisoning was

terminated. Modern-day use of insecticides may reduce food availability and there are isolated reports of it being killed by carbofuran and fenthion (Beason 2020; Beason and Franks 1974; Hussell in Cadman et al. 1987; McAtee 1905; Pelletier in Gauthier and Aubry 1996; Tews et al. 2013).

In Alberta, the Horned Lark was the only species that used cultivated land to any degree. It occurred on cultivated and grazed plots only and was absent in undisturbed grasslands and mowed areas. On roadside counts, it occurred at all land uses and its occurrence was significantly higher at cultivated and grazed stops than at undisturbed sites. It benefits from agricultural activities that create its preferred barren conditions (Owens and Myers 1973). In Saskatchewan, it was more abundant in nonnative crested wheat grass than in native grasslands. Crested wheat grass cover can have twice as much bare ground as native mixed-grass prairie, thereby enhancing habitat conditions (Sutter and Brigham 1998).

Density in eastern Colorado was higher in a drought year than a wet year and similar results were reported for 4 prairie states. Densities declined during a severe drought in North Dakota. Niemuth et al. (2008) analyzed Horned Lark density in relation to the number of ponds present in a North Dakota study area over a 25-year period with extremes from severe drought to very wet conditions. It was more abundant in drier than wetter conditions. In North and South Dakota, Montana, and Wyoming, its abundance was not significant correlated with the amount of precipitation received in the current or previous year (Gorzo et al. 2016). In Colorado, survival was lower on very hot days (35°C or higher), following storm events, and on dry days with a lag period of 1 day. Survival rates were lower during warmer and drier breeding seasons. Projected climate changes may exacerbate these effects (Conrey et al. 2016). Nest survival rates tended to decline with increasing temperatures in Saskatchewan; nests are almost fully exposed to the sun at midday (Gaudet et al. 2020).

The Horned Lark responds positively to grazing. Heavily grazed areas are preferred to those that are lightly or moderately grazed (Dinkins et al. 2002). Grazing reduces the height and density of grass cover, making habitat more favourable.

Applications of toxaphene can be lethal to nestlings and density of the Horned Lark may decrease after spraying this chemical. Malathion and carbaryl do not appear to cause adverse effects. It may be adversely affected by fenitrothian, diazinon, fenthion, and chloropyrfos. In Ontario cornfields, numbers did not change after spraying with fonofos and terbofos to control rootworms (Dinkins et al. 2002).

The Horned Lark appeared to exhibit an aversion to roads and interstate highways in Illinois. Densities increased with distance from roads or highways (Dinkins et al. 2002). In Saskatchewan, it was equally abundant along roads and trails, although it tended to be more abundant along trails (Sutter et al. 2000).

In Wyoming, reproductive success was not lower at wind farms than at reference sites as measured by clutch size, number of fledglings, nestling mass, or daily nest survival rate. There was weak evidence of a higher average number of fledglings per successful nest at wind farms than reference sites. Within wind farms, clutch size and number of fledglings were not related to any development, nest-site habitat, or neighbourhood habitat characteristics. Horned Larks did not

avoid turbines, nesting an average of 185 m from them (range 4-490 m). Nestling mass was weakly negatively related to turbine density within 5 km and, in 1 of 2 years, nest survival decreased as turbine density increased. Turbine densities at scales of 1-5 km were the most informative models suggesting that intensity of development may have a greater influence on productivity than proximity to turbines (Mahoney and Chalfoun 2016).

The Horned Lark usually responds well to fire, especially if it reduces coverage of shrubs and grasses (Earnst et al. 2009). In Arizona, it increased in both native and nonnative grasslands after a wildfire and was more common on burned than unburned plots for 2-3 years after the fire (Bock and Bock 1992). Fire probably has the most important effect in western shrubsteppe communities and may not be particularly important in Ontario.

Spring snowstorms or heavy rainfall may result in nest loss. In Newfoundland, a severe mid-June storm destroyed all 3 nests with young and 4 of 5 nests with eggs were deserted (Cannings and Threlfall 1981). Pickwell (in Bent 1942) reported that late March snows disrupted all territories in 1 area. A period of deep snow resulted in abandonment of all nests. Renesting occurred 3 weeks later when conditions became suitable again. Seven cm or more of snow lasting 2 or more days would destroy a nest. MacDonald et al. (2013) determined that females occasionally took extended recesses from incubation of 59-387 minutes duration during inclement weather, compared with an average of 10.9 minutes for normal recesses. Extended recesses appeared to affect embryo viability. Hatching rate was 91% for nests where females did not take extended recesses and 81% where they did. Extended recesses may be an important mechanism that allows females to breed successfully under adverse weather conditions. In alpine areas of British Columbia, daily nest survival rates were not influenced by temperature alone or by single or cumulative days with more than 1 mm of precipitation. An interaction between temperature and precipitation resulted in much higher nest failure during cold storms than during storms with warmer temperatures (Martin et al. 2017).

The response of nesting females to human intruders varies. Birds that elect to nest near human activity become habituated and may be approached to within 40 cm before they leave the nest. Away from activity, birds may walk or fly from the nest when a human is 25 m to more than 100 m distant. In 1 case, an observer stood between a female and her nest. The female laid an egg on the ground rather than risk exposing the nest by returning to it (Beason 2020; Beason and Franks 1974; Pickwell in Bent 1942; Wackenhut et al. 1983).

The Horned Lark is vulnerable to being struck by aircraft at airports, and it is the most commonly reported aviation bird strike victim in the United States (Beauchesne et al. 2007). It nested in the gravel and grasses immediately adjacent to runways at Lester B. Pearson International Airport in Toronto (personal observation), and its habit of making high courtship flights may increase the risk of being struck by aircraft (Beauchesne et al. 2007).

Dinkins et al. (2002) offered management recommendations for the Horned Lark. These included burning in the spring to reduce woody species; burning, mowing, or grazing to create short sparse vegetation; controlling shrub growth by mowing or grazing; and using only rapidly degrading chemicals of low toxicity and applying them at the lowest possible rate.

Price (2004) predicted that the range of the Horned Lake might expand in southern Ontario if the average summer temperature increased by 2°C. The area of suitable climate in Alberta was anticipated to increase due to a northward expansion and no losses in the south (Nixon et al. 2016).

Status

McIlwraith (1894) stated the Northern Horned Lark was an abundant breeder around Hudson Bay and James (1991) considered it a common breeder along the northern coast. The Prairie Horned Lark was absent in Ontario and North America east of the Mississippi Valley prior to forest clearing by European settlers. Historically, it bred in tallgrass prairies of Illinois, Wisconsin, Minnesota, Iowa, Missouri, Kansas, the Dakotas, Nebraska, and Manitoba. Clearing for agriculture created ideal habitat and it rapidly spread eastward starting in the 1870s. McIlwraith (1894) reported its first occurrence in the province in 1868, stating that it increased annually and was well established as a breeder. By the turn of the 20th century, it appeared as a breeding bird in the Kingston area and spread as far east as Montreal about the same time. By the mid-1930s, it was a common breeder in agricultural areas north to southern Kenora and Sudbury districts and the Ottawa area. It was also common along the western coast of James Bay north to Cape Henrietta Maria and northwestward to the Manitoba border. It has never been very common on the Clay Belt (Baillie and Harrington 1937; Hurley and Franks 1976; Pelletier in Gauthier and Aubry 1996; Pickwell in Bent 1946; Smith 1957). James (1991) considered the Horned Lark a common breeder along the northern coast and in the agricultural south, but rare and local in the Canadian Shield in southern Ontario, in agricultural areas from Sudbury to North Bay and north to the Clay Belt, and in western Rainy River District. It was apparently an abundant breeder in Muskoka and Parry Sound districts in the early 1900s, but there are now only scattered records from this area, probably due to forest regeneration (Hussell in Cadman et al. 2007).

The breeding range of the Horned Lark did not change significantly between atlases, but its probability of observation declined significantly. Declines were significant province-wide, south of the Shield, and in the Great Lakes–St. Lawrence Forest Region in the Shield. The greatest decline was in the southern Shield, and its distribution was greatly reduced on Manitoulin Island. Declines are similar to the trends observed during the first atlas and are probably related to habitat loss due to natural succession and reforestation of marginal farmlands. The northern population along the Hudson and James bay coasts, as well as scattered populations in the Clay Belt and Rainy River District, remained unchanged between atlases. It was most abundant in the agricultural areas of Huron, Lambton, Middlesex, Chatham-Kent, and Essex counties. Another area of high concentration was at Cape Henrietta Maria (Hussell in Cadman et al. 2007).

Population increases in eastern North America were dramatic in the late 19th century until at least the mid-20th century or possibly to almost the end of the 20th century. The only quantitative data are from studies in the first and sixth decades of the 20th century in Illinois. No other bird species increased as dramatically in the state during this period. In June 1909, the Illinois population was estimated at 842,000 birds compared with 5.6 million in 1957 and 4.8 million in 1958. In the last quarter of the 20th century, populations appeared stable, but began to decline in the early 21st century. The increase in the mid-1950s was attributed to the Horned Lark's adaptability to nest within corn and soybean fields. Occupancy in these crops is still 100% in that state, but numbers

nesting in fields have declined. Early planting of crops is thought to be contributing to the decline (Beason 2020; Graber and Graber 1963; Walk et al. 2011).

The long-term (1970-2021) population trends determined by the Breeding Bird Survey (BBS) were annual decreases of 4.33% in Canada and 3.04% in Ontario; the short-term (2011-21) trends were annual decreases of 5.84% in Canada and 6.07% in Ontario. The long-term results were highly reliable; the short-term results were of medium reliability (A.C. Smith et al. 2023). The BBS does not sample the population of Horned Larks that breeds in the Hudson Bay Lowland and the Tundra Region.

POSTFLEDGING PERIOD

Young are fed for a week or more in the territory after leaving the nest and can usually fly when they are about 2 weeks old. They are independent at age 3 or 4 weeks, when juveniles start to flock together. These flocks continue to grow through summer and autumn and adults join the juvenile flocks in August and September (Beason 2020; Pickwell in Bent 1942; Sutton 1924).

MIGRATION

Birds along the northern coast and further north are migratory; most of Ontario's wintering birds belong to this population, although a few Prairie Horned Larks may remain all winter. Southern Ontario breeders tend to move southward for December and January (Beason 2020; Pickwell in Bent 1942).

The Horned Lark is a very early spring migrant, returning in February or early March in the south and late April in Algonquin Park. Males usually return a few to 12 days before females and establish a territory; occasionally birds arrive paired. Pairing occurs immediately upon arrival of the females. At the same time, unpaired northern birds are arriving and continuing northward (Beason 2020; Curry 2006; Tozer 2012). Manning (1952) thought that most birds he saw feeding in flocks along the shores of western James Bay and the southern Hudson Bay coast in May and June were migrants.

On Victoria Island and the Twin Islands, autumn migration starts by September (Manning 1981; Parmelee et al. 1967). Manning (1952) stated that the Horned Lark arrived in numbers in the Moose River estuary on 1 October and it is common to abundant by early September throughout the Hudson Bay Lowland (Wilson and McRae 1993). In the south, migration may extend until late October and November (Curry 2006; Weir 2008).

When the Horned Lark first arrives in spring, it is most common in agricultural fields and along roads. It may concentrate along roads until snow melts from fields. In the south, it inhabits areas similar to those used during the breeding season while it is migrating, but may make greater use of areas such as beaches, sand dunes, airfields, grassy meadows, and overgrazed meadows (Beason 2020; Campbell et al. 1997; Pickwell in Bent 1942; Weir 2008). While staging for autumn migration on the Twin Islands, it was common inland where vegetation was short and dry, but more numerous near the shore at the edge of tundra and on sand beaches (Manning 1981). In the Yukon, open habitats are used during migration, particularly sparsely vegetated areas such as mudflats, open fields, dry tundra, and roadsides (Sinclair et al. 2003).

On Victoria Island, Parmelee et al. (1967) banded a male in September 1962 and recovered it at the same spot in May 1966. It is uncertain if this is an example of breeding site fidelity or migration site fidelity.

Manning (1952) considered the Horned Lark an abundant autumn migrant along the James and Hudson bay coasts of Ontario. James (1991) termed it a common to abundant migrant in the province.

WINTER

Winter habitat is similar to that of other seasons, although the Horned Lark may rely on agricultural fields even more in winter. Roadsides are important habitat when fields are snow-covered. It is nonterritorial in winter, so large flocks may occur. On the prairies, it is most abundant where winter wheat and sorghum are grown. Other anthropogenic areas may be used when there is no snow cover, such as golf courses, airports, and pastures. In Illinois, habitats in order of preference in 1906 and 1907 were corn stubble, pasture, small grain stubble, and wheat. Fifty years later, preferred habitats were bean stubble, alfalfa, and mechanically picked cornfields. During the earlier period, most corn was hand-picked and stalks were left standing; this habitat was unused (Beason 2020; Graber and Graber 1963; Root 1988; Sutton 1927). In New York, it was more likely to be detected in fields with soybean and corn stubble than those with grass cover. It was also more likely to occur in larger fields, with its probability of occurrence increasing with field size for all 3 cover types. Probability of detection in corn and soybean fields was 15-20% in 3.2-ha fields and gradually increased to 75-80% in 17.4-ha fields. In grassy fields, the probability of detection was 5% in 3.2-ha fields and 40% in 17.4-ha fields. Larks were absent in fields smaller than 3.2 ha. Its probability of occurrence increased with increasing amounts of open habitat within 500 m (Rosenblatt and Bonter 2018).

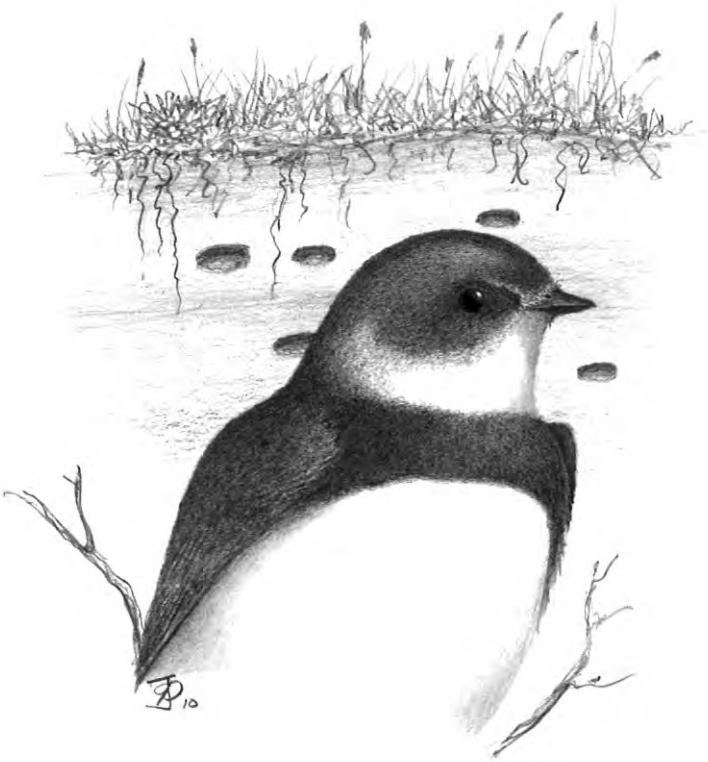
In winter, almost all food is plant material. The Horned Lark consumes waste grain and seeds of forage plants in fields, sedges, grasses, mallows, ragweed, witch grass, foxtails, amaranths, and numerous other weeds. Some dried fruits or berries may be eaten and possibly some insects in dormant phases. It feeds in farmyards and feedlots and, when horses were more common, fed on oats in their droppings along roads (Bent 1942; Pickwell in Bent 1942). It will come to winter bird feeders situated near agricultural fields where it feeds on the ground on mixed seeds (personal observation).

Prior to forest clearing, the Horned Lark was undoubtedly rare or even absent in winter. When McIlwraith (1894) first observed it circa 1869, it was a rare winter visitor. James (1991) considered it an uncommon winter resident in the south, north to Manitoulin Island.

On southern Ontario Christmas Bird Counts (CBC), Freedman and Riley (1980) noted a pronounced but erratic increase since 1959, prior to which it was rarely documented. From 1970-2021, CBC results indicate that the Ontario population was stable, increasing at an annual rate of 0.06%; from 2009-21, it decreased 8.67% annually (National Audubon Society 2022).

Bank Swallow

Riparia riparia



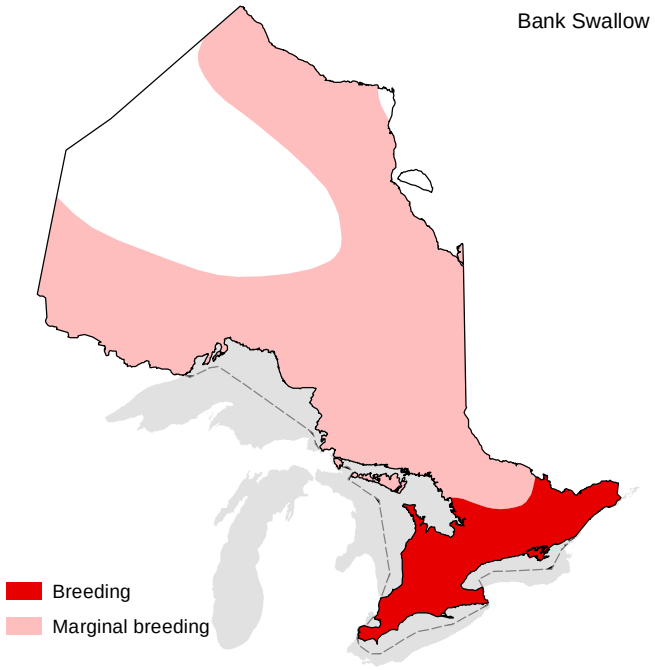
BREEDING SEASON

Habitat Requirements

Breeding habitats of Ontario Bank Swallows were roadside banks (24.8% of records); banks of rivers, streams, lakes, and lagoons (23.6%); farm pastures and fields (20.4%); wooded areas (14.7%); dunes, bluffs, and eskers (8.1%); earth, sand, and gravel cuts, piles, and pits (3.9%); rural and suburban sawmills and parking lots (2.2%); small islands (1.6%); and marsh and swamp edges (0.8%). Some of the descriptions are not a true reflection of the nesting area (Peck and James 1987).

Occupancy rates of lakeshore bluffs (63.0%) and aggregate pits (60.0%) by Bank Swallows were similar in southern Ontario. Colonies in pits were smaller (112 burrows) than those in lakeshores (560 burrows). Bluffs averaged 50.5-73.0% sand in lakeshores and pits. Colony size was not a significant predictor of burrow occupancy in lakeshores. Height of burrows and colony size had no effects on burrow occupancy in gravel pits, but burrow occupancy increased in medium and high burrows as colony size increased. Lakeshore colonies had a 100% persistence rate over 5 years but only 32% of aggregate colonies persisted during all 3 years. Colonies in pits were ephemeral, but new colonies were often established in other locations within the same pit. The probability of a pit

colony being used in consecutive years increased with colony size and the size of the available face (Burke et al. 2021).



The Bank Swallow relies on vertical banks for nesting and therefore has a patchy breeding distribution. It is most common in glaciated areas where there are deposits of unconsolidated soils. In these areas, erosion by water and wind may create steep banks that provide suitable nest sites. It is most common in glaciated areas with higher human populations because road and railway cuts, sand and gravel pits and other construction activities provide nesting opportunities. In the Clay Belt, it may nest where glaciation left deltas, raised beaches, kames, and eskers. In the Canadian Shield, it is restricted to shorelines of lakes, streams, and rivers, and where human activities have created steep banks. Natural nest sites include sand dunes and vertical banks along rivers, streams, lakes, and oceans. Anthropogenic sites include sand and gravel pits, road cuts, and piles of soil or other unconsolidated material. Rarely used natural sites include crevices in cliffs; 1 nest was in a dug hole in the ground that measured approximately 3 by 4 m and 3 m deep. Approximately 35% of Ontario and Quebec nests were in natural sites, the lowest for the country. This was attributed to the high human population, but it may be biased because most records are from areas of high human population. Data from 2001-17 indicate that the proportion of Ontario and Quebec nests in natural habitats increased to 50%, with 60.9% of Ontario nests in natural habitat. The increase in use of natural habitats may be due to policies that require slopes to be gentle in pits and road cuts, or to better coverage of natural habitat in more recent studies. A high proportion of nests are near water because waves or flowing water create suitable nesting substrate. Some colonies in human-made habitat are a considerable distance from water. It requires open areas for foraging, so colonies in extensively forested landscapes are associated with large rivers or lakes (Campbell et al. 1997; Champoux and Bombardier in Gauthier and Aubry 1996; Erskine 1979; Garrison and Taylor 2020; Leighton et al. 2002; Pelletier et al. 2022).

Along the Connecticut River, bank length, slope, vegetation cover, and soil type differed between active colony sites and random sites. Banks with colonies were longer, steeper, less vegetated, and had deeper, better-drained soil with fewer coarse fragments than random sites. Vegetation was the best predictor of swallows nesting at a site, but slope and vegetative cover were highly correlated. Banks that had 0-11% vegetative cover had a mean slope of 79°; banks with more than 11% vegetative cover had a mean slope of 56°. Mean slope at colonies was 89° compared with 55° at random sites. The probability of swallows nesting increased with increasing bank length; 82% of swallows nested in banks longer than 150 m. Potential but unused banks were consistently

shorter with more vegetative cover than used banks. Approximately 50% of banks were occupied, suggesting that nest sites may be limited, and this may explain the high persistence rate of colonies in this area (Silver and Griffin 2009).

In southern Ontario, the Bank Swallow was equally abundant on organic and conventional farms. Its presence was significantly associated with pasture and it was also associated with large, isolated trees and grassy strips between fields that often contained fences, but these relationships were not significant. It was significantly negatively associated with habitat heterogeneity. It was also negatively correlated with hay, streams, use of herbicides, and road, railway, and hydro rights-of-way (Kirk et al. 2011). This study was probably recording foraging Bank Swallows rather than nesting birds.

From the start of nest building until the beginning of egg laying, both members of a pair usually roost in the nest burrow. During incubation and brooding, the female roosts in the nest burrow while the male roosts nearby in another burrow or on trees and shrubs until the young are about 12 days old. Birds nesting near Port Burwell routinely flew to marshes at the base of Long Point to roost for the night. Distances between nest sites and nocturnal roosts were as far as 35 km. Some nestlings were as young as 9 days old when 1 or both parents went to roost in the marsh. Some males left the colony every night during the nestling period. Females tended to spend more nights back in the nest roosting. Marsh-roosting birds travelled quickly between the colony and roost sites and did not appear to forage in the vicinity of the marsh (Falconer 2013). Falconer et al. (2016a) radiotagged 11 males and 11 females in the Port Burwell area at 2 nesting colonies 29 and 33.5 km from the Old Cut Marsh at Long Point. Nineteen (86.4%) spent at least 1 night roosting more than 4.5 km from the nest site and 13 (59.1%) spent at least 1 night roosting near Old Cut or further east while their nests were active. The nocturnal roosts appeared to be within marsh habitat. Some males roosted away from the nesting colony every night; others never did. After the nestlings fledged, most adults did not roost overnight at the colony. Females spent more nights at the colony than males, possibly because females brooded the young at night. New Brunswick swallows frequently changed the roosts that they used. Females were less likely to roost communally during the incubation and brooding periods. Both sexes were less likely to roost communally when the nestlings were young and during inclement weather when young need assistance thermoregulating. After nestlings fledged, adults were less likely to roost communally during adverse weather, with the nest cavity providing better protection (Saldanha et al. 2019). Bank Swallows have also been reported roosting at night in agricultural fields as far as 6 km from the nesting colony.

Most Ontario nests were in burrows excavated by the birds. A high proportion of nests were in banks of sand, clay, or earth (60.6%); 37.5% were in sand, gravel, and earth pits; 1.3% were in sand dunes, and 0.7% were in human-made piles of gravel, sand, and sawdust. Three nests were in plastic tubes inserted into banks. Most nests were near the top of banks. Distances below the top of bank at 31 colonies were 0.2-3.0 m, mostly 0.6-0.9 m. Nest heights above water or land were 0.6-45.7 m, mostly 2-4.6 m. Nests were flat platforms in depressions at the end of burrows. Burrow depths of 297 nests ranged from 0.2 to 1.5 m, with most 0.5-0.6 m deep (Peck and James 1987).

Nests tend to be in near-vertical banks with slopes ranging from 76 to 105°. Soil consistency is important in defining nest-site suitability, and it also affects the depths of burrows. Near Ottawa, the Bank Swallow nested only in banks that had sufficient stability to maintain a 3-m vertical face; unused faces had only a 1-1.5-m vertical area above talus. John (1991) conducted soil penetrability tests and found that most nests were in soils with penetrability readings of 8-9 kg compared with less than 6 kg for unused sites. Preferred soils were mostly good quality construction-grade sands. Soils with lower penetrability may result in instability and erosion of the bank. Outside Ontario, nests have been reported in loess, till, clay, sand, and gravel. In California, most colonies were in soft banks: 22.1% in fine sandy loam, 38.4% in loam, and 8.1% in silt loam. The rest were in sand (3.5%), sandy loam (7.0%), clay loam (2.3%), clay (9.3%), and aggregated clay (9.3%). In Atlantic Canada, the Bank Swallow selected sandstone cliffs and, to a lesser extent, till cliffs; it avoided sand dunes for nesting. At a Wisconsin site, all burrows were in sand or sandy loam. Saskatchewan nests were in sand or fine gravels; most British Columbia nests were in silt, clay, or sand. Elsewhere, nests have been in natural cavities in rock cliffs, in sawdust and manure piles, rarely in drain pipes in concrete walls, in coal piles, in iron ore tailings, in granite dust, and once 5 m underground in an abandoned well (Campbell et al. 1997; Champoux and Bombardier in Gauthier and Aubry 1996; Falconer and Badzinski 2013; Garrison et al. 1987; Graber et al. 1972; Greenlaw 1972; Gross in Bent 1942; Knapton 1988a; Petersen 1955; Power et al. 2020).

Height of burrow entrances above ground of 0-38 m were reported from British Columbia, which represent the extremes reported from anywhere; most were 3-8 m above ground. Nest height is highly dependent on the height of available banks. Burrows are typically in the top third of the bank, and burrow density decreases from top to bottom of the slope. In lower banks, colonies may consist of a single row of burrows 30-40 cm from the top of the bank. In Saskatchewan, height and length of vertical banks affected usage by Bank Swallows. The average height of banks with nesting swallows was higher (1.8 m) than banks without swallows (1.4 m). Banks with colonies were significantly longer (30.9 m) than unused banks (21.9 m). Average heights of banks at nesting colonies were 3.2 m in Pennsylvania and Vermont and 3.3 m in California (Campbell et al. 1997; Garrison and Taylor 2020; Greenlaw 1972; Hjertaas et al. 1988).

The Bank Swallow prefers to nest in colonies. It may occasionally nest solitarily, but most nest in colonies. In Ontario, 48 isolated nestings and 200 colonies were reported for a total of about 9,600 nests; 99.5% were in colonies. Ontario colonies contained 2-1,500 pairs; the average size of 99 colonies was 45 nests. A more recent estimate indicated that the mean size of Ontario colonies was 130 nests and the median was 50 nests. Not all burrows in a colony are occupied. Along the Lake Erie shoreline, 57% of burrows were occupied in 2010 and 53% were occupied in 2011. On the Lake Erie bluffs, colonies are nearly continuous and consist of several thousand nests. In British Columbia, colonies contained 3-3,055 burrows; 52% of colonies had 15-75 burrows. In Michigan, 60% of colonies were small with 50 or fewer nests, but 71% of swallows nested in colonies with more than 100 nests, and 47% were in colonies of 200 or more. In Saskatchewan, colonies averaged 7.7 nests with a maximum of 48, but 68% of nests were in colonies of 10 or more nests. One of the largest colonies of 6,000 nests was reported from Illinois. Burrow site selection is affected by the presence of other burrows. Swallows are most likely to burrow in areas that already have high burrow density.

Large portions of uniformly suitable banks may be unused, with nests clustered in 1 area and densities of burrows greater higher up on the bank. Largest colonies are associated with the highest and longest banks (Campbell et al. 1997; Falconer and Badzinski 2013; Falconer et al. 2016b; Garrison and Taylor 2020; Garrison et al. 1987; Graber et al. 1972; Hjertaas et al. 1988; Hoogland and Sherman 1976; Peck and James 1987, 1997; Petersen 1955).

Although it is colonial, the Bank Swallow is territorial. Shortly after arrival, males start digging a burrow to attract a female. Other birds that approach too closely are threatened vocally or physically attacked. Birds burrowing high up in the bank are dominant and spend much less time in defence than those lower on the bank. Once pair formation occurs, both sexes defend the burrow and its immediate vicinity. The territory size is defined by the area that a bird is capable of defending around the burrow. Near Sundridge, tunnel entrances were consistently in a regular pattern supporting the hypothesis that the distance between burrows was determined by territorial disputes. The regular spacing allowed a greater density of nests within a given area, which may be an advantage of nesting colonially (Ghent 2001). In Wisconsin, the minimum distance between burrows was 10 cm, mostly 12.7-17.8 cm apart. In Pennsylvania, burrows were 17.8-43.2 cm apart; mean distance between burrows was 13.2 cm in California (range 1-59 cm). If a male is unsuccessful in attracting a mate to a burrow, he digs another. Consequently as many as 45% of burrows in a colony may be unoccupied. At active nests, the pair defends the burrow and a small area around it early in the nesting season but only the burrow is defended after the eggs hatch (Garrison and Taylor 2020; Garrison et al. 1987; Petersen 1955).

No information on home range size is available, but it is large. In New York, most flights were within 0.8 km of a colony (Garrison and Taylor 2020). It is likely that longer flights occur regularly in some areas, particularly if colonies in sand and gravel pits are distant from good foraging areas.

Many colony sites are short-lived due to slumping or other factors making them unsuitable. Colonies where massive reproductive failure occurred are seldom repopulated and, if they are, it is usually by different birds. Long-term colonies are associated with long, tall banks with regular erosion to maintain the vertical face, and where most birds in the colony have good nesting success. A large colony on the shoreline of Amherst Island in Lake Ontario was used for at least 2 decades and some British Columbia colonies are 18-25 years old. A Virginia colony was used over 30 years and one in Illinois was over 50 years old. In Saskatchewan, where nest banks and colonies are small, only 32% of colonies were used both years of a 2-year study (Blem and Blem 1990; Campbell et al. 1997; Freer 1979; Garrison and Taylor 2020; Graber et al. 1972; Hjertaas et al. 1988; Weir 2008).

Natal philopatry and adult site tenacity rates are variable, due in part to the ephemeral nature of colonies. In New York, return rates were 8.1% for juveniles, 13.4% for adult males, and 13.0% for adult females, for an overall return rate of 12.3%. The lower rate of return for juveniles is probably related to their higher mortality (80% in the first year). Of returning juveniles, 15 returned to the same colony and 18 moved to a nearby colony. Only 3% of females returned to or near their natal site compared with 12.5% for males. Site fidelity increases with age. In New York, 67% of birds captured on their first return were in the colony where they were first captured, 73% of those captured twice were in the same location where they were last trapped, and all birds returning for the third and fourth time returned to the same location. There was no difference in return rates of adult males

and females. Two-year return rates at a colony where most nests were successful were 19% and 15% compared with 3% and 1% at less successful colonies. In Virginia, 10 of 262 adults (3.8%) returned to the same colony. when this site became unsuitable, 1 bird nested at a nearby site. Return rates documented in other areas are: 50% of yearlings in Wisconsin, 46% of yearlings in New York, 4.4% of adults and 1.1% of young in Iowa and New York, 4.6% of adults in Illinois, 12.5% of adults and 4.8% of young in Connecticut, and 50% of adults and 2.0% of young in Wisconsin. Maximum distances that birds moved when they changed colonies in subsequent years were 15 km in Illinois, 114 km in Wisconsin, and 403 km in Michigan (Blem and Blem 1990; Campbell et al. 1997; Freer 1979; Garrison and Taylor 2020; Graber et al. 1972; Hjertaas et al. 1988; Petersen and Mueller 1979).

In Illinois, 2 of 898 adults (0.2%) were captured at different breeding colonies in the same breeding season. At 7 colonies within a distance of 15 km, 44% of birds changed colonies between years. In Illinois, a colony at a roadside cut was destroyed before any young fledged. None of the adults that nested within this colony were recovered at the nearby 6 colonies, suggesting that they did not attempt to renest. The following year, a new colony was established at the same site. Petersen and Mueller (1979) suggested that the 7 colonies they studied were acting as a regional colony with birds often moving between colonies within the group.

Limiting Factors

Eggs have been reported in Ontario nests from early May until the third week of July, with most present in the first 3 weeks of June. Young were being fed on 13 August in a Grey County nest (Peck and James 1987, 1997). If the weather is favourable upon spring arrival, males initiate tunnel digging almost immediately. In cold or wet springs, burrow construction is delayed until conditions improve. As soon as pairing occurs, both sexes dig using their bills, feet, and wings. It usually takes 4-5 days to complete a burrow, but occasionally as long as 14 days. Burrows at the top of a bank are usually completed in 4-6 days; lower burrows take 6-10 days. Birds lower in the colony must spend considerable time in nest-site defence. Daily excavation rates vary in different substrates: 2.7 cm in gravel, 10.0 cm in coarse compact soil, 8.3 cm in fine compact soil, 12.8 cm in coarse soil with gravel, and 9.4 cm in fine soil. Excavation of the nest chamber requires several days after the burrow reaches its maximum length. The female builds the nest as soon as the chamber is complete, typically taking 1-3 days. Eggs are laid at the rate of 1 a day. Incubation may start with the laying of the third last, penultimate, or last egg. Incubation periods at Ontario nests were 13-16 days, consistent with other reports. It is likely that individual eggs require about 15 days of incubation before they hatch. Hatching of the brood may take place over 2-3 days. Young fledge when they are 18-20 days old; most fledge by mid-July. In Saskatchewan, nesting took an average of 39 days once the burrow and nest were completed: 5 days for laying, 14 days for incubation, and 20 days for the nestling period (Beyer 1938; Falconer et al. 2016b; Garrison and Taylor 2020; Hjertaas et al. 1988; Peck and James 1987; Petersen 1955).

One brood is raised; earlier records of 2 broods appear to be erroneous. Renesting birds occasionally nest in the burrow of a pair that previously fledged young, giving the impression that a pair has raised 2 broods. One instance of 2 broods being produced in a burrow has been documented in Ontario, but it was unknown if the same or different pairs were involved. Replacement clutches are laid if the first clutch is lost in early or mid-season. This may occur in the

same burrow or one recently vacated by another pair. Clutches of 2-7 eggs have been reported in Ontario, with most containing 4-5 eggs. A single clutch of 9 eggs may have been produced by 2 females. Mean clutch size in Ontario was 4.44 eggs compared with 4.09 in Alaska (range 2-6 eggs), 4.87 in Saskatchewan (range 2-7 eggs), 4.98 in Michigan (range 3-8 eggs), and 4.38 in New York (range 2-7 eggs). Nests initiated prior to mid-June have larger clutches and better success rates than later nests. In Saskatchewan, early nests had a mean clutch size of 5.2 eggs compared with 4.3 eggs for later nests; late nests fledged fewer young. Almost all 2-egg clutches and most 3-egg clutches are associated with renesting attempts or late nests (Beyer 1938; Blem and Blem 1990; Campbell et al. 1997; Garrison and Taylor 2020; Gross in Bent 1942; Hjertaas et al. 1988; Hoogland and Sherman 1976; Imlay et al. 2019; Peck and James 1987; Petersen 1955).

Both sexes can breed when they are 1 year old, and they breed every year thereafter. The mating system is monogamous (Garrison and Taylor 2020). Mate guarding is performed by Bank Swallows. For a 7-10-day period after pair formation, the male closely pursues his mate in every flight from the burrow, and this may be as many as 100 times a day. During these flights, the pair is typically chased by 1-5 males seeking extra-pair copulations. Mate guarding appears to be effective because extra-pair copulations are rare (Beecher and Beecher 1979).

Typical foraging habitat during the breeding season is over open meadows and grasslands, but open water and wetlands are used during other periods of the year. During August in Ontario, consistently high numbers foraged in apple orchards but corn and soybean fields were avoided. Forested habitat is avoided while foraging. Grassland is preferred foraging habitat and colonies distant from grasslands are more likely to become extirpated. In California, foraging habitat also included riparian and upland woodlands but these habitats do not appear to be used in Ontario. The Bank Swallow forages almost entirely on flying insects that it captures in the air. Occasionally it may pick dead or moribund insects from the surface of water while it is flying. Rarely, it may land to feed on terrestrial invertebrates when there is a large, localized concentration. At Great Salt Lake in Utah, ground foraging on brine flies was the most commonly observed feeding behaviour. Typically, it forages within 200-500 m of the colony, but may forage several kilometres away on inclement days in spring before egg laying. Birds breeding near Port Burwell foraged less than a few kilometers (usually only a few hundred metres) from the colony, although they occasionally made longer trips. Birds spent most of their time near the breeding colony and were 4 times more likely to be encountered at the colony than 500 m distant from it. Probability of occurrence was approximately 13% 1,000 m from the colony and approximately 5% at 2,000 m. Foraging usually occurs over water, meadows, fields, and pastures, often at heights of 15-33 m, but often very low during inclement weather. Foraging heights may be higher in summer when temperatures are warmer (Anderson-Abbs and Bradbury 2013; Cohen and Dymerski 1986; Falconer 2013; Falconer and Badzinski 2013; Falconer et al. 2016b; Garrison and Taylor 2020; Graber et al. 1972; Paton and Fellows 1994; Petersen 1955; Sinclair et al. 2003).

In Pennsylvania, young were fed small flies, caddisflies, and mayflies almost exclusively by the time they were 6 days old and this continued throughout the nestling period. The diet of nestlings is almost entirely soft-bodied insects that are easy to digest. The diet of 43 young in New York by weight consisted of 33.6% flies, 29.5% beetles, 29.0% bugs, 6.8% hymenopterans, and 1.1%

vegetation. Other insects occurred in insignificant weights in 10.5% of stomachs. Soft-bodied flies comprised about 50% of nestlings' diet when they were young and about 20% later. Hard-bodied beetles comprised about 20% of the nestling diet in June and 40% later. Midges may be important in the diet of Ontario birds. Adults continue to feed young until 3-5 days after they fledge (Beal 1918; Beyer 1938; Falconer 2013; Garrison and Taylor 2020; Petersen 1955).

The diet of more than 300 adults from throughout North America consisted entirely of animal matter, except for 3 seeds found in 3 stomachs that were probably ingested incidentally. With the exception of a few spiders, the diet was comprised of insects. Flies were most important in the diet at 26.6%; these were mostly house flies and crane flies. Beetles constituted 17.9% of the diet, including 5.5% scarab beetles and 5.8% weevils. Ants appeared to be a favourite food, comprising 13.4% of the diet, and the Bank Swallow also ate other hymenopterans, especially parasitic wasps. Leafhoppers, aphids, and treehoppers comprised 8.0% of the diet, and other bugs were also consumed. Dragonflies comprised 2.1% of the diet, lepidopterans 1.2%; grasshoppers were rarely consumed. Other insects constituted 10.5% of the diet, predominantly mayflies. Mayflies were usually eaten early in the season and were important in April when they comprised 43.4% of all food. Consumption of mayflies declined with the season until they were absent in the diet by August. In New York, 21 adults ate 49.8% beetles by weight, 27.6% flies, 13.6% bugs, 3.3% hymenopterans, 4.5% stoneflies, 0.4% spiders, 8.4% other insects, and 0.8% vegetation (Beal 1918; Garrison and Taylor 2020). Those breeding along the bluffs of Lake Erie appear to feed on the abundant emergent midges for at least part of the breeding season; they also prey upon flying ants (Falconer et al. 2016b). The diet of this swallow consists of a relatively low diversity of prey. Nancekivell and Nocera (2025) used DNA to analyze the adult diet in New Brunswick and compared the diet of the Bank Swallow to those of the Alder and Least flycatchers and the Tree, Barn, and Cliff swallows. All species differed in their dietary breadth and prey preferences. The Bank, Tree, and Cliff Swallows ate more aquatic taxa than the other species, which consumed more terrestrial flies. The Bank and Cliff swallows had more restricted diets whereas the other species had broader generalist diets. The approximate frequencies of occurrence of invertebrate groups in the diet of the Bank Swallow were 90% aquatic flies, 10% terrestrial flies, and less than 5% each for lepidopterans, aquatic and terrestrial beetles, and bugs. The approximate frequencies of invertebrate families in the Bank Swallow diet were 60% mosquitoes, 40% midges, 30% limoniid crane flies, 10% long-legged flies, and less than 5% each for marsh beetles and weevils.

There is 1 record outside Ontario of the Bank Swallow being parasitized by the Brown-headed Cowbird. This occurred under unusual circumstances when bank slumping exposed the nest (Garrison and Taylor 2020).

The distribution and abundance of the Bank Swallow is highly dependent on availability of suitable nesting areas. In natural habitats, it requires a combination of complex processes such as hydrology, erosion, sediment deposition, and river migration to provide suitable breeding habitat. Its distribution is very local and sporadic within its general range due to its dependence on sheer banks and the instability of this habitat. It has benefited from human activities that created road cuts and sand and gravel pits. These habitats eventually become unsuitable due to slumping or rehabilitation, or nests may be destroyed in pits due to extraction. New policies on road cuts require

removal of vertical banks and no colonies have been reported in this habitat in Ontario since the 1980s. Human-made slopes and steep banks along watercourses become unsuitable nesting habitat over time. Slopes eventually erode and slump and gradually a talus slope is formed that stabilizes the bank at a gentler slope. When sand and gravel pits are depleted, government agencies typically require that banks be graded to a gentle slope, thereby rendering the site unsuitable for nesting. In many studies, the main cause of breeding failure has been slumping and nest destruction due to erosion or excavation. After a major landslide along the South Nation River in eastern Ontario, 152 burrows were dug in the newly created bank within 8 days. This was on 28 June, late in the breeding season, suggesting that suitable nest sites were limited. Bank stabilization projects along watercourses and the Great Lakes shorelines may permanently eliminate nesting areas, and this has the potential to affect a significant proportion of the breeding population. Many of northern Ontario's rivers have been dammed for hydroelectric generation. These convert flowing water to a series of impoundments that do not provide Bank Swallow habitat. Water-level fluctuations below dams may flood nests or cause erosion during critical periods of the nesting cycle (Bank Swallow Technical Advisory Committee 2013; Blem and Blem 1990; Byer 1938; Campbell et al. 1997; Czerwinski 1996; Falconer 2013; Falconer and Badzinski 2013; Garrison and Taylor 2020; Garrison et al. 1987; Graber et al. 1972; Petersen 1955).

The European Starling and House Sparrow may occasionally appropriate burrows (Garrison and Taylor 2020; Leighton et al. 2002).

Changes in agricultural practices may have been detrimental to the Bank Swallow. Large areas of pasture and hayfields have been converted to row crops or other land uses. Pastures and hayfields provide excellent foraging habitat whereas corn and soybean fields are avoided. There are concerns that it may be affected directly by pesticides or indirectly through a reduction in prey populations, but the actual effects have not been determined (Falconer et al. 2016b).

The Bank Swallow may be parasitized by a number of fleas, mites, and blow flies and these have the potential to reduce productivity. Sites with high flea frequencies are usually not reused in subsequent years (Falconer et al. 2016b).

The Bank Swallow is adversely affected by cold spring weather. Birds may die directly from exposure or indirectly due to low insect availability. In Saskatchewan, 39 were found huddled together but dead during cold weather (Garrison and Taylor 2020).

Bank Swallows frequently dust, often in large numbers, on unpaved roads and roadsides and other areas of exposed soils. This often occurs during the hottest days of summer, suggesting that they are attracted by the heat. Groups may also congregate on paved roads (Graber et al. 1972; Gross in Bent 1942; Petersen 1955). Due to this behaviour, it is frequently killed by vehicles (Gross in Bent 1942). Other Bank Swallows are often attracted to those that have been road-killed, thereby increasing its vulnerability. Dead birds are often found in clusters and flocks may be struck by vehicles (Falconer and Badzinski 2013).

Climate change has the potential to result in a mismatch of timing of insect emergence with the period when nestlings area being fed by the adults (Falconer and Badzinski 2013). Climate change has the potential to result in more frequent and more severe storms. These, coupled with

increased urbanization, lead to higher peak flows in streams during storms thereby increasing the risk of erosion in breeding colonies.

Price (2004) predicted that the Bank Swallow might no longer breed in southern Ontario if the average summer temperature increased by 2°C.

Status

The Bank Swallow appears to have increased in Ontario since European settlement. It was not recorded in the Kingston area in the mid-1800s, but was very common by the turn of the 20th century (Weir 2008). McIlwraith (1894) considered it a common summer resident, breeding throughout the province, and very abundant in the Hamilton area. Sheppard et al. (1936) considered it a very abundant breeder in Niagara Region, nesting in cliffs along the shorelines of Lakes Erie and Ontario and at several locations near Niagara Falls. Baillie and Harrington (1937) stated that it was common but sporadically distributed as a breeding species in the province. Breeding distribution was from the southern border north to Hudson Bay and west to Lake of the Woods, essentially the entire province where suitable nesting areas were present. It was uncommon and not well distributed in the Clay Belt (Smith 1957). During the first atlas, 5,500 pairs were estimated in more than 200 colonies. James (1991) considered the Bank Swallow a locally common breeder in southern agricultural areas and rare in the Canadian Shield and forested areas north to the Hudson Bay coast. In Elgin County, it is an abundant nester in the cliffs along the Lake Erie shoreline. Lancaster et al. (2004) concluded that there were at least tens of thousands nesting along the lake and possibly hundreds of thousands. In 2010 and 2011, Bird Studies Canada surveyed 121 km of the Lake Erie shoreline between Turkey Point and Rondeau Provincial Park and estimated 121,450 individuals in 2010 and 102,250 in 2011 (Anonymous 2011; Falconer and Badzinski 2013). In the 260-km reach between Turkey Point and Point Pelee, the breeding population consisted of more than 100,000 breeding pairs in all 3 years from 2010 to 2012. During this period, numbers fluctuated annually by as much as 30% (Falconer 2013), but from 2010 to 2015 the trend appeared to be stable (Falconer et al. 2016b). Near Port Stanley, almost 100,000 burrows were recorded in 2010 but only 50,000 were present in 2024 (Barlow 2025). Cadman and Lebrun-Southcott (2013) surveyed Bank Swallows along a 14.9-km reach of the Saugeen River near Walkerton from 2009 to 2013. The average number of burrows counted annually was 2,195. There was no significant change in numbers over this period, although there were annual variations as high as 16%. Small colonies appeared and disappeared depending upon the annual suitability of the site, but large colonies were occupied every year. In 2010, 20,500 burrows were reported along the north shore of Lake Ontario, mostly between Ajax and Port Hope. In 27 aggregate pits in Wellington County, 5,300 individuals were counted in 2010; breeding in that county occurred exclusively in pits (Falconer and Badzinski 2013).

The second atlas indicated that the Bank Swallow had declined significantly since the first atlas province-wide and in all regions except the Hudson Bay Lowland. It was most abundant along the Lake Erie shoreline and the Lake Ontario shoreline east of Toronto. Other areas supporting large colonies were the Saugeen and Albany rivers (Sandilands in Cadman et al. 2007). Along the Lake Erie shoreline, the highest breeding density was along the shore of the Norfolk Sand Plain, which includes Long Point westward to Port Stanley (Falconer 2013).

Populations of the Bank Swallow initially increased significantly due to forest clearing and creation of aggregate pits and road cuts, but current trends are uncertain. Most information on trends comes from the Breeding Bird Survey (BBS). BBS results are not very reliable due to the ephemeral nature of colonies and the fact that the BBS samples mostly foraging birds, which may be considerable distances from the nesting colony, and rarely samples actual nesting areas. Long-term (1970-2021) trends determined by the BBS indicate annual decreases of 4.94% in Canada and 6.88% in Ontario. The short-term (2011-21) trends were annual decreases of 0.109% in Canada and 5.97% in Ontario. All trends were of medium reliability except that the Canadian short-term trend was of low reliability (A.C. Smith et al. 2023). Falconer et al. (2016b) acknowledged that the BBS was not well suited to adequately sample colonial birds such as the Bank Swallow.

Cadman and Lebrun-Southcott (2013) noted the disparity in the results of surveys along the Saugeen River and results of the BBS. The Saugeen River population was stable whereas the BBS indicated a precipitous decline. They suggested that removal of steep roadside banks due to changes in highway standards and increased use of berms around aggregate pits might make it more difficult to observe Bank Swallows from roadsides. This would result in a decline in numbers detected by the BBS survey methods. Another possible explanation is the loss of pasturelands and hayfields due to their conversion to row crops. Seeds of row-crop plants are treated with insecticides, so insect biomass in the vicinity of row-crop fields is lower than in most areas. Swallows may be foraging more frequently now in habitats that are infrequently sampled by the BBS. Despite the weaknesses of the BBS in sampling the Bank Swallow, the decline may be real. In Illinois, BBS results indicate an increase in this species (Walk et al. 2011).

More accurate information on the Ontario status of the Bank Swallow is available from surveys of Bank Swallow burrows conducted on Lake Erie, Lake Ontario, along the Saugeen River and other rivers, and in aggregate pits from 2009 to 2014. These data suggest approximately 110,000 individuals along Lake Erie, 20,000 along Lake Ontario, 20,000 along the Saugeen River, and 277,000 in pits and quarries. A conservative estimate of the Ontario population is 409,000 birds, but this excludes estimates from rivers in the Hudson Bay Lowland and miscellaneous habitats such as construction sites. The Hudson Bay Lowland population may be substantial and of provincial significance. Breeding has been recorded along the Severn, Fawn, Winisk, Ekwan, and Moose rivers (Falconer et al. 2016b).

The Bank Swallow is designated threatened in Canada and Ontario. The goal of the recovery strategy for Ontario is to maintain a stable, self-sustaining population of at least 330,000 breeding pairs across the breeding range by 2035. This will require reducing the annual rate of decline by 0.5% for the next 10 years. In the north where there is no targeted monitoring, the short-term goal is to maintain a breeding population distribution across each block by the time of the third atlas in 2021-25 (Falconer et al. 2016b).

POSTFLEDGING PERIOD

After the young are 12 days old, both adults roost outside the nest burrow on trees or shrubs or in marshes. For about a week after fledging, young return to the colony at night and roost in either the nest burrow or other burrows. Shortly after fledging, young and adults roost together during the day on wires and also in trees, on exposed roots in banks, in shrubs, on logs, and on sandbars and

gravel bars. Telephone and hydro lines are used most frequently where they are available. Nocturnal roosts used at this time and until autumn migration are typically in marshes or in trees near water. These are usually large communal roosts of several swallow species. Four roosting areas have been described from Ontario. Historically, very large flocks roosted along the Niagara River, Welland River, and both waterfronts in Niagara District. In the Kingston area, the Bank Swallow has roosted in the Cataraqui and Little Cataraqui marshes, which are dominated by cattails. The Pembroke roost was on a point at the confluence of the Muskrat and Ottawa rivers, and it became an island during high water. Swallows roosted in the canopy of a 0.5-ha stand of black willows 10-15 m tall. This roost was occupied for about 15 years; prior to that swallows roosted in boathouses along the waterfront. In the cattail marshes in the Inner Bay of Long Point, as many as 45,000 Bank Swallows roost nocturnally during the postfledging and autumn migration periods. Most late-summer roosts are near major rivers, large lakes, or in large marshes. Elsewhere, the Bank Swallow has roosted in willows; in marshes along the Mississippi River in Illinois; in a marsh in a bay of Lake Ontario in New York; in a large marsh dominated by cattails, irises, arrowheads, and pickerelweed; in wild rice along a river in Connecticut; and in dense stands of rushes and cattails bordering British Columbia lakes (Beyer 1938; Campbell et al. 1997; Falconer and Badzinski 2013; Falconer et al. 2016b; Garrison and Taylor 2020; Graber et al. 1972; Gross in Bent 1942; Petersen 1955; Ross et al. 1984; Sheppard et al. 1936; Weir 2008).

Juveniles may disperse widely during the postfledging period and visit several nocturnal roost sites, presumably assessing the suitability of potential future breeding sites (Falconer et al. 2016b).

MIGRATION

The Bank Swallow is a diurnal migrant that usually arrives in Ontario in late April or early May, occasionally as early as mid-April or rarely by mid-March. The peak of migration occurs in the second week of May (Falconer et al. 2016b). Spring migration is more rapid and direct than autumn migration. Early arrivals spend most of their time foraging over water, often several kilometres from the eventual nest site. Some birds may be prospecting for suitable nest sites at this time. Adults arrive 2-3 weeks in advance of yearlings and settle in the best locations within the colony. Adults may be done nest construction before yearlings arrive (Garrison and Taylor 2020; Graber et al. 1972; Gross in Bent 1942; Petersen 1955). Autumn migration is much more leisurely and prolonged, and begins in late July shortly after the young fledge. Juveniles begin migration earlier than adults, but stay in the breeding range later. At the premigratory roost in Pembroke, swallows start arriving in July and numbers continue to increase until mid-August, after which there is a decline in numbers with every cold front until the roost is abandoned by early September. Large numbers appear at Prince Edward Point in late July. Most leave the province in early September, with stragglers remaining in the south until late October (Curry 2006; Garrison and Taylor 2020; Graber et al. 1972; Gross in Bent 1942; James 1991; Ross et al. 1984; Tozer 2012; Weir 2008).

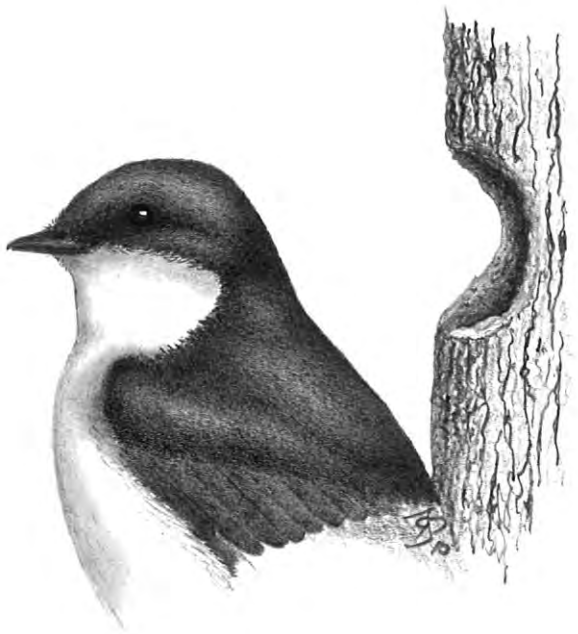
During migration, the Bank Swallow is strongly associated with large rivers and streams, although it may migrate on a wider front in spring. It may also occur over ponds, lakes, marshes, and muskegs and, to a lesser extent, fields and meadows, roadsides, farmsteads, and wooded areas. It often forages along ridges and cliff faces because the turbulent air currents at these sites bring flying insects up from lower levels. It appears to forage as it flies during migration rather than stopping at

specific sites to refuel. A variety of perches may be used during migration including dead trees, fences, hydro and telephone lines, tall plants, cattails, bulrushes, and a variety of human-made objects. During migration, it has roosted overnight in nest burrows and in marshes (Campbell et al. 1997; Graber et al. 1972; Gross in Bent 1942; Imlay et al. 2020; Paton and Fellows 1994).

The Bank Swallow is common to locally abundant during migration (James 1991). Flocks of 250 or less are typical throughout North America in spring. Autumn flocks are much larger, but there are few reliable estimates because of the mixed-species nature of the flocks. Flocks of 5,000 and 4,500 Bank Swallows were seen at Presqu'ile on 2 August 1978 and 11 August 1977, respectively. In the Hamilton area, 10,000 were noted on 10-12 July 1934 and 50,000 were estimated on utility wires near Cayuga on 19-20 July 1983 (Curry 2006; Garrison and Taylor 2020; Gross in Bent 1942; LaForest 1993; Ross et al. 1984; Weir 2008).

Tree Swallow

Tachycineta bicolor



BREEDING SEASON

Habitat Requirements

Ontario Tree Swallow nests were in a variety of habitats, but mostly in open areas. Although 58.9% were in forested areas, including swamps and burns, wooded areas that were used were usually open: 42.2% were in deciduous stands, 37.4% in mixed stands, and 20.4% in coniferous stands. Of the remaining nests, 10.8% were in wetlands (excluding treed swamps, but including cattail and sedge marshes, buttonbush thicket swamps, bogs, and wet meadows); 9.9% were on roadsides and shorelines of rivers and ponds; 7.1% on sand dunes and beaches; 5.5% in farmland, including pastures and fields; 4.1% in rural and urban populated areas, including gardens, cottage areas, lumber mills, streets, golf courses, and canals; and 3-7% on rocky islands and cliffs. More nests were reported from dry than wet areas. Many in wet habitats were where dead trees provided nest sites in open areas suitable for foraging. Nest-box locations were a major factor dictating habitat use (Peck and James 1987).

Natural nesting habitat consists of wetlands and beaver ponds where there are standing dead trees with cavities. Snags along streams, drainage ditches, and fencerows may be used for nesting provided that they are adjacent to open habitat. Substantial open areas are required around the nest for foraging. Nest boxes in open fields or near water are readily used. Near Kingston, Tree Swallows used nest boxes placed at all distances from forest (2-100 m). Boxes furthest from forest

edge were settled first, indicating a preference for nest sites distant from forest. Similar results were reported from Cape Cod, where no boxes under trees were used. In British Columbia, 59% of breeding records were from open habitats associated with humans, especially where nest boxes were available. These habitats included farmlands, rangelands, rural and suburban areas, orchards, golf courses, gardens, and pastures. Of these, 55% were in backyards or farmyards, 20% near water, and 6% in aspen parklands. Other nesting habitats included open fields and meadows, orchards, roadsides, young and mature forests, burns, bottomlands, and campgrounds. Natural habitats used in British Columbia included areas with dead trees for nesting and open spaces for foraging, such as swamps, bogs, beaver ponds, burns, river shorelines, and wet meadows. It tended to nest within 15 m of forest edge, possibly to reduce competition with European Starlings. In the Yukon, it breeds primarily in wetlands and on margins of lakes and rivers but also in open, shrubby areas; deciduous, mixed, and coniferous forests; and burns. In Illinois, nests were associated mostly with swamps or marshes with standing dead timber in or near water. In California, it was equally abundant in oak savannahs with grass or shrub cover, montane hardwoods, and oak woodlands (Aitken et al. 2002; Austin and Low 1932; Barber et al. 1996; Campbell et al. 1997; Graber et al. 1972; Rendell and Robertson 1990; Sinclair et al. 2003; Winkler et al. 2020; Wood et al. 2013).

In southern Ontario, the Tree Swallow was more abundant on organic than conventional farms but not significantly. It was significantly associated with farmsteads, streams, number of tillages, and road, railway, and hydro rights-of way. It was also associated with hay, grassy areas between fields that often contained a fence, and the number of large, isolated trees, but these relationships were not significant. It was significantly negatively correlated with habitat heterogeneity and usage of manure. Negative nonsignificant relationships were with pastures and use of biodynamic spray for weed control, or no weed control (Kirk et al. 2011).

In North Dakota, the Tree Swallow preferred areas with 2-28% tree cover (Cunningham and Johnson 2019).

In early spring, nest cavities may be used as communal roosts during prolonged periods of below-freezing weather. Near Kingston, Stutchbury and Robertson (1990) found 4 adults roosting in a box 1 morning and another morning there were 5-25 birds roosting in 5 boxes. This was after 4 days when the minimum temperature was below freezing, but roosting was not observed after a

single cold day. Roosting was not observed in warmer springs. Most roosting birds were females and only 16% remained to nest, suggesting that some were migrants.

Ontario nests were in bird boxes (84.6%); cavities in trees, snags, and roots (11.0%); cavities in fence posts, utility poles, and pipes (3.2%); holes in buildings and boats (0.5%); unspecified locations (0.4%); recesses and ledges of limestone cliffs (0.05%); mailboxes (0.05%); and cavities in street lights (0.05%). Single nests were reported in a howitzer barrel, a newspaper cylinder, a hole in a sandbank, a car tire, an unused pump, a flower pot, and a hole in a concrete wall. Bird boxes used include those made specifically for Tree Swallows as well as those designed for bluebirds, ducks, and Purple Martins. Most tree nests were in dead trees, but a few were in live trees. Single nests were reported in a floating stump and a floating tree log. Nests were both in old woodpecker nests and natural cavities. Over 80% of tree nests were in 8 species of deciduous trees; the rest were in 4 species of conifers. Preferred species, in descending order of preference, were birches, elms, poplars, willows, and pines. Height of nests in natural situations ranged from 0.2 to 23 m, with most 1.5-6 m up (Peck 1972; Peck and James 1987). Mills (1981) reported a nest in a steam boiler at a mill in Muskoka District.

Near Kingston, nest cavities were in snags from less than 2 m to more than 9 m above water, but 75% were in snags shorter than 6 m. Twenty-seven percent of nests were in tree stumps shorter than 2 m; 46% of cavities that were used were less than 2 m above the pond's surface. Cavities higher than 6 m were used infrequently, but the Tree Swallow occupied the 2 highest available cavities (8.3 and 10 m). Tree Swallow nest cavities differed significantly from the other cavity nesters (Northern Flicker, Great Crested Flycatcher, Eastern Bluebird, Eastern Starling, and Common Grackle), with other species nesting in thicker snags with larger cavity entrances and volumes. Although Tree Swallows usually occupied the lowest cavities with the smallest entrances and volumes, they also used the highest cavities with the largest volumes. The mean distance of nests from pond shorelines was 38.8 m; 77% of nests were within 55 m of shore (Rendell and Robertson 1989). Nests averaged higher in snags (3.4 m) than in boxes (1.5 m); entrance holes were larger in snags, averaging 7.6 cm high and 5.3 cm wide compared with 3.7 cm in diameter for nest boxes (Robertson and Rendell 1990).

Of 4,370 nests reported to Canadian nest record schemes, only 14% were in tree holes, typically created by woodpeckers. The Tree Swallow may also use boxes designed for bluebirds, Purple Martins, Prothonotary Warblers, Wood Ducks, and goldeneyes. In Iowa, the Tree Swallow usurped 1.5% of 534 Prothonotary Warbler nests and apparently killed 2 adult warblers. The Tree Swallow may use any nest box with a cavity entrance larger than 3.3 cm. Two Ontario studies, one of a population using natural cavities and the other in nest boxes, found that entrance cavities facing south or southeast were preferred. This may provide a warmer microhabitat. Some studies demonstrated a preference for south-facing cavities; others have found no significant differences in orientation. Adults require an unobstructed flight path to the cavity; nests may be abandoned if grass grows up in front of the cavity entrance. A number of unusual nests and nest sites have been reported: in eaves of buildings, in a Bufflehead nest, in steel drums containing Mallard nests, in old Cliff Swallow nests, in a fire hydrant, on an active ferry, in holes in the ground, an active Barn Swallow nest on the outside of a building was usurped, in a hole in a railing, in pipes, in a newspaper box, and in a small cavity in the side of an abandoned Bonaparte's Gull nest in a live spruce tree (Aitken

et al. 2002; Austin and Low 1932; Benton 1968; Butler and Campbell 1987; Campbell et al. 1997; Erskine 1979; Erskine and McLaren 1976; Graber et al. 1972; Holroyd 1975; Lumsden 1986, 1989; Munro and Rounds 1985; Rendell and Robertson 1994a; Scerbicke et al. 2024; Sinclair et al. 2003; Tyler in Bent 1942; Winkler et al. 2020).

Lumsden (1986, 1989) summarized Tree Swallow nest-box use in Ontario. It was indifferent to the interior colour of boxes, using both black and white, and had no preference for cavity entrance diameters of 3.5 cm or 4.4 cm. Large nest boxes were preferred, with an inside floor of 15.3 x 15.3 cm and a volume of 4,588 cm3 rather than a floor of 10 x 10 cm and 1,935 cm3 volume. Shallower nest boxes of 12 cm versus 16.5 cm were preferred. Once preferred nest boxes were all occupied, it occupied the other box types. Munro and Rounds (1985) described similar results from Manitoba, where it was indifferent to nest-box colour. It nested in shallow boxes near the ground, and preferred smaller cavity entrances than other species. It demonstrated great variability in nest sites and its habitat selection was the least-successfully classified by statistical analyses of the cavity-nesting species that they studied. Parren (1991) compared selection of nest boxes by Tree Swallows, Northern House Wrens, and Eastern Bluebirds in Vermont. Boxes used by swallows had fewer small woody stems under and around the box than unused sites. Used boxes provided a longer field of view and were further from high perches than those used by wrens. Bluebird and swallow nest sites did not differ significantly.

The Tree Swallow nests singly or colonially, with colonies usually associated with dead, flooded timber or clusters of nest boxes. Most apartment-type houses support only a single pair, but occasionally all compartments are occupied. Despite nesting in colonies, it defends a territory, although there are rare instances of active nests 1-3 m apart and of 2 females nesting in the same cavity. Territoriality is frequently intense against other cavity-nesting species such as Great Crested Flycatcher, Northern Flicker, Black-backed Woodpecker, Purple Martin, Northern House Wren, European Starling, and House Sparrow. Territory size may vary between natural habitats and nest-box populations. Birds nesting in a natural area near Kingston nested an average of 27.l m apart, with 62% of pairs nesting 15-35 m from the nearest pair. A few pairs nested more than 45 m apart; 2 pairs nested within 3.6 m of each other. Nests were evenly distributed and further away from each other than random. Many suitable nest sites were not used and some pairs defended multiple nest sites. Similar results were observed in natural cavities in Oregon, where the average nearest-neighbour distance was 39.4 m (range 17-70 m); 46% nested 17-35 m from their neighbour. Near Kingston, nest boxes were erected in distant clusters. The initial pattern of nest occupation was that 1 pair settled in each of the clusters before a second pair appeared in a cluster. Second pairs in a cluster typically selected the box furthest away from the occupied nest. Territorial defence declined during the nest-building stage so that birds could settle in without territorial dispute about 14 days after the early birds initiated nesting. Nest-box studies suggest defended areas of 6-8 m, but more typically 10-15 m. Territories may be smaller when food is abundant. Feeding territories are not defended (Barber et al. 1996; Harris 1979; Hussell 2012; Mitchell and Robertson 1996; Muldahl et al. 1985; Rendell and Robertson 1989, 1994b; Robertson and Gibbs 1982; Stutchbury and Robertson 1985; Winkler et al. 2020; Whittle 1926).

Home range sizes may be very large. In spring, birds may completely abandon a colony temporarily if the weather is adverse. On Kent Island, New Brunswick, the island was occasionally abandoned, and the nearest land was 10 km away. Adults may forage as far as 60 km from the nest site, with the distance travelled decreasing to 2-5 km during brood rearing (Paynter 1954; Stocek 1986; Winkler et al. 2020). Near Kingston, females tended to be detected further from the nest in the pre-laying period (average 661 m) than during the laying period (225 m). Two females roosted in or near their nest boxes and rarely moved more than 50 m from the nest, one was commonly found at intermediate distances from the nest, and one routinely roosted more than 2.5 km from the nest. Movements of Tree Swallows during the breeding season may be extensive and highly variable. Individuals do not return to the same nocturnal roost night after night (Stapleton and Robertson 2006).

Natal philopatry is low with nestlings dispersing so widely that few are recaptured in subsequent years. At Long Point, 5-10% of fledglings return to breed; of 417 young, 27 (6.5%) returned (De Steven 1980). In Saskatchewan, 0.8% of nestlings returned to a nest-box trail to nest. The nest-box trail was 77 km long and many returns were distant from the natal box (13-50 km). The average distance from the natal nest to the first breeding site was 19.2 km. Only 1 bird returned to nest in its natal box, one to a box across the road, and another returned to within 1.6 km. One nestling first nested in a box 254 km away (Houston and Houston 1987). Also in Saskatchewan, Shutler and Clark (2003) estimated that 4.9% of nestlings returned to breed, and that 23.3% of young that survived their first year returned to breed. Of natal returns, 84 were seen 1 year after hatching, 81 after 2 years, 34 after 3 years, and 1 after 7 years. Some Saskatchewan nestlings dispersed long distances, and dispersal directions were random. One was found nesting 1,965 km away in Wisconsin 4 years later and another first nested in North Dakota 1,125 km from its natal site (Stiles and Houston 1994). In New Brunswick, less than 2% of nestlings returned to nest (Wheelwright and Shultz 1994; Wheelwright et al. 1991). In Colorado, 23% of 611 nestlings returned to their natal 0.5 x 0.5-km nest-box group, but only one (0.16%) nested in its natal box. The remaining 77% that returned to the general area nested in a different 0.5 x 0.5-km grid. Another 15 birds nested about 30 km from their natal nest (Cohen et al. 1989). Natal return rates were 3.7% in Massachusetts, with some first nesting 6.4-145 km from the natal site (Chapman 1935, 1939, 1955). The low return rate may be because the later-returning yearlings may be forced to go elsewhere to secure a nest site or yearlings might disperse indiscriminately and return to the natal area only by chance. Hosner and Winkler (2007) examined North American banding records and found that prior to 1967 65-95% of juveniles returned to within 13.6 km of their banding site; recent data indicated about 25-35%. The change was attributed to changes in recapture-reporting rules. The number of long-distance (more than 100 km) recaptures increased dramatically in the 1970s, presumably due to higher effort and more banders. All datasets revealed that hatch-year birds dispersed significant further than adults. One bird banded as a fledgling in Washington State was recovered the following year in Michigan, a dispersal distance of 2,367 km. Overall, only 2.7% of juveniles dispersed further than 100 km from the natal site, and 85% dispersed less than 15 km.

Adult return rates are 13-60% with some returning to the same nest box but most to the same general area. Forty-one percent of males and 21% of females returned to the same nest box. In

Saskatchewan, the average distance between subsequent nest boxes of adult females was 37.8 km. In Colorado, 66% of returning males nested in the same box compared with 33% of females. In Massachusetts over a 15-year period, 39.6% of adults returned to breed at least once: 43.0% of males and 36.5% of females. In New Brunswick, the female return rate was 30.8%-53.8% (average 45%) and the male return rate was 8.6-50.0%. Some birds may use a nest box for as long as 5 consecutive years; others may move considerable distances between nests. One adult nested 592 km away the following year and another nested 1,085 km away (Chapman 1935, 1939, 1955; Houston and Houston 1987; Mason 1968; Shutler and Clark 2003; Stiles and Houston 1994; Wheelwright and Shultz 1994; Wheelwright et al. 1991; Winkler et al. 2020). Banding data for North America revealed that adults returned to the same banding block 96-98% of the time prior to 1967 compared with 84-89% of juveniles. Later data indicated that 50% of adults and 22% of juveniles returned. There was no difference in dispersal rates or distances between the sexes, but this may have been due to the difficulty of sexing this species (Hosner and Winkler 2007). Eight-seven percent of females that nested successfully at Long Point returned the following year, but only 4.4% of unsuccessful females returned (Bradstreet 1969). Clark et al. (2018) analyzed survival and return rates of Tree Swallows at 8 North American locations, including Long Point and Mud Creek in Ontario. Annual variations in survival were unique to each site and different at the 2 Ontario sites, although they were only 30 km apart. At Long Point, males had a higher return rate than females; the overall return rate was 77%. At Mud Creek, differences in return rates of the sexes were trivial with an overall return rate of 83%. Winter climate conditions were associated with only 9-13% of variation in survival rates at the 2 Ontario sites, but with as much as 66% in British Columbia. Severe cold weather in spring that depressed insect abundance was the greatest factor affecting survival rates in Ontario, particularly for females.

Limiting Factors

Eggs have been reported in Ontario nests from the third week of April until the first week of August, mostly in the last week of May and first week of June (Peck and James 1987). In Algonquin Park, nests are under construction from early to mid-May, eggs are present from late May to late June, nestlings are present from late May to late June, and dependent fledglings have been observed from late June to mid-July (Tozer 2012).

Early arriving pairs claim a nest cavity upon arrival, but nest construction may not start for 1-3 weeks. Late-nesting birds may build a nest in 4-8 days, but these nests are not as well constructed. Earlier-nesting birds may take 2 weeks to build a nest. In southern Ontario, nest construction usually begins in the last week of April and continues into early May. Most eggs are laid in southern Ontario 5-22 May (range 3 May-1 July). In the Kingston area, most clutches are initiated 11-16 May, with a few later clutches laid by yearlings. At Long Point, clutch initiation was 7-28 May. Near Sudbury, the first eggs were laid between 15 May and 2 June (mean 23 May). In Michigan, yearling females began laying an average of 7 days later than older females. Eggs are typically laid at the rate of 1 a day; longer intervals occasionally occur, usually in response to adverse weather. Females can rest 1-7 days between eggs without affecting viability. Incubation usually begins with laying of the penultimate egg, but it may rarely be delayed by as much as a week. Typical Ontario incubation periods were 10-17 days, averaging 13-14 days. The incubation period at 1 nest was 7 days indicating

that incubation was initiated early during the egg-laying phase. At 10 nests, incubation periods were 18-25 days indicating a delay in incubation. Elsewhere incubation periods of 11-19 days have been reported, with most eggs hatching in 14-15 days. The incubation period is strongly influenced by weather and takes longer in cold weather when clutches may be temporarily abandoned. Most clutches hatch in 1-2 days. Rarely, all eggs hatch on the same day, or hatching may occur over 3 days. At Port Rowan, 90% of nestlings from 6-egg clutches hatched on 31 May and 1 June. Fledging occurs at age 15-25 days, but mostly in 18-22 days. Larger broods tend to have longer nestling periods because food delivery rates do not vary according to brood size. Fledging is asynchronous. In Manitoba, only 13.8% of birds fledged from nests on the same day (Austin and Low 1932; Blancher and McNicol 1988; Campbell et al. 1997; Coe et al. 2015; Hussell 2003; Hussell and Quinney 1987; Leffelaar and Robertson 1986; Lombardo et al. 2024; Paynter 1954; Peck and James 1987; Quinney et al. 1986; Stutchbury and Robertson 1985; Tyler in Bent 1942; Wheelwright and Shultz 1994; Winkler et al. 2020; Zach 1982).

Normally 1 brood is raised per season with second broods rare, except perhaps in the southern portion of the Tree Swallow's range. Double broods have been reported in Ontario (Peck and James 1987), and Hussell (1983) reported 2 pairs raising 2 broods in a single season at Long Point. In the first case, eggs were laid in another nest box before the first young fledged. It was uncertain if any young fledged from the second brood. In the second case, eggs were laid in the same box starting 12 days after the last young fledged from the first brood. All young successfully fledged from both broods. Both double-brooded pairs were the earliest recorded breeders at the site. In Colorado, no second broods were documented in thousands of nestings. In Massachusetts, only 1 case of double brooding occurred in 22 years of study (Chapman 1955; Winkler et al. 2020). In Tennessee, 88 of 206 pairs (42.7%) were double brooded. Second broods contained about 1 egg less, fledged 1 less young, and had lower success than single and first broods. Females with second broods initiated clutches 5 days earlier than single-brooded females, a significant difference (Aborn 2020). In Virginia, Monroe et al. (2008) confirmed 18 cases of double brooding, 5% of birds that successfully raised first clutches. Most double-brooded females initiated their first clutches before the peak of clutch initiation. Females with earlier and smaller clutch sizes were most likely to breed twice within a season. Double-brooded females initiated their first clutch 5.4 days after the first egg of the season compared with 12.8 days for single-brooded females. Double-brooded females waited an average of 9.3 days after young from the first nest fledged before starting a second clutch. Renesting is common if the first clutch is lost; females may lay 3 clutches in an attempt to raise a brood. Renesting may occur either in the same or a different cavity. Clutches of 2-12 eggs have been reported in Ontario. Both a 9- and a 10-egg clutch were known to be produced by 2 females. Most clutches contained 5 or 6 eggs. Mean clutch sizes at Ontario study areas were 4.68, 5.60, 5.81, 5.92, and 6.20 eggs. Throughout its range, the clutch size is 2-8 eggs, but typically 4-7. Clutches larger than 8 eggs are probably due to the efforts of more than 1 female. The mean clutch size in 13 populations ranged from 4.7 to 6.2 eggs. There is a slight tendency for clutch size to increase with latitude, and clutch size declines with the season. Seasonal declines in clutch sizes are greater at higher latitudes. This appears to be related to food supply, with insect availability declining more rapidly with time at more northerly locations. Yearlings tend to nest later than adults and consequently have smaller clutches. Later clutches may be 1-3 eggs smaller than early clutches. In Wyoming, females nesting

at high altitudes began laying eggs an average of 10 days later than those nesting at lower elevations and laid an average of 0.4 fewer egg, a significant difference. This may have been a response to the later clutch initiation or the colder weather, or may have been an adaptive mechanism to ensure that there was adequate food to feed the nestlings. In New Brunswick, first nests had significantly larger clutches (5.86 eggs) than replacement nests (5.00 eggs). In Ontario, clutch size did not increase with female age after age 2 years. In New Brunswick, clutch size tended to increase with age until age 4 years, after which it declined (Austin and Low 1932; Blancher and McNicol 1988; Campbell et al. 1997; Chapman 1955; Dunn et al. 2000; Hussell and Quinney 1987; Johnson et al. 2018; Karagicheva et al. 2016; Lombardo 1983; Paynter 1954; Peck and James 1987; Rendell and Robertson 1989; Stutchbury and Robertson 1988; Tyler in Bent 1942; Wheelwright and Shultz 1994; Winkler et al. 2020).

Clutch size in Ontario is influenced by the physical characteristics of the nest cavity and food availability. Near Kingston, clutches were significantly smaller in small nest boxes and natural cavities than in large nest boxes. Clutch size was determined by the area of the floor of the cavity, but was not influenced by cavity volume. Near Long Point, insect biomass varied significantly at 3 study areas, and was significantly correlated with clutch size. The greatest effect was during egg laying when 85% of variation in clutch size was explained by insect biomass. At 1 site, 25% of swallows laid 7 eggs compared with 4% at a site with 90% less insect biomass (Blancher and McNicol 1988; Hussell and Quinney 1987; Quinney 1983; Rendell and Robertson 1989, 1993; Robertson and Rendell 1990). In Quebec, clutch size was negatively correlated with the amount of intensive agriculture, with birds in these landscapes laying fewer eggs than those in landscapes dominated by hayfields and pastures. Greater amounts of pesticides are used in intensive agricultural areas, which may affect swallows' physiology and reduce breeding success (Pellerin et al. 2016).

The Tree Swallow is typically monogamous, but some cases of male polygyny have been reported. In some cases, both females deposited eggs in the same nest and all 3 adults cooperated to raise the brood. More frequently, the second female nested a short distance from the first and the male helped provide food to both broods. Over 3 years, 7%, 8%, and 0% of males were polygynous in Alberta; the frequency of polygyny may be related to food abundance or scarcity of nest sites. Occasionally pairs remate for more than 1 year. This may be more site tenacity rather than prolonged attraction to the same mate. Near Kingston, 50% of broods contained young sired by extra-pair males, totalling 38% of young. Broods contained either 0 or many illegitimate young. Resident males sired only 20% of extra-pair young. In Oregon, 69% of young were fathered by extra-pair males; 44% of broods were entirely extra-pair young and 40% consisted of both extra-pair and within-pair young. One young was fathered by the male but was not related to the female. There was no significant difference in rates of extra-pair paternity between nest boxes and natural cavities. In 93 Wisconsin broods with mixed paternity, 33% of young were sired by the social mate and 67% were sired by an extra-pair male. Successful extra-pair sires were more experienced breeders and were larger and in better condition (Barber and Robertson 1999; Barber et al. 1996; Chapman 1935, 1955; Dunn and Hannon 1991, 1992; Farber 1972; Leffelaar and Robertson 1985; Lifjeld et al. 1993; C.A. Long and Long 1990; Pinkowski 1975a; Quinney 1983, 1986a; Simmons 1985; Stutchbury and Robertson 1985; Whittingham and Dunn 2014; Winkler et al. 2020). Intraspecific nest parasitism

occurred at 5.8% of nests in New York, with 2 eggs appearing in a nest in a day. This was considered an underestimate; the revised estimate was that 9.2% of nests were intraspecifically parasitized. At another 6.7% of nests, eggs disappeared during egg laying. They may have been removed by a parasitic female (Lombardo 1988; Winkler et al. 2020).

Both sexes are capable of breeding at age 1 year. In some populations, few yearlings breed because they are unable to secure a nest site. Yearlings are further disadvantaged because they arrive on the breeding grounds later and have a different plumage than older birds. The proportion of yearling females breeding in a population varies from 10% to 80%; in newly established populations, 70-80% of yearlings breed compared with 6-35% in well-established populations. Essentially all 2-year-olds breed. Nonbreeding birds constitute a floater population which was estimated to be 23-27% of the total population near Kingston. Floaters frequently visit active nests. Originally it was thought that they were helping at the nest but it appears as though they are prospecting for a future nest site. When nest boxes were erected later in the nesting season near Kingston, floaters defended them within a few hours (Chapman 1955; Lombardo 1985; Stutchbury and Robertson 1985, 1987; Winkler et al. 2020).

De Steven (1978) compared the breeding biology of yearling females with that of adults at Long Point. Yearlings had a significantly smaller clutch size (5.1 eggs compared with 5.9), lighter eggs, and laid first eggs an average of 2.6 days later than adults. The percentage of hatched young that fledged was significantly lower for yearlings (92.7%) than for older birds (99.4%), and older birds raised more young.

Almost all the Tree Swallow's food is obtained by aerially foraging on insects. In New York, most foraging occurred within 100-200 m of the nest at heights of less than 12 m. Less than 20% of the time was spent foraging at heights greater than 12 m. In Saskatchewan, it foraged at a mean distance of 182 m from the nest over an area of 1.3 km2. It spent a disproportionate amount of time foraging in and near wetlands and avoided crop fields. Occasionally it lands on the ground to forage, often in flocks. This is typically in response to high concentrations of food such as emerging midges and stoneflies. It may take insects from the surface of water and has taken seeds out of ice in a pond while in flight. In New York mixed swallow flocks, the Tree Swallow foraged much lower than Cliff Swallows. It either foraged in different strata or habitats than Barn Swallows, or the 2 species captured different prey. In northwestern Ontario, 87.9% of foraging time was over water during egg laying, but only 31.6-56.8% during incubation (Cohen and Dymeraki 1986; Erpino 1984; Harris et al. 2024; Hobson and Sealy 1987a; McCarty and Winkler 1999a; Paton and Fellows 1994; Ramstock et al. 1998; St. Louis et al. 1990; Tyler in Bent 1942). Curry (2006) reported Tree Swallows foraging on the ground in yards in Caledonia during a period of unusually cold weather.

Nestlings are brought a variety of flying insects. Young have been fed leafhoppers, aphids, snails, clams, crayfish parts, fish bones, and a variety of fly species, particularly midges. An Ontario study determined the nestling diet to be 46% flies, 26% bugs, 11% mayflies, 5% dragonflies and damselflies, 4% beetles, 4% molluscs, 2% spiders, 1% book lice, 1% hymenopterans, and traces of lacewings, caddisflies, and lepidopterans. At Wahnapitea, snails, clams, and crayfish parts were fed as a calcium supplement to nestlings. In this area, the most important nestling foods by mass were horse flies (14.4%) and burrowing mayflies (13.4%). Non-living, high-calcium foods (mollusc shells

and fish bones) constituted 3.5% of nestlings' food. The nestling diet was 6.4% aquatic compared with 32.3% terrestrial items, and 2.8% semiaquatic animals. Midges comprised 22% of trap biomass but only 5% of the nestling diet. Mayflies were less than 1% of trap biomass but 21% of the nestling diet. Other items fed to nestlings near Sudbury were house flies, hump-backed flies, aphids, leaf bugs, and dragonflies. Midges were 44-92% of items fed to nestlings in different studies in the Long Point–Port Rowan area (Blancher and McNicol 1988, 1991; Chapman 1955; Hussell 1988; Pinkowski 1975a; Winkler et al. 2020). In southern Ontario, the diet of nestling Tree Swallows was predominantly aquatic emergent insects. Barn Swallow nestlings were fed mostly terrestrial insects; the diet of Cliff Swallows was intermediate (Bumelis et al. 2022). Tree Swallow nestlings also fed more on aquatic-emergent prey than Barn Swallow nestlings in Saskatchewan (Diaz Bohorquez et al. 2025).

Near Port Rowan, 74% of the adult diet consisted of flies, mostly nematocerans such as midges. The Tree Swallow also ate other flies, bugs, and dragonflies. The largest insect eaten was a 42-mm dragonfly. It preferentially fed on medium-sized (4-6 mm) insects. At 1 site, 45% of the diet consisted of medium-sized insects compared with 13% availability; at another site, medium-sized insects were 43% of available prey and 61% of food. Small (1-3 mm) and large (7-10 mm) prey were taken significantly less than their availability. Only 18 of 3,318 insects (0.7%) in the diet sample were larger than 10 mm (Quinney and Ankney 1985). Blancher and McNicol (1988, 1991) reported a greater variation in diet near Sudbury. It was affected by the acidity of the lakes that swallows nested beside. They fed on emergent insects such as midges, mayflies, dragonflies, damselflies, and caddisflies. Egg-laying females ate snails, fish bones, and calcareous grit to obtain calcium. Midges and house flies are small, but were important in the diet due to their abundance. Large prey species were eaten much less frequently, but were important to the diet in terms of mass: giant casemaker caddisflies (7.0%), lappet moths (6.2%), crimson-ringed whiteface (a dragonfly, 4.6%), and soldier flies (3.9%). Flies comprised 70-75% of the adult diet. Egg-laying females also preyed on mayflies (15%) as well as midges and black flies. Later in the season, adults ate more dragonflies and damselflies (10%) and a variety of smaller terrestrial prey. Midges and black flies were consumed primarily in the morning. Horse flies were most likely to be eaten in wetlands with extensive littoral areas. Terrestrial species were eaten mostly late in the season. It preferentially selected mayflies, particularly burrowing mayflies. Prey 1-35 mm long contributed significantly to the diet. With the exception of 5 families of large moths with mean lengths of 13-19 mm, almost all terrestrial prey was less than 10 mm. Several aquatic food items were longer than this including all odonates and several mayfly, caddisfly, and fly species. At Vermilion Bay, St. Louis et al. (1990) found that midges less than 8 mm long were the dominant insect and assumed that this was the major food item. Swallows appeared to respond to emerging midges and fed on concentrations of them. There was no apparent preference for species of midges. Nancekivell and Nocera (2025) used DNA to analyze the adult diet in New Brunswick and compared the diet of the Tree Swallow to those of the Alder and Least flycatchers and the Bank, Barn, and Cliff swallows. All species differed in their dietary breadth and prey preferences. The Tree, Bank, and Cliff swallows ate more aquatic flies and other taxa than the other species, which consumed more terrestrial flies. The 2 flycatcher species and the Tree and Barn swallow had broader generalist diets than Bank and Cliff Swallows, which had more restricted diets. The approximate frequencies of occurrence of invertebrate groups in the diet of the Tree Swallow were 90% aquatic

flies, 15% terrestrial flies, 10% lepidopterans, 10% aquatic beetles, 10% terrestrial beetles, and 5% or less for bugs, hymenopterans, caddisflies, mayflies, and odonates. The approximate frequencies of occurrence of invertebrate families in the Tree Swallow diet were 60% limoniid crane flies, 35% mosquitoes, 35% midges, 10% marsh beetles, 10% ground beetles, and 5% or less for long-legged flies, bristle flies, flower flies, snipe flies, and leafroller moths.

Beal (1918) examined 343 Tree Swallow stomachs, including some from Ontario. It was the only swallow that ate an appreciable amount of vegetable matter: 80 stomachs contained vegetable matter, and 35% contained nothing else. The diet consisted of 80.5% animal and 19.5% vegetable matter. Vegetable matter eaten was predominantly bayberries (16.9% of the diet); they were eaten all summer. Other seeds and fruits eaten were those of red cedar, dogwoods, Virginia creeper, grasses, and lady's-thumb. Flies constituted 40.5% of food items, but only of 5 families: crane flies, horse flies, robber flies, flower flies, and house flies. Beetles comprised 14.4% of the diet including 5.9% scarab beetles and 1.9% weevils. Other invertebrates eaten included ants (6.4%), other hymenopterans (7.6%), stink bugs, treehoppers, aphids, chinch bugs, lepidopterans (1.1% annually, mostly adults but some caterpillars), dragonflies, mayflies, and spiders. Almost 2% of the diet in August and September consisted of grasshoppers, with an annual rate of 0.4% of the diet; grasshoppers were not actively selected. These results differ significantly from Ontario studies. Midges are important in the Ontario diet, and the Tree Swallow has not been reported eating any vegetable matter. In New York, it ate a wide range of insects from at least 11 orders, but flies were most frequently consumed. Bugs, odonates, and other taxa were equally important some years. Dragonflies, damselflies, and brachyceran flies were actively selected. Bugs were eaten in proportion to their availability. It ate food 1-50 mm long, but insects 3-5 mm long formed the greatest proportion of the diet. Insects 0-3 mm were selected (McCarty and Winkler 1999a). In Saskatchewan, aquatic flies and odonates comprised most of the diet of adults and nestlings. The nestling diet contained higher proportions of terrestrial flies and a wider dietary niche than adults, indicating a seasonal change in adult feeding habits (Michelson et al. 2018). When feeding over running water, the diet may change to stoneflies, mayflies, and caddisflies; the latter 2 orders are also consumed when feeding over ponds or lakes. It has fed on crustaceans, water boatmen, bulrush and other sedge seeds, fragments of rose thorns, and flying ants (Tyler in Bent 1942; Winkler et al. 2020).

In Ontario, 1 of 4,585 (0.02%) Tree Swallow nests was parasitized by cowbirds (Peck and James 1997). Winkler et al. (2020) knew of only 1 other definite record of cowbird parasitism and concluded that cavity nesting probably limited parasitism. In British Columbia, 0 of 3,329 nests were parasitized (Campbell et al. 1997). Mills (1988) experimentally parasitized 15 Ontario nests with a cowbird egg. One egg disappeared the day before swallows hatched; only 7 of the 14 remaining eggs hatched. All 7 cowbird young died 3-12 days after hatching. Six of the 7 nests fledged all swallow nestlings, but the other failed completely. He concluded that the Tree Swallow was a poor host for the cowbird, in part due to cavity nesting, but also because adults are often off the nest foraging for prolonged periods. Hauber (1998) artificially parasitized a nest in New York by putting a young cowbird in it. The cowbird nestling was accepted and it appeared to fledge successfully. It was concluded that the cowbird does not typically parasitize the Tree Swallow because the 2 species

were historically separated and the cowbird may not recognize it as a potential host, and nest defence in swallow colonies may deter cowbirds.

Food availability can be a significant limiting factor that may affect reproductive success. Prey abundance may be affected by weather, nutrient levels in wetlands used for foraging, lake acidity, and whether a lake supports fish. Food availability may affect the ability of single parents to raise a brood. In the Kingston area, both adults appear to be necessary for young to fledge, but in the Long Point area and Alberta, where insects are more abundant, single parents successfully fledged most, if not all, young (Dunn and Hannon 1992; Leffelaar and Robertson 1985, 1986; Quinney 1986b; Winkler et al. 2020). At Port Rowan, insect abundance significantly affected nestling growth rates and survival. Of females attempting to raise 6 young, the average number of fledglings was 6.0 where insects were abundant and 5.5 where insects were less abundant. All young that died appeared to have starved (Quinney et al. 1986). Nest-box occupancy was always 98% or higher at sites with high insect abundance but varied between 75% and 96% at sites with relatively low insect abundance (Hussell 2012).

In New Brunswick, weather conditions significantly affected swallow foraging behaviour. Birds were completely absent when the weather was unsuitable, presumably due to a lack of flying insects, but all were present when conditions were suitable. Swallows were never seen at the colony when the temperature dropped below 13°C. The mean temperature was 19.7°C when birds were present and 11.2°C when they were absent. When temperatures were 13-20°C, birds were more likely to be present if the sun was shining. Birds were often, but not always, absent during rain. Stocek (1986) concluded that temperature was an important influence on swallow movement to 15°C. Between 15 and 20°C, the presence of sunshine and duration of rain had a significant effect on whether swallows remained in the area. Other studies demonstrated that nest success is significantly lower in colder years, particularly when there is accompanying precipitation. In Saskatchewan, where productivity declines have been demonstrated in cold, wet years, egg mortality was high 1 year with very hot temperatures. In the same area, a heavy snowfall early in the season resulted in swallows abandoning their nests and renesting (Austin and Low 1932; Chapman 1935, 1939, 1955; Houston 1982; Houston and Houston 1998; McCarty and Winkler 1999b). During cold weather birds may succumb to starvation or directly to cold. In New York, over 85% of birds found dead in nest boxes during a cold spell were yearlings. Yearlings are more susceptible to cold because of inexperience in using plant food when insects are scarce, finding and capturing insects, and finding a safe refuge during inclement weather. Almost complete nest failure may occur in populations during cold, rainy weather in spring (Lombardo 1986; Shutler and Clark 2003; Stiles 1998; Tyler in Bent 1942). Later nesting birds are less successful in raising young with the condition of offspring explained by weather conditions, emphasizing the importance that delays due to inclement weather may have (Dawson 2008). Cold springs that depressed insect abundance were the most significant factor affecting survival of females at Long Point and Mud Creek (Clark et al. 2018). In British Columbia, clutch size, number of eggs hatched, and number of young fledged were lower in years with high amounts of early season snowfall and cooler temperatures (McArthur et al. 2017).

In New York, foraging Tree Swallows focused on ponds with higher nutrient levels and no fish. In spring, when they are vulnerable to cold weather and food shortages, they selected feeding areas that produced the greatest number of insects. Later in summer, when insects were abundant everywhere, no preference for ponds was exhibited (McCarty 1997).

Near Sudbury, lake acidity explained 31.5% of variation in clutch size. Nestling growth increased with increasing water alkalinity but decreased if fish were present. Fledging success increased as wetland or lake pH increased. At acidic sites, clutches averaged 0.8 egg less per clutch, and 1.3 fewer nestlings fledged per successful nest. Fledglings on acidic sites were significantly smaller. Midges are unaffected by acidity; at wetlands with pH greater than 6.0, nestlings were fed 30% mayflies compared with 11% at acidic sites. Caddisflies were important foods at pH 5.0-6.0, but were seldom eaten elsewhere. Calcium-rich foods are important to developing nestlings and egg-laying females. These were obtained locally in wetlands that were not acid stressed; adults nesting at acidic wetlands travelled as far as 2 km to obtain mollusc shells. More dragonflies and damselflies were eaten at acidic wetlands and where there were no fish. Emergence traps indicated fewer insects at acidic areas. The diversity of food that was available and fed to nestlings was also a function of pH. Thirteen of 14 mollusc species fed regularly to nestlings occurred only where the pH was higher than 6.0. Thirteen of 18 mayfly genera occurred only where the pH was higher than 6.0 and none were observed at a pH of less than 5.0. The important mayfly in the diet, a burrowing mayfly, occurred only in lakes larger than 12 ha with a pH above 6.0. Increasing acidity resulted in a switch in diet from acid-sensitive mayflies to more tolerant flies (midges), a decline in the diversity of foods eaten, a change in the size and type of calcium-rich food fed to nestlings, and a decline in number of young fledged (Blancher and McNicol 1988, 1991). At Vermilion Bay, more acidic lakes had lower densities and levels of emergence of midges. Tree Swallows foraged at their nest-site lakes when emerging insects were abundant, but foraged elsewhere when prey was scarce (St. Louis et al. 1990).

In Saskatchewan, males nesting at croplands spent 14% of their time near the nest box compared with 62% for males in grasslands; agricultural females spent 19% of their time at the nest box compared with 35% for grassland females. Reduced insect availability in agricultural areas increased the time spent away from the nest to forage. Wetlands in agricultural sites had higher concentrations and frequencies of detections of neonicotinoid insecticides than wetlands in grasslands. Heavier pesticide use in agricultural areas may reduce prey biomass and availability. Birds at agricultural sites may reduce parental care in response to lower food availability and focus more on satisfying their own energy demands. Nestlings raised in grasslands were in better condition than those raised in cropland (Stanton et al. 2016). In Saskatchewan, Michelson et al. (2018) compared the diet of the Tree Swallow in grassland and row-crop agricultural landscapes with similar densities of wetlands. More than 75% of the adult and nestling diets were composed of aquatic invertebrates at all sites and in all years. Nestlings consistently had a higher proportion of terrestrial flies in their diet and a broader diet than adults. The proportions of all prey sources (aquatic and terrestrial) were similar in croplands and grasslands indicating that wetlands provide essential habitat that may buffer some of the effects of agriculture. Small patches of seminatural habitat such as roadside ditches with grasses and herbaceous vegetation, trees, and shrubs may provide adequate insect prey even in areas dominated by row-crops. Bellavance et al. (2018) studied the effects of agricultural

intensification on prey availability and nestling diet in Quebec. In crop-field landscapes, arthropod abundance was highest early in the season, increased to a small peak in mid-June and then decreased strongly. In non-agricultural landscapes, arthropod abundance increased at an increasing rate throughout the sampling period, with greatest abundance occurring in early July. Landscapes that were 50% cultivated showed only a slight increase in arthropod abundance throughout the sampling period. Associations between fly subgroups and landscape composition differed between trap and nestling diet samples suggesting that prey selection was altered by agricultural intensification. Results suggested that agriculture can alter the availability of preferred prey for the Tree Swallow.

Because the Tree Swallow is a cavity nester, nest-site availability is one of the greatest limiting factors. The provision of nest boxes may result in establishment of a population in an area where it was formerly rare or absent. At Long Point, it was traditionally absent most years. The first year that nest boxes were erected, 2 pairs nested in the 6 boxes. A decade later, 152 pairs nested in the 171 available boxes. The scenario of populations being created as a result of nest-box programs is common throughout its range (Austin and Low 1932; Holroyd 1975; Houston and Houston 1998; Winkler et al. 2020). In the Kingston area, significantly more nests in boxes were successful than those in natural cavities. Adults appeared to prefer boxes to natural cavities. Similar results were observed in Oregon. Near Kingston, higher nests in natural cavities were significantly more successful, with nests less than 4 m from the ground suffering highest predation rates. Nest height was the primary factor affecting nest success (Barber et al. 1996; Rendell and Robertson 1989; Robertson and Rendell 1990).

The Tree Swallow experiences competition for nesting cavities even where cavities are relatively common. Near Kingston, it had 5 competitors for natural cavities: Northern Flicker, Great Crested Flycatcher, Eastern Bluebird, European Starling, and Common Grackle. In nest boxes, the only competitors were bluebirds and Northern House Wrens. Great Crested Flycatchers were usually successful in evicting swallows; in some cases swallows were triumphant over flickers, but occasionally flickers took over swallow nests and they may remove swallow eggs. Northern House Wrens may be significant competitors for nest sites, but usually only within 20-30 m of a forest edge. Wrens may puncture eggs or kill young, or fill the cavity with twigs, which typically results in desertion. The most significant competitors appear to be House Sparrows and starlings. Most Tree Swallows were evicted from villages and towns once the House Sparrow arrived. The Tree Swallow may take over Purple Martin and bluebird nests and it also may be evicted by them. It may compete successfully with the Prothonotary Warbler for nest sites. Other species that have been documented taking over Tree Swallow nests include Buffleheads, red squirrels, and northern flying squirrels (Austin and Low 1932; Erskine and McLaren 1976; Graber et al. 1972; Holroyd 1975; Lumsden 1989; McIlwraith 1894; Rendell and Robertson 1990, 1991; Robertson and Rendell 1990; Tyler in Bent 1942; Winkler et al. 2020).

At Fox River and Green Bay, Wisconsin, PCB concentrations in eggs, newly hatched young, and 12-day-old nestlings were significantly higher at contaminated sites than control areas. This is one of the highest contaminated areas in North America, but PCBs did not appear to affect nesting success. Birds nesting around other areas of the Great Lakes had lower PCB burdens, except for the

Cornwall area which had similar levels (Custer et al. 1998). McCarty and Secord (1999) concluded that PCBs were a hormone disruptor that may affect its behaviour. In Atlantic Canada, Burgess et al. (2001) documented increased levels of PCBs, DDE, dioxin, and selenium in Tree Swallows nesting near known contaminated areas. All sites were less contaminated than polluted areas in the Great Lakes and St. Lawrence and Hudson rivers. In southern Ontario, Bishop et al. (2000) studied the effects of pesticides used in apple orchards on the Tree Swallow. It experienced significant declines in reproduction with increased pesticide exposure and toxicity. Pesticides resulted in declines in egg fertility and daily egg and chick survival. Organochlorine concentrations in eggs did not correlate with reproductive outcomes, but cumulative toxicity scores and organochlorine concentrations were significantly correlated suggesting a combined effect of residual organochlorine concentrations and current-use pesticides. Organochlorine compounds, particularly DDE, are likely to affect egg survival in some orchards and other compounds such as oils and sulphur appear to be potentially toxic. Although the fungicides applied in the apple orchards appeared to have low toxicity to birds, they are applied repeatedly at high rates and often in combination with other chemicals and contributed to the overall toxicity score of nests. Swallows that nested in orchards in British Columbia had 7.7 times more DDT, 2.8 times more DDE, and 4 times more DDD than swallows nesting in other habitats. Despite the high contaminant burden, there was no apparent effect on reproductive success. Contaminants were accumulated locally rather than on the wintering grounds (Elliott et al. 1994). Bouland et al. (2012) examined the sex ratio of broods of Tree Swallows nesting in the floodplain of a river in Virginia that was contaminated with mercury. Broods in contaminated sites contained a mean of 31% males compared with 46% in uncontaminated areas. The bias toward female-dominated broods in contaminated areas may be due to endocrine disruption. The Tree Swallow is vulnerable to polycyclic aromatic hydrocarbons which are highly correlated with egg failure. Nestlings of birds nesting near wastewater treatment facilities in southern Ontario are exposed to brominated flame retardants and stain repellents. Due to the predominance of aquatic prey in its diet, the Tree Swallow is an important bioindicator of environmental contaminants. Many colonies have been established in the Great Lakes Basin to monitor pollutants (Hopkins et al. 2024).

In Quebec, Pigeon et al. (2013) determined that intensive agriculture can lower the fitness of adults, but females are able to buffer these impacts so that they do not affect nestlings.

The reproductive success of Tree Swallows nesting under 765 kV and 69 kV transmission lines in Ohio was compared with control areas. Significant reductions in breeding success under power lines occurred at all sites. The mean number of young fledged was 3.53 under power lines compared with 4.54 at control sites. Areas under high-voltage lines may be suboptimal breeding habitat (Doherty and Grubb 1998). In Manitoba, it avoided nesting in areas of high radiation. Nest boxes that were selected had a mean exposure of 9.3 µC per kg per day compared with highs of 38.7 µC per kg per day. Zach and Mayoh (1982) concluded that birds may be forced to use nesting boxes in higher radiation areas when breeding densities are higher, and this may reduce breeding success or growth of nestlings.

In New Brunswick over a 24-year period, the breeding population on an island decreased over 90%. The major reason for the decline was low immigration rates to the island, followed by survival

rates of males and females. Natal philopatry rates were less than 6%, so local recruitment and reproduction rates had little effect on population trends (Taylor et al. 2018). Near Kingston, Cox et al. (2018) determined that population trends depended upon juvenile recruitment, adult return rates, and fledging success. The number of nesting attempts, clutch size, and hatching rate had little effect.

In Montana, salvage logging after a forest fire significantly decreased the number of breeding Tree Swallows (Hutto and Gallo 2006). In Quebec boreal black spruce forests, it occurred only in recent burns and was absent in clear-cuts and all forest stages (Imbeau et al. 1999).

Tree Swallows nesting in boxes exposed to playback of natural gas compressor noise spent less time incubating, had fewer eggs hatch, and produced fewer young than neighbours in quiet boxes (Williams et al. 2021).

Price (2004) predicted that the breeding range of the Tree Swallow might contract in southern Ontario if the average summer temperature increased by 2°C. Bradley (2015) summarized results from across Canada that examined its adaptability to changing temperatures. Birds at Long Point were much more flexible in their timing of initiation of egg laying and thus better adapted to changing temperatures than birds nesting further north. In Michigan, the first egg dates of older females got earlier with warmer April and May temperatures but yearling female first egg dates did not change with increasing temperatures (Lombardo et al. 2024).

Status

Ontario's Tree Swallow population increased after deforestation due to European settlement, and again when nest-box programs were initiated. McIlwraith (1894) considered it a common summer resident. Sheppard et al. (1936) stated that it was rare in Niagara Region. Baillie and Harrington (1937) concluded it was probably the most common swallow in the province, nesting throughout the south and commonly to southern James Bay and the Manitoba border. They thought that it probably nested throughout the province. Smith (1957) considered it very common in the Clay Belt. The first atlas confirmed that it was common throughout the province, with highest concentrations in the Kawartha Lakes area. Populations appeared to be lower in the extreme southwestern portion of the province (Quinney and Dunn in Cadman et al. 1987). James (1991) termed it a common to locally abundant breeder throughout the province, except in the Hudson Bay Lowland where it is rare.

The second atlas demonstrated that there had been no change in the range of the Tree Swallow since the first atlas. Breeding evidence was obtained in virtually every square south of the Shield. Its probability of observation declined significantly in the province between the 2 atlases. Declines were experienced in the Canadian Shield with populations remaining stable in other regions. It was most abundant south of the Shield. This was to be expected given the open habitat in this area and the numerous nest boxes that are present. In the Shield, it is restricted mostly to wetlands and areas of human populations. It is less common in the Hudson Bay Lowland, probably due to a scarcity of trees with cavities suitable for nesting (Lepage in Cadman et al. 2007).

Michel et al. (2016) used Breeding Bird Survey (BBS) data to analyze population trends of the Tree Swallow over broad geographic areas. In the east, Tree Swallow trends were declining in New

England and the Maritimes, but increasing throughout the mid-Atlantic and southern Great Lakes regions, and were stable in interior Quebec and Ontario. There was little concordance among the trends of avian species of aerial insectivores. The strongest relationship was observed in the Great Lakes area where declining trends of the Barn Swallow were positively correlated with those of the Purple Martin and Tree Swallow, which showed a slight but nonsignificant decline. Overall, the Tree Swallow exhibited the most stable and increasing population trajectory. Although the aerial insectivores are often considered to be a guild that is declining, only the Chimney Swift exhibited significant declines in over half its population trajectories. The lack of concordance among the species suggests that they are not showing similar responses to local ecological processes. Results indicated that declining population trends among aerial insectivores are not universal either within or across species. There was limited evidence that declines are concentrated in any single region of North America.

Long-term (1970-2021) population trends determined by the BBS were annual decreases of 1.05% in Canada and 2.42% in Ontario. The short-term (2011-21) trends were annual decreases of 1.11% in Canada and 1.08% in Ontario. All results were highly reliable except that the short-term Ontario trend was of medium reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Shortly after fledging, young and adults leave the nesting area and gather in good foraging areas such as meadows bordering marshes or rivers (Tyler in Bent 1942). In large areas of its Ontario breeding range, the Tree Swallow may be absent by mid-July, but remains common at roosts. The Pembroke roost is at the confluence of the Muskrat and Ottawa rivers on a small point that becomes an island during high water. It is a 0.5-ha stand of black willow 10-15 m tall. Swallows roost in the canopy, starting in early July. This roost had been used for about 15 years by 1984 with swallows roosting in boathouses prior to that. In Kingston, birds start flocking in early July and gather on utility wires and trees, usually near marshes. The major roost there is in the cattail marsh along the Cataraqui River. This roost has been used traditionally for at least 32 years. Major roosts are used throughout autumn migration, with new birds arriving from the north and flocks leaving constantly after mid-August (Ross et al. 1984; Weir 2008).

MIGRATION

The Tree Swallow is a diurnal migrant that flies low to very high, often in loose flocks. It typically arrives in the province in mid-April, rarely in late February (James 1991). There are indications that it now arrives earlier than historically; McIlwraith (1894) reported that it did not arrive until early May. Males usually arrive several days before females and start defending a nest cavity, but occasionally the sexes arrive together. Older birds of both sexes tend to arrive earlier than younger birds, at least until age 4 years (Winkler et al. 2020). Southward migration begins soon after the young fledge. Many breeding areas are devoid of birds by late July, with almost all breeding areas vacated by late August. Migrants have been observed flying south over Lake Ontario in late July and early August. Many of the early flocks there disappear by late August, but are replaced continuously by flocks arriving and departing throughout September. Large numbers leave the Kingston area in mid-October when the first frosts occur. At communal roosts, there were significant numbers of swallows present at the end of July, with a peak in mid-August; the roost was abandoned in late August. Large

exoduses from the roost coincided with colder weather. Occupation of the Pembroke roost occurs in early July with numbers peaking in the second week of August. Thereafter, numbers drop with each cold front until the roost is abandoned in early September. Although large areas of its range may be devoid of birds by late July, the Tree Swallow is typically present in the province until mid-October, with some records into November or early December (Ross et al. 1984; Weir 2008).

During spring migration, watercourses, especially major rivers that flow north-south, are very important habitat. In southern Ontario, the Grand River is a spring migration corridor. There may still be snow on the ground and ice on ponds when the Tree Swallow arrives. Ice-free watercourses and marshes are often essential as a source of early emerging insects. It may be some time after spring arrival before it spreads over the general landscape. Even then, it prefers areas with water and abundant insects such as beaver ponds, lakes, streams, rivers, damp meadows, sewage lagoons, and ditches. During autumn migration, it is still strongly associated with north-south flowing rivers and watercourses as well as water bodies, but these habitats are not as critical as in spring (Campbell et al. 1997; Curry 2006; Graber et al. 1972; Tyler in Bent 1942).

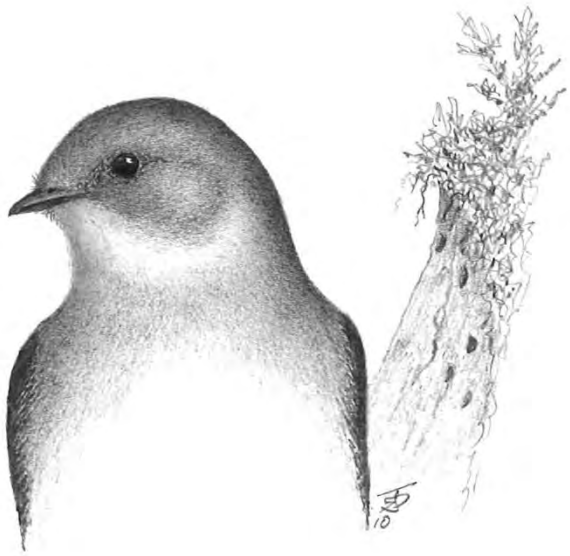
Premigratory roosts are critical habitats that support significant numbers of swallows. Roosts typically support more than 1 species of swallow, so that it is frequently difficult to estimate Tree Swallow populations. On 10 August 1983, it was estimated that 115,000 swallows entered the Pembroke roost, and Tree Swallows vastly dominated the numbers. Ross et al. (1984) reported 250,000 Tree Swallows in a roost at Matchedash Bay, and flocks of 20,000 at Lake Chemung near Peterborough and in Holland Marsh. At the Kingston area roost, it was estimated that 80-90% of the swallows were Tree Swallows. Numbers fluctuated from about 125,000 swallows in late July to 221,000 in mid-August down to 462 on 24 August in 1986 (Weir 2008). In the United States, the Tree Swallow may gather in roosts numbering in the tens or hundreds of thousands, or even millions (Tyler in Bent 1942). Doppler weather radar has revealed fairly regular spacing (100-150 km) of migratory roost sites through North America (Winkler et al. 2020).

In New York, Zelt et al. (2017) compared spring arrival dates, autumn departure dates, and length of the breeding season for 1888-1939 and 1967-2012. There was little climate change during the first period but significant warming during the second period. The Tree Swallow arrived significantly earlier in spring during the second period, but there were no differences in its autumn departure dates or length of breeding season.

The Tree Swallow is common to locally abundant during migration (James 1991). Flocks of 1,000-5,000 have been observed in spring. Autumn flocks of 4,000-10,000 occur frequently in staging areas, with a maximum of 25,000 (Curry 2006; LaForest 1993; Weir 2008).

Northern Rough-winged Swallow

Stelgidopteryx serripennis

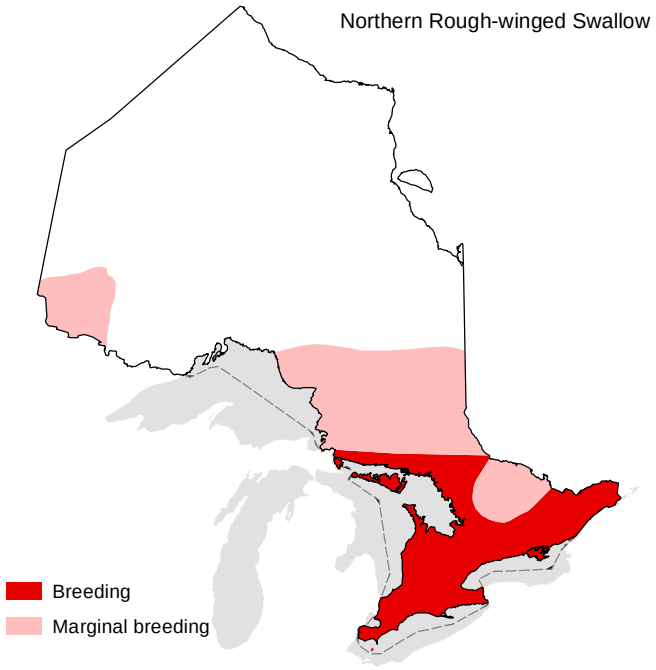


BREEDING SEASON

Habitat Requirements

Northern Rough-winged Swallow breeding habitats in Ontario include farmland fields and pastures (30.7% of nests); river and stream banks and floodplains (25.3%); wooded areas (22.6%); rocky bluffs and cliffs (7.8%); gravel pits, quarries, and road cuts (7.4%); artificial structures such as bridges, planing mills, canals, and dykes (3.5%); islands (1.2%); urban parks (0.8%); and sand dunes (0.8%). Approximately 44% of nests were in human-influenced habitat (Peck and James 1987). De Jong (2020) stated that 30-60% of Canadian nests were in altered habitats; Messely (in Gauthier and Aubry 1996) concluded that only 25% of Canadian nests were in altered areas. In British Columbia, 54% of nests were in human-influenced habitats compared with 25% 14 years earlier. Thirty-five percent of nests were near water; other studies have reported a majority of nests near water. The most frequently used habitats are earthen banks along watercourses, roads, railway lines, and in gravel pits and stockpiled soil piles. Similar habitats are used for nesting throughout its range (Beal 1918; Campbell et al. 1997; De Jong 2020; Dingle in Bent 1942; Graber et al. 1972; Lunk 1962; Messely in Gauthier and Aubry 1996; Sheppard et al. 1936).

Males rarely spend the night in the burrow and the female does so only during laying, incubation, and brooding. Night roosting in the burrow does not occur prior to laying. During the



breeding season, swallows roosted at night in small willows and aspens around a pond and in cattails. Lunk (1962) surmised that groups of males gathered nightly throughout the breeding season and that they were joined by females not on the nest and possibly later by newly fledged young.

Ontario nests were in tunnels in sand or clay banks of rivers, creeks, and roads (48.4% of nests); in drainage holes in concrete bridges and culverts (33.5%); in crevices in rock and shale cliffs and rock road cuts (5.5%); in drainage and ventilation pipes (2.6%); in tunnels in sawdust piles and sand dunes (1.3%); in holes in trees (0.6%); in a hole in a concrete wall (0.3%); in a crevice in a stone wall (0.3%); in a hole in a boathouse wall (0.3%); and on a ledge beneath a concrete wall (0.3%). One tree nest was in an old woodpecker cavity; another was in a natural cavity. One cliff nest was in a cave with an entrance measuring 0.6 by 1.1 m. There were 19 records of it nesting in Bank Swallow colonies and it often used old Belted Kingfisher burrows. One nest under a bridge was in a broken Cliff Swallow nest. Nests were 0.2-18 m above ground or water, with most 0.9-2.4 m up (Peck and James 1987).

Of nests reported to Canadian nest records schemes, 68% were in natural sites and 32% were in gravel pits and road cuts, plus in Ontario nests were in holes in cement, brick, or stone walls. In Ontario and Quebec, 50% of nests were in human-made sites, the highest percentage in the country. A high proportion of nests were in sand and clay banks, frequently in burrows abandoned by Bank Swallows, Belted Kingfishers, or small mammals. Unusual nest sites include semi-trailers and a barrel. The rough-winged swallow nests in any available crevice, including eavestrough gutters and wharves. It frequently uses pipes, crevices in cliffs, and human-made structures for nesting. In British Columbia, 89% of nests were in burrows excavated by Bank Swallows and Belted Kingfishers as well as artificial burrows, drainage pipes, and blasting holes drilled into rock faces; 11% were in crevices in cliffs. One British Columbia and 1 Ontario nest were in a nest box. In Michigan, artificial burrows placed into the face of gravel pits were readily accepted, often within seconds of installation. In British Columbia, nests were 0.3-30.0 over ground or water, with most 2.2-4.5 m up. Burrow length was 15-123 cm (average 60 cm). In Pennsylvania, it nested in drainage pipes 122 cm long with a diameter of 10.2 cm. Average distance from the entrance to the centre of the nest was 82.4 cm (range 53-117 cm). Only 6.8% of nests were built at the inner ends of pipes. In British Columbia, nests were 25-90 cm from the entrance (average 60 cm). In Illinois, nests were 25-90 cm from the entrance, mostly 45-50 cm. There is no correlation between the burrow entrance and its exposure to the elements or compass direction. Some unusual nest sites were inside a garage where

the nest was accessible only when the door was open, and on a steamship that made daily round trips of 77 km along a river. The adults followed the ship to tend to the nest and feed young (Blake 1953; Campbell et al. 1997; De Jong 2020; Dingle in Bent 1942; Erskine 1979; Fleming 1907; Graber et al. 1972; Hill 1988a; Lunk 1962; Nickell 1949; Stedman and Sinbeck 1988). Over 4 years in Michigan, Lunk (1962) found no evidence of its excavating cavities, although it very rarely threw some sand out of existing cavities. He concluded that it depended almost entirely upon existing cavities constructed by Bank Swallows or Belted Kingfishers. Hill (1988a) stated that it rarely, if ever, excavated its own nest burrow and De Jong (2020) concurred. Bergstrom (1953) reported it completing a nest excavation in Connecticut. Solitary nests in piles of fill suggest that it may occasionally excavate its own burrow. Use of burrows dug by other species is most frequent.

The rough-winged swallow is not strongly territorial. Pairs may occasionally nest in the same cliff suggesting that it may be loosely colonial. During nest-site selection and nest construction, the pair spends considerable time perched near the nest. A close approach by an intruder may provoke vocalizations and the intruder may be chased for several seconds. Both sexes share defence of the nest. Once the nest nears completion, tolerance of neighbours increases until no aggression occurs. Perches near the nest are used as a vantage point for maintaining the territory, but perches are not defended. Members of 2-3 pairs may use these perches at different times without conflict. Colonies are typically small, 2-65 pairs, but usually under 10 pairs. In Michigan, the closest that pairs nested was 4.4 m. It frequently nests within 30 cm of Bank Swallows with no aggression and the 2 species appear to be indifferent to each other. There are usually only 1 or 2 rough-winged swallow nests within a Bank Swallow colony. In British Columbia, a large Bank Swallow colony was usurped by rough-winged swallows. Seventy-five pairs of rough-winged swallows nested among 356 burrows. The local sites that had previously been used for nesting were abandoned. The following year, Bank Swallows reclaimed their original colony. In Ontario, 313 isolated nests have been reported plus 68 colonies totalling approximately 259 nests, an average of about 4 nests per colony. In Canada, the average colony size is 4 pairs, except in British Columbia where colonies average 10 pairs (Campbell et al. 1997; De Jong 2020; Graber et al. 1972; Lunk 1962; Messely in Gauthier and Aubry 1996; Peck and James 1997). No information is available on the breeding season home range, but the rough-winged swallow may fly hundreds of metres to obtain food for nestlings (De Jong 2020).

Natal philopatry is very low. In Michigan, a first-year bird nested within 600 m of where it was hatched. No other young returned, indicating considerable dispersion. There are no other records of young returning to breed near their natal site. Adults may use a site for more than 1 season. Burrows are frequently reused, but not necessarily by the same birds. In some cases, burrows were used in as many as 5 consecutive years, all by different females, but evidence suggested that the same male returned. In Michigan, 1 female nested in the same site in 2 years, and it appeared as though the same males returned frequently (Blake 1953; De Jong 2020; Lunk 1962).

Limiting Factors

Eggs have been found in Ontario nests from early May until the third week of July; most are present in the first 3 weeks of June (Peck and James 1987). In Algonquin Park, nests are under construction from early to late May, eggs are present from late May to mid-June, and dependent fledglings have been observed from late June to mid-July (Tozer 2012).

Once a pair selects a nest site, a few pieces of nesting material may be placed in it, but actual nest construction may be delayed a week or more. In Michigan, the mean time taken to build a nest was 6.2 and 7.0 days over 2 years (range 3-20 days). The minimum time occurred during a second nesting when there was no lag time during construction, and maximum times occurred during adverse weather. Usually another 3-4 days elapse between nest completion and initiation of egg laying. This interval may be as long as 13 days under adverse weather conditions, or may not occur in replacement nests. An egg is laid daily, but a day was skipped in 16.4% of Michigan clutches. Of 17 Michigan nests, continuous incubation began in 2 nests with the third-to-last egg, 12 with the penultimate egg, and 3 with the last egg. The mean incubation period of last-laid eggs was 16 days (range 15.5-16.5 days). Two Ontario clutches had incubation periods of 15 days. Hatching of the brood occurs over 0.5-3.5 days. The nestling period is 17-22 days, with most young leaving the nest at age 18-21 days (mean 19-19.5 days). Younger members of a brood tend to leave at an earlier age than older chicks. Young may all leave the nest on the same day, or fledging may be spread over 2 days. The complete nest cycle from nest building to fledging is a minimum of 45 days (De Jong 2020; Dingle in Bent 1942; Lunk 1962; Peck and James 1987).

One brood is raised per year; 1 attempt at renesting may occur if the loss is early in the breeding season. After 10 June, females may be physiologically incapable of laying another clutch. Replacement nests may occur either in the same or a different burrow. If another burrow is used, it is typically very close to the first one, occasionally as far away as 80 m. The interval between the initial loss and initiation of laying of the second clutch is 10-11 days. Clutches of 2-8 eggs have been reported in Ontario, with most nests containing 4-6 eggs. The normal clutch size is 4-8 eggs, mostly 5-7 eggs. In Michigan, the mean clutch size was 6.25 eggs. There appears to be a general increase in clutch size with latitude, but differences are not substantial (Blake 1953; De Jong 2020; Dingle in Bent 1942; Campbell et al. 1997; Graber et al. 1972; Lunk 1962).

The rough-winged swallow is monogamous and capable of breeding at age 1 year. Breeding continues every year thereafter provided it is successful in finding a suitable nest site. There may be a considerable population of floaters that are unable to find a nest site (De Jong 2020; Lunk 1962).

The rough-winged swallow is predominantly an aerial forager. It tends to feed more over open water and at lower heights than other swallows. During inclement weather, it may forage very close to ground or water. It has eaten cracked corn beneath a bird feeder during the breeding season, taken floating insects from the surface of water, fed on the ground on dead midges washed up on a lake shore, and eaten larvae on dead fish and flies on waterfowl scat. Spring foraging is usually in the vicinity of the nesting area, but it may desert the breeding area during inclement weather to find more profitable feeding sites (De Jong 2020; Lunk 1962; Screws 1993; Sealy 1982).

Food brought to the young appears to be predominantly flower flies, other flies, and hymenopterans, and possibly crane flies and mayflies (Lunk 1962). Beal (1918) examined 136 stomachs, including some from Ontario. All food was animal material except for some unknown woody material in 1 stomach, a piece of root in another, and 2 currant seeds in a third stomach. Vegetable material amounted to 0.21% of food. Food was predominantly insects as well as a few spiders and a single snail. Flies were favoured, comprising 32.9% of the diet. Hymenopterans were next in importance at 30.9% and were eaten regularly. Of the hymenopterans, ants comprised 12.0%

of the total diet, but were 35.5% of prey in July and 22.9% in September. Beetles constituted 14.8% of the diet, especially scarab and leaf beetles and weevils. Bugs comprised 14.9% of food items and were eaten regularly May through September, but not in April. Eighty percent of bugs were consumed in August and September, with the most common in the diet being stink bugs, treehoppers, leafhoppers, and ebony bugs. Other insects eaten in small amounts included moths, grasshoppers, dragonflies, and mayflies.

Nest-site availability may be the most significant limiting factor to rough-winged swallows. Only 10% may find suitable burrows when they arrive in spring. Occupancy of artificial burrows is high and almost immediate, even in deliberately selected suboptimal habitat. Fresh digging of any kind immediately attracts birds. At Bank Swallow colonies, 1 or more pairs are almost always present, and they usually eventually find a nest site. Swallows also investigate fresh Belted Kingfisher burrows. Some birds may remain in the general area of Bank Swallow colonies for as long as 3 weeks; after this, they may lose the urge to initiate nesting. As a result, there may be a considerable population of floating nonbreeders, reinforcing the contention that the rough-winged swallow rarely digs its own burrow. Local populations may greatly benefit from proper management and rehabilitation of pits and quarries and installation of artificial burrows (De Jong 2020; Lunk 1962).

The rough-winged swallow may be affected by cold, wet weather in spring. Prior to egg laying, adults may completely abandon nesting areas during inclement weather. Young nestlings may die of hypothermia during cold springs, and nestlings and young fledglings are vulnerable to starvation when it is cold and wet and there are few insects flying. In Michigan during a period of very cold, wet weather a female and 3 males were found in a burrow and 3 females and 1 male were in another burrow. An adult found dead in a burrow was presumed to have died during this period (De Jong 2020; Lunk 1962).

Nests in streambanks are vulnerable to flooding during heavy rain events. Streambank erosion may also result in slumping and loss of nests. Even nests in sand and gravel pits may be lost due to erosion in heavy rainstorms (De Jong 2020; Lunk 1962).

Status

The rough-winged swallow has increased significantly in Ontario and eastern North America, and probably throughout its range. McIlwraith (1894) knew of only a single record from London, where it had been found breeding the previous 1-2 years. In the Toronto area, Fleming (1907) thought that it was probably a rare summer resident. Baillie and Harrington (1937) stated that it was not particularly numerous, but found in some numbers in certain areas. At this time, the breeding range was known to be from the southern border of the province north to Ottawa and southern Georgian Bay, and probably to Manitoulin Island. It was assumed that it bred near Lake of the Woods. The first Kingston record was 2 pairs in 1925 (Weir 2008). During the first atlas, it was common and widespread south of the Canadian Shield, but uncommon in the southern portion of the Shield (Taylor in Cadman et al. 1987). James (1991) considered it a locally uncommon breeder north to Sault Ste. Marie and North Bay and locally rare north to Kenora, Thunder Bay, and Chapleau.

The second atlas demonstrated that the distribution of the Northern Rough-winged Swallow had not changed significantly since the first atlas. It was not detected in many squares in the

southern portion of the Canadian Shield where it had been observed previously. Its probability of observation declined significantly province-wide and in all regions except the Hudson Bay Lowland. It was most abundant in southwestern Ontario, particularly near Great Lakes shorelines. It was most abundant in western Lambton County, Essex County, near Rondeau, east of Long Point, in Niagara Region, and all areas near large rivers or the Great Lakes. Higher densities were also associated with the Grand River in Waterloo and Brant (Sandilands in Cadman et al. 2007).

The rough-winged swallow benefitted from the growth of human populations, which resulted in an increase in nest sites. It was scarce in the northeastern United States until the last third of the 19th century and was first documented in New York in 1870. A major northward expansion occurred between 1950 and 1970 (De Jong 2020; Lunk 1962; Messely in Gauthier and Aubry 1996).

Long-term (1970-2021) trends determined by the Breeding Bird Survey (BBS) indicated annual decreases of 1.24% in Canada and 2.21% in Ontario. The short-term (2011-21) trends were an annual increase of 1.21% in Canada and an annual decrease of 2.93% in Ontario. The long-term trends were highly reliable but the short-term trends were of medium reliability (A.C. Smith et al. 2023). The BBS is not well suited to monitoring rough-winged swallow populations because it typically detects it when it is foraging away from the breeding area.

Michel et al. (2016) used BBS data to analyze population trends of the Northern Rough-winged Swallow over broad geographical areas and to compare its trends with those of other aerial insectivores. Populations were stable in the Great Lakes, New England, and the coastal southeast areas or increasing throughout North America east of the Rocky Mountains. It exhibited the lowest probability of decline of the species that were studied. Although the aerial insectivores are often considered to be a guild that is described as having a negative trend, only one of the 5 species examined, the Chimney Swift, exhibited significant declines in over half its populations trajectories. Results indicated that declining population trends among aerial insectivores are not universal either within or across species.

POSTFLEDGING PERIOD

Broods stay together for a short period after fledging, usually accompanied by 1 or both parents. Adults feed the young during this period, but it is uncertain for how long (De Jong 2020). After fledging, broods move freely over a wide area, but spend considerable time in groups on suitable wires, fences, and trees. In Michigan, 1 brood roosted along a broken-down fence sheltered by shrubs and woods. Broods leave the nesting area shortly after fledging and accompany other swallows in areas more suitable for foraging and roosting, such as near larger lakes and rivers. Some rough-winged swallows use the roost in the cattails at the Cataraqui Marsh near Kingston (Lunk 1962; Weir 2008).

MIGRATION

The rough-winged swallow appears to be a strictly diurnal migrant. Both migrations are prolonged and not particularly noticeable. Spring arrival is 1-2 weeks in advance of Bank Swallows. In the south, it typically arrives in mid-April, with some appearing in early April. In Algonquin Park, arrival is in early May with some arriving in late April. Autumn migration appears to begin shortly after the young fledge, and adults move southward in advance of juveniles. Migrants have been observed flying

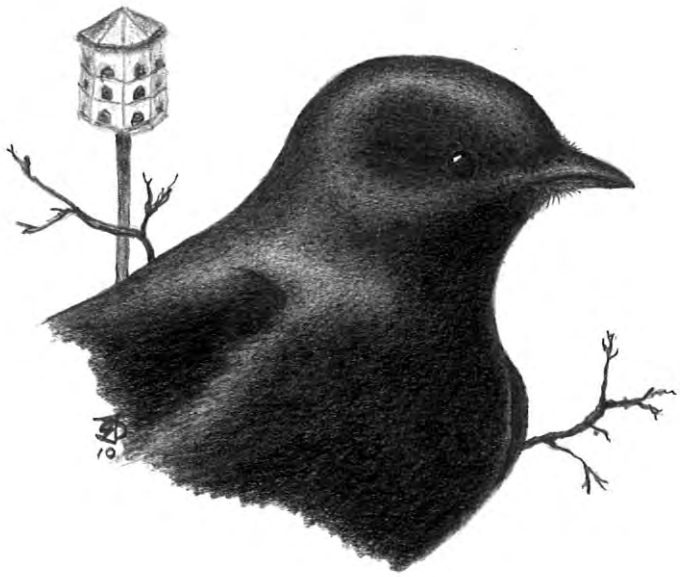
south over Lake Ontario in late July. Most leave Algonquin Park before the end of August. In the south, most leave by the end of September with late records in November and December (Black and Roy 2010; Campbell et al. 1997; Curry 2006; De Jong 2020; Graber et al. 1972; Tozer 2012; Weir 2008).

During migration, the rough-winged swallow is most common near water. In spring, rivers and lakes that are ice free and provide a source of flying insects are important foraging areas. It may also feed over shallow ponds, open creeks, sewage lagoons, meltwater areas, and anywhere with open water. Foraging may also occur over open woodlands, especially during autumn migration. When insects are abundant in autumn, it feeds over ponds, streams, and meadows. It occurs most frequently in natural habitats, but is occasionally found around suburban gardens and farmsteads during autumn migration. In addition to occasionally using traditional swallow roosts, it may roost singly or in small numbers on open perches such as dead trees or shrubs, or roots projecting out of stream banks (Campbell et al. 1997; De Jong 2020; Graber et al. 1972).

James (1991) considered the rough-winged swallow an uncommon to locally common migrant. In spring, it migrates singly or in very loose flocks, usually of fewer than 10-20 birds. In spring and especially autumn, it may occur in small numbers in larger aggregations of swallows. In autumn, larger numbers (100-800) may congregate (Curry 2006; La Forest 1993; Weir 2008).

Purple Martin

Progne subis



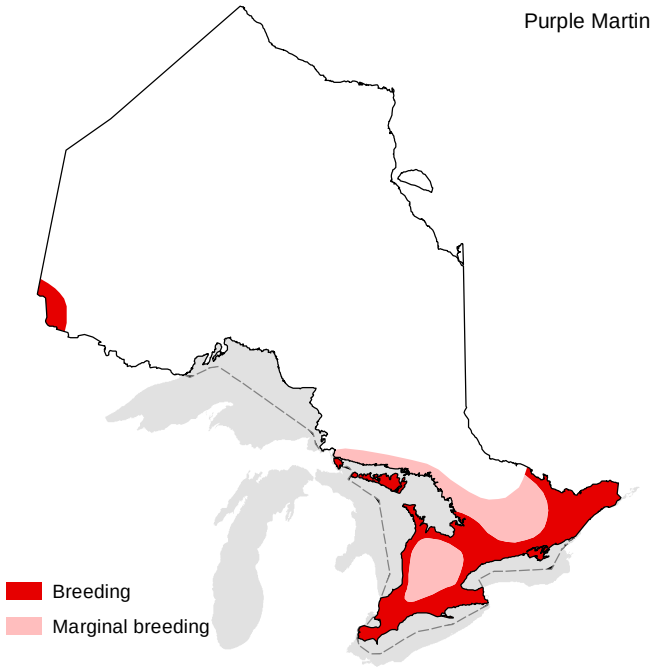
BREEDING SEASON

Habitat Requirements

In Ontario, the Purple Martin has nested in urban gardens and commercial areas, parks, and cottage areas (62.7%); on rocky shorelines and islands (14.8%); in wooded areas and clearings (7.7%); on treed sand-dune/marsh areas (7.7%); in farmland, including pastures (6.5%); and in a limestone cliff (0.6%). Many nests were at the edge of water and most were close to permanent water (Peck and James 1987). It formerly nested in the Gothic architecture of buildings in Hamilton (McIlwraith 1894).

Throughout its range, the Purple Martin is strongly associated with water. Historically, prior to erection of nest boxes, it was probably associated with riparian areas, wooded ponds, and beaver ponds with snags containing old woodpecker nests. Now that it is dependent upon nest boxes, it is found almost exclusively in cities, towns, and other human settlements, although close proximity of water appears essential. In the Kingston area, all martins were associated with human habitation and human-made martin houses. None were found in heavily forested areas without human habitation. In British Columbia, it originally nested in cavities of old buildings in Vancouver, a habitat that has since been abandoned. Now it nests in sheltered estuaries and harbours where abandoned pilings provide nest sites. It also inhabits deciduous second growth near water, mudflats, power line rights-of-way, and farmland where snags are present for nesting. Almost all British Columbia nests were

close to water in forested or urban habitat (Brown et al. 2021; Campbell et al. 1997; Jackson and Tate 1974; Weir 2008).



In Ontario, the Purple Martin breeds mostly in colonies of 2-40 pairs, averaging 8, with colony size dictated by martin house size. Forty-seven single nests were reported. Most nests were in elevated, human-made boxes, mostly apartment-type houses but also some single-unit houses. Other artificial nesting sites included holes in walls, roofs, and eaves of buildings, and behind awnings; in town towers and church belfries at heights of 7.6 to 15 m; behind metal siding on buildings; inside a building under a ledge at 7.6 m; in the bottom of a tire on a post at 1.7 m; in a hole in a fencepost at 1.2 m; in an electric light standard; in pipe holes of a wrecked boat's engine boiler, just above water; in the swing bridge at Huntsville (Mills 1981); and in a half-sunken dredge. Natural nest sites included a colony in holes in a limestone cliff at 30 m and a single nest in a tree cavity at 4.6 m. Nests in martin houses were 2.1-12 m from ground (Peck and James 1987). In 1955, a pair nested in a natural tree cavity at Long Point (Holroyd 1975). Sheppard et al. (1936) reported a large colony on the main street of St. Catharines, where it nested in the upper portions of old stores.

In eastern North America, the Purple Martin now nests almost exclusively in nest boxes, but western populations still frequently nest in natural cavities or in other human-made features. Early Alberta naturalists reported it nesting in small cavities in burnt-over forests. Nesting in trees adjacent to lakes continued at least until 1955 in Alberta. As early as 1910, it started using nest boxes and does so almost exclusively there now. In the west, it continues to nest mostly solitarily in natural or woodpecker cavities in trees or cacti. Of about 3,000 nests reported to Canadian nest record schemes, only 7 were in trees or stubs. In Illinois, it rarely nested in natural situations even historically but in 1966, birds were found nesting in tree stumps standing in water of the Mississippi River. A colony was reported on islands in the Gulf of California where it nested in crevices under ledges and boulders on steep slopes and in chimney-like columns of rock. A Wisconsin nest was in a natural cavity in a tree at ground level. It has nested among large boulders in Lac des Milles Lac, Minnesota, and in a tall, dead pine perforated with woodpecker cavities in Florida. It appears to prefer dead trees when nesting under natural conditions, but occasionally nests in live trees if they have woodpecker holes. Nests have been reported 0-40 m from ground, with most 2.4-5.5 m up (Banks and Orr 1965; Brown et al. 2021; Erskine 1979; Finlay 1971, 1975; Graber et al. 1972; Pistorius 1975; Sprunt in Bent 1942).

Now most nests are in artificial nest boxes built especially for martins. It prefers larger and deeper compartments than are generally available in commercially sold apartments; deeper cavities increase nesting success. Aluminum houses are preferred to wooden ones in some areas and vice versa in others. Wooden houses buffer temperatures better, but are more likely to attract starlings. There is no difference in percentage of occupied houses in city and rural areas, but suburban areas support significantly fewer martins than urban and rural houses. Breeding success was higher in houses that were near water. Occupancy rates were higher in houses closer than 30 m to a building. In Ohio, some sites became unsuitable due to gradual overshadowing of the nest house by trees and buildings. Occupancy rates are not affected by density of trees or shrubs in the area, but there are fewer martins as vegetation height increases. Excessive noise or smell may result in nest-site abandonment. A site may also be unattractive if there are no nearby wires for perching (Brown et al. 2021; Jackson and Tate 1974; Mayfield 1964; Perry and Bloch 1987). Numerous other artificial structures have been used for nesting. Native Americans erected hollowed-out gourds for nesting martins as early as 1712. Each gourd is a single cavity. Gourds are often preferred to nest boxes because the cavity is larger and deeper. Gourds are still frequently put out for nesting martins in the southeastern United States, but much less frequently elsewhere. Martins also nest in many types of structures not specifically designed for them. Most commonly used are cracks and crevices in buildings, but the incidence of this is declining due to more modern building design. The older Gothic architecture provided numerous nest sites, and older towns near rivers were most likely to support colonies. Occasionally, it nests in traffic light or street light standards that have crevices. It has also nested in cracks and cavities in civil defence sirens, a flag pole, aviation warning balls on hydro transmission lines, bridge superstructures, and portholes of decommissioned ships. It also nests in nest boxes built for waterfowl. In Florida, 6 nests were found in 3 active oil rigs, which had a complete arc cycle of 5-6 m every 5-10 seconds. Another unusual nest was in a gourd attached to the mast of a moving ship (Brown et al. 2021; Campbell et al. 1997; Copley et al. 1999; Graber et al. 1972; Hofstead 1995; Leighton et al. 2002; Limoges and Bombardier in Gauthier and Aubry 1996; Maehr et al. 1988; McIlwraith 1894; Sprunt in Bent 1942; Weir 2008).

The Purple Martin is highly colonial, particularly in the east. Colonies larger than 35 pairs are rare, even where multiple apartment houses are available. The largest reported eastern colony was 300 pairs nesting under boulders and in rock crevices on islands in Minnesota. The largest natural colony of western birds had more than 100 pairs nesting in a sandstone cliff. Despite being colonial, it is territorial. Nests in natural situations in the west were at least 100 m apart, with median nearest-neighbour distances of 325 m and 238 m over 2 years. In apartment houses, a territory consists of 1 or more rooms of the apartment and the porches adjoining the rooms. Roofs of martin houses are not defended and defence does not occur away from the house. Males frequently defend several rooms at the beginning of the nesting season then relinquish some later on. The largest maximum territory size in Texas was 36 rooms, and the largest minimum territory size was 18 rooms. For 30.3% of males, the maximum and minimum territories were the same, averaging 4.1 rooms. Of males that initially defended multiple rooms, 21.5% defended only 1 room as their minimum territory size. Only 12.6% defended 1 room for both their maximum and minimum territory. Shrinking of the territory usually occurs when nestlings are being fed. Defence of multiple rooms early in the nest season may promote polygyny if another female moves into one of the rooms. Usually the male stops guarding

additional females allowing yearlings or floaters to take possession of a room. These birds consistently challenge the dominant male, who often gives up some of the rooms in his territory. Once established, neighbouring males rarely fight or trespass. They may even defend the neighbour's territory when he is absent (Brown 1979; Brown et al. 2021; Morton et al. 1990). In western populations nesting in natural cavities, larger territories of 20-30 m are defended (0.1-0.3 ha), and birds may control cavities as far as 115 m away (Brown et al. 2021).

Natal philopatry is low. In Maryland, less than 2% of young returned to breed (Morton and Patterson 1983). In Texas, less than 1% of birds banded as juveniles were recovered the following year in their natal colony. Only 8% returned to any colony within the 6 km2 where most colonies were located. Brown and Bitterbaum (1980) suspected that those that returned to the natal area did so coincidentally rather than homing. Of birds returning to within 8 km of the natal colony in Texas, 79% were males. Five percent of yearlings returned to breed in their natal colony in Ohio and Maryland. Of 46 yearling birds that were recaptured in the breeding season in Michigan, 28 (61%) were found at the natal site, 7 (15.2%) were within 12-35 km, 8 (17.4%) were within 45-93 km, and 3 were at distances of 160, 274, and 338 km (Allen and Nice 1952; Brown et al. 2021; Morton et al. 1990). In Alberta, 2 nestlings returned: one to the natal area and the other nested 37 km away (Finlay 1971). Tarof et al. (2011) recorded a return rate of 22% of fledglings in Pennsylvania. Some of these may have nested a considerable distance from their natal area. de Greef et al. (2012) reported average dispersal distances of juveniles of 63 km (range 0-2,644 km). Most (70.9%) dispersed 50 km or less from the natal site; 1.6% dispersed further than 500 km. Longitudinal dispersal averaged further (97 km) than latitudinal dispersal (54 km).

Adult nest-site tenacity is fairly high. In Pennsylvania, birds were studied at 2 breeding colonies 19 km apart, at other colonies within 50 km of the core colony area, and at a large premigratory roost that was known to attract Purple Martins from distances of 200 km or more. Of birds breeding at age 1 year, 84% of females and 87% of males returned the following year. Of birds that bred at a colony in their first and second years, 91% of females and 84% of males returned to breed again (Stutchbury et al. 2009). In Texas, approximately 35% of nesting mature birds returned to the same breeding area. In Maryland, 55% of adults nested at the same colony as in previous years, and many nested in the same apartment house. In Ohio, 1 bird nested 16 km from its previous nest site; another nested 160 km away (Brown and Bitterbaum 1980; Brown et al. 2021; Morton et al. 1990).

Limiting Factors

Eggs have been found in Ontario nests from the last week of May until the first week of August, with most present in the last half of June (Peck and James 1987). In the south, nest building may not be initiated for 6-8 weeks after arrival, but this interval may be 2-4 weeks in Ontario; 2-3 weeks elapse before nest building in Michigan. Adults arrive before yearlings and have a longer period between arrival and nest building; yearlings may begin nesting 1-2 days after claiming a nest site. In Alberta, adults took an average of 13.6 days for nest construction compared with 7.6 days for yearlings; later-nesting birds built the nest quicker. When age groups were combined, time for nest construction averaged 11.8 days (range 5-27 days). More time may elapse between nest completion and egg laying. In Alberta, this interval averaged 3.2 days (range 0-9 days); the interval in Michigan was 4-5 days. Eggs are laid at the rate of 1 a day. Full incubation occurs by the time the penultimate egg is

laid. The incubation period has been reported as 12-20 days, but is typically 15-18 days. Estimates of less than 14 days may be errors. Incubation periods of 14-17 days have been reported in Ontario. Most eggs within a clutch hatch in 24-36 hours, rarely 4 days. Young fledge when they are 24-37 days old, but 28-29 days is probably typical. Nestlings leave one at a time and usually do not all leave on the same day. Broods of 6 may take 3 days to leave the nest; fledging of a brood may take as long as 8 days. If a nestling remains in the nest after the rest have left, adults continue to feed it until it fledges (Allen and Nice 1952; Brown et al. 2021; Campbell et al. 1997; Finlay 1971; Graber et al. 1972; Johnston and Hardy 1962; Morton and Derrickson 1990; Peck and James 1987; Sprunt in Bent 1942).

Typically 1 brood is raised a year; only 1 is raised in Ontario. Double broods have been confirmed only in Texas. Clutches of 2-7 eggs have been reported in Ontario, with most containing 4 or 5 eggs. Overall, clutches of 1-8 eggs have been reported, but 3-6 is typical. Clutch size declines with season, chiefly because later-nesting yearlings have smaller clutches. Yearlings produced fewer eggs than adults in Texas (4.11 compared with 4.97 eggs) and Alberta (4.29 compared with 5.00 eggs). Replacement clutches average 0.5-1.0 egg smaller than first clutches. In Alberta, all replacement clutches contained 4 or 5 eggs compared with 5 or 6 eggs for first nests (Allen and Nice 1952; Brown 1973; Brown and Bitterbaum 1980; Brown et al. 2021; Campbell et al. 1997; Finlay 1971; Graber et al. 1972; Peck and James 1987, 1997; Sprunt in Bent 1942).

The age at first breeding is 1 year; copulation has been observed by birds that were only 29 days old. Juveniles that have been fledged for as little as 6-7 weeks may start to defend nest sites. Although most yearlings breed, there is also a floating population of males and females. Stutchbury (1991) determined that male floaters without territories were present in an Arizona population. Floaters intruded on territory holders early in spring prior to egg laying but incursion decreased to almost zero during egg laying and incubation. Most floaters (21 of 41 adult males and 46 of 47 subadult males) obtained territories by gaining control over some of the cavities defended by a territorial male. In the other cases, floaters defended territories where the previous owner was no longer present. Most floaters eventually established a territory after 2-29 days. Brown (1978a) noted nonbreeding floaters in Texas that included males, females, adults, and first-year birds. These birds did not successfully acquire a nest and breed. Nest-site availability did not appear to be limiting in this population. Some yearling males are unsuccessful in defending a nest site, or they may be expelled from nest boxes by starlings or House Sparrows. In a Maryland colony, 12.9% of yearling males were unmated compared with 3.6% of adult males and 0.6% of females. This suggested that there was a shortage of females in the population. Birds breed every year if they can find a suitable nest site. Mate replacement may occur if 1 member is lost. When the male disappears, often no other males show interest in the widow, and she raises the brood herself. When a female is lost, the male usually finds a replacement in 2-4 days. The new females ignore the previous clutch; a new nest is built over it and another clutch is laid. The same individuals rarely remate in subsequent years even when both are present. Two of 15 (13%) pairs whose both mates were present remated in Maryland. The annual pair bond dissolves after young fledge (Brown 1978b, 1979, 1983; Brown and Bitterbaum 1980; Brown et al. 2021; Finlay 1971; Morton and Derrickson 1990).

The Purple Martin is typically monogamous, although polygyny occasionally occurs. In Texas, about 20% of males were polygynous early in the season, but only 5% continued as polygynists

throughout the season. Polygyny usually occurs when a female allows a second female to settle in a male's multi-compartment territory before he has relinquished part of it. The male provides parental assistance to both females, although generally more to the first female (Brown 1975, 1979; Brown et al. 2021; Southern 1959). Females are frequently subjected to forced extra-pair copulations so not all young in a nest may be related to the male. Older males father a high percentage of eggs in their nests but yearlings may not be related to any of the young in their nests (Morton 1987). Intraspecific nest parasitism may occur occasionally early in the laying period. In Oklahoma, 7 of 394 nests (1.8%) contained parasitic eggs; no cases of parasitism were reported from hundreds of nests in Texas (Davis 1988; Morton et al. 1990; Wagner et al. 1996).

Almost all food is captured aerially, frequently at altitudes of at least 50 m. The Purple Martin forages higher than other swallow species, often to heights of 150 m. When it is cool in the spring, it may feed low over ponds and lakes to take aquatic insects. Rare foraging techniques include gleaning insects off foliage, taking caterpillars or other insects while walking on the ground, and skimming insects off the surface of water or even diving into water. It may rarely converge on swarms or mass emergences of insects. It does not forage when temperatures are below 9°C due to the scarcity of flying insects and may require temperatures of at least 13°C to forage successfully and survive. Foraging does not occur during rain regardless of temperature. Food may be a limiting factor for nestlings because the number of feedings per nestling is negatively related to brood size. Chick starvation is common (Brown 1976: Brown et al. 2021; Wagner et al. 1996). In Illinois, it preferred to forage over fallow fields followed by, in order of frequency, shrubby areas, oat fields, soybean fields, alfalfa fields, and corn fields (Graber et al. 1972). In Quebec, 33 Purple Martins from 7 colonies had foraging ranges of 0.4-65.2 km2 (mean 8.28 km2). Their foraging habitat consisted of 25.4% developed land, 17.6% cropland, 16.0% forest, 13.5% water, and 2.4% wetlands (Dunoyer et al. 2024).

The Purple Martin feeds almost exclusively on insects, although it may consume a few spiders. The insects eaten appear to reflect local availability and vary seasonally and geographically. Young nestlings are fed mostly small crushed beetles, but older nestlings are fed larger prey including dragonflies, grasshoppers, butterflies, small snails, and eggshells. Favoured nestling foods included monarch butterflies and green darners (Brown 1978b; Brown et al. 2021; Finlay 1971; Sprunt in Bent 1942). Walsh (1978) studied the diet of nestlings in Alberta in 1970 and 1971. Darners (a family of dragonflies) constituted 22% and 27% of the weight of insects fed to young over the 2 years. Percentages of other insects fed to young were flower flies (29% and 17%), brush-footed butterflies (1% and 23%), midges (10% and 4%), horntails (5% and 5%), ants (4% and 6%), long-horned beetles (5% and 2%), skimmers (dragonflies) (1% and 4%), narrow-winged damselflies (4% and 1%), house flies (3% and 1%), bees (2% and 1%), caddisflies (2% and 1%), water boatmen (2% and 1%), and others (8% and 6%). Brush-footed butterflies were significantly more important in the diet in the second year because nesting was initiated later when these species were more abundant. The mourning cloak butterfly was taken most frequently; its adults do not emerge until later in the summer. In Quebec, the diet of 29 nestlings was comprised of 38.5% flies, 34.2% beetles, 11.1% lepidopterans, 7.3% mayflies, 3.1% caddisflies, 2.3% bugs, 2.0% hymenopterans, 1.0% odonates, and 0.5% neuropterans. As nestlings aged they were fed more beetles and mayflies and fewer flies. The

nestling diet was initially dominated by small soft-bodied prey. Older nestlings were fed larger, more chitinous prey such as beetles (Dunoyer et al. 2024).

Beal (1918) examined the contents of 205 adult stomachs. The food was entirely animal matter, predominantly insects with a few spiders and other arthropods. Hymenopterans were the most abundant food and constituted 23% of food items, including 3.5% ants. Flies were second in abundance at 16.1%. Important fly families were crane, house, and robber flies. Bugs comprised 14.6% of the diet, including stink and ebony bugs. Beetles totalled 12.5% of food, including weevils and ground, tiger, and scarab beetles. Adult moths and butterflies comprised 9.5% of the food. Dragonflies were a favoured food, comprising 15.1% of items consumed. This suggests that dragonflies are actively hunted and, since many were larger species, they are a significant component of the diet. Grasshoppers and crickets constituted 1.1% of the diet; miscellaneous insects and invertebrates were 8.1%. These included mayflies, spiders, isopods, mollusc shells, and fish vertebrae. Adults feed on a wide variety of insects, with 57 families of insects found in the diet in a Kansas study. The overall diet includes beetles, bugs, damselflies, dragonflies, leafhoppers, grasshoppers, crickets, butterflies and moths, wasps, bees, caddisflies, spiders, cicadas, winged termites, mayflies, tent caterpillars, scarab beetles, ground beetles, weevils, aphids, ebony bugs, ichneumonid wasps, crane flies, robber flies, and harvestmen. The diet varies seasonally based on insect availability. Flies and soft-winged bugs predominate early in the season with true bugs, butterflies and moths, hymenopterans, and dragonflies consumed later; beetles are eaten throughout the breeding season (Brown et al. 2021; C.D. Riggs 1947; Sprunt in Bent 1942). Johnston (1967) studied seasonal variation in the martin's diet in Kansas. Beetles were consistently a high proportion of the diet varying between 32% in June and 68% in April. Scarab and ground beetles and weevils were the most important beetles. True bugs comprised only 2% of the May diet but 28% of the June diet. Soft-winged bugs were unimportant most of the breeding season except in May when aphids comprised 17% of the diet. Flies formed 3-20% of the diet with the minimum in August and maximum in April. Crane flies were the most important of this group. Consumption of hymenopterans was low in April (2%) and May (8%), but was 35% in June and 32% in August. Ichneumonid wasps were the most important hymenopterans. Butterflies were important only in August when they comprised 14% of the diet. The variety and mass of insects eaten was greatest in August. DNA metabarcoding of Purple Martin fecal samples from 2 sites in the United States and one in Winnipeg determined that 71 species of 39 families in 10 orders of invertebrates were consumed. The most important orders were flies, lepidopterans, and odonates, with lesser numbers of beetles, mayflies, bugs, and hymenopterans. Ticks and orthopterans were least important; caddisflies were consumed only at Winnipeg but were fairly common in the diet (Forsman et al. 2022). In Quebec, the diet of 69 chick-rearing adults was comprised of 42.1% beetles, 25.6% flies, 9.6% lepidopterans, 9.5% bugs, 6.0% hymenopterans, 4.3% caddisflies, 1.2% mayflies, 1.1% fleas, 0.5% odonates, 0.08% neuropterans, and 0.08% orthopterans (Dunoyer et al. 2024). Wade (1966) stated that Purple Martins consumed 2,000 mosquitoes per day. He concluded that this was conservative, and that 10,000-12,000 might be eaten in a day. Kale (1968) concluded that mosquitoes are a negligible item in the diet. Behaviour patterns of mosquitoes and martins result in them seldom overlapping, and none of the literature reporting it eating large numbers of mosquitoes is

substantiated. Martins and mosquitoes very rarely occur together in the same place or at the same time. The claim that martins regularly consume 2,000 or more mosquitoes a day is incorrect.

Cowbird parasitism of the Purple Martin is rare, or perhaps non-existent. Campbell et al. (1997) reported an incident of cowbird parasitism in Michigan where the egg was rejected. Brown et al. (2021) concluded that reports of cowbird parasitism were not credible.

Adverse weather is a significant limiting factor to the Purple Martin. It is not well adapted to cold or rainy weather in spring and early summer. More northerly populations are small and ephemeral due to weather effects. Regional populations as far south as the mid-Atlantic states are periodically eliminated or reduced due to cold weather. During cold weather that lasts 3-4 days, eggs may become chilled as a result of adults' spending longer times foraging. These eggs do not hatch and are abandoned. When weather is cold, adults cannot find insects and they may perish as well. A hurricane in June 1972 eliminated populations from Virginia and Massachusetts west to the Great Lakes. It was estimated that 90-100% of nestlings and thousands of adults died, while survivors deserted colonies. After 3 days of temperatures below 6°C, territorial defence ceased and as many as 10 adults huddled together in a single compartment. When the cold snap extended another day, some adults died. After significant declines, it may take as long as a decade for populations to recover. Excessive summer heat coupled with parasites may cause death of nestlings; they may jump from the nest under these conditions (Brown 1976; Brown et al. 2021; Finlay 1976; Graber et al. 1972; Mayfield 1964; Sprunt in Bent 1942). Cold or wet weather may delay nesting and result in smaller clutch and brood sizes. Young that fledge later in the season have lower annual survival rates because of less foraging time and experience before migration (Tarof et al. 2011).

Availability of nesting cavities is another significant limiting factor. Existing colonies often increase in size if additional houses are provided, or new colonies may become established with provision of houses. Nest-site availability was the major limiting factor at Long Point, and populations started to recover in British Columbia when a nest-box program was initiated (Brown et al. 2021; Copley et al. 1999; Holroyd 1975). Raleigh et al. (2019) concluded that the use of artificial nesting houses was a significant component in the conservation of eastern populations of the Purple Martin. Nest success in artificial nesting structures was greater than 85%; clutch size and the number of fledglings produced was slightly higher in structures with entrances designed to exclude starlings.

There is intense competition for nest sites, particularly from starlings and House Sparrows. These 2 species take over nest cavities or make them unsuitable for nesting by stuffing them full of grass. Both species throw out martin eggs and young and usurp nests. Starlings may trap adults inside and enter and kill them. Population declines have been attributed to competition with House Sparrows and European Starlings; local extirpations of martin populations may occur without human intervention. Native species may also compete for nest cavities including Tree Swallow, Northern Rough-winged Swallow, Great Crested Flycatcher, Northern House Wren, Eastern Bluebird, House Finch, and Red-headed Woodpecker (Allen and Nice 1952; Brown 1981; Brown et al. 2021; Copley et al. 1999; Graber et al. 1972; Jackson and Tate 1974; Perry and Bloch 1987; Sheppard et al. 1936).

Price (2004) concluded that the range of the Purple Martin might increase in southern Ontario if the average summer temperature increased by 2°C.

Status

McIlwraith (1894) stated that the Purple Martin was generally distributed in Ontario, but common nowhere. At Toronto, Fleming (1907) reported that it was a regular summer resident, but local and declining in numbers. Sheppard et al. (1936) considered it common but very local in the former Welland County, where it nested only in houses erected for it. In the former County of Lincoln, it was less common and local in small colonies. Baillie and Harrington (1937) considered it a common breeder in the south, especially in and around towns, north to Manitoulin Island, northern Frontenac County, and Renfrew County. It also bred at Kenora, Lake of the Woods, and near Lake Superior wherever suitable breeding sites were available. Mills (1981) noted a general increase in the mid-1970s in Muskoka and Parry Sound districts. James (1991) termed it a locally common summer resident north to Georgian Bay and Ottawa, uncommon and local north to Sudbury, and an occasional straggler in the north to Kenora and Thunder Bay.

The second atlas showed that the range of the Purple Martin had contracted significantly since the first atlas. It was no longer present at Lake Temagami, Lake Nipissing, Thunder Bay, Dryden, or in the Sudbury area. It disappeared from much of the southern Canadian Shield and the inland areas of southwestern Ontario. South of the Shield, it was predominantly associated with the shorelines of Lakes Huron, Erie, and Ontario, and along the St. Lawrence and Ottawa rivers. Its probability of observation declined significantly province-wide and in every region where it occurred, except in the Boreal Forest Region where it is rare. It was most abundant in the Niagara Peninsula, Chatham-Kent, and Essex and Lambton counties, with areas of moderate density around Lake Simcoe, along the St. Lawrence and Ottawa rivers, and in Prince Edward County (Cadman in Cadman et al. 2007).

Purple Martin populations have fluctuated considerably historically. It was probably uncommon prior to European settlement, but prospered with forest clearing, construction of buildings, and provision of nest sites for it. It probably reached its peak population in the mid-19th century. Populations declined significantly in the late 19th century due to introduction of the European Starling and House Sparrow. In New York, the population declined 30-50% between 1860 and 1910 due to these 2 species. In 1911, the Purple Martin was the third most abundant bird in Montreal; by 1974, Quebec colonies were scattered and the largest known colony was 70 birds. The northern limit of its range shifted southward in the 20th century. It no longer occurs in the Northwest Territories and it does not occur as far north in British Columbia as previously. In April 1982, it suffered a serious decline in Ontario and New York and probably Quebec because of unusually cold temperatures (Brown et al. 2021; Limoges and Bombardier in Gauthier and Aubry 1996). Long-term (1970-2021) Breeding Bird Survey (BBS) data indicate an annual increase of 0.772% in Canada and an annual decrease of 3.5% in Ontario. The short-term (2011-21) trends were an annual increase of 5.92% in Canada and an annual decrease of 0.998% in Ontario. The long-term data were highly reliable; the short-term data were of low reliability (A.C. Smith et al. 2023).

Michel et al. (2016) used BBS data to analyze population trends of the Purple Martin over broad geographic areas and to compare its trends with those of other aerial insectivores. Purple Martin populations were stable in the extreme northeast but declined in the Great Lakes region, with

stronger declines in the north and west. Southern Ontario was one of the areas experiencing the greatest rate of decline. There was little concordance among the trends of the aerial insectivores. The strongest relationship was observed in the Great Lakes area, where declining trends of the Barn Swallow were positively correlated with those of the Purple Martin and Tree Swallow. The Purple Martin exhibited the second-highest probability of decline behind the Chimney Swift. Although the aerial insectivores are often considered a guild that is described as having a negative trends, only 1 of the 5 species examined, the Chimney Swift, exhibited significant declines in over half its population trajectories. Results indicated that declining population trends among aerial insectivores are not universal either within or across species.

POSTFLEDGING PERIOD

Young begin catching insects 4-5 days after fledging and are independent 7-10 days after fledging. When young fledge, they are immediately led away from the nesting colony by the adults to what have been termed grouping or gathering areas. Large numbers of broods assemble in these areas. Gathering areas may be in trees and on television aerials, but most frequently on utility wires. Birds congregate under concrete bridges in some places. Twenty-six broods assembled 90 m to 1.6 km from the nesting area and most were within 1 km of the nest; 15 broods were not found within a 1.6-km radius. Broods remain at the gathering area 2-3 days after the last young fledges then leave before they are completely independent. It is uncertain where they go, but they may join premigratory roosts. While at the gathering area, fledglings may return to roost at the nest at night or during daytime storms, but typically only until 7-10 days after fledging (Brown 1978b; Brown et al. 2021; Morton and Patterson 1983). In Maryland, a nesting colony of 3 apartments was used as a postbreeding roost. Young continued to use the colony for roosting until early August. Of juveniles using the colony, 74 (54%) had been raised in the colony and 63 (46%) were immigrants. Broods native to the site that had a parent present were most likely to have all brood members in the roost, even though they were scattered throughout the compartments and houses (Morton and Patterson 1983). During autumn in Streetsville, both young and adults congregated in spruce trees around houses, and adults were still fledging young (Mitchell 1947).

Flocking into premigratory roosts by adults occurs as soon as young fledge. In the southern portion of the Purple Martin's range, large late-summer roosts of 100,000-200,000 have been reported. Precise roosting locations may vary year to year, but the general location of large roosts appears to be traditional. Although roosts may occur in a variety of habitats, many are associated with water. In 1986, a swallow roost in cattails in the Kingston Cataraqui Marsh contained at least 600 martins in late July and over 2,400 in mid-August. In Pembroke, Purple Martins roosted on a point at the confluence of the Muskrat and Ottawa rivers in the canopy of a 0.5-ha stand of black willows 10-15 m tall. At the eastern end of Hamilton Harbour, 1,500 were present in a roost on 6 September 1959. In Illinois, dense willow stands 3-6 m tall along watercourses were particularly favoured for roosts. Roosts also occurred on city buildings, power lines, and sandbars in rivers. One large roost was in a 12-ha hawthorn thicket. In South Carolina, a roost of almost 2 million swallows was on an island in a lake. In Arizona, groves of cottonwoods were used as roosts. A roost in a New Jersey city was on the main street in a 1-ha grove of silver maples. Although there were hundreds of similar areas, only this area was ever used. In this area, there were only 150 breeding pairs, but at

least 15,000 martins came to the roost every night (Brown et al. 2021; Cater 1944; Curry 2006; Graber et al. 1972; Ross et al. 1984; Russell and Gauthreaux 1999; Sprunt in Bent 1942; Weir 2008).

Home range size during the postfledging season is unknown, but may be extremely large. In Arizona, it was thought that birds at a premigratory roost covered approximately 1,400 km2 during the day; at a South Carolina roost, some birds flew as far away as 100 km in a day (Cater 1944; Russell and Gauthreaux 1999).

MIGRATION

Migration is on a broad front, with most of the eastern population crossing the Gulf of Mexico. Autumn migration may begin when young fledge, so departure may be staggered within an area and vary year to year. Autumn migration may be nocturnal, at least in part (Brown et al. 2021; Graber et al. 1972).

In southern Ontario, most birds arrive in mid-April with early arrivals in late March. In the southern Shield, arrival extends through May, with a few arriving in mid-April. Autumn migration is underway in August, with most leaving the province in early to mid-September, but stragglers may occur until mid-October (Black and Roy 2010; Curry 2006; LaForest 1993; Mills 1981; Tozer 2012; Weir 2008).

The first spring arrivals are adult males followed closely by adult females, although both sexes of adults may arrive at nearly the same time. In Michigan, yearlings often arrive weeks after older birds. Yearling breeders return significantly later than all other age classes. Males returned earlier than females for all age classes (Allen and Nice 1952; Morton and Derrickson 1990).

In British Columbia, migrants occurred in open areas of coastal lowlands, where they often foraged over large lakes, harbours, estuaries, bays, marshes, agricultural fields, and intertidal areas (Campbell et al. 1997).

During migration, the Purple Martin may roost colonially in urban areas and towns, but it may also roost in areas associated with forests and water. Fournier et al. (2019) identified 48 migration roost sites and determined that forest islands (small forests surrounded by unsuitable habitat) were used for roosting more frequently than they occurred in the landscape and that martins roosted in areas further from water than availability. Seventy-five percent of roost locations were in forests, 13% were in agricultural areas, 8% were in urban areas, 2% were in wetlands, and 2% were in cut forests. Results suggested that it routinely uses forested habitat and that forested islands are preferred. These habitats may afford enhanced predator protection and the surrounding open spaces may provide suitable foraging habitat. Previous anecdotal information indicated that it roosted near human development, but this study demonstrated that it preferred more remote areas.

In New York, Zelt et al. (2017) compared spring arrival dates, autumn departure dates, and length of the breeding season for 1888-1939 and 1967-2012. There was little climate change during the first period but significant warming during the second period. The Purple Martin arrived significantly earlier during the second period, but there were no differences in its autumn departure dates or length of breeding season.

James (1991) considered the Purple Martin a common to locally abundant migrant in Ontario.

Barn Swallow

Hirundo rustica

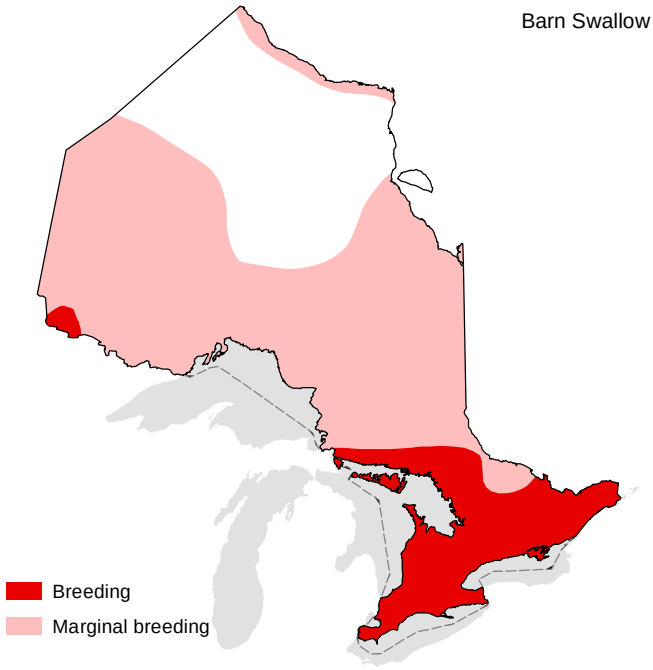
BREEDING SEASON

Habitat Requirements

In Ontario, the Barn Swallow breeds in a wide variety of habitats, but is essentially absent in extensively forested areas and muskeg. Breeding habitats were farmland, including crop fields, pastures, and coniferous plantations (36.0% of records); at lake and river shorelines and along road rights-of-way (30.5%); in wooded clearings, including cottage areas and parkland (25.6%); in urban areas, including residential and commercial land (17.2%); on rocky cliffs and islands (15.8%); in marshes, bogs, meadows, and floodplains (3.9%); in sand-dune areas (3.7%); and on tundra (3.2%). Nesting in wet habitats appeared to be due to presence of open areas for foraging. The primary influence on habitat selection was presence of human-made structures for nesting, such as bridges and buildings. More than 88% of nests were on artificial sites (Peck and James 1987).

The Barn Swallow was negatively correlated with organic farms and more abundant on conventional farms in southern Ontario. Field sizes were smaller on organic farms. Herbicides, insecticides, and chemical fertilizers were applied at conventional farms; biodynamic sprays were

used at organic farms only. It was significantly negatively correlated with the amount of hedgerows but was positively correlated with farmsteads (Kirk et al. 2011).



Breeding habitat typically contains open areas for foraging, a nest site with a vertical or horizontal substrate that is protected from the elements by a roof or overhang, and a source of mud. Historically, the Barn Swallow nested in caves and rock crevices and occasionally in hollow trees, but it now occurs mostly in agricultural areas, cities, suburbs, and along highways where there are buildings and culverts. In British Columbia, 80% of nests were in human-influenced habitats: 34% in rural areas, 21% in cultivated farmlands, and 20% in suburban and urban areas. Associated foraging areas included rural and urban backyards, farmyards, farmland, roadsides, weedy fields, near water (lakes, marshes, and streams), meadows, orchards, and vineyards (Brown and Brown 2020; Campbell et al. 1997; Fitch 1958; Samuel 1971).

Both members of a pair may roost together in the nest cup over night, but begin roosting elsewhere once the young are near fledging (Brown and Brown 2020).

Ontario nests were inside or outside buildings, on beams and posts, under eaves and awnings, under roof peaks, on walls, on verandahs, on light fixtures and wires, over windows and doors, and on pipes and ventilators (71.6% of records); under bridges and in road culverts (14.9%); on rock faces and in caves (12.2%); on dredgers and trucks (0.8%); on concrete walls (0.3%); and on a tree limb (0.2%). Occasionally, the Barn Swallow nested in unusual sites, including on hanging pieces of paper and cloth, a gear wheel, a pulley, a leaning plank, and a sunflower seedhead tacked to a barn beam. The only nest found in a tree was on a limb at a major fork in a white birch. Most nests were attached by mud to a vertical surface close to an overhead horizontal surface; many were on horizontal ledges or various substrates. Old nests were often reused and occasionally old Eastern Phoebe and American Robin nests were used. Nests in road culverts were 3-9 m from ground or water. Nest heights in other areas ranged from 0.3 to 10.7 m, with most 2-3 m up. Three exceptions were nests 15.2 m up on a bridge, 25.9 m up on a tower platform, and 45.7 m up on a rocky cliff (Peck and James 1987). The Barn Swallow has nested on rock faces and cliffs at 10 locations in Algonquin Park (Tozer 2012). Other unusual nest sites were reported in Ontario: on a ferry in the Kingston area (Weir 2008); a nest attached to a wire running between the peaks of a small barn (Rayner 1988b); and in a parking garage in Kingston. It had access to the garage only when a vehicle went in or out (Fairfield 2001). Artificial nesting structures are frequently built for Barn Swallows in Ontario. These are 2.1 x 1.8 m roofed wooden structures on 3.6-m poles with predator guards on them. Wooden artificial nest cups

are provided within the structure. Usage of these by swallows is very low, probably because they are too small. Larger structures measuring approximately 3 x 3 m are often successful in attracting nesting Barn Swallows (personal observation).

Erskine (1979) examined approximately 5,000 nest record cards across Canada. Only 48 nests (1%) were on cliffs or in caves, 54% were in buildings, 33% were on the outside of buildings, and 12% were on other structures. In Manitoba, Knapton (1988a) reported 6 nests on an 8-m high cliff face on an island in Lake Winnipegosis. Three nests were in natural cavities of the rock and the others were on the cliff face. Traditionally, the Barn Swallow nested predominantly in caves or in crevices in rock faces. It prefers to nest 1.2-7 m or more away from entrances to caves and buildings, and in the darkest portions of culverts that are typically avoided by Cliff Swallows. Most Quebec nests were on artificial substrates, but some were under rock outcroppings on cliff tops, on trees, and inside caves. In British Columbia, 1% of nests were in caves, cliffs, or banks of sand or rock, and in tree cavities. The rest were on artificial structures: 92% in or on buildings, and 4% on other structures such as wharfs or bridges. All Illinois nests were in or on buildings or under cement or metal bridges and culverts. In the Yukon, picnic shelters at campgrounds are regular nesting sites. There are numerous reports of it nesting on boats and ferries that travelled daily distances of 20 km or more. It has nested on moving oil pumps in Saskatchewan, on a train in British Columbia that carried passengers over a 3-km portage, and in wells and abandoned mine shafts. An Ohio nest was suspended from a wire, and nests have been built on top of coils of wire and in a willow tree overhanging a river. Height of British Columbia nests was 0.3-30 m, with most 2.4-3.5 m up (Bent 1942; Brown and Brown 2020; Campbell et al. 1997; Graber et al. 1972; Landry and Bombardier in Gauthier and Aubry 1996; Lesher 1988; Murray 1962; Radford 1971; Redmond and Murphy 2007; Samuel 1971; Sinclair et al. 2003; Stewart 1954). In North Carolina, Barn Swallows readily used artificial nest cups attached to concrete girders under a pier (Mercadonte and Stanback 2011). In Mississippi, it nested exclusively on bridges. No bridges without water under them were used. Bridges constructed primarily of wood and that did not have utility wires nearby were used significantly less than expected. Bridges on gravel and dirt roads were used significantly less than expected. Significantly more bridges oriented on a north-south axis were used than east-west bridges. Bridges with nests had a significantly shorter span (5.38 m compared with 11.79 m), higher end walls (1.76 m compared with 1.26 m), and were wider (12.18 m compared with 9.51 m) than bridges without nests. The minimum culvert opening it used was 0.9 by 0.9 m. The mean height above ground or water at the centre point of the bridge was lower for bridges with nests (2.12 m compared with 2.57 m), but the difference was not significant. Nests were very close to the floor (4.34 cm from the top of the nest to the floor of the bridge) and away from the edge of bridges (average 4.25 m). Cement construction was the main factor in determining bridge use for nest construction. Reasons for selecting these nesting parameters may be that utility lines provide necessary perches; wooden bridges are more accessible to predators and may contain creosote that may be toxic or noxious to birds; unpaved roads are more likely to have wooden bridges through which dust and small pebbles can sift through to the nest; and bridges with a north-south exposure of the opening may afford protection from prevailing winds and adverse conditions (Jackson and Burchfield 1975).

Nest-site selection is influenced by the presence of old nests. Some nests have been used for as long as 30 years. Birds that use old nests lay their clutches an average of 12 days earlier than those constructing a new nest and fledge 44% more young. Previous reproductive success at a given nest does not affect the likelihood of it being reused (Safran 2006). In Colorado, 60% of pairs switched nests between their first and second broods. This proportion did not change even if the number of vacant nests increased. Pairs were more likely to settle in old (86%) than new nests (14%). Pairs were more likely to switch to an old (81% of birds that switched) than a new nest (19%), especially if they had first occupied an old nest. Nest switching provided some pairs the opportunity to decrease nest mites in their second nest compared with the first. Birds that settled in an old nest then switched raised significantly more fledglings. The optimum reproductive strategy appears to be to use an old nest for the first nesting attempt and switch to another nest for the second attempt (Donahue et al. 2018).

The Barn Swallow is a territorial species that nests singly or in small, loose colonies. In Ontario, 161 colonies supported 2-59 nests (average 10). When nesting in caves, there are usually only 1-2 nests present. Occasionally colonies of 3-30 pairs have been found in natural areas. Colonies are more common at artificial sites. Colony size increases with barn size. At 15 barns in Wellington County, colony sizes ranged from 1 to 48 nests (average 14). Colony sizes reported elsewhere were: British Columbia, 3-83 nests, mostly 5-14; New York, 2-22 and 2-30; Kansas, 2-14; and an average of 2-3 in Mississippi. Colonies larger than 35 nests are infrequent, with 90 nests the largest reported colony. It appears to be ill-adapted to colonial nesting and may be forced to form colonies where nest sites are limited. Pairs within colonies maintain individual distance and act independently of other pairs. Nests tend to be spaced 2-4 m apart, but may be as close as 61 cm to each other if the birds cannot see each other. Nests without visible neighbours are occupied much more frequently than those with visible neighbours. Hiding the nest from neighbours can reduce the amount of time spent guarding the nest. Nesting in colonies may be disadvantageous because reproductive success may be lower in colonies, less food is available near large colonies, and there is more ectoparasitism, predation, infanticide, and brood parasitism in colonies. Males defend nest sites and their mates, as well as preferred perches nearby. Birds defend from neighbours and unmated birds searching for nest sites or mates. Individuals defend against others of the same sex. Two active Ontario nests were touching each other and 2 on the same beam were only 20 cm apart. Elsewhere, nests have been reported as close together as 10 cm, but nests are typically much further apart. Mean internest distances were 1.7 m in British Columbia, 2.3-3.7 m in Nebraska, and 3.7 m in Oklahoma and in Missouri. Close nests almost always have different approaches for the adults (Bent 1942; Brown and Brown 2020; Campbell et al. 1997; Mercadonte and Stanback 2011; Peck and James 1987; Salvadori et al. 2011; Shields and Crook 1987; Smith and Montgomerie 1992; Snapp 1976).

Home range size is variable, depending on weather and availability of mud for nest building. Birds in larger colonies may have to travel further for insects due to local depletion. In Kansas, 1 pair confined most of their foraging to 8 ha. Most activity of nesting birds occurred within 100 m of the nest barn, but birds occasionally foraged 400-800 m away. Most years, nesting material was gathered close to the nest site, but in a drought year a pair travelled 850 m to gather mud (Fitch 1958). In New

York, birds foraged at sheltered beaver ponds during cool, windy weather. These were 1-6 km from the colony (Shields 1984). In West Virginia, birds foraged within 1.2 km of the nest (Samuel 1971).

Natal philopatry is low: 0.44% in Kansas, 0.57% in Oklahoma, 0.0% in Nebraska, 1.0% in Pennsylvania, and 2.0% in New York and Massachusetts. The 2% that returned in New York represented 7 birds, of which only 5 nested. None bred in their natal colony and their median dispersal distance was 6,375 m with one recovered 15 km from the natal site. Three of the 4 known-sex returning birds were males. In Oklahoma, all nestlings that returned were males. All nested in a culvert other than their natal one. Of returning yearlings in Massachusetts, 95% were males (Brown and Brown 2020; Iverson 1988; Shield 1984).

Adult site fidelity is high. Once a site has been used, it is likely to be used long term. This includes unusual sites, such as an active steamer boat where birds nested in 55 consecutive years. Marked birds have returned to Ontario and British Columbia sites 5 consecutive years. In New York, approximately 40% of adults returned to breed the following year. Annual adult mortality may be 50-70%, so a high proportion of living birds returned. Of returning adults, only 7% changed colonies, 36% of those that returned to the same colony used the same nest, and an additional 29% returned to the same nest cluster. Forty-eight percent of males and 24% of females reused the same nest in subsequent seasons. Most of the colony switches between years were by females. One female moved to another colony and subsequently returned to the original one. Birds that changed colonies failed to raise young the previous year. Successful birds were much more likely to return to the same colony, nest cluster, and nest, and retain the same mate. Mean dispersal distances from the previous year's nest were 25 m for successful males, 820 m for unsuccessful males, 95 m for successful females, and 1,155 m for unsuccessful females. All colony switches and most cluster switches were associated with nest failure or loss of a mate. For replacement nests and second nests in a season, 53% reused the same nest, 88% nested in the same cluster, and 98% nested in the same colony. Within seasons, successful birds were more likely (78%) to switch nests than unsuccessful birds (32%), but the reverse was true between seasons: 53% for successful birds and 67% for unsuccessful birds. Other reported adult return rates are 87.5% and 19.6% in Oklahoma, 34.0% in Massachusetts, 21% in Kansas, 12.3% in Nebraska, and 13% in Pennsylvania. A 10-year study in southern Ontario documented a return rate of 25.9%. In Oklahoma, 16.6% of returning birds used the same nest; mean distance moved from the previous nest was 12.1 m (Bent 1942; Brown and Brown 2020; Campbell et al. 1997; García-Pérez et al. 2014; Iverson 1988; Peck and James 1987; Samuel 1971; Shields 1984; Weir 2008).

Limiting Factors

Eggs have been found in Ontario nests from the second week of May until the third week of August, mostly in the last 3 weeks of June (Peck and James 1987). In Algonquin Park, nests are under construction from early May to mid-July, eggs are present from mid-May to late July, nestlings are present from early June to early September, and dependent fledglings have been observed from mid-July to early September (Tozer 2012).

Nest building may start 5-14 days after spring arrival, but delays as long as 10 days are common during cold, wet weather. The average time to build a new nest was 6.4 days in West Virginia (range 3-10 days), 15 days in British Columbia, and 8-12 days in Illinois. New York nests took 11 days to build

whereas nest renovation time averaged 4-8 days; old nests took 2-5 days to repair in Kansas. Eggs may be laid 1 day after the lining is completed, or not until 2 weeks later. Eggs are laid at the rate of 1 a day, but occasional egg-laying intervals of 2-6 days occurred in Ontario. Initiation of incubation is variable and may start with laying of the third or penultimate eggs in 5-egg clutches. Incubation periods of 9-17 days have been reported in Ontario, mostly 13-14 days. These incubation periods indicate incubation well before clutches were complete as well as delays in incubation. In British Columbia, the incubation period was 12-17 days, mostly 15 and 16 days, and averaging 14.6 days in 1 study. Generally, the incubation period is reported as 13-16 days and most frequently as 15 days. The nestling period is 15-27 days, but mostly 20-23 days. The entire nesting cycle takes 41-51 days (Bent 1942; Brown and Brown 2020; Campbell et al. 1997; Graber et al. 1972; Peck and James 1987; Samuel 1941; Smith and Montgomerie 1992; Voss et al. 2008).

Many pairs raise 2 broods in a season. Second broods are common in Ontario and are often produced in the same nest. Occasionally a different nest is used for the second brood or a new nest may be built on top of the old one. Near Kingston, 30% of pairs raised 2 broods. Higher rates of second broods have been documented: 90% in Manitoba, 37% in British Columbia, 67% in Massachusetts, and 49% in New York. There are reports of the Barn Swallow raising 3 or 4 broods, but this has not been substantiated. These probably represent replacement nests; it may lay as many as 4 clutches in an attempt to raise 2 broods. Birds that initiate nesting early are more likely to raise a second brood; those that use an old nest are more likely to raise 2 broods than those that build a new nest. In New York, 18% of late nesters attempted a second brood compared with 82% of early nesters. In Manitoba, there was no difference in initiation dates at old and new nests. Clutches of 2-7 eggs have been reported in Ontario, with most containing 4 or 5 eggs. Throughout North America, the clutch size is 2-7 eggs, but mostly 4 or 5; clutches of 10 eggs have been reported in British Columbia. Five eggs are most frequent in first clutches and 4 eggs in second clutches. In West Virginia and Kansas, mean clutch size was 4.6 eggs for first clutches and 4.1 for second clutches. In New Brunswick, early nesting birds had larger clutches. Yearling females lay smaller clutches than adults. In small colonies, yearlings laid an average of 5.7-6.2 eggs for their 2 clutches compared with 6.8-7.5 for adults. In large colonies, yearlings laid 6.2-6.4 eggs compared with 7.9-8.3 for adults (Bańbura and Zieliński 1998; Barclay 1988; Bent 1942; Brown and Brown 2020; Campbell et al. 1997; Graber et al. 1972; Imlay et al. 2019; Peck and James 1987; Ramstack et al. 1998; Samuel 1971; Snapp 1976).

Both sexes are capable of breeding when they are 1 year old. In some populations, many yearlings are unable to find a mate and do not breed (Brown and Brown 2020; Shields 1984).

The Barn Swallow is typically monogamous. In Michigan, a male defended a territory with 2 active nests during the first clutch period in 1979. The 2 nests were 0.7 m from each other. The male guarded both females during and prior to egg laying, but only incubated eggs in the first nest. This was the first documented case of polygyny reported in North America (Wolinski 1985). Polygyny may be the reason that some nests have been reported unusually close to each other. The pair bond usually remains intact for both broods (Samuel 1971), but divorce may occur if the pair is unsuccessful in raising a brood in the first attempt. Successful pairs may reunite the following year. At some nests, there may be a third adult. These birds may contribute somewhat towards feeding

of young, but have no influence on reproductive success. Mostly they appear to be trying to replace one of the mated birds. Rarely, the presence of the third adult may result in formation of a polygynous trio (Brown and Brown 2020; Medvin et al. 1987). Extra-pair copulations are common with 22% of nestlings being extra-pair in an Ontario population (Smith et al. 1991). Females rarely parasitize other nests (Brown and Brown 2020).

The Barn Swallow typically forages aerially during the day. It tends to feed lower than Tree Swallows and especially Cliff Swallows, so there may not be significant competition for food among these species. The Barn Swallow seldom forages at heights greater than 10 m and often feeds less than 1 m from ground; occasionally it forages at heights of 20-30 m. Many of the other swallow species feed on small, swarming insects. The Barn Swallow prefers single large prey but takes small insects when they are abundant. It prefers to forage in open habitats over grassy pastures, plowed fields, and water, and around farmyards and domestic animals. In Illinois, favoured foraging habitats were shrubby edges, alfalfa and sweet clover fields, pastures, ungrazed grasslands, roadsides, and drainage ditches. In Saskatchewan, it tended to forage within 400 m of the nest. It preferred to forage in and near wetlands and avoided crop fields. Often it feeds on insects flushed by farm implements, grazing livestock, humans, and flocks of other bird species. Occasionally it lands on the ground to feed on dead or moribund insects, or picks insects off plant, artificial, or water surfaces while it is in flight. During bad weather, it may fly a few centimetres above water and pick insects out of the water, or pick flies off barn walls. It has foraged at night in artificially illuminated areas or even in darkness when attempting to raise a very late brood (Bent 1942; Brown and Brown 2020; Cohen and Dymerski 1986; Graber and Graber 1963; Greenberg 2001; Harris et al. 2024; Hobson and Sealy 1987a; Paton and Fellows 1994; Ramstack et al. 1998; Samuel 1971).

Nestlings are fed insects exclusively. Females feed the young of the first brood more frequently than the male. If a second brood is attempted, feeding frequency by the female starts to decrease 5 days before egg laying in the second nest and ends once laying begins. The male does not increase his efforts in feeding to compensate for less feeding by the female. Survival rates of first broods decline once the female stops feeding and survival decreases with decreasing time between the first and second nests (Naef-Daenzer et al. 2011). Adults do not compensate for poor aerial insect supply on cool days and decrease their energy expenditure by foraging less under these conditions. The energy expended foraging increases with temperature, resulting in a surplus intake under favourable conditions and allowing the brood to accumulate body reserves (Schifferli et al. 2014). Brown and Brown (2020) found 21 families of insects in nestlings' diet in Nebraska. The 15 most common families were, in decreasing order of abundance: dance flies, long-legged flies, blow flies, flower flies, snout moths, snipe flies, ants, scarab beetles, clear-winged moths, flesh flies, lanternflies, house flies, robber flies, soldier flies, and picture-winged flies. Near Cambridge, fecal sample analyses determined that the first brood consumed 11 taxa and the second brood consumed 13 taxa. Only 2 species (9.1%) were eaten by both broods: a stream mayfly and a blow fly. The first brood consumed tiger moths, tent caterpillars, 3 genera of net-spinning caddisflies, mosquitoes, black flies, and horse flies. The second brood consumed 2 species of plant bugs, gypsy moths, oblique-banded leafrollers (a moth), crane flies, 3 species of bristle flies, and weevils. Caddisflies appeared to be important in the diet of the first brood but were not consumed by the second brood. Flies appeared

to be more important in the diet of the second brood. Results suggested that prey availability changes seasonally resulting in the 2 broods having differing diets (Sandilands and Morningstar 2018). McClenaghan et al. (2019a, 2019b) conducted a similar but more comprehensive study in Peterborough County based on 271 nestling fecal samples. A total of 472 taxa were identified, including 130 arthropod families in 13 orders. Flies were the most frequently detected order in nestlings' diet. Bristle flies were the most abundant family, and a cluster fly that is parasitic upon earthworms was the most frequently detected species. Mosquitoes, horse flies, and house flies were frequently fed to nestlings. Small aerial insects less than 3 mm in length represented 76.3% of available insects but constituted only 6.8% of nestlings' diet. Larger aerial insects represented 23.7% of available insects and constituted 16.7% of the diet. Prey items averaged 4.9 mm in length (range 1.1-20.3 mm); available insects averaged 3.4 mm (range 0.1-38.9 mm). Diet varied by site, brood, and year, with site explaining most of the variance. Nestlings were fed different prey items over time and at different sites because prey availability changed temporally and among sites. Eight families of flies were consistently fed to nestlings across sites, broods, and years: bristle flies, limoniid crane flies, crane flies, blow flies, root-maggot flies, house flies, deer flies, and mosquitoes. Change in diet among sites and years was related to prey availability; most prey was fed to nestlings when it was more abundant. Their results indicated that the Barn Swallow has a flexible diet that is adjusted according to changing prey availability; reproductive performance was not affected by prey availability (McClenaghan et al. 2019a, 2019b). Bumelis et al. (2022) determined that nestlings were fed predominately terrestrial prey. Tree Swallow nestlings fed mostly on aquatic prey; Cliff Swallow nestlings had an intermediate diet. In Saskatchewan, Barn Swallow nestlings were fed mostly terrestrial prey, only increasing their aquatic food input when water sources were more available (Diaz Bohorquez et al. 2025).

Adults feed themselves while capturing food for their young, so it is likely that the adult diet is similar. Adults may occasionally eat eggshells or oyster shells provided by humans. Beal (1918) examined 476 stomachs. The diet consisted of 99.8% animal material, almost entirely insects except for a few spiders and snails. Small amounts of vegetation were taken incidentally, but occasionally a berry or seed was ingested intentionally. Real plant food was found in only 4 stomachs and consisted of elderberry, dogwood, and buckwheat seeds. Flies dominated the diet at 39.5% of items; flies were found in 75% of stomachs and constituted 82% of the March diet. House flies dominated the flies consumed, but Barn Swallows also ate crane, horse, and robber flies. Beetles were next in abundance at 15.6%. Eighty species of beetles were found in stomachs, with weevils and ground, lady, and scarab beetles dominating. Bugs comprised 15.1% of the diet, mainly leafhoppers, aphids, and seed, stink, and leaf bugs. Hymenopterans other than ants comprised 12.8% of the diet; ants constituted 9.9%. The lepidopterans consumed were mostly adults, and these comprised 2.4% of the diet. Other items in the diet included grasshoppers and crickets (0.51%), dragonflies (4.0%), mayflies, spiders, and snails. At Vancouver International Airport, it consumed insects from 8 orders, but predominantly hymenopterans (40%), flies (31%), bugs (15%), and beetles (12%). It also ate lepidopterans, odonates, and thrips. The hymenopterans were mostly ants. The flies were predominantly blow flies and the bugs were mostly leaf-footed, seed, and stink bugs. Compared with the abundance of insects captured in traps, it selected for hymenopterans, selected against beetles, flies, and lepidopterans, and consumed bugs at rates similar to their abundance. It selected for insects 4-8 mm in length and

against large (more than 8 mm) and small (0-4 mm) insects. Insects 4-8 mm long represented only 10% of available prey but comprised 70% of the diet. Small insects represented about 80% of insects captured in traps but slightly less than 30% of the diet. Although a wide range of insects was consumed, over half the diet consisted of only 4 taxa: 29% ants, 12% blow flies, and 11% seed and stink bugs. It appeared to select aerial insects of intermediate size, with weak flight, and that occurred at relatively high densities. Selection against beetles and flies may have been due to their small size; lepidopterans may have been selected against because of their large size. Prey profitability increases with the tendency of prey to aggregate in large swarms, such ants and blow flies (Law et al. 2017). Nancekivell and Nocera (2025) used DNA to analyze the adult diet in New Brunswick and compared the diet of the Barn Swallow with those of Alder and Least flycatchers and Bank, Tree, and Cliff swallows. All species differed in their dietary breadth and prey preferences. The Barn Swallow and the 2 flycatcher species consumed a greater diversity of terrestrial flies than the other species, which ate more aquatic taxa. Barn and Tree swallows and the 2 flycatcher species had broader generalist diets whereas Bank and Cliff swallows had more restricted diets. The approximate frequencies of occurrence of invertebrate groups in the diet of the Barn Swallow were 90% aquatic flies, 90% terrestrial flies 10% terrestrial beetles, 10% bugs, and 5% or less lepidopterans, aquatic beetles, hymenopterans, mayflies, odonates, and spiders. The approximate frequencies of occurrence of invertebrate families in the diet of the Barn Swallow were 30% bristle flies, 30% dung flies, 30% root-maggot flies, 30% deer flies, 30% house flies, 25% flower flies, 20% snipe flies, 10% ground beetles, and 5% or less leafroller moths and marsh beetles.

Four of 3,351 Ontario nests (0.12%) were parasitized by the Brown-headed Cowbird. In British Columbia, 0 of 2,426 nests were parasitized. In Oklahoma, 2 of 67 nesting attempts were parasitized, both in the same nest. There are single records of parasitism from Iowa, Manitoba, and Maryland, 3 from Oklahoma and Pennsylvania, and an undetermined number from Kansas. Parasitism does not have serious implications. Cowbird eggs rarely hatch and there is only 1 record of a cowbird fledging from a Barn Swallow nest (Brown and Brown 2020; Campbell et al. 1997; Lowther 1985; Peck and James 1997; Rothstein 1975; Wolfe 1994).

Extreme weather conditions may be one of the greatest limiting factors to the Barn Swallow, particularly cold, wet weather in spring. Adverse spring weather may result in death of nestlings and adults. Adults may huddle together and manage to survive 2-3 days when temperatures are –8 to –9°C, but colder temperatures or prolonged cold results in mortality. Spring weather temperatures probably regulate population sizes at the northern limits of its range. Extremely hot summer temperatures often result in nestling mortality. Mortality is more common in steel-roofed buildings than in wooden barns (Bent 1942; Brown and Brown 2020; Campbell et al. 1997; Samuel 1971). Higher survival rates occur in years with lower wind speeds (Imlay et al. 2022).

García-Pérez et al. (2014) studied the influences of climate on annual survival rates in Barn Swallows in Seattle and southern Ontario. They estimated survival rates in relation to the El Niño Southern Oscillation (ENSO), the North Atlantic Oscillation (NAO), and the total number of consecutive days with maximum daily temperatures less than 11°C during the breeding season. In the Seattle area, both the ENSO and NAO affected survival, but these had no effect on southern

Ontario swallows, with survival rates remaining constant. Temperature also had no effect on Ontario Barn Swallow survival.

In New Brunswick, Imlay et al. (2017) determined that insect abundance did not affect nestling survival or mass. Near Peterborough, McClenaghan (2018) concluded that food availability during the breeding season may not be a limiting factor. Prey availability was unrelated to timing of reproduction, the number of nests at a breeding site, or the reproductive output of individual nests. Put et al. (2021) concluded that Canadian populations were below carrying capacity and that food limitation was not regulating populations.

The House Sparrow may be a significant limiting factor to the Barn Swallow in some areas. In the late 1800s, significant declines of Barn Swallows occurred as a result of House Sparrows, and it was extirpated from large areas of New England at this time. House Sparrows affect Barn Swallow nests by removing nest material, pecking eggs, and removing or pecking nestlings. In Maryland, egg loss resulted in decreased clutch size, some nests were abandoned as a result of egg or nestling loss, and fewer birds had time to raise a second brood. It was estimated that House Sparrows caused a decline of 44.7% in reproductive output (Brown and Brown 2020; Graber et al. 1972; Weisheit and Creighton 1989). In Wellington County, Salvadori et al. (2011) concluded that House Sparrows were a significant problem at some sites, evicting Barn Swallows or forcing them to nest in suboptimal locations.

The Northern House Wren may occasionally puncture eggs, and other species have been known to usurp nests. These include Eastern Phoebe, Tree Swallow, Cliff Swallow, and bats. This happens infrequently and is usually not a significant limiting factor (Bent 1942; Brown and Brown 2020; Butler and Campbell 1987). In Wellington County, Salvadori et al. (2011) concluded that Cliff Swallows were affecting Barn Swallow populations at some sites by nesting in Barn Swallow nests and immediately inside barn doors, forcing Barn Swallows to nest deeper in the barn. The Barn Swallow prefers to nest in good light.

Mite infestations in nests and blowflies may cause nestling mortality, and mites may significantly reduce reproductive success. Adults avoid nests with high mite populations. Presence of mites may explain why some pairs move to another nest for their second brood (Barclay 1998; Bent 1942; Brown and Brown 2020).

Habitat availability for the Barn Swallow has fluctuated considerably. Initially nests sites were scarce, but increased with human settlement and construction of barns and outbuildings that provided ideal nesting habitat. Forest clearing greatly increased the amount of foraging habitat. Many wooden barns have since been replaced by steel structures that provide limited nesting sites and often no access to the interior of the building. The tendency to larger farms has reduced the number of outbuildings. In Wellington County, old wooden barns supported larger colonies than modern, 1-storey structures. Barn Swallows are more abundant in pastured areas than fields with cereal crops, and the number of dairy farms, dairy cows, and pastures in Ontario has declined significantly since 1978. Conversely, increased numbers of cottages and camps in the north, as well as more roads with bridges and culverts have increased potential nest sites (Bent 1942; Brown and

Brown 2020; Campbell et al. 1997; Graber and Graber 1963; Landry and Bombardier in Gauthier and Aubry 1996; Salvadori et al. 2011; Sheppard et al. 1936).

The Barn Swallow may be adversely affected by disturbance. Birds nesting in barns frequently leave when disturbed, even if it is dark outside. Nests in barns may be abandoned if livestock is placed below them. Checking nests after nestlings are 15 days old or disturbing poorly attached nests may result in nestlings jumping to their death or the nest becoming dislodged (Campbell et al. 1997; Samuel 1971). Humans may actively destroy nests due to the nuisance from excreta (Salvadori et al. 2011) and nests may also be removed to avoid the annoyance of the aggressiveness of the adults.

In Wellington County, Salvadori et al. (2011) suggested that predation by cats could be a significant problem for swallows nesting in barns. At a minimum of 2 of the 15 barns they surveyed, cats contributed to the loss of Barn Swallows.

At Vancouver International Airport, the Barn Swallow constituted approximately 35% of all birds struck by aircraft (Law et al. 2017). Collisions with aircraft may be common at airports throughout its range.

Status

The Barn Swallow was probably rare in Ontario and much of North America prior to European settlement. Population increases probably started in the early 1800s when it began nesting on buildings. Baillie and Harrington (1937) considered it a common breeder near habitation from Lake Erie north to at least Lake of the Woods and Chapleau, and they had a record of a dead bird from Moose Factory. Sheppard et al. (1936) reported that it was common throughout Niagara Region, especially around mixed farming areas. In the Clay Belt, it was common wherever there was a settlement (Smith 1957). Peck (1972) reported an old nest in a shed at Cape Henrietta Maria. During the first atlas, it was common in the south, except for a gap in the heavily forested Algonquin Highlands; uncommon to the transcontinental railway; and rare in the north where there are few buildings (Clark and Clark in Cadman et al. 1987). James (1991) considered it abundant in the south and locally uncommon in the north to Hudson Bay.

The second atlas demonstrated that the probability of observation of the Barn Swallow had declined significantly province-wide and in the Great Lakes–St. Lawrence and Boreal forest regions. It was found in every square in the Great Lakes–St. Lawrence Forest Region south of the Canadian Shield except for a few on Manitoulin Island. Breeding evidence was obtained in every square but one in the Carolinian Forest Region. The decline was most prevalent in the Shield. It was most abundant south of the Canadian Shield, particularly in the agricultural areas of the southwest. It was less common south of the Shield in areas that were extensively forested and in large urban areas (Lepage in Cadman et al. 2007).

Barn Swallow populations have fluctuated considerably throughout North America. Populations may have peaked in the mid-20th century. In Illinois, the state population was estimated at 300,000 in 1909 compared with 910,000 in 1957. Graber and Graber (1963) attributed this in part to alfalfa, which became the dominant hay crop. Alfalfa fields were one of the best foraging habitats. Repeat surveys in Illinois in the early 2000s indicated that it had continued to increase its range and numbers

since earlier surveys. This was despite the facts that there were fewer open barns for nesting and less grazed pastureland, a favoured foraging habitat. It began nesting under bridges and large culverts there (Walk et al. 2011).

Long-term (1970-2021) Breeding Bird Survey (BBS) trends indicate that the Barn Swallow decreased at an annual rate of 2.55% in Canada and 2.04% in Ontario. The short-term (2011-21) trends were annual decreases of 1.1% in Canada and 2.23% in Ontario. All results were highly reliable (A.C. Smith et al. 2023).

In Wellington County, Salvadori et al. (2011) monitored Barn Swallow populations at 15 farms from 2008 to 2010. The number of first broods decreased at a rate of less than 1%, indicating more stable populations than the decline reported by the BBS. Despite the small drop in numbers of breeding pairs, the number of young produced increased by 0.5% from 2008 to 2009 and increased a further 8.2% from 2009 to 2010. It has declined significantly in Algonquin Park. Until the end of the 1980s, it nested on almost every building and culvert with suitable nest sites along Highway 60. Surveys conducted from 2007 to 2011 indicated a maximum of about 25 pairs along this route. At 7 sites that formerly supported a cumulative total of 82-87 nests, 0 supported nesting swallows in 2011 (Tozer 2012). Savignac (2011a) concluded that, although the Barn Swallow has declined significantly in Canada and Ontario, it is still more abundant than it was prior to European settlement.

Michel et al. (2016) used BBS data to analyze population trends of the Barn Swallow over broad geographic areas and to compare its trends with those of other aerial insectivores. The Barn Swallow declined throughout New England, the Maritimes, and the Great Lakes region, with strongest declines to the north and east. It increased in Wisconsin, Indiana, Illinois, and Ohio. In the southeast, it was largely increasing or stable, with declines in the mid-Atlantic region, Kentucky, and Tennessee. There was little concordance among the trends of the aerial insectivores. The strongest relationship was observed in the Great Lakes area where declining trends of the Barn Swallow were positively correlated with those of the Purple Martin and Tree Swallow. Of the 5 species studied, the Barn Swallow exhibited the third-highest probability of decline behind the Chimney Swift and Purple Martin. Although the aerial insectivores are often considered a guild that is described as having a negative trend, only 1 of the 5 species examined, the Chimney Swift, exhibited significant declines in over half its population trajectories. Results indicated that declining population trends among aerial insectivores are not universal either within or across species. Put et al. (2021) determined that the Barn Swallow had declined significantly throughout Canada, but the severity of the decline varied geographically.

The Barn Swallow is currently listed special concern in Ontario and Canada.

POSTFLEDGING PERIOD

Broods may travel 0.5 km or further from the nest to roost on wires and remain close by for several days, although young may return to sleep at the nest a few nights after fledging. Young are fed by adults about a week after fledging then disperse widely. A Kansas nestling was found 115 km from the natal area 41 days after banding (Brown and Brown 2020). In British Columbia, fledglings in non-agricultural habitats travelled a maximum of 5 km from the natal site compared with 19 km for those raised in cropland and pasture (Boynton et al. 2020).

In British Columbia, habitat use by fledglings was not random. Cropland was selected, followed by marshes, grasslands, pastures, urban areas, water, barren sites, unknown habitats, and treed areas. Cropland was used significantly more than all other habitats; 36% of habitat used was cropland, which constituted 22% of available habitat. Marshes were used significantly more than all lower-ranked habitats; 20% of habitat used was marshes, which constituted 27% of available habitat. Natal habitat had no effect on postfledging survival, which was low (44%). Crop habitat appeared to be important for fledglings (Boynton et al. 2020).

The Barn Swallow often congregates in diurnal and nocturnal roosts from postfledging until autumn migration. During the day, it regularly perches on fence wires and hydro and telephone lines approximately 10 m up, but does not use high-tension lines that are 30 m up. A nocturnal roost of about 5,000 birds was reported in London in 1898 in a dense stand of willows. The traditional roost at Pembroke is in a stand of black willows at the confluence of the Muskrat and Ottawa rivers. This site was used for more than 15 years. Barn Swallows also roost in the marshes at Presqu'ile Provincial Park and in the Cataraqui Marsh and Little Cataraqui Marsh near Kingston. In addition to traditional late summer nocturnal roosts, it may temporarily roost in cornfields and grain fields (Bent 1942; Campbell et al. 1997; Graber et al. 1972; LaForest 1993; Ross et al. 1984; Samuel 1971; Weir 2008).

D.R. Evans et al. (2020) tracked Barn Swallows from fledging until autumn migration. Only 40-44% survived to migrate. Nestling body condition was significantly correlated with survival.

MIGRATION

The Barn Swallow migrates by day, typically at heights of 30 m or less, but occasionally as high as 75 m. It may also migrate nocturnally when crossing large water bodies such as the Gulf of Mexico. In spring, it tends to migrate singly, in pairs, or in small groups. Autumn flocks may be much larger and mixed with other swallow species (Bent 1942; Brown and Brown 2020; Graber et al. 1972). Birds banded in Ontario have been recovered in Massachusetts and Louisiana; a bird banded in New Jersey was recovered in Ontario (Brewer et al. 2018).

McIlwraith (1894) stated that the Barn Swallow arrived early in May. It typically arrives in the southern portion of the province in mid-April now, occasionally in late March. Arrival in the southern Shield is typically in the last week of April with early arrivals in early to mid-April (Black and Roy 2010; Lancaster et al. 2004; Mills 1981; Smith and Montgomerie 1992; Tozer 2012; Weir 2008).

Spring arrival usually coincides with the first few days when temperatures reach about 20°C. Arrival dates at a particular colony may be very consistent year to year, but vary considerably from colonies a short distance away. In Illinois over a 25-year period, swallows arrived at 1 barn 11-13 April and 13-17 April at another. In Virginia, arrival at 4 barns in a small study area was on 6, 16, 20, and 21 April (Graber et al. 1972; Samuel 1971).

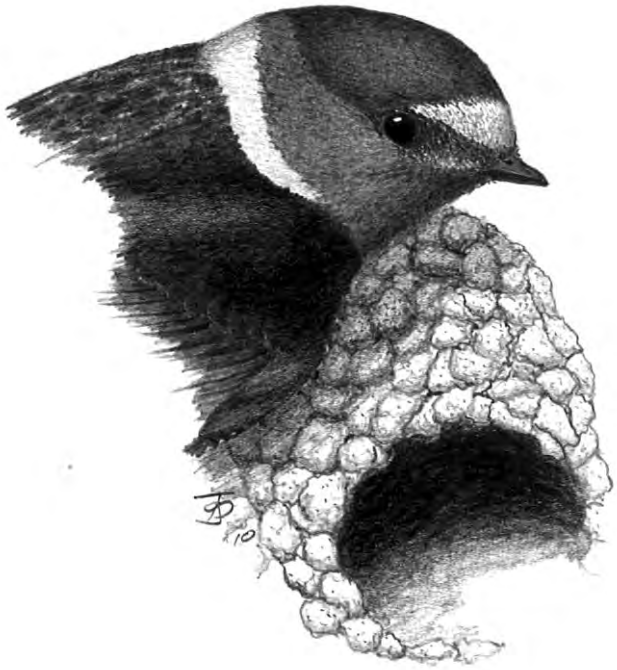
Autumn migration may begin in mid- to late July, with peak numbers in Ontario postbreeding roosts in the last week of July and first week of August. Most birds leave the province by the last week of August or first week of September, but in southern Ontario there are occasional stragglers into late October, rarely to mid-November or even early winter (James 1991; Smith and Montgomerie 1992; Tozer 2012; Weir 2008).

The Barn Swallow forages while it migrates and occurs in habitats similar to those used during the breeding season. Migration often occurs along coastlines, rivers, and lakeshores, and birds concentrate over lakes and ponds during cold weather. It occurs in suburban areas during migration where it forages over gardens, parks, fields, shopping malls, airports, and anywhere with open space. It is probably more abundant outside suburban areas in habitats such as fields, orchards, farmyards, feedlots, rural residences, and anywhere with an abundance of insects. During migration, it tends to avoid forested areas (Brown and Brown 2020; Campbell et al. 1997).

The Barn Swallow is common to abundant during migration. Spring flocks tend to be smaller, with flocks of about 100 common, but flocks larger than 1,000 occasionally occur. Large numbers may occur in roosts prior to autumn migration: 4,000-6,000 have been reported in the Cataraqui Marsh; 5,600 along Little Cataraqui Marsh; 3,000 in Dundas Marsh; and 4,000 in the Presqu'ile Marsh. During autumn, flocks of 500-1,000 or as many as 1,500 may occur (Curry 2006; James 1991; LaForest 1993; Weir 2008).

Cliff Swallow

Petrochelidon pyrrhonota

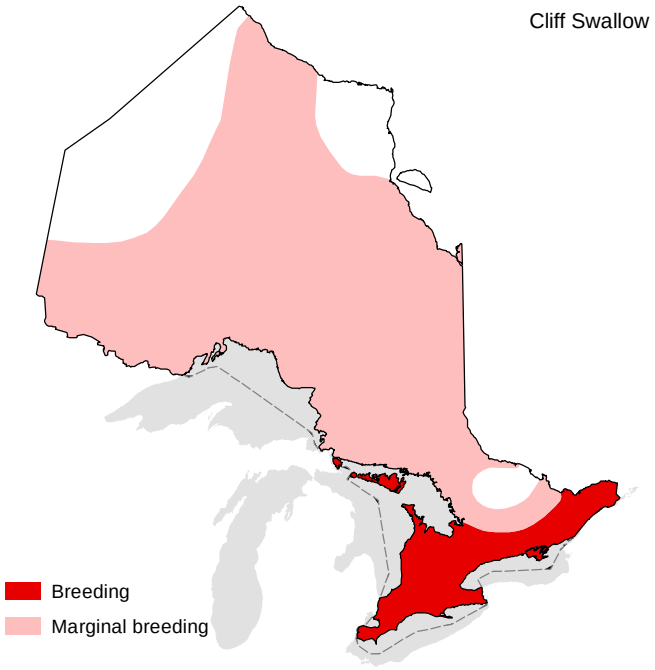


BREEDING SEASON

Habitat Requirements

In Ontario, Cliff Swallow breeding habitat includes rural residential, urban, and industrial areas (31.4% of records); farmland, including pastures (22.1%); shorelines of rivers, lakes, and marshes (20.4%); clearings in wooded areas (8.9%); cottage areas, parklands, mines, and hatcheries (6.0%); roadsides (4.6%); cliffs (0.9%); and sand dunes (0.3%; Peck and James 1987). One southern Ontario colony was on a rock face created by a quarry. Another nest was reported from a cliff in Dundas in 1932 and a single pair nested on the Niagara Escarpment face in 1989 and 1990 (Curry 2006).

Over 80% of British Columbia sites were in human-influenced areas: 40% in urban and suburban areas; 26% in rural areas; 15% in cultivated farmlands or pasture; and miscellaneous sites including reservoirs, industrial areas, and recreational areas. Water, in the form of rivers, streams, lakes, marshes, and estuaries, was present at 13% of sites (Campbell et al. 1997). The Cliff Swallow avoids extensively forested areas and is found in grasslands, towns, fragmented forests, and riparian areas (Brown et al. 2020). Its essential habitat requirements are open areas for foraging; a vertical surface for nesting, preferably with an overhang; a supply of mud for nest building; and fresh water for drinking



(Mayhew 1958). Throughout its range and particularly in the east, it is strongly associated with water. Aerial insects tend to be more abundant near water and bridges and culverts are potential nest sites.

Early in the season, the Cliff Swallow roosts in trees before a nesting colony is selected and until the nest site is big enough to sleep in. One female roosted in the same tree 4 consecutive nights (Brown et al. 2020).

Ontario nests were in or on buildings (73.7% of records), under bridges (25.0%), on rock cliffs (0.9%), in a road culvert (0.2%), and on the wall of a dam (0.2%). Buildings used, in order of preference, were barns, houses and cottages, commercial buildings, sheds, schools, boathouses, churches, airport hangars, lighthouses, grain elevators, train stations and firehalls, pavilions, post offices, and mobile homes. Most nests on outsides of buildings were under the eaves and placed against the overhang and the vertical wall. Some were on vertical walls only, under roof peaks, on light fixtures, under veranda roofs, and under balconies and window ledges. There were 15 reports of nests in buildings on beams, rafters, walls, and ceilings. Nests under bridges were on girders and abutment walls; cliff nests were on vertical surfaces beneath overhangs. More nests (46.7%) faced southerly than in any other direction. Nests on buildings, bridges, and dams were 0.9-30 m from the ground, mostly 3-6 m up. Nests on cliffs and quarry faces were 3-9 m up. Occasionally, old Barn Swallow nests were domed over and used (Peck and James 1987).

Erskine (1979) examined more than 20,000 nest records in Canada and determined that 23% of them were in natural sites on cliffs, almost all in the west. The rest were on buildings, bridges, culverts, and dams. Less than 0.5% of nests from Ontario and Quebec were on natural sites with most on human-made structures. In British Columbia, 85% of reported nests were on bridges, and 9% were on other structures: water towers, a dam, and old Barn Swallow nests. The 5% natural nests were on rock cliff faces and consolidated sand or clay banks. There was 1 report of it using a nest box. In the Yukon, 50% of colonies were on buildings, 30% on bridges, and 20% on rock cliffs. The Cliff Swallow has also nested on irrigation structures; in concrete culverts; among the outer sticks of a Great Blue Heron nest; in or over old Barn Swallow, Eastern Phoebe, and American Robin nests, and active Bank Swallow nests; inside open sheds or barns; at entrances to caves; under branches of large trees; in water towers and grain elevators; under pilings; in an old freight car; and in road tunnels. It occasionally nests on sandstone, sand, and clay banks. It prefers bridges that are over water; when colonizing a new bridge, the area over water is selected first. Concrete culverts higher than 1.5 m are preferred, taller than the Barn Swallow prefers. Multiple culverts are preferred, and it

may switch culverts year to year. Wooden (and sometimes metal) bridges are avoided because mud does not adhere to them as well as to concrete bridges. The Cliff Swallow prefers painted barns with a rougher texture to painted barns for nesting. Caves used for nesting are usually of the limestone sinkhole type and nests are placed on the ceiling immediately inside the entrance. In buildings, the nest is usually at the closest available site to the entrance. It appears to require a large entrance when it nests in a barn or shed. In West Virginia, only 2 of 9 nest sites had entrances smaller than 2.4 x 2.4 m. When these entrances were even partially closed, the nests were abandoned. Although most nests on cliffs are under overhangs, some appear fully exposed. When it rains, it becomes apparent that these nests are situated in the only locations that do not become wet. The need to shelter the nest from rain explains the patchy distribution of nests on some cliffs (Brown et al. 1991, 2020; Campbell et al. 1997; Emlen 1952, 1954; Graber et al. 1972; Gross in Bent 1942; Leighton et al. 2002; Manning 1952; Mayhew 1958; McIlwraith 1894; Samuel 1971; Silver 1993; Sinclair et al. 2003; Storer 1927; Taverner 1928; Weir 2008).

Old nests are frequently reused and are preferred provided they are not infested with parasites. In British Columbia, 96% and 91% of pairs nested in old nests over 2 years. Use of an old nest saves considerable time and energy and may enhance reproductive success because the female expends less energy building the nest. Nests that are protected from the elements may last as long as 13 years. When a new nest is constructed, the Cliff Swallow prefers to build adjacent to another nest or between 2 nests, thereby reducing the effort required to build the nest. In Quebec, 86.6% more nests were built attached to another than expected by random, and 39.9% fewer solitary nests were built than expected. In some colonies, nests are so dense that some do not touch the original nesting substrate. It readily uses artificial nests constructed of clay, ceramics, plaster, and plaster of Paris. Placing horizontal boards under eaves can give swallows a better substrate for attaching the nest (Emlen 1954; Gauthier and Thomas 1993a; Meek and Barclay 1996; Storer 1927).

The Cliff Swallow is highly colonial but occasionally nests solitarily. Peck and James (1997) reported 488 colonies and 109 single nests representing 7,639 nests in Ontario. The average size of 359 Ontario colonies was 15 nests. Colonies tend to be small in the east and much larger in the west. Weir (2008) reported a colony with 100 nests, but most colonies in the Kingston area are smaller than 15 nests. In British Columbia, colonies contained 3-1,375 nests. Over 60% of colonies had 25 or fewer nests and another 33% had 26-100 nests. There were only 6 known colonies of 500 or more nests (Campbell et al. 1997). The largest colony in the Saskatoon area was 1,100 nests (Leighton et al. 2002). Graber et al. (1972) reported 1 colony of 256 nests in an Illinois barn, but stated that most colonies contained 12-100 nests. Mean size of colonies in Nebraska was 38 nests (range 2-3,700). In that state, colonies most frequently contain 200-400 nests and colonies of 1,000 are common (Brown and Brown 1996; Brown et al. 1991, 2020). Sinclair et al. (2003) stated that some Yukon bridges had 5,000-10,000 birds, but mostly 200-500. Brown et al. (2020) stated that colonies may contain as many as 6,000 active nests. Within a colony, nests may be in scattered clusters or in very dense concentrations; Storer (1927) reported 400 nests in an area of 9 m^2 in California and Emlen (1952) reported 900 nests merged into a single mass. Solitary nests are frequently close to a colony (Brown et al. 2020; Graber et al. 1972). Once a nest site is selected, the area where the nest is going to be built is defended. Once a nest is built, other birds attempting to build a nest 8-12 cm below

the nest entrance are attacked. In addition to defending the nest interior, birds defend the area that they can reach with their bill from the nest entrance. Spout entrances of occupied nests are seldom closer together than 10 cm (Brown et al. 2020; Emlen 1952).

Home range sizes may be very large. Birds may range widely in spring to inspect nesting colonies. In Nebraska, birds covered 23 km along a river and visited several sites before selecting one. Once a colony is selected, foraging occurs within a large area that may be as far as 6.4 km from the nest site, but usually within 1.5 km. Birds do not travel as far during nest building and egg laying, but wander further before and after these periods. Birds have been documented travelling 1.6 km for mud (C.R. Brown 1988; Brown et al. 2020; Buss 1942; Emlen 1952, 1954; Storer 1927).

In California, 19% of yearlings returned to the natal colony compared with 48% of adults. In West Virginia, no yearlings returned the following year; 37% of Nebraska yearlings returned. Of returning juveniles, 59% returned to the natal colony in California, 48% in Texas, and 74% in Nebraska. Of 551 returning juveniles in Nebraska that returned to a different colony, most returned to a colony within 3.5 km. One yearling hatched in Nebraska first nested near Edmonton, 1,700 km northwest. Some California yearlings first nested 77 km from the natal site. Males are slightly more likely to return to the natal site than females. Yearlings appear to prefer colonies similar in size to the natal one, even if they return to a different colony. Thirty to 50% of adults return to the colony where they were captured. Of returning birds captured the following year, 82% were at the same colony in California compared with 59% in Nebraska and 45% in Texas. Most others returned within 3.5 km, but some nested as far as 64-66 km away. Adults are more likely to return if they bred successfully the previous year. As birds age, they occasionally switch to smaller colonies in subsequent years. As many as 5-9% of adults switch colonies within a season, usually selecting a nearby colony but occasionally one as far as 64 km away. Most returning birds came from nests and colonies that had low parasitism rates by swallow bugs. Returning birds usually do not use the same nest; only 1 of 5,609 birds that returned in California used the same nest (Brown and Brown 1996; Brown et al. 2020; Mayhew 1958; Samuel 1971; Sikes and Arnold 1984).

Colonies may be used in alternate years, or as infrequently as once in 5 years; other colonies are used perennially. A colony at Moosonee was reported by Schueler et al. (1974) to be present from at least 1965; Wilson and McRae (1993) found that it still supported a minimum of 6 nests. Often only about a third of available colonies are used in a given year. Sites that support large colonies are most likely to be used the following year. When a colony is reused, colonies that were large in size tend to decrease; previously small colonies increase. Presence of fleas and swallow bugs that overwintered may be a factor in colony use; areas of high infestation are avoided (Brown and Brown 1996; Brown et al. 2020; Mayhew 1958; Sikes and Arnold 1984). C.R. Brown et al. (2002) found that the only reliable predictors of colony size were the amount of standing and flowing water within 1 km of the site. The amount of flowing water was associated with how frequently a site was used. Larger colonies had higher land-use diversity, more cultivated cropland, less grassland, and more roads and buildings within the foraging range than smaller colonies. Perennially used sites had more consistent colony sizes year to year. Rarely used colonies had varying colony sizes.

Brown et al. (2014) examined the relationships between colony size and age of birds in Nebraska. Colony age composition was not affected by colony size, colony initiation date, or parasites. As

colony size increased, the proportion of juveniles present increased. Colonies initiated later in the season supported more juvenile birds. Yearlings arrive later than adult males and seldom initiate nests in already occupied colonies. This explains the high proportion of juveniles in colonies that are initiated later in the season.

Limiting Factors

Eggs have been found in Ontario nests from the last week of May until the first week of August, with most present in June (Peck and James 1987). Presence of young in a nest on 4 May in Simcoe County and young being fed in the nest on 24 August in Haldimand-Norfolk suggest earlier and later egg dates (Peck and James 1997). In Algonquin Park, nests are under construction from mid-May to mid-July, eggs are present from early to late June, and nestlings are present from late June to mid-August (Tozer 2012).

Timing of colony occupation may vary significantly annually and is affected by temperature. Once birds have selected a colony, another 3-5 days may elapse before a nest site is selected; occasionally this takes as long as 12 days. Large colonies become active sooner than small colonies. The time it takes to build the nest depends on the time of year, weather, and location of the nest. In West Virginia, nests took an average of 13.0 days to build in May and June, but only 8.4 days in July. Nest building took about 7 days in Wyoming, 3-27 days in Nebraska, and 8-18 days in Quebec. Nest building may be suspended by as long as a week during cold weather and even longer during periods of drought when mud may be unavailable for nest construction. Nests that share walls with other nests take less time to build. Egg laying may commence before the nest is complete, even before the dome is completed. Eggs are laid at the rate of 1 a day. All laying within a colony may take place over a 9-12 day period. Intermittent incubation may start after 2-3 eggs are laid, but is not continuous until the last egg is laid. Incubation periods of 12-17 days have been reported in Ontario, and 20 days for 1 nest. In other areas, incubation periods of 10-19 days have been documented, but the typical incubation period is 13.5-16 days. Eggs that hatch in less than 11 days may have been physically transported into a nest but incubated elsewhere. All eggs typically hatch within a 24-hour period. Fledging occurs at age 20-26 days, mostly at 21-24 days. In West Virginia, the total time from laying of the first egg until fledging was 38-48 days (Brown and Brown 1996; Brown et al. 2020; Buss 1942; Campbell et al. 1997; Emlen 1954; Gauthier and Thomas 1993a; Grant and Quay 1977; Mayhew 1958; Meek and Barclay 1996; Myers 1957; Peck and James 1987; Ramstack et al. 1998; Samuel 1971; Stoner 1945).

It is uncertain whether the Cliff Swallow raises 1 or 2 broods annually. The confusion results because renesting birds typically move to another nest or even another colony for their second nesting attempt, and often use a nest where another brood was raised. Gross (in Bent 1942) stated that it regularly raised 2 broods. This was subsequently disproved, but many authors still cite this work and make the same mistake in interpreting their own data. Many studies with banded birds found no evidence of second broods, so it was generally concluded that second broods were never raised (Buss 1942; Grant and Quay 1977; Mayhew 1958; Ramstack et al. 1998). Rare cases of second broods have been documented in Nebraska (Brown et al. 2020), West Virginia (Samuel 1971), and Quebec (Gauthier and Thomas 1993b). Double broods have been reported in Ontario (Peck and James 1987) but it is uncertain if this was confirmed through banding. Renesting is common if a

clutch is lost. Clutches of 2-7 eggs have been reported in Ontario. One 7-egg clutch was laid by more than 1 female. Most clutches contained 3 or 4 eggs, and 4-egg clutches were most frequent (Peck and James 1987). Clutches of 1-8 eggs have been reported in North America, with rare records of 9, 11, 12, 13, and 15 eggs in a nest, but most clutches contain 3 or 4 eggs. Clutches larger than 6 eggs are probably due to intraspecific parasitism. Small clutches may be due to egg destruction by neighbouring birds. First clutches are larger than replacement clutches. Mean size of first clutches was 4.0 in British Columbia, 4.01 in Quebec, 3.74 in Nebraska, 3.32 in Virginia, and 3.31 in West Virginia. Mean size of second clutches was 2.7 in Quebec, 3.00 in Virginia, and 2.88 in West Virginia. In Quebec, first clutches fledged an average of 1.84 young per nest compared with 0.4 for second clutches. Clutch size declines by about 1 egg over the season and later clutches have lower success rates. Yearling females lay smaller clutches (3.3 eggs) than 2-3-year olds (3.7 eggs; Brown and Brown 1989, 1996, 1999; Brown et al. 2020; Campbell et al. 1997; Gauthier and Thomas 1993b; Grant and Quay 1977; Gross in Bent 1942; Imlay et al. 2019; Mayhew 1958; Myers 1957; Ramstack et al. 1998; Samuel 1971).

The age at first breeding for both sexes is 1 year, and breeding occurs every year thereafter. The mating system is seasonally monogamous, with the pair bond dissolving once young fledge. Renesting females frequently select a different mate. Reunion of pairs in subsequent years appears to be coincidental when both birds return to the same portion of the colony (Brown et al. 2020; Samuel 1971).

Intraspecific nest parasitism is common. In Nebraska, as many as 43% of nests contained parasitic eggs; 33% of Pennsylvania nests contained parasitic eggs. These are either laid in neighbours' nests or physically transferred in the bill. In most cases, the parasite's and host's nests are adjacent to each other or separated by 2-5 nests. Maximum distance recorded was 1.98 m. Nest-guarding males may tolerate intruding females while they lay an egg. Frequently the parasite removes one of the host's eggs before laying a parasitic egg. Parasitic females laid fewer eggs in their own nests, but more eggs overall than nonparasitic birds. The mean number of parasitic eggs in 21 nests was 1.57 (range 1-4). While the parasites are in hosts' nests, they may be parasitized themselves. In Nebraska, 54.2% of parasites were parasitized, and a third of birds that destroyed eggs in other nests had an egg destroyed. Birds occasionally parasitize nests by transferring young in their bills. Parasitism rates are highest in colonies where reproductive success is variable. Spreading eggs out enhances chances that some of the birds' reproductive effort will produce fledglings in colonies where success is uncertain (Brown and Brown 1988, 1989; Brown et al. 2020). Extra-pair copulations also occur, but the extent of extra-pair young in populations is unknown (Brown et al. 2020).

The Cliff Swallow prefers to forage over grasslands, hayfields, watercourses and water bodies, and shorelines, which may be particularly favoured. It may be attracted by hay mowers, horses walking through tall grass, and other activities that may stir up insects. Hills and wooded areas tend to be avoided, but it may feed on the lee side of bluffs or road cuts where insects concentrate. Although some birds forage singly, most forage socially. As many as 75-1,000 birds have foraged in areas as small as 10 m^2. More often they occur in towers of birds 5-30 m above ground. Most food is captured aerially, and it feeds predominantly on insect species that swarm. Although it may occasionally forage with Barn Swallows, the Cliff Swallow commonly feeds at heights of 30-50 m.

This is much higher than the Barn Swallow forages, so the 2 species are vertically stratified and have different diets. When the weather is cool or rainy, there are no thermals to push insects high, and the Cliff Swallow usually feeds at altitudes of 5 m or less over water. It has taken moribund midges from the surface of a pond in Colorado, mayflies from pavement in Alabama, and walked on the ground to feed on ants. At Great Salt Lake in Utah, foraging on the ground for brine flies was the most common feeding technique. Early in the nesting season, all birds may desert the colony for several hours to forage communally. Later on, foraging bouts are much shorter and less social. Birds in large colonies must travel further due to local depletion of insects around the colony (C.R. Brown 1988; Brown and Brown 1996; Brown et al. 1991, 2020; Cohen and Dymerski 1986; Emlen 1952, 1954; Graber et al. 1972; Hobson and Sealy 1987a; Paton and Fellows 1994; Ramstack et al. 1998; Samuel 1971; Stoddard 1988). Colonies act as information centres. When a bird returns to the colony after an unsuccessful foraging trip, it watches its neighbours. When a neighbour returns with food, the unsuccessful bird follows it to its food source. In large colonies, birds often join the large groups that continually stream between the colony and food source. In small colonies, birds may spend time on their own searching for prey (Brown et al. (2020). During cool weather when prey is scarce, individuals that find prey may give a special call to alert others to the food source (Stoddard 1988).

The Cliff Swallow feeds almost exclusively on flying insects, but rarely consumes spiders and snails. Prior to age 6-7 days, nestlings are fed small soft-bodied insects, often flies and soft-winged bugs. After that, the diet of young is similar to that of the adults (Brown et al. 2020). Bumelis et al. (2022) determined that the diet of nestlings consisted of a mix of terrestrial and aquatic emergent insects. Barn Swallow nestlings consumed predominantly terrestrial insects; Tree Swallow nestlings ate mostly aquatic emergent insects. In New Brunswick, Imlay et al. (2017) examined the effects of insect abundance on Cliff Swallow nestling survival and growth rates. Areas of lower insect abundance were not related to lower nestling survival or mass.

Beal (1918) examined 375 stomachs which contained 99.3% animal material. The vegetation included juniper berries; 2 stomachs were completely filled with them. The diet consisted of 26.9% beetles (weevils and lady, ground, and dung beetles), 26.3% bugs (leafhoppers and leaf, seed, leaf-footed, and stink bugs), 20.5% hymenopterans other than ants (mostly bees and wasps), 14.0% flies, 8.2% ants (mostly winged forms), 0.7% grasshoppers, 0.5% lepidopterans, and 3.0% dragonflies, lacewings, spiders, and snails. Brown and Brown (1996) examined the diet in Nebraska and found 17 insect families prevalent. In order of importance, they were leafhoppers, long-legged flies, black flies, ants, dance flies, midges, horse flies, mosquitoes, argid sawflies, lanternflies, sweat bees, hump-backed flies, crane flies, flower flies, ground beetles, green lacewings, and seed bugs. Eighty-four insect families from 10 orders were represented in the diet. These included 17 families of beetles, 18 families of flies, 2 families of mayflies, 17 families of bugs, 7 families of hymenopterans, 4 families of lepidopterans, 2 families of odonates, and 3 families of orthopterans. It also feeds on shore flies and shore bugs (Brown et al. 2020; Graber et al. 1972; Stoddard 1988; Storer 1927). The insects that are consumed reflect local availability and may vary considerably among colonies situated only a few kilometres apart. In Nebraska, 10 of the 15 insect families consumed most frequently were ones known to swarm or otherwise congregate. Cliff Swallows drink exclusively on the wing by skimming surface water (Brown et al. 2016). Nancekivell and Nocera (2025) used DNA to analyze the adult diet

in New Brunswick and compared the diet of the Cliff Swallow to those of the Alder and Least flycatchers and the Bank, Tree, and Barn swallows. All species differed in their dietary breadth and prey preferences. The Cliff, Bank, and Tree Swallows ate more aquatic taxa than the other species, which consumed more terrestrial flies. The Cliff and Bank swallows had more restricted diets whereas the other species had broader generalist diets. The approximate frequencies of occurrence of invertebrate groups in the diet of the Cliff Swallow were 80% aquatic flies, 30% terrestrial flies, 20% lepidopterans, and 5% terrestrial beetles. The approximate frequencies of occurrence of invertebrate families in the diet of the Cliff Swallow were 45% limoniid crane flies, 15% mosquitoes, 10% root-maggot flies, 10% leafroller moths, and 5% snipe flies.

Cowbird parasitism has not been documented in Ontario, but rare cases have been confirmed in British Columbia, Illinois, and Pennsylvania. Opportunities for parasitism occur because swallows often initiate egg laying before the nest is complete, and some nests lack spouts or cones. Rare incidents of parasitism by House Finches and House Sparrows have been reported. Swallow nestlings typically starve to death in parasitized nests (Brown et al. 2020; Buss 1942; Campbell et al. 1997; Graber et al. 1972; Gross in Bent 1942; Mayhew 1958).

The Cliff Swallow may be adversely affected by weather that is too cold, too hot, too dry, or too wet. Cold weather is the most significant factor. When spring temperatures are less than 10°C for 3-4 days, extensive mortality of adults may occur. During cold spells, adults may not leave the nest and die of starvation if the cold persists. As a result of unseasonably cold weather in June 1 year in Illinois, about 95% of the population died. Events such as these have been reported throughout much of its range. Females may be more susceptible to cold due to the stresses of egg laying. Cool weather may also have indirect effects on survivorship. Nesting may be delayed in late springs resulting in smaller clutch sizes and lower likelihood of renesting. Insects are less abundant in cool weather, so nestling growth rates may be retarded. Mortality and adverse effects due to cold weather are more severe in small than in large colonies (Brown and Brown 1996; Brown et al. 2018, 2020; Buss 1942; Graber et al. 1972; Gross in Bent 1942; Henny et al. 1982; Jaramillo and Rising 1995; Krapu 1986). Hot weather in June may result in extensive mortality of nestlings because they frequently attempt to fledge prematurely to escape the heat in the nest. In Nebraska, best success occurred in cooler summers, with lower brood survival in warmer Junes (Brown and Brown 1996, 1999; Graber et al. 1972). Dry weather reduces the availability of mud for nest construction. If mud is scarce, birds may have to travel further and expend more energy in nest construction. Birds may also be forced to use nearby mud supplies that are not of suitable texture. This has resulted in large-scale failure of colonies due to nests falling. In some cases, colonies moved and nested in unsuitable habitat or on unsuitable substrate so they were close to a supply of mud. Reproductive success at these colonies is typically low (Buss 1942; Emlen 1954; Graber et al. 1972; Krapu 1986). Nests on buildings and cliffs may be weakened by significant rainfalls and fall. In Nebraska, a thunderstorm resulted in at least 1,400 nests falling from a cliff and there are other reports of colonies failing completely due to severe rain events. Nests along watercourses may be swept away by high water levels (Brown and Brown 1989; Buss 1942; Graber et al. 1972; Silver 1993).

Cliff Swallow populations began to decline shortly after introduction of the House Sparrow. The problem is greatest in agricultural landscapes, but also occurs in natural cliff colonies. House

Sparrows actively take over swallow nests with essentially no resistance. Early in the breeding season, when adults leave the colony en masse to forage for 1-2 hours, sparrows often remove swallow eggs and nestlings and take over the nests. Hundreds of young may be killed even if sparrows do not use the nests. Small colonies are most vulnerable to House Sparrows, who usually take over the entire colony. Even very large colonies may eventually be lost to sparrows, with colonies as large as 2,000 nests being lost. Sparrows also fill nests with feathers, and swallows avoid using old nests containing masses of feathers. In bridge-nesting colonies in Arkansas, Cliff Swallows nesting near House Sparrows had significantly lower nest success (30% of nests fledging at least 1 young) than those nesting where there were no House Sparrows (61% of nests successful). Only 8% of nests were occupied by swallows nesting near sparrows compared with 48% in colonies with no nearby sparrows. Swallow colonies often increase in size if sparrow populations are controlled (Brown et al. 2020; Buss 1942; Campbell et al. 1997; Emlen 1954; Graber et al. 1972; Gross in Bent 1942; Krapu 1986; Leasure et al. 2010; Robinson 1989; Silver 1993, 1995).

Ectoparasites have a significant influence on the behaviour and reproductive success of the Cliff Swallow, with the primary parasites being the swallow bug and bird fleas. The swallow bug is found almost exclusively on the Cliff Swallow and can survive in unused nests for 3 years without feeding. Swallows avoid nests heavily infested with this species, and this explains why usage of many colonies is intermittent. Nestling weight is decreased by 18-22% in nests infected with swallow bugs and survivorship of nestlings declines by as much as 50%. Fleas appear to have no impact on nestling body weight or survivorship, but may reduce annual survival of adults by 33%. Feather mites are positively associated with the Cliff Swallow's daily survival rate and provide direct benefits by consuming old oil, pollen, fungi, and harmful bacteria on the feathers (Brown and Brown 1986, 1996, 1999; Brown et al. 2006, 2020).

Human activities and disturbance may affect Cliff Swallows. Once barn painting became fashionable, many colonies were deserted. The oil in the paint often makes the sides of the barn too slippery for nest attachment. Birds that nest in barns are frequently disturbed by human activities, and leave the barn even if it is dark outside. Nests within barns are usually abandoned if the entranceway is partially closed, if livestock is placed under nests, or if any building or structural alterations occur near the nest. Researchers often remove some or all the nest spout. In these nests, there is a significantly lower hatch rate, a longer incubation period, and a shorter fledging period. Time that adults expend repairing nests results in decreased time spent in care of young. Even minor changes to nests result in reduced reproductive success. Many colonies on buildings are destroyed by humans because of the mess that the birds make (Buss 1942; Campbell et al. 1997; Graber et al. 1972; Gross in Bent 1942; Hamilton and Martin 1985; Samuel 1971; Silver 1995).

The Cliff Swallow often rests on roads and is vulnerable to being killed by vehicles. A 30-year study in Nebraska found that the frequency of road-killed swallows declined sharply following occupancy of roadside nesting sites, and that birds found killed on roads had longer wings than the population at large. Swallows may have adapted to traffic by decreasing their wing length, thereby becoming more agile and improving chances of escape (Brown and Brown 2013).

The Cliff Swallow bioaccumulates contaminants such as toxaphene, mercury, lead, zinc, DDE, PCBs, chromium, and selenium in body tissues somewhat, and may be a reliable bioindicator (Brown et al. 2020).

Price (2004) concluded that the Cliff Swallow may no longer nest in southern Ontario if the average summer temperature increases by 2°C.

Status

Prior to European settlement, the Cliff Swallow was rare in eastern North America. Eastern populations initially increased due to construction of culverts, bridges, and buildings (Brown et al. 2020). In Toronto, Fleming (1907) considered it a regular but local breeder and noted that it was not as common as it had been. This was probably due to the presence of House Sparrows, which caused a population decline throughout its range. In the Kingston area, only one was reported in the mid-19th century, but by 1909 it was common. It declined in this area in the 1930s due to House Sparrows. It was formerly abundant in Leeds County, uncommon in the 1930s, and virtually absent during the first atlas (Weir 2008). In Elgin County, it was common in 1891, uncommon in 1954, and uncommon and local in 2000 (Lancaster et al. 2004). In Niagara Region, Sheppard et al. (1936) had only 2 records from 1918. Baillie and Harrington (1937) stated that it was irregularly distributed north to southern Sudbury District, Algonquin Park, and Ottawa, but with a breeding record at Severn River on the Hudson Bay coast. They concluded that it was not a common species and that it was declining. During the first atlas, most squares contained less than 100 pairs, but it was more abundant in the north within the few squares that it occurred than it was in southern Ontario squares. It was absent from much of the Algonquin Highlands and northern Ontario, with scattered records from Pickle Lake, Moosonee, Fort Albany, and Big Trout Lake. A small cliff-nesting colony was found along the Attawapiskat River about 100 km from James Bay (Taylor in Cadman et al. 1987). James (1991) considered the Cliff Swallow a locally common resident north to Pickle Lake and Moosonee and occasional to rare to Hudson Bay.

The second atlas indicated that the probability of observation of the Cliff Swallow had declined significantly since the first atlas province-wide and in the Great Lakes–St. Lawrence and Boreal forest regions. In the northern portion of the Boreal Forest Region, there was no apparent change, but there was a significant decline in the road-accessible portion of this forest region. There was a significant increase in the Carolinian Forest Region. It was most abundant south of the Canadian Shield, particularly in southwestern Ontario west of Toronto. An exception was Niagara Region where it was not detected in most of the inland squares (Cadman in Cadman et al. 2007).

In eastern North America, the Cliff Swallow initially increased significantly and then declined. It appeared to peak in numbers in the eastern United States from 1840 to 1860; population declines started about 1880 as the House Sparrow spread. In the early 20th century, its population increased in some areas, probably due to its adaptation of nesting under bridges and in large culverts (Graber et al. 1972; Landry and Bombardier in Gauthier and Aubry 1996; Mayfield 1988; Silver 1995; Walk et al. 2011).

Long-term (1970-2021) population trends determined by Breeding Bird Survey data indicated annual decreases of 1.53% in Canada and 4.44% in Ontario. The short-term (2011-21) trends were

annual decreases of 1.24% in Canada and 0.798% in Ontario. The long-term trends were highly reliable; the short-term trends were of medium reliability for Canada and low reliability for Ontario (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Both adults feed the fledglings for 3-5 days after they leave the nest. Young are often led back to the nest for the night when they are still dependent, and also during the day during adverse weather conditions. Soon after fledging, young gather together and form crèches that may contain as many as 1,000 birds. Crèches may assemble on wires, in trees, or on cliffs (Brown et al. 2020).

Once the young fledge, some adults roost in nests, but others use trees and marshes. Young and adults congregate together beginning in late July. Most frequently, they gather on wires, occasionally in trees and marshes and on cliffs. The roost may be 2-3 km or more from the colony, and birds from several colonies may join together. The Cliff Swallow tends to avoid roosting with other swallows. It rarely perches on low barbed-wire fences as the Barn Swallow does, and the Barn Swallow avoids high-power lines 30 m up that are regularly used by Cliff Swallows. Late-summer roosts in West Virginia and Maryland always had meadows nearby and there was usually a stream in the vicinity. Premigratory roost sites are traditional. Some in West Virginia have been used for 30 years. Birds congregate on the same location on power lines every year, although there are hundreds of kilometres of identical wires in the area. At one of these sites, all birds roosted 1 night in an adjacent cornfield, using corn leaf axes and tassels of cobs as resting sites (Brooks 1949; Brown et al. 2020; Emlen 1952; Gross in Bent 1942; Samuel 1971).

Once they are independent, juveniles travel among colonies and inspect nests, as do adults. Juveniles enter nests and actively defend them, and occasionally sleep at night in nests, often in a different nest or colony for 1-2 weeks before leaving the general area. It is likely that they are prospecting for suitable nest sites for the following year. After young fledge, birds of all ages travel widely and visit colonies 60 km or further away. In Nebraska, postbreeding males confined their activities to 15-19.5 km along a river valley for 6-8 days (Brown et al. 2020).

MIGRATION

The Cliff Swallow is a strictly diurnal migrant. It migrates in flocks, often in the company of other swallow species, especially Tree Swallows and Barn Swallows, but also Bank Swallows. Migration in both directions is very leisurely and spans several months (Brown et al. 2020; Gross in Bent 1942; Samuel 1971).

Adults that have previously nested at a colony are first to arrive, followed by other adults, and finally juveniles. Arrival is typically shortly after a few days of warm weather when temperatures are about 20°C. In Ontario, the Cliff Swallow arrives in late April or early May with most arriving in mid-May. Autumn migration begins shortly after the young fledge. Most have left the province by the end of August or mid-September, with stragglers persisting into October. In Algonquin Park, autumn migrants are evident as early as July (Curry 2006; Mills 1981; Tozer 2012; Weir 2008).

During migration, the Cliff Swallow is strongly associated with water, particularly in spring when insects may be scarce. In the Yukon, migrating flocks congregate at lakes and wetlands, and in British Columbia, flocks occur over lakes, ponds, sloughs, and marshes. These are important sources of

flying insects, but it also forages over cliff faces, fields, sewage lagoons, rivers, farmsteads, aspen groves, beaches, and sand dunes. During spring migration in Illinois, largest aggregations and peak numbers coincided with conspicuous swarms of midges (Campbell et al. 1997; Graber et al. 1972; Sinclair et al. 2003).

The Cliff Swallow is a common migrant in Ontario (James 1991), with most flocks containing 50 or fewer birds. An estimated 10,000 were seen at Callander in Parry Sound District and Nosbonsing in Nipissing District on 12 August 1949. Tremendous numbers were observed again at Nosbonsing on 26 August 1952 (Mills 1981).

Ruby-crowned Kinglet

Corthylis calendula

BREEDING SEASON

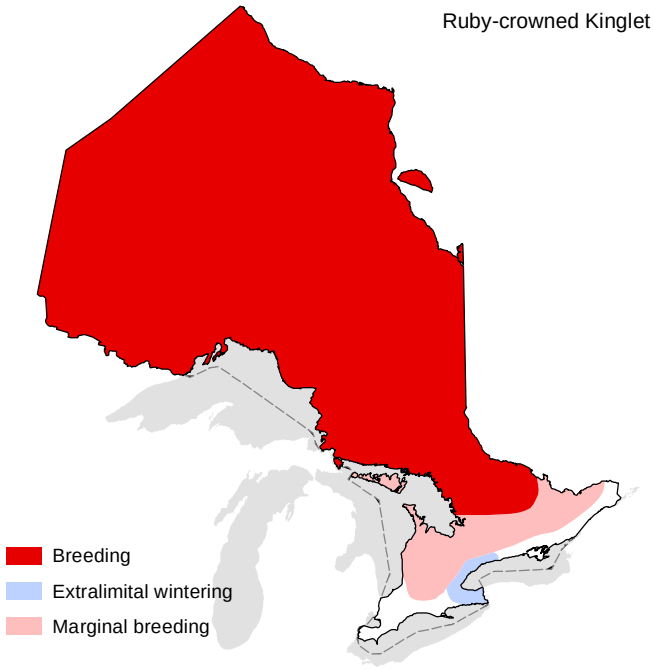
Habitat Requirements

In Ontario, the Ruby-crowned Kinglet has nested in open black spruce and black spruce–tamarack muskegs, and once each in mixed woods, the edge of a burn, an open jack pine stand, and in an isolated tree near a beaver meadow. Habitats used for breeding were typically open and were either wet or near water (Peck and James 1987).

In the Boreal Forest Region of Ontario, the abundance of the Ruby-crowned Kinglet was affected by the amount of merchantable hardwoods and decreased with increasing hardwoods. It was associated with stands dominated by conifers, especially those that were slightly older than average (Rempel 2007).

Near Pickle Lake, the Ruby-crowned Kinglet was the most frequently encountered species in coniferous and mixed forests (James 1980). In northwestern Ontario, it nested predominantly in coniferous forests and mixed forests and deciduous shrub communities, and seldom in deciduous forest and coniferous and mixed shrub communities (McLaren and McLaren 1981). On the eastern coast of James Bay and inland Quebec, it was one of the most common and evenly distributed breeding birds of spruce forests (Manning and MacPherson 1952). It occurred all along the northeast

shore of Lake Superior, but was most frequent in black spruce stands. One nest was in a wet swale at the edge of a burn that was overgrown with black spruce, white spruce, white birch, and alders (Baillie and Hope 1943). Near Hearst, it nested in lowland coniferous clear-cuts 13-19 years old and in uncut upland mixed and lowland coniferous stands (Welsh and Fillman 1980). In the Clay Belt it was significantly associated with nutrient-rich, dry forests (Welsh and Lougheed 1996).



In the Great Lakes–St. Lawrence Forest Region in the Canadian Shield, the Ruby-crowned Kinglet breeds in mature and old-growth white pine stands (Kirk et al. 2012). In jack pine stands near Gogama, it was rarely observed, usually wandering in from adjacent spruce swamps to forage. James and Peck (1995a) considered it conceivable that these birds could have nested, although there was no indication that they did. It appeared to be dependent on spruce for nesting. In Algonquin Park, MacLulich (1938) found it mainly in coniferous and black ash swamps. Also in Algonquin Park, Martin (1960) considered it characteristic of boreal forest. It was most frequent in balsam fir–spruce forests and also occurred in black spruce–white cedar swamps and rarely in hemlock stands.

Bent (1949) stated that the Ruby-crowned Kinglet was typical of black spruce bogs in the Toronto area and that it was rarely seen outside this habitat during the breeding season. In southern Ontario, there are records of it nesting in scattered conifers in highly disturbed areas. These included a nest in a large white spruce on the University of Guelph campus (Curry 2006), a pair in a grove of spruce in a camping area in Prince Edward County (Richards 1983), and a nest in 2 rows of spruce along a gravel road in a residential area of Fort Erie (Andrle 1978). The general habitat in this area was groves and rows of spruce and pine scattered among dwellings.

The Ruby-crowned Kinglet is one of the species characteristic of the Boreal Forest Region, where it occurs predominantly in spruce and balsam fir stands, but also occasionally in jack pine and rarely in hemlock stands (Erskine 1977). In the Saskatchewan boreal forest, it was in a guild associated with conifers and was typical of spruce stands. It occurred mostly in dry stands with moderate nutrient amounts (Kirk et al. 1996). It was associated mostly with drier stands in the Boreal Forest Region of Quebec and Labrador (DesGranges and LeBlanc 2012). In Alaska, it was the only species that showed differences in breeding density among forest stands suffering different levels of mortality due to an outbreak of spruce beetles. Breeding densities in stands of high spruce mortality were 45% of those in moderate mortality stands and 29% of those in low mortality stands. Matsuoka et al. (2001) concluded that the lower density was probably related to lower density of spruce in general rather

than to loss of large-sized white spruce. In subalpine areas of New Hampshire, it was most abundant in virgin spruce stands and was most likely to be found in swamps near a wet depression or small water body (Sabo 1980). In Minnesota, its abundance was associated with black spruce and lowland conifers. Thirty-two percent of the variation in its abundance was explained by the amount of conifers within 200 m, 30% by presence of nutrient-poor stands of black spruce and cedar, and 22% by the amount of upland forest within 500 m; 16% of variability was negatively associated with the amount of non-forest within 200 m. It preferred black spruce or white cedar forests with upland forests in the broader landscape, similar to the Golden-crowned Kinglet. The Ruby-crowned Kinglet preferred more nutrient-poor stands and the Golden-crowned Kinglet preferred more productive stands. Both species were found in some stands suggesting that they might also segregate on smaller microhabitat scales or by foraging techniques. The Ruby-crowned Kinglet was uncommon in tamarack stands (Zlonis et al. 2017). In Saskatchewan, its abundance was significantly correlated with the amount of forest in the landscape, with relative abundances of 78 in white spruce stands, 50 in mixed-wood stands, and 13 in trembling aspen stands (Hobson and Bayne 2000). In the northeast, it was in a guild associated with mature coniferous lowland forests (Niemi and Pfannmuller 1979). In the Great Lakes–St. Lawrence Forest Region, it breeds in forests with mixed conifers and northern hardwoods, particularly those with white spruce, black spruce, and white birch. Highest density occurs in black spruce bogs and it prefers areas close to water (Swanson et al. 2021). In balsam fir–white cedar stands in eastern Quebec, it occurred in equal densities in riparian and nonriparian stands (LaRue et al. 1995). In British Columbia coniferous forests, it was equally abundant in riparian and nonriparian forest during the breeding season and spring migration. During autumn migration and winter, it was significantly more abundant in riparian forest, which had an understory of alders and willows (Wiebe and Martin 1998). In the Yukon, it nests most often in mature, spruce-dominated forests and also in mixed forests dominated by conifers. It is scarce in deciduous trees, in mature black spruce forests, and in black spruce–tamarack forests (Sinclair et al. 2003). In British Columbia, 8 of 25 nest records (32%) were in suburban cultivated areas, but the high proportion of nests in this habitat was probably biased by observer distribution. In other habitats, 8 were in coniferous forest, 4 in mixed forest, and 1 in deciduous forest (Campbell et al. 1997). Barrette and Darveau (in Gauthier and Aubry 1996) considered the Ruby-crowned Kinglet a habitat generalist in Quebec. It nested in mixed woods, dense coniferous forests, stands of scattered spruce on the edge of tundra, jack pine plantations, stands of white spruce more than 50 years old, and sometimes in hardwood forests. Ralston et al. (2019) concluded that it had broad habitat preferences and an ability to use multiple boreal forest habitats.

In some areas, the Ruby-crowned Kinglet is associated with older-growth forest; in other areas it may nest in younger forests. In Saskatchewan, it occurred more frequently in forests that were older than 100 years old, typically those that were 100-110 years old. Abundance was considerably less in forests older than 140 years. Cumming and Diamond (2002) concluded that the association with age might be because the percentage of coniferous cover increased with forest age. Also in Saskatchewan, Kirk et al. (1996) considered it an old-forest species, but did not sample forests stands older than 80 years. Thompson et al. (1999) reported similar results in balsam fir forests in Newfoundland. In Quetico Park, it was most abundant in intermediate-aged forests (67-73 years), with slightly fewer numbers in mature and old-growth forests, and very few in early successional

forests (Apfelbaum and Haney 1985). In Quebec, it nested in clear-cuts with saplings less than 5 m tall, and in young and mature forests. Imbeau et al. (1999) did not observe it in recent burns. It was significantly less abundant in young clear-cuts where saplings were less than 2 m tall than in other habitats.

In the boreal forest of Newfoundland, the Ruby-crowned Kinglet tended to be more frequent in natural than harvested landscapes. In natural landscapes, the proportion of forested sites it inhabited varied by the percentage of the landscape that was forested. Occupancy rates were 10% in landscapes with 10% forest cover, 40% at 50% forest cover, and 70% at 60% and more forest cover. In harvested areas, occupancy rates were uniform at 30-40% regardless of the amount of forest cover (Taylor and Krawchuk 2006).

The Ruby-crowned Kinglet is not an area-sensitive species and has been found nesting in isolated groves and rows of conifers in southern Ontario. In Saskatchewan, its abundance was not correlated with forest size. It was significantly more common in fragmented mixed-wood forest than in contiguous forest and its presence was negatively correlated with the amount of forest cover within 5 km (Hobson and Bayne 2000). Lindell et al. (2007) reviewed studies that determined its abundance in relation to forest edge and found that it exploited edge habitat. In Newfoundland balsam fir stands, it was equally abundant in riparian edges, nonriparian edges, and forest interior. Its abundance was similar in 20-50-m riparian strips left adjacent to clear-cuts (Whitaker and Montevecchi 1997, 1999).

Limited data on nocturnal roosts indicate that the Ruby-crowned Kinglet rests solitarily on tree branches close to the trunk.

All nests reported to the Ontario Nest Records Scheme were in coniferous trees: 19 in spruce and 2 in pine. They were suspended from horizontal or drooping lateral branches or forks and supported by smaller twigs. Seven nests were positioned against the trunk of a tree and 10 were 0.9-3 m from the trunk, often at ends of branches. Nests were well concealed. Three were 0.9-1.2 m from the top of the tree and one was at the top of a small black spruce 1.3 m tall; another was only 0.4 m above ground in a pine sapling. Nests were 0.4-15 m from the ground, with most 2.7-7 m up (Peck and James 1987, 1997). Richards (1983) reported a nest in Prince Edward County 11.5 m from the ground and 2.5 m from the trunk near the end of a horizontal limb of a spruce. Andrle (1978) found a nest in a Norway spruce in Fort Erie that was 8 m from the ground, 1.5 m from the trunk, and 0.3 m from the tip of the branch. Swanson et al. (2021) described 11 nests found in Algonquin Park. Six were in black spruce and the other 5 were in white spruce. Their average height was 12.0 m (range 6-17 m). Nests in black spruce were usually 1-2 m from the top among dense foliage near the trunk. In white spruce, nests were 1.7-2.5 m from the trunk in dense clumps of hanging branchlets. In all cases, nests were protected from above by overhanging foliage.

Elsewhere, Ruby-crowned Kinglet nests are almost always in conifers, particularly spruce, but also in fir and some of the western conifers. In British Columbia, 3 of 25 nests (12%) were in deciduous trees. Nests are well concealed and usually near the top of a tree. Nest height varies depending on the height of available trees. Nest heights of 0-30 m have been reported (Bent 1949; Campbell et al. 1997; Swanson et al. 2021).

Territories in Algonquin Park averaged 2.9 ha (range 1.1-6 ha). One male regularly sang from a site 0.5 km from the nest. Territories were larger in mixed woodlands than in more homogeneous black spruce bogs. During a spruce budworm outbreak in Algonquin in 1945, territory size was 2.5 ha (Swanson et al. 2021). Also in Algonquin Park, territory depth was 3.6-18 m; the bottom of the canopy layer and the top of the shrubs was 3.0 m and treetop level was 23 m (Martin 1960). Kendeigh (1947) reported that 2 territories north of Lake Nipigon were both about 1.0 ha. Barrette and Darveau (in Gauthier and Aubrey 1996) reported that territory size was 1.01 ha in the Boreal Forest Region of Ontario. In subalpine forests of New Hampshire, territory size was 0.6 ha (Sabo 1980).

No information on natal philopatry is available and the only data on adult site fidelity are from Algonquin Park. Of 27 territorial males, only 1 (3.7%) was found the following year, more than 200 m from his previous territory (Swanson et al. 2021).

Limiting Factors

Eggs have been found 2-23 June in Ontario, with most reported 10-14 June (Peck and James 1997). In Algonquin Park, females were observed carrying nesting material almost immediately after arrival in mid-April. The nest takes about 5 days to complete. A new nest is built for replacement clutches following failure or predation. Both hatching and fledging occur over many days, so incubation may be initiated before the clutch is complete. The first nests were found in Algonquin Park on 12 May and the earliest incubating female was seen on 30 May. The first chicks fledged 1-2 July but renesting attempts continued into July; 1 female initiated incubation in her third nest on 3 July (Swanson et al. 2021). A captive pair incubated for 16 days (Swanson et al. 2021); the incubation periods at 2 natural Ontario nests were 13 and 14 days (Peck and James 1987). Hatching took place over a 3-day period for a captive pair. The young left the nest at age 16 days at 1 Algonquin nest (Swanson et al. 2021), but young left at age 12 days at 1 British Columbia nest (Campbell et al. 1997).

A single brood is raised annually, but renesting occurs if a clutch is lost. Ontario clutches contained 5-10 eggs (average 8 or 9 eggs; Peck and James 1997). The overall range of clutch size is 4-12 eggs, with average clutch size variously reported as 7.25, 7.64, and 9.8 eggs. In British Columbia, clutches of 1-9 eggs were reported, with 4-7 eggs most frequent (Campbell et al. 1997). Bent (1949) reported that the Ruby-crowned Kinglet laid 5-11 eggs. He concluded that sets of 4 eggs were probably incomplete, 7-9-egg clutches were most common, and larger clutches were rare.

The Ruby-crowned Kinglet first breeds when it is 1 year old. It is monogamous and the pair bond lasts about 2 months. In Algonquin Park, pairing occurred in early May with the female leaving once the chicks fledged in early July (Swanson et al. 2021).

The Ruby-crowned Kinglet typically forages in trees during the breeding season, but also in shrubs, particularly in nonbreeding seasons. In Ontario and the Northwest Territories, 91.0-92.0% of foraging occurred in conifers. During the breeding season in Algonquin Park, it fed mostly in white and black spruce in dense foliage near the tops of trees. It also hover-gleaned for flying insects on flowering white birches. In Saskatchewan, it used spruce more for foraging than its availability; trembling aspen was used less than expected. In New Hampshire, 99.3% of foraging was in conifer foliage. Most prey is found by gleaning from the surface of leaves and branches with some hovering to capture prey under leaves. It occasionally hawks insects. In subalpine areas of New Hampshire, it

foraged aerially more than the Golden-crowned Kinglet, hovering 25-35% of the time and hawking 5-10% of the time. The Ruby-crowned Kinglet is a much more generalized forager than the Golden-crowned Kinglet. In New Hampshire, 61.4% of foraging occurred distal to the trunk and 38.6% near the trunk but it showed no significant differences in its usage of inner and outer branches in Saskatchewan. Mean foraging heights there were 7.3 m in conifers and 9.5 m in deciduous trees, significantly different from other species. In New Hampshire, 4.4% of foraging occurred 2-5 m from the ground, 52.2% 5-8 m up, and 43.4% more than 8 m up (Carlisle et al. 2012; Cumming 2004; Greenberg et al. 1999; Keast and Saunders 1991; Sabo 1980; Swanson et al. 2021). It may visit sapsucker wells to obtain sap and insects and there is 1 record of it visiting a hummingbird feeder (Swanson et al. 2021). Bain (1984) observed a Ruby-crowned Kinglet 2.5 km offshore over Lake Ontario actively feeding on clouds of tiny flying insects. During a sleet storm in North Carolina, kinglets either hovered close to a stone wall and jabbed their bills into the recesses in the wall or perched woodpecker-like on the rough surface to feed on remnants of dead insects trapped in spider webs (Hespenheide 1962).

In an aviary-raised brood, adults brought the young very small caterpillars, cicada larvae, small crickets, moths and butterflies, ant pupae, and snails. The Ruby-crowned Kinglet is predominantly an insectivore, preferring flying insects, but it eats other arthropods and some vegetable matter. Contents of 294 stomachs of birds in California consisted of 94% animal matter and 6% vegetable matter. Wasps and ants were favoured and comprised 32% of food items. Other animal food included 26% bugs (assassin and lace bugs, leafhoppers, jumping plant lice, and scale insects), 17% flies, 13% beetles, 3% lepidopteran caterpillars and adults, and 2% spiders and pseudoscorpions. Vegetable matter eaten consisted of 4% miscellaneous materials including seeds of poison oak and leaf galls; less than 1% fruit, mostly elderberries; and 0.01% weed seeds. Dogwood fruit and sumac berries are occasionally eaten. Other plant material reported in the diet includes red cedar and wax myrtle berries. Most of the arthropods eaten are small and less than 4.5 mm in length. Other insects eaten during the breeding season include aphids, mealy and leaf bugs, lady and bark beetles, and larch sawflies. During an outbreak of black-headed budworms in New Brunswick, the mean daily consumption was only 10 budworms indicating no significant response to the abundance of budworms. Over 2 years in Maine, spruce budworm larvae and pupae constituted 16% and 0% of the invertebrates consumed (Bent 1949; Gage et al. 1970; Keast and Saunders 1991; Mitchell 1952; Swanson et al. 2021). In New Brunswick, Morris et al. (1958) found no relationship between the abundance of the Ruby-crowned Kinglet and numbers of spruce budworms.

Cowbird parasitism has not been reported in any Ontario Ruby-crowned Kinglet nests (Peck and James 1997). Andrle (1978) reported a male feeding a young cowbird at Fort Erie. Boxall (1981) reported a young cowbird being fed by a pair of kinglets in British Columbia. This was only the 15th record of cowbird parasitism and only the third record of cowbirds being successfully fledged. Swanson et al. (2021) reported no additional cases of cowbird parasitism, but parasitism appears to be more prevalent in British Columbia where 3 of 21 nests (14.3%) were parasitized. In addition, there were 8 records of kinglets feeding fledged cowbirds (Campbell et al. 1997). In Quebec, 2 of 23 nests (8.7%) were parasitized (Barrette and Darveau in Gauthier and Aubry 1996). McIlwraith (1894) reported a nest from Lennoxville, Quebec that contained 8 kinglet eggs and 1 cowbird egg.

Habitat change or loss may be affecting abundance of the Ruby-crowned Kinglet. Initial forest clearing after European settlement reduced the amount of suitable breeding habitat. During the second atlas, it disappeared from a few areas where it was present during the first atlas. These included the Sault Ste. Marie area where there is much more young forest than previously, and east of Georgian Bay and south of Lake Nipissing, where there is currently much more deciduous forest (Crins in Cadman et al. 2007). These changes are probably due to forestry practices and natural succession. In boreal forest in Saskatchewan, Cumming and Diamond (2002) found it significantly more in post-rotation-aged forest. Barrette and Darveau (in Gauthier and Aubry 1996) concluded that logging was the biggest threat in the boreal forest but that it appeared to tolerate logging practices such as stand thinning and selective thinning. They noted that replanting of abandoned farmland with conifers had created suitable breeding habitat, including areas where the original forest cover was deciduous. Vanderwel et al. (2009) summarized studies examining the effects of partial timber harvesting in the Boreal Forest Region. Abundance of the Ruby-crowned Kinglet did not change when 30% or 50% of trees were removed, but it decreased when 70% of trees were removed. In the Ontario Canadian Shield, there was no difference in its abundance in mid-successional clear-cuts and similarly aged stands following fire. It was significantly more abundant in early successional clear-cuts than young burns. It was equally abundant in mid-successional and mature stands but significantly less abundant in early successional than mature stands (Zimmerling et al. 2017). In Newfoundland, its survival was significantly affected by landscape type. The breeding season survival rate of kinglets was significantly higher in natural landscapes than in clear-cut landscapes. Many birds in clear-cut landscapes appeared to be transients and there were 3-4 times more transients in cut than uncut landscapes (Whitaker et al. 2008).

On Anticosti Island, the Ruby-crowned Kinglet was not adversely affected by browsing by high populations of white-tailed deer. Browsing reduced abundance of deciduous species in recent clear-cuts but coniferous regeneration was unaffected. It made moderate use of the shrub layer for foraging, but preferred conifers (Cardinal et al. 2012).

In Alberta, there was no difference in the abundance of the Ruby-crowned Kinglet at noisy compressor stations and quiet well pads. It appeared to be unaffected by chronic noise (Bayne et al. 2008). It was significantly more abundant at seismic lines than in adjacent forest interior but was significantly less abundant at pipelines and well pads than in forest interior adjacent to these features (Bayne et al. 2016).

DesGranges and Morneau (2010) concluded that the Ruby-crowned Kinglet was sensitive to climate change in Quebec. Its abundance is correlated with the Boreal Forest Region and cooler and wetter summers, so it may be adversely affected by warmer summer temperatures. Its abundance in the Boreal Forest Region of Quebec and Labrador was associated with cooler temperatures and moderate amounts of breeding season precipitation (DesGranges and LeBlanc 2012). In Ontario, its distribution was negatively correlated with the end of the growing season and positively correlated with total precipitation during the growing season (Venier et al. 1999).

Status

McIlwraith (1894) was not aware of any breeding records for the Ruby-crowned Kinglet from southern Ontario and did not report on its occurrence elsewhere in the province. Baillie and

Harrington (1937) concluded that it was an uncommon summer resident throughout Ontario, but that it was much more regular and common north of Muskoka District. They considered it a common breeder at Moose Factory. Near Pickle Lake, it was uncommon to common throughout the area and exhibited the highest breeding density of any bird species (James 1980). During the first atlas, Klinkenberg (in Cadman et al. 1987) concluded that it was common throughout central and northern Ontario but was rare in southwestern and southeastern Ontario. James (1991) considered it a common summer resident across the north and in the southern Canadian Shield and occasional and rare south of the Shield.

The second atlas demonstrated that the Ruby-crowned Kinglet continued to be rare south of the Shield and common further north, although it was sparsely distributed in the extreme southern portion of the Shield. South of the Shield, there were few squares where it was observed in during both atlases except on Manitoulin Island and the Bruce Peninsula indicating that it is an irregular breeder south of the Shield. Its abundance increased with latitude, perhaps reflecting the abundance of spruce. Its probability of observation increased significantly for the entire province between atlases. Significant increases occurred in the Boreal Forest Region and the Hudson Bay Lowland, but there was a significant decrease in the Great Lakes–St. Lawrence Forest Region both in and south of the Canadian Shield (Crins in Cadman et al. 2007). The area south of the Shield is marginal habitat due to scarcity of natural spruce. The decline in the extreme southern portion of the Shield may be due to maturation of forests and gradual replacement of conifers by tolerant hardwoods.

Long-term (1970-2021) Breeding Bird Survey data indicate an annual increase of 0.532% in Canada and an annual decrease of 0.794% in Ontario. The short-term (2011-21) trends were an annual decrease of 1.4% in Canada and an annual increase of 1.86% in Ontario. All trends were of medium reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

At an Algonquin Park nest, the female left after the young fledged and the male fed them for 10 days with the fledglings following him over the full extent of the territory (Swanson et al. 2021).

Major and Desrochers (2012) captured 7 Ruby-crowned Kinglets in Quebec regenerating clear-cuts during the postfledging period. None were captured in plots where the fruit had been removed.

MIGRATION

The Ruby-crowned Kinglet is thought to be a nocturnal migrant (Graber et al. 1979), although there is evidence of daytime movement as well. Bain (1984) reported occasionally observing kinglets reaching the northern shore of Lake Ontario in an exhausted state, having flown directly across the lake during spring migration.

The sexes exhibit differential timing of migration, with males migrating earlier than females in spring, and females migrating earlier than males in autumn (Swanson et al. 2021). At Long Point, males arrive 12.0 days earlier in spring than females. Females leave 3.4 days earlier than adult males and 5.0 days earlier than hatch-year birds in autumn (Mills 2005a). Swanson et al. (1999) examined differences in timing of migration of the sexes for South Dakota and eastern North America. Males

migrated significantly earlier in spring at all latitudes by 10-15 days and migrated significantly later than females in autumn.

McIlwraith (1894) stated that the Ruby-crowned Kinglet was present for only 2-3 days in southern Ontario during spring, but that it was exceedingly abundant in the latter part of August and early September. It is now present for a more extended period in spring and the peak of autumn migration is in late September, with it rarely appearing in very late August during autumn migration. At Long Point, the spring passage midpoint in spring was 29 April over 21 years (Mills 2005a). In southern Ontario, a few may arrive in late March, but most arrive in mid-April through mid-May. Autumn migration begins in early September in Muskoka and Parry Sound districts and peaks around 1 October. In the south, birds arrive in mid- to late September and are common throughout October. Most leave the province by early November, but stragglers persist into December (Curry 2006; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008). At Long Point, the autumn passage midpoint over 19 years was 12 October (Mills 2005a).

During migration, the Ruby-crowned Kinglet is often associated with flocks of chickadees, warblers, nuthatches, the Brown Creeper, and the Golden-crowned Kinglet. It uses a variety of habitats during migration. It may occur in swampy thickets along streams or around bodies of water, in trees and shrubs in residential areas, in coniferous and deciduous forests, in thickets, and in brushy hedgerows. In British Columbia, it prefers mixed coniferous forests during migration and often inhabits edges of muskegs, lakes, ponds, and alpine meadows. In the Yukon, it usually forages in shrubby areas, with highest concentrations occurring in wetlands, but it is also common in backyards and shrubby areas in towns. In Kansas, it preferred edge situations and thickets of willows, dogwoods, vines, and tall elm saplings (Bent 1949; Campbell et al. 1977; Fitch 1958; Leighton et al. 2002; Sinclair et al. 2003; Swanson et al. 2021). It prefers gaps in forest to forest interior for foraging (Swanson et al. 2021). Rodewald and Brittingham (2002) compared its abundance in different habitats during autumn migration in Pennsylvania. It was most abundant in forest interior followed by pole-stage forest, suburban forest, forest edge, shrub-sapling-stage forest, and forest-agricultural edge. Results were significantly different only between forest interior and forest-agricultural edge. Rodewald and Brittingham (2004) found that it was significantly more abundant in shrub-sapling-stage forest than other habitats studied. Of the remaining habitats, it was more abundant, in decreasing order, in forest-agricultural edge, pole-stage forest, forest interior, and suburban forest, with no birds detected in the latter habitat. In Pennsylvania, the Ruby-crowned Kinglet was found significantly more in shrub-dominated habitats than in forest (Smith and Hatch 2008). In Pennsylvania forests during spring migration, it selected upland forest significantly more than riparian forest, which had an understorey of shrubby species (Rodewald and Matthews 2005). Kirsch et al. (2013) found no difference in its abundance in upland and floodplain forests in Wisconsin and Minnesota during spring migration. On 2 islands in the Gulf of Maine, it was significantly more abundant on the island dominated by shrubs than the one dominated by trees (Suomala et al. 2010). These studies suggest that the Ruby-crowned Kinglet may be present in a variety of habitats and that usage of given habitats may vary geographically.

The Ruby-crowned Kinglet may defend territories during migration, at least in spring. In Illinois, males defended territories against other males in a ritualistic display. The length of time that

territories were defended was uncertain, but some birds appeared to remain in the same area for about a week (Graber et al. 1979). In Kansas, it was solitary during migration and individuals tended to settle for days in 1 location. No birds were marked, but birds were often seen on successive days in the same tree or thicket. Those kept under observation for extended periods usually remained within a radius of a few metres (Fitch 1958).

Limited data suggest that the Ruby-crowned Kinglet may exhibit site fidelity during migration. Somershoe et al. (2009) reported a kinglet that was caught at a Florida banding station during 3 different migration periods.

Outside the breeding season, the Ruby-crowned Kinglet may use a wider range of woody species for foraging. At Prince Edward Point during migration, 55% of feeding groups were in deciduous trees and the remainder were in conifers; 39% of foraging was by foliage gleaning (Keast and Saunders 1991). During autumn migration in Idaho, it foraged more in deciduous trees and shrubs than in conifers. Feeding in Illinois may occur in hawthorns and other small trees during spring migration. During migration and winter, it usually forages among leaves on the outer tips of high, smaller (less than 1.3 cm diameter) branches, but also on buds and at the base of pine needles, on the bark of small branches, and rarely on the ground or dead herbaceous plants (Graber et al. 1979).

Beal and McAtee (1912) analyzed the contents of 294 stomachs collected in the United States during migration and winter. The diet consisted of 94% animal matter (insects, spiders, and pseudoscorpions) and 6% vegetable matter (fruit and weed seeds). Ants and wasps were the dominant food items, comprising 32.4% of the diet. Bugs were next in importance, constituting 25.7% of the diet. They included leafhoppers, jumping plant lice, aphids, scale insects, and assassin, mealy, and lace bugs. Thirteen percent of the diet consisted of beetles, including bark and lady beetles and weevils. Flies constituted 16.9% of the diet, with the greatest numbers consumed in January and February. Lepidopterans comprised only 3% of the diet. Although it ate a few caterpillars, minute cocoons of clothes moths were the most important lepidopterans. Two stomachs contained grasshoppers, and spiders and pseudoscorpions constituted 2% of the diet. Fruit represented less than 1% of the diet and most of it was elderberries. Most vegetable food consisted of seeds of poison oak and leaf galls. Some diet information is available for Illinois migrants, but data for the 2 kinglet species were combined. Spring data were mostly for Ruby-crowned Kinglets; autumn results were mostly for Golden-crowned Kinglets. In spring, gnats were most frequent in the diet (33% of food items), followed by beetles (black-margined loosestrife and water scavenger beetles) at 25%. The autumn diet consisted of 33% lepidopterans, especially winged moths, and 29% bugs. Both species of kinglets were opportunistic, feeding on the most abundant insects and sometimes exclusively on 1 species (Graber et al. 1979). During autumn migration in Idaho, the Ruby-crowned Kinglet foraged on spiders, stilt and spittle bugs, leafhoppers, jumping plant lice, and beetles at a rate greater than their abundance. Species consumed less than their abundance included stink bugs, ants, wasps, yellowjackets, lepidopterans, and moths (Carlisle et al. 2012).

Mills (2005b) examined spring and autumn migration dates for the Ruby-crowned Kinglet at Long Point from 1975 to 2000 to determine if there were any responses to global warming. Based

on first arrival dates, it arrived significant earlier with time, advancing spring migration by 5.3 days per decade. When quartile means were used to analyze spring migration, the trend was toward later arrival, but not significantly. In autumn, hatch-year birds departed significantly later over time, 2.2 days per decade during 1981-2000.

The Ruby-crowned Kinglet is vulnerable to being killed at television towers and other tall structures. In Illinois, it represented 1% (46 of 4,700) of all birds killed at television towers (Graber et al. 1979). Seventy-three were killed at the Lennox generating station near Kingston (Weir 2008). During migration in Toronto, the Ruby-crowned Kinglet was among the species least vulnerable to striking urban windows (Colling et al. 2022).

In Pennsylvania, an outbreak of the viburnum leaf beetle resulted in almost complete mortality of the southern arrowwood, formerly the third most abundant shrub species. Prior to the infestation, spring migrating Ruby-crowned Kinglets gained significant mass after daylight but no weight gains occurred after the infestation (Smith and Hatch 2017).

McClure et al. (2013b) created a phantom road by playing traffic noise in an otherwise undisturbed forest during autumn migration. Abundance of the Ruby-crowned Kinglet declined somewhat with increasing noise intensity. At 37 dB(A), an average of 3.0 kinglets was detected compared with 2.0 at 55 dB(A). It may have a tendency to avoid noisy environments during migration.

The Ruby-crowned Kinglet is an abundant migrant in Ontario (James 1991). At Presqu'ile, sightings of 300 a day are common in spring. At Prince Edward Point, 2,000 have been recorded on a single spring day. Autumn numbers are often higher, with record daily numbers at Prince Edward Point of 4,000 (LaForest 1993; Weir 2008).

WINTER

In winter, the Ruby-crowned Kinglet occurs in habitats similar to those used during migration. In the lower Colorado River valley, it was most abundant in areas of tall, dense vegetation and scarce or absent from areas with low volumes of foliage (Laurenzi et al. 1982). In California, its abundance increased with the availability of shrubs or trees and decreased with presence of roads or structures (Kalinowski and Johnson 2010).

During severe cold, significant mortality of the Ruby-crowned Kinglet may occur which may depress breeding populations the next spring (Swanson et al. 2021).

The Ruby-crowned Kinglet is rare and irregular in winter in Ontario north to Durham Region (James 1991). In the Hamilton area, some birds have persisted into February or even March, suggesting successful overwintering (Curry 2006).

Ontario winter population trends determined from Christmas Bird Count data indicate an annual decrease of 0.85% 1970-2021 and an annual increase of 5.21% 2009-21 (National Audubon Society 2022).

Golden-crowned Kinglet

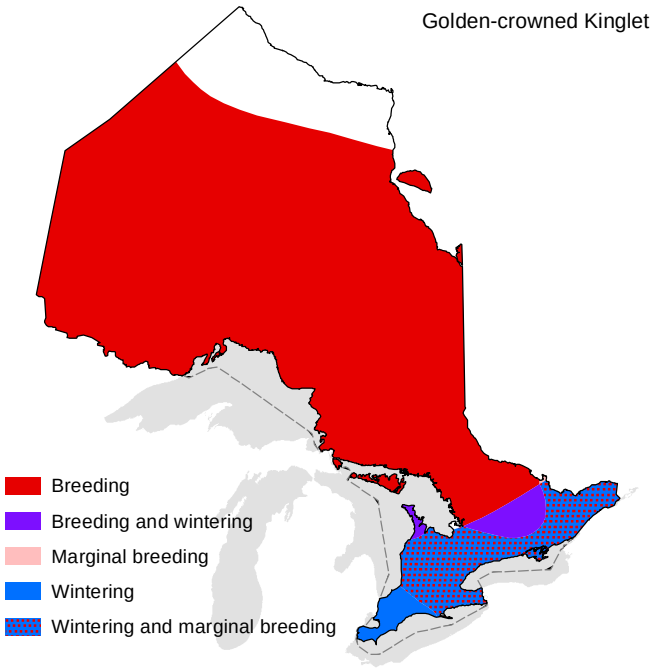
Regulus satrapa

BREEDING SEASON

Habitat Requirements

In Ontario, the Golden-crowned Kinglet nests in dense stands of large coniferous trees. Nest sites may be either within forests, at edges or clearings, or near water (Peck and James 1987).

In the Boreal Forest Region of Ontario, the Golden-crowned Kinglet was associated with older, closed, coniferous forests that were in a mature forest matrix. It was also associated with intact forests with low amounts of edge (Rempel 2007). Near Pickle Lake and in northwestern Ontario, it was most abundant in mixed forests, followed by coniferous forests without and with understorey. It was absent from deciduous forests (McLaren and McLaren 1981). Near Pickle Lake, it seldom occurred in small numbers in coniferous forests (James 1980). Along the northeastern shore of Lake Superior, it preferred mixed woods containing a high percentage of spruce and balsam fir (Baillie and Hope 1943). Near White River, it was significantly more abundant in mature forests than in clear-cuts 3-25 years old. It was the most specialized species for residing in mature forests (Venier and Pearce 2005). In the Clay Belt, it was associated with dry stands with moderate nutrient levels (Welsh and Lougheed 1996) and was a late-succession species (Welsh 1993).



In white pine stands in the Great Lakes–St. Lawrence Forest Region in the Canadian Shield, abundance of the Golden-crowned Kinglet was significantly correlated with the basal area of non-pine conifers (Kirk et al. 2012). In jack pine stands near Gogama, it readily foraged on pines but was only present where a small proportion of the forest was spruce, where there was suitable nesting habitat. Some territories included deciduous trees but these were essentially unused. It first appeared when trees approached 20 years of age, but was never numerous in any age of forest, probably because spruce was never abundant (James and Peck 1995a). In Algonquin Park, it was most abundant in fir-spruce forests followed by black spruce forests, black spruce–white cedar forests, mixed white birch–poplar–balsam fir–black spruce forests, and hemlock stands. It was absent in stands without a significant coniferous component (Martin 1960). In southern Ontario, the Golden-crowned Kinglet has recently started breeding in mature spruce and pine plantations, particularly those with spruce (Curry 2006; Lancaster et al. 2004).

In Ontario, the Golden-crowned Kinglet is associated primarily with spruce and fir in the Shield and Hudson Bay Lowland. These stands may occur in upland and lowland habitats as well as bogs and fens. In the southern portion of the Canadian Shield, it may occur in mixed stands of spruce, fir, and occasionally hemlock associated with deciduous species. Bogs and fens dominated by black spruce, occasionally mixed with tamarack or white cedar, may also be inhabited. South of the Shield, it occurs in older plantations dominated by spruce, bogs and fens, and occasionally in hemlock stands or mature mixed-wood forests containing hemlock or spruce.

The Golden-crowned Kinglet is an obligate conifer specialist. Throughout its range, spruce is the most important species, with black spruce important in the Boreal Forest Region, white spruce in the Great Lakes–St. Lawrence Forest Region and western Canada, and red spruce in the east. Balsam fir is another important species in Ontario and eastward. It may nest in pine–balsam fir stands but at lower densities than in spruce. Nesting may also occur in pure hemlock and tamarack stands in the east, but at much lower densities than in spruce or fir. It occasionally inhabits stands of white cedar, but only if they are mixed with spruce or another preferred coniferous species. There appear to be few records of it nesting in white cedar, but it has been reported nesting in cedar bogs (more likely fens) in Michigan. Nesting is frequent in black spruce–balsam fir stands and may be common in mixed deciduous-coniferous stands, especially those with a high proportion of spruce and/or fir present. In New Hampshire and Maine, it was most abundant in spruce–balsam fir stands, followed by pure balsam fir stands and those dominated by white pine. Nesting seldom occurred in

deciduous stands with scattered conifers. In the south outside its traditional breeding range, it may nest in coniferous plantations dominated by white spruce or Norway spruce or spruce mixed with pine. Pure pine plantations do not appear to be acceptable, but kinglets have nested in 10-20-m wide strips of spruce and pine plantings in New York. Plantations become suitable for breeding when the trees are about 15 cm diameter at breast height (DBH) and 35-40 years old. Kinglets select the densest areas in plantations for nesting. Plantations that have been row-thinned are usually unoccupied. In the Yukon, it is a habitat specialist that nests only in old-growth white spruce forest that borders rivers, lakes, and wetlands. Forests that are inhabited are characterized by dominant large white spruce, a high density of snags, and an extensive ground cover of mosses, forbs, and dwarf shrubs. In British Columbia, it inhabits forests that are primarily dense and old-growth or advanced second growth. Mixed forests of fairly open structure are preferred, but even isolated trees in city parks or similar settings have been used for nesting. In Saskatchewan, the Golden-crowned Kinglet nested most frequently in mixed forests dominated by white spruce and trembling aspen. It was absent in stands younger than 100 years old and occurred most frequently in stands older than 140 years. These stands tended to have a higher proportion of conifers than younger stands. In northern Minnesota, it preferred to nest in black spruce–tamarack bogs, although it also nested in mixed stands dominated by balsam fir, white spruce, and red pine with scattered tamarack, white birch, trembling aspen, and jack pine. In subalpine areas of New Hampshire, it was associated primarily with virgin spruce stands and was usually associated with water, but only damp depressions rather than larger bodies of water as in the Yukon. In natural stands, it may prefer more open canopies with 70% or less canopy closure, but only the densest plantations are used. In spruce-fir stands in Maine, it was associated with a dense coniferous overstorey and an open forest floor, and was positively correlated with softwoods with DBH of 10-15 cm. On the Apostle Islands in Wisconsin, it was most abundant in jack pine–white pine stands followed by hemlock–yellow birch and aspen stands. In central Quebec, its abundance was higher in jack pine stands than in spruce stands and other habitats surveyed. In Newfoundland, it was 1 of the 10 most abundant species in balsam fir stands. In Idaho, it nested in pure pine plantations. The Golden-crowned Kinglet may persist in burned forests if the burn is light and in selectively thinned woodlands, but is absent in severe burns and clear-cuts (Andrle 1971; Beals 1960; Bent 1949; Bock and Lynch 1970; Campbell et al. 1997; Capen 1979; Crawford and Titterington 1979; Cumming and Diamond 2002; Dawson 1979; DeGraaf et al. 1998; Erskine 1977; Galati 1991; Galati and Galati 1985; Larivée and Darveau in Gauthier and Aubry 1996; Niemi and Pfannmuller 1979; Sabo 1980; Sinclair et al. 2003; Swanson et al. 2020; Temple et al. 1979; Thompson et al. 1999; Titterington et al. 1979). The Golden-crowned Kinglet nests in forests with no to dense understorey, but its abundance is inversely correlated with the intensity of understorey browsing by deer (Swanson et al. 2020).

In most natural forests, the Golden-crowned Kinglet appears to prefer mature stands. In the Yukon, it is an obligate old-growth spruce forest species (Sinclair et al. 2003) and it prefers older growth in British Columbia (Campbell et al. 1977) and Saskatchewan (Cumming and Diamond 2002). In the northern boreal forest of Saskatchewan, it was associated with older stands more than any other species analyzed and occurred only in old-forest sites. It also occurred in the driest stands available with slightly below average nutrient enrichment (Kirk et al. 1996). It was most abundant in Quetico Park communities that were 112 years old; it was not present in younger or older stands

(Apfelbaum and Haney 1985). It was associated with mature stands in the Ontario portion of the Clay Belt (Welsh 1993) and most abundant in mature stands near White River (Venier and Pearce 2005). In Quebec, it bred in black spruce clear-cuts with saplings 2-5 m tall and in young and mature forests. It was absent in recent cuts and burns (Imbeau et al. 1999). In Pennsylvania, it had a positive affinity for old-growth forest and exploited coniferous cover and complex vegetation structure typically associated with older forests. It occurred in 18.2% of old-growth hemlock–white pine–hardwoods forests compared with 3.7% of similar forests state-wide in Pennsylvania and 5.7% of forests on the Appalachian Plateau (Haney 1999). In New England, it was most prevalent in forests of sawtimber size, averaging 23 cm DBH or greater for coniferous species. These stands were dominated either by spruce-fir or hemlock (DeGraaf and Chadwick 1987). In West Virginia, spruce forests were colonized once trees reached a height of 10-15 m (Swanson et al. 2020).

DeGraaf et al. (1998) characterized the microhabitat preferences of the Golden-crowned Kinglet in New Hampshire and Maine. It was positively correlated with coniferous trees larger than 10 cm DBH and negatively correlated with deciduous trees 2-10 cm DBH and the total foliage volume of deciduous trees larger than 10 cm DBH and smaller than 2 cm DBH. In boreal forest habitat in New York, Vermont, Maine, Nova Scotia, and Newfoundland, it occurred in a variety of spruce-fir forest types. It was negatively correlated with the number of dead snags and preferred low canopy cover with low coverage by deciduous tree species (Ralston et al. 2019). In Minnesota, it was positively associated with the amount of coniferous cover within 200 m, the amount of upland deciduous forest within 1 km, the amount of upland coniferous forest within 500 m, basal area, black spruce and white cedar stands, and stand age. It was negatively correlated with non-forested habitat, the amount of tamarack within 200 m, and the number of habitat patches within 200 m. Both species of kinglets preferred black spruce or cedar forests with upland forests in the broader landscape. They appeared to be separated based on the productivity of stands, with the Golden-crowned Kinglet preferring more productive stands than the Ruby-crowned Kinglet (Zlonis et al. 2017).

Freemark and Collins (1992) and McCracken et al. (1998) considered the Golden-crowned Kinglet to be a forest-interior or area-sensitive species. Neither of these designations appears to be correct. In New York, Andrle (1971) found it nesting in plantations ranging in size from 0.8 ha to approximately 24 ha, and almost half of those in which kinglets were found were smaller than 4 ha. Peck and James (1987) reported that it frequently nested on woodland edges. In Newfoundland balsam fir stands, Whitaker and Montevecchi (1997, 1999) considered it a habitat generalist with respect to forest edge. There was no significant difference in its abundance in riparian edges, nonriparian edges, and forest interior.

All Ontario nests were in living conifers: 9 in spruce and 1 in a hemlock. Two nests were within 1 m of the top of the tree. Nests were suspended from horizontal branches or forks and secured to smaller, drooping branches. They were well concealed and placed near the tree trunk to as far as 4 m from it. Nest heights were 2.4-13 m, with most 2.4-10.7 m up (Peck and James 1987, 1997).

Throughout its range, the Golden-crowned Kinglet nests almost exclusively in coniferous trees, but 2 British Columbia nests were in deciduous trees. In the east, the most common nest trees are black and white spruce and balsam fir, with substantially fewer nests in hemlock. In plantations, Norway spruce may be used for nesting and there is 1 record of a nest in a red cedar. Nests are

extremely well hidden and essentially invisible from the top or sides. The sun never shines in nests and they are so protected by overhanging foliage that they remain dry even in torrential rain and heavy wind. A high proportion of nests are in the crowns of trees and most are near the end of limbs. Some nests may be near the trunk, but do not touch it so that they are unaffected by rainwater running down the trunk. Nests have been reported 1.3-19.6 m from the ground. These heights are biased towards lower nests because they are easier to find. Nests are more typically near the top of trees. In a Minnesota area, all nests were found and the average height of 19 nests was 15.3 m (range 8.2-19.6 m). Eleven faced east, 6 southwest, and 1 northwest; prevailing winds were from the west (Bent 1949; Campbell et al. 1997; Galati 1991; Galati and Galati 1985; Swanson et al. 2020).

Territorial defence is by the male, predominantly by singing but skirmishes occasionally occur between males. Both sexes remain within the territory during the breeding season and the male tends to perch in the same trees each day vocalizing from dead branches of coniferous trees 3.6-10.7 m from the ground. Territorial defence ceases after young of the second brood fledge. North of Lake Nipigon, territory size ranged from 0.4 to 2.0 ha (average 1.2 ha). In Algonquin Park, territory size averaged 0.34 ha (range 0.09-1.3 ha). In balsam fir–spruce stands, territory depth ranged from 3 m (the bottom of the canopy and the top of the shrub layer) to 12 m, which was the top of the conifers. In hemlock stands, territories ranged from 3 to 8 m from the ground, which was below the bottom of the canopy. In subalpine forests in New Hampshire, territories averaged 0.6 ha. In northern Minnesota, territories averaged 1.6 ha (range 0.9-2.5 ha). The pair with the largest territory had no competing kinglets on its border. Territory size appeared to be determined by the number of pairs present and the type of vegetation bordering the territory. Six territories in Maine spruce forests averaged 0.72 ha (Galati 1991; Galati and Galati 1985; Kendeigh 1947; Martin 1960; Morse 1977; Sabo 1980; Swanson et al. 2020).

Limited information is available on natal philopatry. In northern Minnesota, Galati (1991) banded 57 nestlings and none returned. There is no information on adult site fidelity.

Limiting Factors

Eggs have been found in Ontario nests in late May and are presumably present throughout May (Peck and James 1987). In Algonquin Park, nest construction occurs from late April to early May and a second-brood nest was built in mid-July, nests with young have been documented in mid-June, and dependent fledglings occur from late June to mid-August (Tozer 2012).

In northern Minnesota, nests were constructed in an average of 5 days (range 4-6 days). One nest in Maine was initiated in early April and took about a month to complete. If a nest is abandoned or destroyed, construction of a new nest begins the next day and is usually completed in about 5 days as are nests for the second brood. The first egg is usually laid the day after the nest is completed, and 1 egg is laid per day. Usually effective incubation does not occur until the laying of the last or penultimate egg, but 1 female started incubating when the second of 9 eggs was laid. The incubation period is typically 14-15 days, with some eggs taking as long as 19 days to hatch. Hatching may take place over 2-4 days. Young start to crawl out on twigs and branches 30-60 cm from the nest about 2 days before they fledge. The entire brood fledges within a period of 15-105 minutes. Although young have left the nest at age 14-19 days, 18-19 days is typical. Young that leave the nest at age 14-16 days do so prematurely and few of these survive. In second broods, the last

fledglings were independent 58 days after the second nest was started and the time spanning both broods was 94 days (Bent 1949; Galati 1991; Galati and Galati 1985).

The Golden-crowned Kinglet regularly builds 2 nests and raises 2 broods per season. Pairs begin building the second nest about 8 days after eggs begin hatching in the first nest and initiate egg laying in the second nest 6 days after the construction of it is started. Pairs regularly renest after a clutch is lost or abandoned. In northern Minnesota, all first clutches contained 9 eggs. Of the second clutches, 4 had 9 eggs and 2 had 8. The average clutch size was 8.85 eggs including both first and second clutches. Eastern birds tend to lay larger clutches than western birds. Average clutch size for eastern birds is 8.6 eggs (range 5-11); western birds lay an average of 7.6 eggs. Overall clutch size has been reported as 4-11 eggs, with 8 or 9 eggs most frequent. In an experiment, eggs of 2 pairs were destroyed each time they completed a clutch. Both females laid 9 eggs in the first 2 nests and 8 eggs in the third (Bent 1949; Campbell et al. 1997; Galati 1991; Galati and Galati 1985; Swanson et al. 2020).

No information is available on the age at first breeding. The mating system is monogamous and pairs remain together for a single breeding season. The pair typically raises both broods in the territory established in the spring by the male. One pair abandoned its territory after 2 unsuccessful nesting attempts and established another approximately 60 m away (Galati 1991; Swanson et al. 2020).

The Golden-crowned Kinglet prefers to forage in the mid-canopy of coniferous trees, typically by gleaning insects from outer twigs. In the Boreal Forest Region of Ontario, 96.0% of foraging occurred in conifers (Greenberg et al. 1999). In the Kingston area, 80% and 88% of feeding groups at 2 sites were in conifers and the remainder were in low shrubs. The Golden-crowned Kinglet was a conifer specialist whereas the Ruby-crowned Kinglet was a generalist. Foliage gleaning predominated by both species (42% of attacks on prey by the Golden-crowned Kinglet) and the Golden-crowned Kinglet fed much more by clinging to or hanging from the foliage (Keast and Saunders 1991). In Maine, it foraged at heights of 0-16.8 m (mean 8.0 m). Foraging occurred mostly in spruce, 38.2% of the time at the tip of foliage, 9.2% on small live twigs as large as 5 mm, 13.9% on dead twigs, 30.3% on dead branches, 5.2% distally on branches, 1.6% proximally on branches, 0.8% in deciduous growth, and 0.8% on the ground (Morse 1967). In Arizona, the diet of the 2 kinglets was similar but they differed significantly in their method of prey attack and in their choice of tree species for foraging. The habitat selection of the 2 species differed mostly in tree species selection. The Golden-crowned Kinglet hovered less (11.2% compared with 18.2% of attacks by Ruby-crowned Kinglets) and gleaned more (86.9% compared with 80.3%). For the Golden-crowned Kinglet, 44.3% of foraging was 0-33% of the distance from the tip, 31.8% was 33-66% of the distance, and 23.9% further than 66% from the tip. Foraging occurred more frequently in tall trees than expected, but Golden-crowned Kinglets selected the middle portions of trees more frequently. Ruby-crowned Kinglets preferred the upper third (Franzreb 1984). In Parry Sound District, there was no significant change in the Golden-crowned Kinglet's foraging habitat during the breeding, midsummer, and autumn periods. It was associated with conifers at all times. Foraging was mostly by hovering and occurred at heights of 6.5-13.4 m (Mills 2007). In Saskatchewan, it used white spruce more for foraging than its availability and trembling aspen less than its availability. It occurred slightly more

frequently in canopy than subcanopy trees. Although there was no significant difference in foraging rates from the inner portions of branches to their tips, usage increased from the inner portion of the tree to the outside (Cumming 2004). In subalpine forests in New Hampshire, foraging locations were 51.6% distant from the trunk and 48.0% proximal to the trunk; 94.1% in conifer tree foliage, 5.5% in deciduous foliage, 0.4% on the forest floor, and 0% in herbaceous foliage. Foraging frequencies were 38.2% at 5-8 m, 34.9% at 2-5 m, 23.3% above 8 m in the upper canopy, and 3.3% in the understorey 0.1-2 m above ground (Sabo 1980). In northern Minnesota, it foraged almost exclusively among spruce, fir, and pine branches (Galati 1991; Galati and Galati 1985).

Both parents are required to raise a healthy brood. Nestlings are initially brought tiny insects; the size of prey increases as they age. Spiders are initially rejected as food by nestlings but are eaten when they are older. Of 98 food items brought to nestlings at Minnesota nests, 90 were insects and 8 were spiders. The dominant food items were aphids (21.4%), flower flies (15.3%), geometer moths (11.2%), and harvestmen (10.2%) as well as bugs, flies, caddisflies, butterflies, sawflies, and bark lice. Other prey items fed to young include lacewings, crane flies, mosquitoes, treehoppers, midges, and small snails. A single Golden-crowned Kinglet north of Lake Nipigon had eaten 35 spiders and 65 flies. Adults feed largely on bark beetles, scale insects, moth adults and larvae, and aphids and their eggs. Other insects eaten include springtails, grasshoppers and crickets, book and bark lice, adult damsel and harlequin bugs, treehoppers, aphids, leafhoppers, lacewings, weevils, click beetles, lady beetles, soldier beetles, caddisflies, adult and larval butterflies and moths, march flies, gall midges, leaf-miner flies, flower flies, crane flies, midges, mosquitoes, deer flies, bees and wasps, larch sawflies, and braconid wasps. This kinglet is fond of spruce budworm caterpillars and moths, but it seldom consumed black-headed budworms in New Brunswick even when they were abundant. It has been observed apparently drinking from Yellow-bellied Sapsucker wells, but it may be attracted to the insects rather than the sap. It has taken insects attracted to sugar maple sap in the spring. It drinks at seeps, springs, and streams and obtains water from snow or frost when water is frozen (Bent 1949; Gage et al. 1970; Galati 1991; Galati and Galati 1985; Kendeigh 1947; Swanson et al. 2020). Near Manitouwadge, abundance of the Golden-crowned Kinglet increased significantly overall and in young and intermediate-aged stands (1-36 years old) with increasing numbers of spruce budworms. There was no significant response to budworm numbers in stands 60-223 years old (Venier et al. 2009). In New Brunswick, Morris et al. (1958) found no relationship between its abundance and spruce budworms. In Maine spruce-fir forests, it showed a significant feeding response to increasing numbers of spruce budworm larvae and pupae; its abundance was significantly associated with budworm larvae numbers. Because it feeds on the tips of branches where budworms first appear in early stages of an infestation, it has the opportunity to respond reproductively to this early increase in food (Crawford and Jennings 1989). Mitchell (1952) examined 23 stomachs during a spruce budworm outbreak in Maine. They contained 13% and 0% budworm larvae and pupae by volume in 2 years.

Brown-headed Cowbird parasitism rates of Golden-crowned Kinglet nests appear to be low, although few nests have been reported. In British Columbia, 3 of 22 nests (13.6%) were parasitized and there were an additional 6 incidents of Golden-crowned Kinglets feeding cowbird fledglings

(Campbell et al. 1997). In Port Colborne, Black and Roy (2010) reported adult kinglets feeding a cowbird on a branch with a young kinglet still in the nest.

Golden-crowned Kinglet populations may be affected by logging activities or die-off of spruce or fir. Vanderwel et al. (2007, 2009) summarized studies that examined the effects of partial timber harvest in the Boreal Forest Region with particular reference to Ontario. There was no change in its abundance when 30% of trees were removed. It decreased when 50% of trees were removed and became locally extirpated when 70% of trees were removed. It experienced a 25% decrease when about 35% of trees were removed, a 50% decrease when 50% of trees were removed, and a 75% decrease when about 67% of trees were removed. In the Canadian Shield of Ontario, it was significantly more abundant in early successional clear-cuts than in early successional burns, but equally abundant in mid-successional clear-cuts and burns. It was significantly less abundant in early successional than mature stands and equally abundant in mid-successional and mature stands (Zimmerling et al. 2017). In Alberta, it declined significantly when 80% of trees in deciduous forests were removed and when 50-100% of trees were removed in coniferous forests. In Saskatchewan, it was significantly more abundant in stands older than typical rotation age. In Idaho, light selective thinning in stands had no significant effect on its density. In British Columbia high-elevation forests, it was more affected by forest harvesting (clear-cuts of 10, 1, and 0.1 ha, and selection thinning) than most species. Maturation of spruce plantations in the south is increasing available habitat in this area. Once these stands become mature enough to be row-thinned, they may become less suitable (Andrle 1971; Cumming and Diamond 2002; Dickinson et al. 1988; Harrison et al. 2005; Medin and Booth 1989; Swanson et al. 2020).

In Alberta, Bayne et al. (2016) studied the effects of energy sector disturbances on the Golden-crowned Kinglet. It exhibited no response; its abundance at seismic lines, pipelines, and adjacent forest interior was similar.

Cold spring weather may delay nesting. In Minnesota, clutch initiation varied by as much as a month (Galati 1991).

Status

McIlwraith (1894) concluded that the Golden-crowned Kinglet was generally distributed as a breeder throughout the province, but was aware of only a single breeding-season record from the south. Baillie and Harrington (1937) considered it an uncommon summer resident from the southern border north to at least the transcontinental railway and west to Thunder Bay District and probably to Lake of the Woods. They concluded that it was probably much more common than the scattered breeding records indicated and that its breeding range likely included the entire province. In Muskoka District, it was regular only in the northeast during the breeding season. Although more widely distributed in Parry Sound District, it was still not very common (Mills 1981). During the first atlas, it was sparsely distributed in the Hudson Bay Lowland due to the scarcity of tall, mature conifers; widely distributed through the Boreal Forest Region where it probably occurred in every square; scattered in distribution in the Great Lakes–St. Lawrence Forest Region in the Canadian Shield; and confined to a few mature plantations south of the Shield (Klinkenberg in Cadman et al. 1987). James (1991) considered the Golden-crowned Kinglet common across the central forested portion of the province and rare and local in the northern Hudson Bay Lowland and south of the

Shield. In many areas south of the Shield, it was unknown as a breeder historically and has colonized plantations within the last 2-4 decades (Curry 2006; LaForest 1993; Lancaster et al. 2004; McCracken et al. 1998; Weir 2008).

The breeding distribution of the Golden-crowned Kinglet remained essentially the same between the atlases. Its probability of observation increased significantly province-wide and in the Great Lakes St. Lawrence and Boreal forest regions. Increases south of the Canadian Shield were probably due to maturation of coniferous plantations, but the reasons for increases in other regions are uncertain. Highest densities occurred in northwestern Ontario, including Woodland Caribou Provincial Park and a substantial area north and east of Red Lake. Densities were almost 4 times as high in the Boreal Forest Region than in the Shield portion of the Great Lakes St. Lawrence Forest Region. Highest densities in the southern Shield area occurred in the Algonquin Highlands (McLaren in Cadman et al. 2007).

Long-term (1970-2021) population trends determined from Breeding Bird Survey data indicate an annual decrease of 0.356% in Canada and an annual increase of 0.842% in Ontario. Short-term (2011-21) trends were annual decreases of 4.22% in Canada and 4.85% in Ontario. The long-term results were highly reliable; the short-term trends were of medium reliability for Canada and low reliability for Ontario (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Fledglings group together on a branch on an adjacent tree and remain close to each other for the first 3-4 days. One family remained within 120 m of the nest for the first 11 days out of the nest. For the first 8 days after fledging, young were never seen outside their parents' territory, but they began to wander further after that. About 5 days out of the nest, fledglings make their first attempts to catch food and by days 12-16 they collect a good deal of food on their own, although they still actively pursue the adults for food. Young are not fed by the adults after they are 16-17 days out of the nest (Swanson et al. 2020).

Major and Desrochers (2012) captured small numbers of Golden-crowned Kinglets in regenerating clear-cuts in Quebec during the postfledging period.

MIGRATION

Long-distance migration is nocturnal as evidenced by kills at television towers and large overnight changes in populations at staging areas (Graber et al. 1979; Swanson et al. 2020). Birds have been recovered in Ontario that were banded in New Jersey, Ohio, Pennsylvania, and Michigan, and 1 bird that was banded in Tilbury was recovered in Louisiana (Brewer et al. 2018). Miles and Prior (1999) demonstrated that diurnal movement occurs at least during spring migration. A male banded at Long Point was recaptured at Selkirk Provincial Park exactly 3 hours later. The straight-line distance between the 2 banding station is 45 km, almost all over the open water of Lake Erie. It is more likely that it travelled overland, meaning that it would have travelled a minimum of 58-70 km depending upon the route followed.

Spring migrants typically return to the southern portion of the province in late March and early April, although some may occur in early March. The peak of spring migration is in mid-April with most migrants gone by early to mid-May; stragglers rarely persist until 1 June. Autumn arrival in southern Ontario is in mid- to late September with the heaviest flight in the first half of October. Most of those that leave the province are gone by mid-November. The peak of female migration in autumn is 10-15 days earlier than for males (Curry 2006; Keast 1980; Lancaster et al. 2004; Tozer 2012; Weir 2008). In Illinois, waves of autumn migrants were associated with the passage of cold fronts (Graber et al. 1979).

During migration, the Golden-crowned Kinglet still shows a propensity for habitats dominated by or containing coniferous tree species. It may occur in a much wider variety of habitats than during the breeding season. Migration habitats may include pine, fir, and spruce forests; mixed forests; deciduous forests; old fields; urban parks; urban and suburban yards; homesteads; rangelands; fencerows; shelterbelts; brushy thickets; orchards; and gardens. During autumn migration in Pennsylvania, its relative abundance by habitat was forest interior, 0.67; forest edge, 0.52; shrub-sapling-stage forest, 0.21; suburban forest, 0.20; pole-stage forest, 0.19; and forest-agricultural edge, 0.03. There was no significant difference in its abundance among these habitats (Bent 1949; Campbell et al. 1997; Graber et al. 1979; Rodewald and Brittingham 2002; Swanson et al. 2020).

During autumn migration in Idaho, the Golden-crowned Kinglet was associated with conifers and foraged mostly by gleaning from a perch, although hovering was also common. Hovering was done much less frequently than by the Ruby-crowned Kinglet (Carlisle et al. 2012).

During migration, the Golden-crowned Kinglet is an opportunistic forager, taking insects that are most abundant and sometimes feeding exclusively on a single species. Information on diet of migrants was collected from Illinois but results from the 2 kinglet species were pooled. In spring, gnats were most common in the diet (33%), followed by beetles (leaf and scavenger beetles). In autumn, lepidopterans were most important (33%), especially winged moths; bugs comprised 29% of the diet (Graber et al. 1979). During autumn migration in Idaho, it foraged on spittle bugs, jumping plant lice, beetles, wasps, and lepidopterans in greater proportion than their availability. Potential prey items that were consumed less than their availability included spiders, stilt and stink bugs, leafhoppers, hymenopterans, ants, yellowjackets, moths, and flies (Carlisle et al. 2012).

On rare occasions, the Golden-crowned Kinglet collides with television towers and windows during migration (Graber et al. 1979; Swanson et al. 2020).

The Golden-crowned Kinglet is a common to locally abundant migrant in Ontario (James 1991).

WINTER

Lepthien and Bock (1976) analyzed Christmas Bird Count (CBC) data and concluded that the Golden-crowned Kinglet preferred areas with significant levels of winter precipitation. Root (1988) observed that it avoided the northern boreal woodlands and coniferous forests of Canada. It avoided areas where January temperatures were colder than −18°C; all the highest abundance peaks occurred where the temperature rarely dropped below freezing. Lawrence (1949a) reported 2 overwintering Golden-crowned Kinglets near the Mattawa River where night-time temperatures dropped as low as −23°C.

In winter, the Golden-crowned Kinglet continues to be associated mainly with coniferous habitats, which may be either upland or lowland forests. Its affinity for older-growth conifers disappears in winter and it may be found in conifers of all age classes. Other habitats may be used, including deciduous and mixed forests, riparian areas, urban and suburban habitats, orchards, and shrubbery around houses. South of the Shield, coniferous plantations provide important winter habitat. In Ohio, the minimum size of woodland it was observed in during winter was 24 ha, but the Golden-crowned Kinglet demonstrates no evidence of area sensitivity in winter in Ontario (Bent 1949; Graber et al. 1979; LaForest 1993; Lancaster et al. 2004; Mills 1981; Swanson et al. 2020).

Smith (2003) analyzed results of Winter Bird-Population Studies in southern Ontario. The Golden-crowned Kinglet was one of the species that showed the clearest affinity for forest habitat. Numbers of birds detected per km^2 were: farmland, 0; mixed-rural, 2.5; forest, 4.4; urban natural, 0.7; urban natural areas smaller than 10 ha, 0.2; urban natural areas with open water, 0; and city, 0. In Missouri, it was almost twice as abundant in fully stocked forests than in open forests (Kendrick and Thompson 2013).

The Golden-crowned Kinglet is the smallest North American passerine and is therefore susceptible to freezing during cold weather. In Missouri, its detectability increased with decreasing temperatures. It appeared to be more active during cold weather (Kendrick and Thompson 2013). Blem and Pagels (1984) determined that the lipids stored during the day by foraging kinglets were insufficient to prevent hypothermia if the birds were exposed to 0°C overnight. They observed kinglets moving into squirrel dreys at dusk, presumably to roost. They concluded that roosting within squirrel dreys and even huddling would be insufficient to prevent hypothermia. Heinrich (2003) confirmed that Golden-crowned Kinglets huddle together during winter nights. Roosts of 2-4 huddled together in a snow-covered brush pile, a branch of a spruce 12 m up, and 4 m up under thick branches in a white pine. They did not go into torpor to conserve energy. The birds apparently did not return to the same roost every night but instead foraged until nightfall and huddled together tightly near where they ended up at dusk. Despite its habit of huddling at night, the Golden-crowned Kinglet is highly vulnerable to mortality during cold winter weather. During severe weather during the winter of 1976-77, Graber and Graber (1979) found 2 dead kinglets in their Illinois study area. Density of birds in all habitats dropped to zero and they believed that the population had suffered 100% mortality. Late-winter declines have been noted in Saskatchewan and Ohio and these may be related to mortality. Spring and summer numbers fluctuate considerably, probably due to differing winter mortality rates. Severe declines have been documented after harsh winters. In New Hampshire, breeding season populations decreased 56% after the severe winter of 1976-77 and sharp declines in populations were observed across the continent after the unusually harsh winters of 1976-77 and 1977-78 (Graber et al. 1979; Larivée and Darveau in Gauthier and Aubry 1996; Sabo 1980; Swanson et al. 2020).

In winter, the Golden-crowned Kinglet continues to forage mainly in mid-portions of tall trees (predominantly conifers). It also forages on branches and dead leaves in shrubs. Occasionally it feeds on the ground and in winter may find considerable food on the snow under trees. It may also forage subnivally by going under branches partially covered by snow and feeding in melted areas close to

the base of the trunk, or by going down holes in the snow (Bent 1949; James 2001; Swanson et al. 2020).

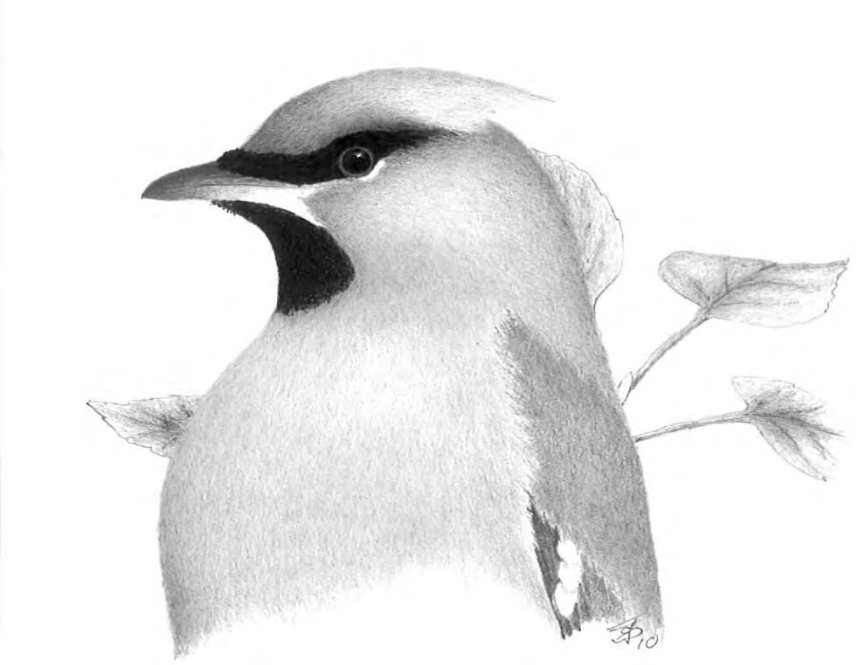
The winter diet of the Golden-crowned Kinglet consists of soft-bodied arthropods such as insects, mites, and spiders and their eggs, and very small amounts of vegetable matter (Swanson et al. 2020). Heinrich and Bell (1995) examined 15 gizzards of Maine kinglets foraging in spruce-fir stands in winter. Of 483 prey items, 59% were lepidopteran caterpillars, and 95% of these were geometer moths. Small caterpillars were the only food items found consistently in all birds. The volume of caterpillars consumed was greater than any other prey. Other prey items included spiders, aphids, flies, beetles, springtails, and insect eggs. Four individuals had eaten small seeds and 3 had a red flocculant in their gizzards that was presumably fruit. Noticeably scarce in the diet were springtails. Only 4 had been eaten in total by all the birds. These were of at least 2 species, neither being the snow springtail which was present in the millions on the snow. They concluded that it foraged opportunistically and that their diet reflected prey abundance in conifers, except for the very abundant springtails. The winter diet of a few kinglets was reported from Illinois (Graber et al. 1979), but results from the 2 species were combined. The diet consisted of 39% bugs, 25% mistletoe fruit, 17% spiders, and 16% cutworms. In winter, it has been documented eating stoneflies (Swanson et al. 2020) and taking bites out of a persimmon fruit (Bent 1949).

The Golden-crowned Kinglet is uncommon during winter in the south (James 1991). Its presence may be somewhat sporadic; it is more common during mild winters (Weir 2008).

CBC data for Ontario from 1970 to 2021 indicate that the Golden-crowned Kinglet population increased annually by 1.18%. During 2009-21, the population decreased 8.67% annually (National Audubon Society 2022).

Bohemian Waxwing

Bombycilla garrulus



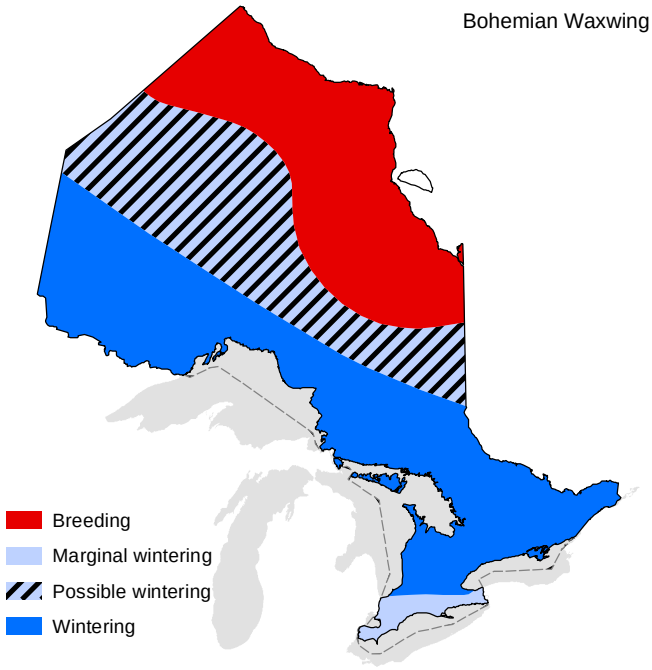
BREEDING SEASON

Habitat Requirements

During the first atlas, most records of the Bohemian Waxwing were along major northern rivers. All were observed along river banks with none seen on open muskeg (Cadman in Cadman et al. 1987). During the second atlas, it was also found inland in open spruce-tamarack woods with an understorey of willow and alder. This habitat is where the first nest was discovered in the province. The pair was observed at the ecotone of this habitat and a sedge meadow (Peck and Coady in Cadman et al. 2007; Peck et al. 2004a).

Throughout its range, the Bohemian Waxwing breeds predominantly in open coniferous forests, ecotones of boreal forest with tundra and alpine habitats, and early stages of succession after burns or clear-cuts. It nests most often in open coniferous stands, especially those dominated by spruce and pine, and, to a lesser extent, tamarack and balsam fir. It also nests in stands with a mixture of conifers and birch or poplar. Trees tend to be widely spaced in breeding habitat, but there may be a dense understorey of willows or alders; some stands have few shrubs. Virtually all nest sites are near plentiful supplies of fruit and open areas where waxwings can capture insects by flycatching. Beaver ponds, swamps, muskegs, taiga, and older burns and cuts provide good breeding habitat. In British Columbia, habitats also include mature, open coniferous forest edges (dominated mostly by

spruce), with interspersed aspens, alders, and willows and numerous drowned or dead trees. Edges of ponds, swamps, or bogs provide open foraging areas and dead trees are used for perching when hawking insects (Anderson 1909, 1915; Bent 1950; Campbell et al. 1997; Erskine 1977; Sinclair et al. 2003; Witmer 2020).



The first and only nest found in the province was 3.2 m from the ground in a 7-m tall white spruce with a diameter at breast height of 24 cm. It was on a horizontal branch with some additional branches supporting it along the sides. The nest was 15 cm from the tree trunk. The nest was poorly concealed, but blended in well with the moss and other twigs at the site (Peck et al. 2004a).

Most nests are in conifers, particularly older ones with hanging moss, although the Bohemian Waxwing may also nest in small, dead black spruce in shrubby bogs. It has nested in black and white spruce, jack pine and other pine species that do not occur in Ontario, tamarack, and balsam fir. There is 1 record of it nesting in alder, a deciduous species. Nests have been reported 1.2-15.2 m from the ground, but most are 3.0-7.6 m up. It tends to nest lower in bogs and very wet areas because the trees are stunted, but in drier areas it may nest near treetops at greater heights. Nests may either be on a horizontal limb near the tree trunk or at the tip of a branch. One nest was in the fork of the main trunk of a small fir (Anderson 1909, 1915; Bent 1950; Campbell et al. 1997; Sinclair et al. 2003; Witmer 2020).

The Bohemian Waxwing is nonterritorial. Conspecifics may be tolerated within 1 m of the nest provided they are not courting the female. Male aggression toward others near incubating females is probably mate guarding rather than territoriality. It is gregarious even during the breeding season. Although many pairs nest individually, there is a tendency for small groups (2-5) of pairs to be clumped together, with large expanses of potentially suitable habitat unused. Nests are situated near areas of high concentrations of fruit; proximity to water may also be important. Observations over a 3-day period confirmed that Ontario's first nest was solitary and not part of a nesting aggregation. No information is available on the size of the breeding season home range (Bent 1950; Campbell et al. 1997; Jehl 2004; Peck et al. 2004a; Witmer 2020).

No information on natal philopatry is available, but it is highly unlikely that any juveniles return to their natal area to nest. The Bohemian Waxwing is highly nomadic. It is unlikely that breeding birds return to the same general area in subsequent years. Breeding locations usually vary annually, probably in response to fruit supplies. It may be a common to abundant breeder at a site in 1 year and rare or completely absent the next (Bent 1950; Jehl 2004; Witmer 2020).

Limiting Factors

The Bohemian Waxwing is often a late breeder, timing nesting so that there are ample supplies of ripe fruit when the young fledge. Nest building most commonly occurs from mid-June into July, but some nests are built in late May. Fledging may occur from mid-June until mid-August, but mostly in July. The Ontario nest had a full clutch on 13 June. Nest building takes 3-5 days. It is likely that 1 egg is laid per day. The female begins incubating once the last egg is laid. The incubation period is 13-15 days, but mostly 13-14 days (Campbell et al. 1997; Letourneau in Gauthier and Aubry 1996; Peck et al. 2004a; Sinclair et al. 2003; Witmer 2020).

There are no records of second broods for the Bohemian Waxwing and it is unknown if renesting occurs if the first nest fails. The Ontario nest contained a clutch of 4 eggs. The typical clutch size is 4-6 eggs, although at least 1 2-egg clutch appeared to be complete and clutches of 7 eggs have been reported. The most common clutch sizes are 4 and 5 eggs (Anderson 1915; Bent 1950; Campbell et al. 1997; Letourneau in Gauthier and Aubry 1996; Peck et al. 2004a; Witmer 2020).

There is little information on the age of first breeding, but it is known that at least some yearling birds do not breed. The mating system is apparently monogamous, with pairing occurring as early as in winter. There is no information on whether mates remain together for more than 1 year (Witmer 2020).

Early in spring, the Bohemian Waxwing may feed on sap oozing from trees, particularly maples and birches. It may consume flowers of various tree species. During the early part of the breeding season, it is largely insectivorous. It gleans insects from vegetation and is a proficient flycatcher, sallying from exposed perches that are usually near water to capture aerial insects. Fruit becomes very important in the diet as the breeding season progresses and continues to predominate in the diet until spring. Fruit is so important in the diet that it regulates its distribution and possibly its population. It plucks and swallows whole fruits from a perch, often clambering or occasionally briefly hovering to obtain fruit. It sometimes feeds on the ground for fallen fruit or fruits of herbaceous species such as strawberries (Anderson 1909; Bent 1950; Sinclair et al. 2003; Witmer 2020).

Both parents feed the young regurgitated food that includes buds, fruits, and insects. Insects fed to young include mosquitoes, beetles, flying ants, dragonflies, and caddisflies. Adults eat a variety of insects such as scale insects, flies (especially mosquitoes and midges), mayflies, stoneflies, beetles, dragonflies, sawfly larvae, bugs, grasshoppers, and aphids. It may also consume spiders and snails. Although arthropods may be seasonally important in the diet, sugary fruits are characteristic of the Bohemian Waxwing's diet. Its diet is much like that of the Cedar Waxwing but differs from other frugivores that feed both on sugary and fatty fruits. Early summer fruits that are consumed include strawberries, mulberries, and juneberries. Later in the summer, fruits of raspberries, blackberries, honeysuckles, and cherries are important. It may feed extensively on buffalo-berry, but the most important fruits in late summer through winter are those of mountain-ash and red cedar. Other fruits commonly eaten are those of hawthorn, rose, chokecherry, cotoneaster, highbush cranberry and guelder-rose, bearberry, snowberry, hackberry, barberry, alder, holly, buckthorn, asparagus, greenbrier, bittersweet, mistletoe, dogwood, sumac, spicebush, columbine, matrimony vine, black alder, Russian olive, wild grape, apple, and viburnum (Anderson 1909; Bent 1950; Witmer 2020).

No cases of parasitism by the Brown-headed Cowbird have been reported. It is unlikely that the Bohemian Waxwing could successfully fledge cowbirds because of its predominantly fruit diet and late nesting. In addition, the cowbird is scarce or absent in large portions of this waxwing's range. A deserted nest containing 3 waxwing and 2 cowbird eggs was reported in British Columbia, but the record was not accepted because of potential confusion with the Cedar Waxwing (Campbell et al. 1997; Witmer 2020).

Status

Schueler et al. (1974) reported that the Bohemian Waxwing was fairly common near the confluence of the Sutton and Warchesker rivers in 1962, 1964, and 1965. They obtained the first evidence of breeding for the province when they collected a female with a brood patch there on 19 July 1964. Birds were reported near Kapuskasing in the summer of 1976 (Speirs 1985). During the first atlas, family groups were found in 3 locations and young being fed by adults were photographed along the Winisk River in 1984 for the first confirmation of breeding. It was found in 13 squares along several rivers in the Hudson Bay Lowland in northwestern Ontario. Birds appeared to be very thinly scattered and possibly confined to river valleys, although that is where more atlassing effort was directed (Austen et al. 1994; Cadman in Cadman et al. 1987). James (1991) considered the Bohemian Waxwing a locally rare summer resident in the northern portion of the Hudson Bay Lowland. Wilson and McRae (1993) reported it erratically through June and July at Ekwan with a high count of 10 on 14 June. They concluded that breeding probably took place somewhere nearby. They observed 4 on 4 June in a tamarack fen near Moosonee but were uncertain if these were migrants or breeding birds.

During the second atlas, the Bohemian Waxwing was found in the eastern portion of the Hudson Bay Lowland and at 4 locations in the Boreal Forest Region. It was detected in 16 squares during the second atlas compared with 13 in the first, confirming that it remained a rare and local, but widespread breeder. The most southern record was approximately 80 km northeast of Cochrane, at about the same latitude of the Kapuskasing record. Breeding was confirmed in 2 locations during the second atlas. In addition to the nest found near the James Bay coast north of the Swan River, fledged young were found 50 km southeast of Peawanuk in an extensive burn with bog vegetation on 13 July 2003 (Peck and Coady in Cadman et al. 2007; Peck et al. 2004a).

Peck et al. (2004a) found the first nest for the province on 12 June 2003 north of the Swan River near the James Bay coast. This was the most eastern nest record for the Bohemian Waxwing for North America and it now appears to be established as a summer resident in northern Ontario and Quebec. In Quebec, there have been several sightings of individuals and flocks during the breeding season, including several flocks seen in June 1991 on the east side of James Bay (Letourneau in Gauthier and Aubry 1996). Results of the second atlas and other records demonstrate that the Bohemian Waxwing is not confined to river valleys as appeared to be the case during the first atlas.

The overall North American population appears to be stable or increasing. A population increase in the 1970s was attributed to widespread planting of ornamental fruiting plants in the wintering range, particularly mountain-ash (Witmer 2020). Breeding Bird Survey data for 1970-2021 indicated that the Bohemian Waxwing decreased at the rate of 2.66% annually in Canada. Results were of low reliability and there are no data for Ontario (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Nestlings fledge when they are 14-18 days old and depend upon their parents for at least 2 weeks. In British Columbia, fledged young still dependent upon the adults can be observed until the end of August. In North America, families may stay together for long periods, even until the end of January (Campbell et al. 1997; Witmer 2020).

During late summer in the postbreeding period, Bohemian Waxwings in British Columbia occur in wet coniferous forests with white or black spruce and tamarack, in subalpine firs, and pine stands growing close to lakeshores, muskegs, swampy areas, river banks, and old burns. These habitats are often interspersed with birches, alders, willows, and shrubs such as red-osier dogwood and highbush cranberry (Campbell et al. 1997).

MIGRATION

The Bohemian Waxwing withdraws from the most northerly areas of its breeding range and undertakes regular migration. In British Columbia, few remain north of latitude 56°N, but it winters in the southern portion of the Yukon. Most winters some appear as far south as Atikokan and presumably along most of the northern shoreline of Lake Superior. It migrates from the breeding areas in northwestern North America to the western United States, eastern Canada, and the northeastern United States. It is highly gregarious during migration, forming flocks that range in size from a few individuals to hundreds or even thousands of birds. It is also irruptive, occasionally occurring in large numbers far south of its normal wintering area, and there is no regular periodicity to these flights. During strong flight years, thousands may occur along a broad axis that extends from Atikokan east to Sudbury and Ottawa. Some wander south into the Kingston area where the largest flocks usually occur around Perth and Westport. In some years, large flocks reach the shores of Lake Ontario, especially at Prince Edward Point. At Kingston, irruptions occurred in 20 of 59 years, but a few birds appeared during 42 of these years. During migration, flocks may be comprised solely of Bohemian Waxwings, but they are often mixed with Cedar Waxwings and occasionally with American Robins and Pine Grosbeaks. At the southern edge of its range, small flocks or individual birds are most frequent, often associated with Cedar Waxwings (Bent 1950; Campbell et al. 1997; Elder 2002; McIlwraith 1894; Sinclair et al. 2003; Weir 2008; Witmer 2020).

Single birds and small flocks are more common in early autumn and late spring. It is often difficult to distinguish autumn migration from winter wanderings. Within the normal winter range, birds arrive in early November and northward migration begins in mid-March (Bent 1950; Elder 1997; Tozer 2012; Weir 2008; Witmer 2020).

During migration, the Bohemian Waxwing abandons the coniferous forests that are favoured for breeding and seeks habitats that support fruit-bearing trees and shrubs. These include roadsides, riparian corridors, gardens, towns, cities, open forests, orchards, vineyards, parks, lakeshores, and aspen stands. In Algonquin Park, it regularly feeds on the berries of winterberry holly (Campbell et al. 1997; Tozer 2012; Witmer 2020).

In Atikokan, robins migrated through the area in late October. They often seriously deplete fruit resources before the waxwings arrive (Elder 2002).

WINTER

Although there is no regular frequency to winter invasions, they appear to be related to crop failures in the normal wintering range. Large invasions to southern Ontario often coincide with failure of showy mountain-ash berries, a favoured winter food of the Bohemian Waxwing (Bent 1950; Campbell et al. 1997; Earley 2008; Poon 2008).

In non-irruption years, a high proportion of the Bohemian Waxwing population winters in the Boreal Forest Region. In this region, small flocks may occur in uninhabited by humans where fruits from native trees and shrubs provide an adequate food source. It is likely that the bulk of the population winters near human habitation where it feeds on fruit on ornamental plantings. In the Saskatoon area, where it is an abundant winter resident, it occurs mostly within the city where there is abundant fruit, as well as in surrounding towns, villages, and farmyards. Much smaller numbers occur in natural habitats. In southern Ontario, it is mostly associated with residential areas, but may occur anywhere that there is suitable fruit, such as along roadsides and at the University of Guelph arboretum. The presence of fruit is the key habitat component for wintering Bohemian Waxwings. They wander widely in search of fruit and have an incredible ability to find isolated fruit crops. Once a suitable supply of fruit is found, the waxwings remain until it is completely exhausted and then move on. In the Atikokan area, birds arrive each autumn, eat all the available fruit and then disappear until the next year. The composition of flocks is fluid, being small in autumn and building up through winter with largest flocks in December and January. Winter aggregations of birds are very mobile locally, but flocks tend to be sedentary over winter on a regional basis. Despite the mobility of wintering flocks, at least some wintering birds return to the same location between years (Earley 2008; Elder 2002; Erskine 1977; Leighton et al. 2002; Sinclair et al. 2003; Witmer 2020).

In extreme cold, Bohemian Waxwings may clump together or roost together in the cover of vegetation (Witmer 2020).

In winter, the Bohemian Waxwing eats predominantly sugary fruit and may eat 2-3 times its own weight in fruit a day. Mountain-ash is highly preferred over other fruits. In the north it eats mostly showy and American mountain-ash berries; in the south it mostly eats European mountain-ash berries. Red cedar berries are also a favourite. Highbush cranberry and guelder-rose berries may be important in the diet in late winter and early spring because these berries persist through the winter. Other fruits it eats in winter are those of hawthorn, grape, rose, apple, cotoneaster, pear, privet, barberry, Russian olive, buckthorn, bittersweet, common lilac, holly, flowering crab, gooseberry, dogwood, and buffalo-berry. It requires some protein in its diet, so it may eat scale insects; silver maple stamens; buds of white elm, ash, red and silver maple, cottonwood, cherry, and poplar; seeds of Siberian elm, Manitoba maple, birch, and hollyhock; tree bark (which may be roughage rather than food); and mineral sources such as dirt, chalk, and bits of white-washed walls. It rarely comes to feeders because few people put out the fruit that it requires, but it has taken raisins, dried currants, and minced prunes. When food resources become scarce, the Bohemian Waxwing may resort to eating canned peas, rotten apples, and cranberries gleaned from garbage, and food put out for dogs. Because most of the winter diet is sugary fruit, it needs to drink copious amounts of water. When water is unavailable, it eats snow. There is an observation of a flock of waxwings flying out from perches in dead trees to catch snowflakes in the same manner that they capture flying insects

(Bent 1950; Bergtold 1931; Black and Roy 2010; Campbell et al. 1997; Dunn and Tessaglia-Hymes 1999; Earley 2008; Elder 1997, 2002; Jensen 1959; Leighton et al. 2002; McIlwraith 1894; Mills 1981; Pittaway 1990; Poon 2008; Sinclair et al. 2003; Witmer 2020).

The American Robin competes with both waxwing species and defends food resources against them. A single robin can defend a fruit tree against as many as 15 waxwings at once, but once flock sizes become larger, the waxwings prevail (Bent 1950; Pietz and Pietz 1987; Witmer 2020).

The Bohemian Waxwing is especially vulnerable to collisions with windows because ornamental fruit trees are often near them. It is also vulnerable to collisions with cars while feeding on fruit along roadsides (Witmer 2020).

This waxwing may be particularly vulnerable to pesticide poisoning when feeding on fruit crops and insects that have been treated. It increased significantly in the mid-1970s after the banning of DDT, suggesting that it was adversely affected by this pesticide (Witmer 2020).

In winter, the Bohemian Waxwing is a rare winter resident in the north south to Lake Superior, but it may be irregularly rare to locally abundant south to Lake Erie in irruption years (James 1991).

The Bohemian Waxwing appears to be occurring more frequently in southern Ontario than formerly and also in larger numbers. It was first recorded on the Guelph Christmas Bird Count (CBC) in 1993, although there were a few previous count-week records. Numbers on subsequent CBCs there were 237 in 1995, 7 in 1997, and 308 in 2007 (Earley 2008). In the Hamilton area, its frequency of occurrence and numbers increased dramatically starting in 1955. From 1960 to 1986, the annual winter totals were in the single digits, but larger numbers have been present since the winter of 1989-90. At least some are seen almost every winter now in the Hamilton area (Curry 2006). During the invasion winter of 2007-08, there were 48 April records for the Greater Toronto Area, especially in the City of Toronto. Most sightings were of flocks. Prior to that winter, there were records from April for only 8 years, and most of these were of 1-3 birds (Poon 2008). CBC results for Ontario indicate an annual increase of 7.42% 1970-21 and an annual decrease of 10.24% 2009-21 (National Audubon Society 2022).

Cedar Waxwing

Bombycilla cedrorum

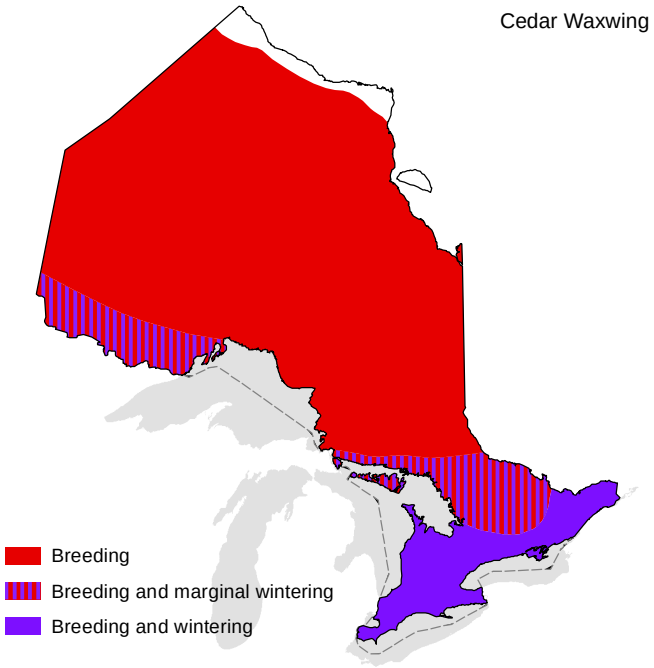
BREEDING SEASON

Habitat Requirements

Ontario Cedar Waxwing nests were found in both upland and wetland forests (36.6% of nests). Forests that were used for nesting were usually open and included deciduous, mixed, and coniferous stands. Overgrown fields and pastures supported 25.9% of nests, which included hawthorn meadows, the most commonly used habitat of this type in the south. Urban gardens and parks supported 14.7% of nests; 7.2% were along roads and shorelines of lakes and rivers; 6.3% were in campgrounds and cottage areas; 4.9% were in orchards; 1.7% were in treed bogs, beaver ponds, and marsh edges; 1.4% were in rocky outcroppings; and 1.2% were in treed sand dunes (Peck and James 1987).

In the Clay Belt portion of the Boreal Forest Region, the Cedar Waxwing exhibited a preference for bogs and shorelines of lakes and rivers (Smith 1957).

In the Great Lakes–St. Lawrence Forest Region in the Canadian Shield, the Cedar Waxwing nests in mature and old-growth white pine stands (Kirk et al. 2012). Near Gogama, it did not nest in pure



jack pine stands, but probably nested in young mixed woods where pin cherry provided fruit (James and Peck 1995a). It was also absent in pure jack pine stands near Parry Sound (James 1979a). It was common along rivers and on lakeshores in Algonquin Park (MacLulich 1938). Also in Algonquin Park, it nested in wet and dry bogs, black spruce stands, black spruce–white cedar stands, and in white birch–poplar forests. In bogs, it spent most of its time on snags, and occurred from the top of the shrub layer (1.5 m from the ground) to heights of 9 m atop dead stubs. In spruce-cedar stands, it occurred from the bottom of the canopy and top of the shrub layer (2 m) to near the top of the canopy (5.8 m). In poplar-birch stands, it occurred from the top of the shrub layer (1.5 m) to the canopy top (11 m). Martin (1960) considered it a boreal forest species.

In Durham Region in the Great Lakes–St. Lawrence Forest Region south of the Shield, it nested in a very young pine plantation still dominated by willow shrubs, in open deciduous woods, and in a mature pine plantation with a small patch of sugar maple–red oak forest (Speirs and Orenstein 1975).

In southern Ontario, the Cedar Waxwing was more abundant on organic than conventional farms, but not significantly. Its presence was significantly correlated with the presence of hedgerows and road, railway, and hydro rights-of-way. It was also associated with the amount of riparian and upland woods but these relationships were not significant. It was negatively associated with farmsteads, number of large isolated trees, and grassy strips between fields that often supported fences, and pastures, but not significantly (Kirk et al. 2011).

Throughout its range, the Cedar Waxwing nests in open woodlands, old-field habitats with numerous trees and shrubs, orchards, and urban and suburban areas with fruit-bearing trees and shrubs. It frequently nests in riparian areas that provide trees and shrubs for nesting, fruit, water for drinking, and emerging aquatic insects. Other habitats it may use include semi-open upland woods on river bluffs, hills, and escarpments; shrub thickets; pine and oak barrens and savannahs; pine plantations; and utility rights-of-way. In British Columbia, most nests were in human-created habitat such as suburban gardens (42.7%) and rural areas (18.7%) where low trees and shrubs were abundant, water was available, and there were good supplies of insects, berries, and other soft fruit. Natural breeding habitats included riparian thickets and forests along rivers, edges of lakes, and beaver ponds; tamarack muskegs; edges of second-growth coniferous forests; and regenerating burns. In North Carolina, its occurrence was significantly negatively correlated with forest canopy

(Bielefeldt and Rosenfield 1994; Campbell et al. 1997; Crouch 1936; Faanes and Andrew 1983; Gentry et al. 2006; Inman et al. 2002; Lea 1942; Leighton et al. 2002; Lumpkin and Pearson 2013; Mossman and Hoffman 1989; Mossman et al. 1991; Rothstein 1971; Shaffer and Tardif in Gauthier and Aubry 1996; Witmer et al. 2020; Yahner et al. 2002).

Some studies examined the habitat of the Cedar Waxwing at the landscape scale. In North Dakota, it did not exhibit a clear response to amount of tree cover in either open or wooded landscapes. It preferred areas with 52-75% tree cover (Cunningham and Johnson 2016, 2019). In North Carolina, it was negatively correlated with the amount of tree canopy at the 200-m scale. As canopy cover increases, shrub coverage decreases. It was positively correlated with landscape diversity at the 200-m scale, but not significantly. Heterogeneous landscapes consisted of a mosaic of forest patches, lawns, and pastures with interspersed infrastructure. Homogeneous landscapes consisted of unbroken tracts of forest. It was negatively correlated with the amount of exurban development at the 1,000-m scale (Gilbert and Ferguson 2019). In Saskatchewan, it showed no preference for forest type, but was more common than expected in fragmented landscapes (Hobson and Bayne 2000).

Forest type does not appear to be particularly important but Erskine (1977) noted that the Cedar Waxwing was one of the most frequently detected species in tamarack bog forests in the Boreal Forest Region. Other forest types it has nested in include hardwood swamps, ash-basswood lowland forests, aspen-birch, pine and mixed pine-hardwood stands, coniferous lowland forests, bur oak–green ash lowland forests, white birch–yellow birch–white cedar, hemlock–yellow birch, and red maple swamps (Back 1979; Beals 1960; Capen 1979; Dawson 1979; Faanes and Andrew 1983; Golet et al. 2001; Niemi and Pfannmuller 1979; Noon et al. 1979; Samson 1979).

Temple et al. (1979) considered the Cedar Waxwing associated with late seral stages of mixed-wood forests. Most authors consider it to be an early successional species. In Pennsylvania, Haney (1999) reported it in 18.2% of old-growth forests, 82.4% of woodlands statewide, and 91.9% of forests in the Appalachian Plateau. He considered it to have a negative affinity for old-growth forest. In Alberta aspen stands, it was significantly more abundant in young than mature or old-growth stands (Schieck et al. 1995). In Quebec, Imbeau et al. (1999) detected it in recent burns and clear-cuts where saplings were shorter than 2 m to 5 m tall. It was absent in young and mature forests. Erskine (1977) reported that it occurred in burns and clear-cuts in the Boreal Forest Region that were in the early shrubby stages of succession. Kirk et al. (1996) stated that it was associated mainly with young stands in the western Boreal Forest Region and virtually absent in mature stands. In northeastern hardwood stands, it occurred in 27% of plots in disturbed and successional habitats, but in only 3% of mature undisturbed areas (Noon et al. 1979). In northeastern aspen-birch stands, it occurred only in the seedling-sapling stage and was absent in more mature stands (Back 1979). In northeastern pine stands, it was absent in mature stands, but occurred in the seedling-sapling and pole stages (Capen 1979). In New York over a 35-year period, a successional plot transformed from an open agricultural field to a second-growth forest. The Cedar Waxwing increased significantly with time on this plot (Brooks and Bonter 2010).

Some studies identified habitat associations of the Cedar Waxwing. In North Dakota aspen forests, its abundance was positively correlated with the percentage of ground cover. This is a

function of its preference for open-canopy areas because ground cover tends to be sparser under closed canopies (Grant and Berkey 1999). In northeastern mixed-wood forests, it was associated with increasing abundance of spruce or fir (Temple et al. 1979). In the northeast, it was in a guild that was most abundant in young plantations and disturbed shrubby areas; very common in alder, mature coniferous lowland forests, aspen regeneration, and recent clear-cuts; and common in grassland, and mature coniferous upland and deciduous forests (Niemi and Pfannmuller 1979). In Wisconsin, it was associated with the Black-throated Green Warbler, which had an affinity for yellow birch and its associates: spruce, fir, white cedar, and hemlock (Beals 1960). In the western Boreal Forest Region, it was in a guild associated with coniferous tree species. It occurred in mesic stands with moderate nutrient levels (Kirk et al. 1996). In the mid-Atlantic states, it was negatively correlated with the basal area of trees and positively correlated with coniferous trees, moisture, percent ground cover, slope, and the amount of forest cover within 2 km (Robbins et al. 1989).

The Cedar Waxwing is an edge species. It occasionally nests in the interior of forests, but only if the trees are well spaced with openings between them. It nests in small and large gaps in forests as well as at edges. In southern Ontario, its probability of observation was negatively correlated with the amount of forest 100 m from edge, woodlot size, the amount of forest within 2 km, and the amount of regional forest cover; the last 3 relationships were statistically significant. It had some of the strongest relationships for edge of all species tested (Austen et al. 2001). In Pennsylvania, it nested on hydro rights-of-way cut through forests, but not in the forests. In Michigan, 20 nests were found in a small white pine plantation, and there was a definite tendency to place nests at either end of it. The most central nests were about equidistant from the 2 ends of the plantation, 47 m and 48 m from edge. The most plausible explanation for nesting near the edge of the plantation was to be near suitable foraging habitat. In Rhode Island red maple swamps, the Cedar Waxwing occurred in swamps smaller than 1 ha, but was absent in swamps 1-5, 6-10, and 11-20 ha (Erskine 1977; Golet et al. 2001; Rothstein 1971; Taylor and Taylor 1979; Witmer et al. 2020; Yahner et al. 2002).

Ontario nests were usually well hidden in living trees, shrubs, and vines. The Cedar Waxwing nested both in deciduous (32 species, 65.5% of nests) and coniferous (8 species, 34.5%) species. The most frequently used species were hawthorn (57 nests), spruce (46), pine (42), maple (38), apple (34), and white cedar (21). Nests were placed in crotches as well as on horizontal limbs and were more often away from the trunk than against it. Distances from the trunk ranged from 0.2 to 4.6 m, but mostly 0.9-2.4 m. One nest was wedged between a rock face and the roots of a cedar tree. It usually builds its own nest, but 1 pair added to an old Common Grackle nest and used it. One female laid eggs an empty Willow Flycatcher nest and shared incubation duties with the flycatcher. Another nest was built on top of a deserted Yellow Warbler nest. Nests were 0.8-18 m from the ground, with most 1.8-3.7 m up (Peck and James 1987). Nests in Muskoka and Parry Sound districts were often at the edge of a forest 0.8-13.7 m from the ground (Mills 1981). Burton (1958) found 41 nests in York, Peel, and Simcoe. Thirty-three were in hawthorns, 7 in maples, and 1 in an apple tree. Nests were 1.1-4.6 m from the ground, but most were within 3 m of the ground. Other nest-tree species previously reported for the province were red cedar, black spruce, Norway spruce, willow, pine, and hemlock and one nest was in a grape vine. In eastern Ontario, common nest-tree species were red cedar, hawthorn, bur oak, white cedar, and apple (Witmer et al. 2020).

Throughout its range, the Cedar Waxwing nests predominantly in living trees and shrubs, and occasionally in vines. Unusual nests were in woodpecker holes, on lampposts, on a building, and on a cliff. Nests were in sugar and red maple, red and bur oak, white birch, white and red pine, red cedar, apple, pear, hackberry, domestic plum, sycamore, white elm, Kentucky coffee-tree, dwarf chinquapin oak, cottonwood, hawthorn, European larch, staghorn sumac, and willow. In British Columbia, deciduous trees (29 species) were used 3 times as often as conifers, except in the interior where twice as many deciduous trees were used. Willows, alders, and domestic fruit trees were used for nesting most often. Nine species of conifers and 15 species of shrubs were used. In New York, the Cedar Waxwing used hawthorns for nesting more than expected based on their availability. Sixty percent of nests were in hawthorns. White pine was also used more than expected; areas selected for nesting had more hawthorns and apples than random sites. Nest orientation relative to the trunk did not deviate from random. In order of frequency, nests may be saddled on a horizontal branch, in a fork in a branch, on a branch next to the trunk, in a fork in the trunk, or in a vine supported by a tree or shrub. Nests have been reported as far as 4.1 m from a tree trunk. Nest heights range from 0 (on a cliff) to 15.2 m with most 2.0-4.0 m up. Height of nests in southeastern Ontario was 1.1-9.2 m, with an average of 2.59 m (Campbell et al. 1997; Crouch 1936; Lea 1942; Lovell and Stamm 1948; Murphy et al. 1997; Nickell 1955; Post 1916; Putnam 1949; Rothstein 1971; Saunders 1911; Tyler in Bent 1950; Witmer et al. 2020).

Although some authors stated that the Cedar Waxwing is nonterritorial, it defends a small area around the nest. The defended area includes a perch from which the male can see and guard the nest. In Ohio, 3 territories measured 226, 188, and 918 m^2. In 1 case, a territory was almost 0.4 ha in area and the guarding post was on a tall elm 91 m from the nest. The territories reported in Ohio may be larger than average because some authors described the territory as extending only a few feet from the nest. Because only a small area is defended, nests may be quite close to each other and semi-colonial nesting may occur. Active nests are commonly only 6-7 m from each other and occasionally there is more than 1 nest in a single tree. Near Toronto, 11 nests were within a radius of 7.6 m in a clump of white pine. Densities of 4.9, 14.1, and 44.4 nests per ha have been reported in loose colonies. The only activities confined solely to the territory are incubation and feeding of the nestlings. Territoriality diminishes as the season progresses. Even at the height of the breeding season, the Cedar Waxwing is highly gregarious, forming flocks that forage together. At a colonial nesting area in North Carolina, 1 pine tree was used as a congregating point for the flock and adults hawked insects from it to feed their young. Adults flew to the activity tree and congregated prior to departing as a group to the food supply to feed the nestlings. When adults returned with food for their young, they again congregated in the activity tree before dispersing to their respective nests. Banding has demonstrated that flocks during the breeding season are cohesive units. Flocks from different areas may gather together in prime foraging areas, but individual flocks arrive and depart at different times. Home ranges may be quite large; adults may forage 2 km from where they gather food for their young (Allen 1939; Crouch 1936; Lea 1992; Mountjoy and John in Cadman et al. 1987; Putnam 1949; Rothstein 1971; Snavely and Witherington 1986; Tyler in Bent 1950; Witmer et al. 2020).

There is no evidence that any birds return to their natal area to breed. In Ontario, 0 of 42 nestlings returned the following year to breed and 0 of 174 nestlings returned in Ohio. Adult site fidelity is

very low and consistently lower than for most passerines. In Ontario, 0 of 27 adults returned; 2 of 54 (3.7%) returned in Ohio (Putnam 1949; Witmer et al. 2020). Low site fidelity may be related to the Cedar Waxwing's habit of nesting wherever fruit is abundant, and this may vary from year to year. It may be abundant at a given location in 1 year and absent in the next (Saunders 1911).

Limiting Factors

The Cedar Waxwing is one of the later-nesting species. Eggs have been found in Ontario nests from the last week of May until mid-September, with most reported in the last week of June and first half of July (Peck and James 1987). In York, Peel, and Simcoe, the peak of nesting occurred in July and August, although there were numerous records from June and September. The earliest record was a nest with 3 eggs on 8 June and the latest was one with 3 young on 20 September (Burton 1958). In the Kingston area, nest building began in early June and peaked in the fourth week of June (Witmer et al. 2020). In Algonquin Park, nest construction extends from late May to early July, eggs are present from late May to mid-July (mostly late June to mid-July), nestlings occur from mid-July to late August, and recently fledged young have been documented from late July to early September (Tozer 2012). Throughout its range, the Cedar Waxwing nests late so that there is ample fruit available to feed the nestlings. In the northeastern United States and eastern Canada, some birds may nest as early as the first week of June, but the peak of nest initiation occurs in the last half of June with a suggestion of a second peak of activity at the end of July. Second broods or replacement clutches may be initiated in late August. Eggs may be present in nests as late as the end of September and there is 1 record of a bird incubating eggs in mid-October in Michigan. The Cornell Nest Records Scheme indicated a shift in timing of nesting in the east. Prior to 1970, 17% of nests had their first egg after 24 July and 36% of nests were initiated after 15 July. After 1970, 44% of nests were initiated after 24 July making the number of nests started early and late in the season almost equal. It is possible it is evolving toward later nesting to reduce cowbird parasitism (Allen 1939; Crouch 1936; Leck and Cantor 1979; Putnam 1949; Tyler in Bent 1950; Witmer et al. 2020).

First nests may take 3-9 days to build, but usually 5-7 days. The time taken to complete a nest decreases with the season; replacement nests may be built in 2 days. In Ohio, it took 6-8 days to build nests between 30 May and 10 June compared with 4.5 days between 12 and 21 June. Egg laying usually starts as soon as the nest is complete but as many as 3 days may elapse before the first egg is laid. Eggs are laid at the rate of 1 per day. Incubation may be initiated from the laying of the first egg to laying of the last egg. The incubation period of 31 Ontario nests was 10-13 days, but mostly 11-13 days. Other studies reported incubation periods of 10-16 days, but 12-13 days appears to be the most frequent incubation period. Hatching takes place over a 2-day period, confirming that incubation usually begins before the clutch is complete. It has been estimated that 2 broods could be raised in approximately 75 days from the beginning of the construction of the first nest to fledging the second brood. Laying of the first egg in the second nest occurs from the day before the young in the first nest fledge until 3 days after fledging. Second nests are usually in the same territory and within 10 m of the first nest (Allen 1939; Campbell et al. 1997; Crouch 1936; Lea 1942; Lovell and Stamm 1948; Nice 1941; Peck and James 1998a; Post 1916; Putnam 1949; Saunders 1911; Snavely and Witherington 1986; Tyler in Bent 1950; Witmer et al. 2020).

The Cedar Waxwing frequently raises 2 broods. In eastern Ontario, less than a third of pairs raised 2 broods; 7 of 8 Ohio pairs (87.5%) raised a second brood. One author suggested that 3 broods were probably raised in a season, but there is no evidence of this and it appears unlikely. The author of a Michigan study concluded that only a single brood was raised. Renesting is common if a clutch is lost. Ontario birds used the same nest or built a new one nearby for replacement clutches. Second nests are often in the same tree as the first. One Ontario study found no evidence of second clutches or renesting. Clutches of 2-6 eggs have been reported in Ontario, with most containing 4 or 5 eggs. A single 8-egg clutch was laid by 2 females. Throughout its range, clutches of 2-7 have been reported, but the normal clutch size is 3-5 eggs. Six-egg clutches are rare and larger clutches may be laid by more than 1 female. Most nests contain 4 or 5 eggs. Clutch size diminishes as the season progresses. In Ohio, first clutches averaged 4.57 eggs compared with 3.86 eggs for second clutches (Allen 1939; Burton 1958; Crouch 1936; LaForest 1993; Lea 1942; Leck and Cantor 1979; Peck and James 1998a; Putnam 1949; Tyler in Bent 1950; Witmer et al. 2020).

The age at first breeding is 1 year and it appears as though all birds breed every year. The mating system is monogamous and no cases of polygyny have been reported. Pairs tend to remain mated for all nests within a breeding season, but it is unknown if the same birds pair again in subsequent years. Birds do not attain the full complement of waxy appendages on their wings until their third year. Most birds mate with birds of the same age, having the same tip-index category. Third-year birds tended to initiate nesting earlier and have larger clutches and raise more young than younger birds (Mountjoy and Robertson 1988; Putnam 1949; Witmer et al. 2020).

The Cedar Waxwing is an accomplished flycatcher and often perches near watercourses or water bodies to capture emerging aquatic insects. It inspects and gleans the bark of trees for insects and may occasionally forage on insects on tree trunks by hovering or perching on the bark or small twigs beside the trunk. It also forages in the peripheral branches of fruiting trees and shrubs to obtain fruit or insects and takes arthropods from spider webs. In spring, it feeds on sap of maples. It has taken insects from floating waterlily pads. While feeding on grapes in Niagara Region, it perched on wires or trees near the edge of the vineyard, descended to the top of the nearest vine, plucked a single grape, and returned to the perch to eat it. Birds may occasionally hover and pluck fruit from a tree or shrub. In a laboratory experiment, blueberries in the 7.5- and 11.0-mm classes were eaten 97% and 80% of the time, respectively; 71% of the berries in the 12.8-, 14.0-, and 20.5-mm size classes were picked up and dropped within 2 seconds. Berries in the 17.6-mm size class were never eaten. Berries in the 2 smallest size classes (7.5 and 11.0 mm) were swallowed with little or no manipulation but waxwings were able to eat larger fruits only by smashing them repeatedly with their bills. Although larger berries provided a greater absolute amount of sugar, the 7.5-mm size provided the highest rate of sugar ingestion because they were handled faster. The Cedar Waxwing has been known to gorge itself to death on fruit and it is also vulnerable to alcohol intoxication and death after eating fermented fruit. It drinks copious amounts of water and occasionally pecks at mud of sodium-rich roadside pools. Occasionally it eats snow to obtain water and may flycatch snowflakes from a perch (Allen 1939; Avery et al. 1993; Burtt et al. 1976; Campbell et al. 1997; Crins 2002; Gorchov 1988; McIlwraith 1894; Nice 1941; Pinkowski 1976c; Putnam 1949; Royall 1989; Somers 2010; Tyler in Bent 1950; Witmer et al. 2020).

The male feeds the female fruit, frequently chokecherries and black cherries, while she is incubating. Both adults feed the young by regurgitation. Only the male feeds the fledglings of the first brood if a second brood is attempted. Initially nestlings are provided small insects, spiders, and juice of cherries and other small fruits. By age 4 days, young are fed whole fruits and rarely insects. In Michigan, 87% of food brought to nestlings consisted of fruit, predominantly juneberries, pin cherries, and blueberries. Young may also be fed beetles, snails, and the fruit of black cherry, chokecherry, and pokeweed. In the Kingston area, red-osier dogwood fruits were the most frequent food item fed to nestlings; they were also fed raspberries and chokecherries. As early as the first day out of the nest, young often peck at matter on leaves and one was seen walking up and down a limb hunting and eating insects on its second day out of the nest. A captive bird first fed itself at age 21 days, or 3-7 days after fledging (Allen 1939; Crouch 1936; Lea 1942; Nice 1941; Post 1916; Putnam 1949; Saunders 1911; Snavely and Witherington 1986; Tyler in Bent 1950; Witmer et al. 2020).

The Cedar Waxwing eats more fruit than most other birds throughout the year (84% of the diet), selects sugary fruits, and captures aerial and vegetation-borne insects. Beal (1897a) analyzed the contents of 152 stomachs collected in the United States. The diet consisted of 87% vegetable matter and 13% animal matter. The vegetable matter included 74% wild fruit or seeds and 13% cultivated fruit. Except for a few snails, the animal food consisted of insects, including the elm leaf beetle, aphids, grasshoppers, and bugs. Witmer (1996a) examined 212 stomachs from the northeastern United States and compared the diets of the Cedar Waxwing and the American Robin. The waxwing's annual diet was comprised of 84% fruit, 4% flowers, and 12% insects. It ate fruit almost exclusively (99%) from October through April. Frugivory declined dramatically in May when there was low availability of fruit, accompanied by a significant increase in consumption of petals and stamens of flowers (44% of the May diet). Frugivory increased sharply in June with the ripening of early summer fruits such as juneberry, mulberry, and strawberry. Insects were consumed May through September but fruit dominated the diet in these months. It was consistently more frugivorous than the robin in every month. Red cedar berries were prominent in the waxwing's diet in winter and spring (40-50% October through April, 27% of the annual diet) and apples and crabapples were next in prominence in the diet in winter (21% February through April). Cherries comprised 37% of the diet June through September. Naturalized cherries were consumed in June and July, pin cherries July through September, and chokecherries and black cherries were eaten mostly in August and September. There was a broad overlap in fruit selection by the Cedar Waxwing and the robin, but the overall patterns of fruit use were different. In winter and spring, the waxwing ate more red cedar berries (45%) than the robin (5%); sumac was eaten by the robin most of the year, but not by the waxwing; in autumn, berries of 4 species of dogwoods were prominent in the robin's diet (7% of its annual fruit diet), but the waxwing ate the fruits of only the flowering dogwood (3% of its annual fruit diet). In Ontario, however, the Cedar Waxwing has eaten the berries of other dogwood species. The waxwing avoided the fruits of gray dogwood, southern arrowwood, spicebush, Virginia creeper, staghorn sumac, and bayberry, but these were all eaten by the robin. The waxwing ate fruits of many nonnative species such as Morrow's honeysuckle, guelder-rose, and common buckthorn. The waxwing and robin ate similar amounts of cherries during summer and autumn, 50% and 69%, respectively. The fruits eaten by this waxwing had lower lipid and higher hexose content, larger fruit mass, higher water content, and more dry pulp per fruit than those that

were avoided. It cued in on fruits with high sugar content and avoided lipid-rich fruits. Five insect orders comprised 81.7% of the animal food consumed: beetles (mostly scarab and leaf beetles), hymenopterans, flies, lepidopterans, and bugs. Scale insects were eaten in May and June. Mollusc shell fragments were found in the stomachs of 3 females. Of 33 birds collected in a Maine spruce forest, 28 had eaten spruce budworm larvae and pupae. These birds had eaten an average of 82.5% insects in July. Fruits reported in the diet of the Cedar Waxwing by other authors include those of silverberry; downy, roundleaf, and alder-leaved juneberry; red cedar; hackberry; white and red mulberry; chokecherry; black cherry; wild strawberries; golden currant; cultivated blueberries; Morrow's honeysuckle; bittersweet; cultivated grapes; mountain-ash; English hawthorn; asparagus; apple; privet; red-osier dogwood; crabapple; huckleberry; and Canada moonseed. Beetles are the most important animal food, especially leaf beetles and weevils. It also eats carpenter ants, willow and other sawfly larvae, caterpillars, crane flies, spiders, mayflies, emerging winter stoneflies, cankerworms, tent caterpillars, and rarely dragonflies (Allen 1939; Avery et al. 1993; Breiding 1946; Campbell et al. 1997; Dexter 1951; Dowler and Swanson 1982; Fitch 1958; Gorchov 1988; Pinkowski 1976c; Putnam 1949; Saunders 1941; Shane and Shane 2000; Somers 2010; Tyler in Bent 1950; Witmer 1996b).

In the past 50 years, Cedar Waxwings have appeared in the east with orange instead of yellow tail bands. This colour variation is caused by pigments derived exclusively from dietary sources, particularly Morrow's honeysuckle. The introduction of Morrow's honeysuckle has had a positive effect on the Cedar Waxwing. It performs well on this fruit and includes much of it in its diet from July until mid-October. The abandonment of farmland created large areas of suitable habitat for nonnative honeysuckles, and they also thrive in disturbed areas such as roadsides, old fields, and stream banks (Hudon and Brush 1989; Witmer 1996b). Birds with orange-tipped feathers have been observed in Ontario, indicating that it has consumed Morrow's honeysuckle berries (Curry 2006).

The Cedar Waxwing does not defend food resources, but it may be affected by other species that do. Pietz and Pietz (1987) observed a single robin that defended an ornamental crabapple tree against flocks of Cedar Waxwings over a period of 2 weeks. The robin was successful in preventing waxwing flocks as large as 15 from foraging in the tree but was overwhelmed once waxwing flock size reached 30. The Northern Mockingbird also defends fruit resources and is most aggressive toward the Cedar Waxwing. Mockingbirds have been known to force waxwings to the ground and kill them with their bills (Hedrick and Woody 1983).

Peck and James (1998a) reported that 70 of 952 Ontario Cedar Waxwing nests (7.4%) were parasitized by the Brown-headed Cowbird. In York, Peel, and Simcoe, 4 of 41 nests (9.8%) were parasitized. More than half the nests were found in mid-July and none of these were parasitized (Burton 1958). Parasitism rates vary considerably geographically. In Michigan, the overall parasitism rate in 4 studies was of 27 of 345 nests (7.8%). In Ohio, no parasitism was observed in 200 nests; 0 of 23 Minnesota nests were parasitized; 4 of 445 British Columbia nests (0.9%) were parasitized; and 4 of 329 southern Quebec nests (1.2%) were parasitized (Campbell et al. 1997; Hanski et al. 1996; Lea 1942; Putnam 1949; Rothstein 1976a). The Cedar Waxwing is a poor host for the Brown-headed Cowbird. Most nests are initiated after the cowbird's peak egg-laying period, the waxwing is a rejecter of cowbird eggs, and the fruit diet that adult waxwings feed nestlings may be inadequate

for cowbird young because they are adapted to developing on insects. There are a few reports of waxwings feeding cowbird fledglings and waxwings have successfully fledged cowbirds in Illinois. Almost 90% of cowbird eggs are rejected and some of the accepted ones may fail due to the frugivorous diet (Campbell et al. 1997; Lowther 1991, 1997; Rothstein 1976a). Parasitism typically occurs during the host's laying period and about 85.5% of these eggs are rejected by nest desertion and egg damage or ejection. Three days after the last egg is laid, the waxwing switches from rejection to acceptance. In many parasitized nests, all waxwings fledge; in other cases, all young starve. Even though fruit does not provide adequate nourishment for the cowbird nestling, it continues to beg and receive the bulk of the food (Campbell et al. 1997; Rothstein 1975, 1976a, 1976b).

Rothstein (1973a) found a high rate (24.7%) of hatching failure in nests near Michigan farms and 12.0% of nests completely failed. The percentage of eggs not hatching reported in other studies was 5.5%, 15.6%, and 10.9%. In orchards, 27.3% of nests experienced total failure whereas no non-orchard nests failed completely. Thirty percent of orchard nests were completely successful compared with 75% for non-orchard nests. Results suggested that pesticides might be implicated in egg failures, but there was no evidence to support this. In British Columbia, 52 waxwings died and 27 were partially paralyzed after feeding in an orchard that had been sprayed with parathion (Witmer et al. 2020).

In New York, nest success depended upon nest-tree species and vegetation density. Although hawthorn was the preferred nest tree, nest success was not significantly higher in hawthorn than in other species; nests in white pine were most likely to fledge nestlings. Successful nests had greater canopy cover and more trees within 50 m than random sites (Murphy et al. 1997).

Nests initiated later in the season have a higher success rate than early nests. In Ohio, only 22% of 45 nests built before 20 June were successful compared with 51% of 51 nests initiated later. Loss of early nests appeared to be due in part to inattentiveness by the adults. Storms were also common during the early period and heavy rain and wind accounted for 10 of 29 early desertions (Putnam 1949).

The Cedar Waxwing is highly likely to desert the nest if it is disturbed by humans, particularly early in the nesting process (Crouch 1936; Saunders 1911; Witmer et al. 2020).

The Cedar Waxwing is highly vulnerable to being killed by vehicles. It frequently feeds along roadsides and its habit of descending from a perch to the fruit source and returning to the perch to eat it frequently exposes it to on-coming traffic. Dowler and Swanson (1982) reported high mortality associated with highway plantings in Texas. Fruit-bearing shrubs were planted in the median, at the edge of the highway, and along ramps. As vehicles passed, feeding flocks flew up, crossed the highway, and returned immediately with several birds being struck on each occasion. All 298 mortalities were associated with shrubs planted in the median of the highway.

Forestry practices are beneficial to the Cedar Waxwing. Forest management creates openings and edges that improve nesting habitat. Forest thinning and clearing also promotes the growth of fruit-bearing shrubs (Shaffer and Tardif in Gauthier and Aubry 1996; Witmer et al. 2020). In selectively thinned northern hardwood stands near Sault Ste. Marie, it increased in abundance 3-4 years after

harvest. It was much more common in thinned than control stands. It was associated with thinned stands supporting few hardwood saplings, but preferred sugar maple regeneration to small shrubs (Holmes and Pitt 2006). In the Carolinian Forest Region of southern Ontario, there was no difference in its abundance in uncut forests and those where selective thinning or diameter-limit cuts had occurred (Holmes et al. 2004). In the Canadian Shield of Ontario, there was no difference in its abundance in early successional and mid-successional clear-cuts than in burns in the same seral stages. It was significantly more abundant in early successional than mature stands but equally abundant in mid-successional and mature stands (Zimmerling et al. 2017).

In Pennsylvania and New Jersey over a 15-year period, the basal area of hemlock declined from 56% of the total basal area to 46% due to the hemlock woolly adelgid, and coverage by understorey deciduous shrubs increased. The Cedar Waxwing increased over this period, probably due to the increased coverage by shrubs and more openings in the canopy (Toenies et al. 2018).

In Alberta, there was no significant difference in the Cedar Waxwing's abundance at seismic lines, pipelines, or well pads than in forest interior adjacent to these structures (Bayne et al. 2016).

Status

The Cedar Waxwing has always been a common breeder in Ontario. It probably increased in response to deforestation associated with European settlement and with clear-cutting in extensive forests. Baillie and Harrington (1937) considered it a common summer resident, breeding north to at least the southern end of James Bay and west to Lake of the Woods. During the first atlas, its range was determined to cover essentially the entire province. It was widespread and common in southern Ontario but less abundant in the far north (Mountjoy and John in Cadman et al. 1987). James (1991) considered it a common summer resident north to at least Big Trout Lake and Attawapiskat, and probably rare to the north coast in the west and to Sutton Lake in the east.

The second atlas demonstrated that there had been no change in the distribution of the Cedar Waxwing. There was no significant change in its probability of observation province-wide but significant declines occurred in the Great Lakes–St. Lawrence Forest Region, both in and south of the Canadian Shield. Possible reasons for declines include natural succession from shrublands to forest and destruction of hedgerows. Highest abundance occurred south of the Shield, especially in a broad band along Lake Erie from Rondeau to Long Point, on the Bruce Peninsula, west of Toronto, and in another broad band between the Shield and Lake Ontario from Lake Simcoe to the Kingston area. Scattered areas of high abundance occurred in the Shield portion of the Great Lakes–St. Lawrence Forest Region and the Boreal Forest Region. It became less abundant northward (Kits in Cadman et al. 2007).

Surveys were undertaken in Illinois in the 1900s, 1950s, and 2007-09. The Cedar Waxwing was not detected during the 2 earlier periods. It is now common and rapidly increasing there, most likely because of the large increase in food availability. Fruiting trees, shrubs, and evergreens are common landscape plants in developed areas and these are preferred foraging and nesting substrates (Walk et al. 2011).

Long-term (1970-2021) Breeding Bird Survey data indicate annual decreases of 0.233% in Canada and 0.529% in Ontario. The short-term (2011-21) trends were annual decreases of 3.64% in

Canada and 5.09% in Ontario. The Ontario short-term trend was of medium reliability; the other trends were highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Young leave the nest when they are 14-18 days old and are fully capable of flight. They remain near the nest for 2-8 days and may return to the nest the day after fledging but not again. In some cases, fledglings may remain near the nest for as long as a month, but most disperse much sooner. Young are fed completely by the adults until 7-8 days after fledging and are independent by the time they are 21-30 days old (Witmer 2020).

After independence, young form small flocks that fly about feeding on fruit and catching flies. Flocks occur in the latter part of July and early August and are joined by adults in late August. These flocks grow in numbers and remain evident until autumn migration. During the postbreeding period, waxwings are found most frequently in areas with fruit-producing shrubs, including riparian areas. In Michigan, all juveniles were caught in riparian habitat, which was in a mix of alder, honeysuckle, and mature trembling aspen, rather than in 100-year-old upland trembling aspen stands. Most adults were also caught in riparian habitat. In Pennsylvania, family groups were seen on a hydro right-of-way through forested habitat but not in the forest. During the postfledging period in Pennsylvania, 22 adults and 22 juveniles were captured in clear-cuts compared with 1 adult and 0 fledgling in adjacent mature forest habitat (Akresh et al. 2009; Crouch 1936; Putnam 1949; Stoleson 2013; Yahner et al. 2002). In Minnesota, Streby et al. (2001b) did not capture any waxwings in regenerating clear-cuts during the breeding season, but caught 16 fledglings and 37 adults during the postbreeding period. In Quebec, Major and Desrochers (2012) caught Cedar Waxwings in regenerating clear-cuts during the postfledging period.

MIGRATION

Although some overwinter in the breeding range, most Cedar Waxwings are migratory. Migration is poorly understood because of low levels of philopatry and the difficulty of distinguishing between nomadism and true migration. In spring, some birds may still be migrating while others are nesting. Spring migration is prolonged and begins for all age classes in March, but birds do not arrive on the breeding grounds until late May. Breeding populations may not stabilize until mid- or late June, or even early July north of Lake Superior. At Prince Edward Point, there was a tendency for third year and older birds to arrive earlier in spring. The difference in timing between alpha and other birds was significant in 1985 but not in 1984 (Mountjoy and Robertson 1988). In Ontario, true spring migrants arrive after mid-May and the peak of spring migration is in late May and early June. In autumn, wandering flocks of juveniles and postbreeders are difficult to distinguish from migrants. Autumn migration may be prompted by cold fronts or depletion of fruit supplies. Most migratory flocks form in August and leave the northern part of the range in late August and September. Adults migrate southward about a month earlier than juveniles. In Muskoka and Parry Sound districts, waxwings begin flocking in August. Some years they are locally scarce by the end of that month but flocks sometimes linger if the fruit crop is good. Large flocks have been documented in mid-August in Algonquin Park. The main autumn movement in the south is from August through October with peak numbers from late August until mid-September; stragglers may still be moving through in early December (Curry 2006; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008).

Ontario birds have been recovered in Alabama, Oregon, Texas, Guatemala, and Mexico. Five birds banded in autumn in Iowa, Wisconsin, or Ontario were recovered in spring or summer in British Columbia, California, or Oregon 1-4 years later. Two birds banded within 5 days of each other in St. Thomas were recovered in Alabama and Oregon. Individuals may winter in widely separated areas in different years, so there is limited site fidelity during migration. Most migration occurs during the day, but mortalities at Florida television towers suggest that some nocturnal migration occurs (Baillie and Hope 1943; Brewer et al. 2018; Brugger et al. 1994; Mountjoy and Robertson 1988; Weir 2008; Witmer et al. 2020).

During spring migration in Pennsylvania, Smith and Hatch (2008) detected the Cedar Waxwing 5.7 times more often in shrubs than in forest habitat. During migration, it frequents open forests that support fruiting trees and shrubs (Witmer et al. 2020). In British Columbia, it occurs in many open-forest habitats during migration, but is most numerous in anthropogenic areas such as roadside thickets, orchards, urban parks, shrubby gardens, residential yards with berry trees, hedgerows, sewage lagoons, and shrubbery along hydro rights-of-way. In natural areas, it frequents second-growth forests; forested margins of tidal flats; riparian thickets of willow, red-osier dogwood, and elderberry; riparian cottonwood stands; juniper groves; beaver ponds; burns; and spruce and tamarack muskegs (Campbell et al. 1997).

During autumn migration in New York, approximately 20% of fecal samples contained Bella honeysuckle fruit, 10% contained fruit of red-osier and gray dogwoods, and 35% contained common buckthorn berries (Mudrzynski and Norment 2013). From mid-September to mid-October, flocks of juveniles appear at local concentrations of fruit in New York, moving on once crops are depleted (Witmer et al. 2020).

During migration, some Cedar Waxwings are killed by television towers and other tall structures, but the incidence of this is relatively low because it is predominantly a diurnal migrant. It is commonly killed by striking windows. This may occur in seasons other than migration whenever fruit is available near residences (Witmer et al. 2020).

McClure et al. (2013b) created a phantom road by playing traffic noise in an otherwise undisturbed forest during autumn migration. The Cedar Waxwing appeared to avoid the noise and was virtually absent when noise levels reached 55 dB(A).

The Cedar Waxwing is a common to locally abundant migrant. Daily high counts of approximately 200-4,000 have been recorded in both spring and autumn (Curry 2006; LaForest 1993; Weir 2008). At the Port Burwell Hawk Watch in Elgin County, 3-hour counts included 280 on 1 October, 188 on 9 September, and 185 on 19 September (Lancaster et al. 2004).

WINTER

Historically, the winter distribution of the Cedar Waxwing was probably confined to areas where red cedar occurred. It now has a much wider distribution due to planting of ornamental fruit-bearing trees and shrubs (Anonymous 2006). Throughout its range, presence of red cedar is still the primary factor defining where it occurs in high densities. Many small abundance peaks are associated with large river valleys (Root 1988). In winter, it occurs in areas with fruit-bearing trees or shrubs in open

woodlands, parks, gardens, second-growth forests, forest edges, and suburban areas (Witmer et al. 2020).

In winter, the Cedar Waxwing is nomadic, staying in an area rich in fruit until the resource is depleted and then moving elsewhere. Fidelity to wintering areas in subsequent years is low at 5.5%. In the Hamilton area, some birds remain into winter if there is a good berry crop; these birds usually dissipate in February and March. In other years, birds do not appear until February and March. These are likely birds that have wandered there after depleting fruit crops elsewhere. Christmas Bird Count (CBC) results for Ontario are irregular, with marked irruptions at unpredictable intervals. Large irruptions in the eastern United States are believed to result from fruit-crop failure at higher latitudes. In some years, peak numbers coincide with those of the Northern Mockingbird, Northern Cardinal, and especially the American Robin (Curry 2006; Freedman and Riley 1980; Hamilton 1997; Witmer et al. 2020).

In Ontario, wintering Cedar Waxwings have been documented feeding on the fruit of common buckthorn, red cedar, mountain-ash, and pokeweed. It has fed on female white-marked tussock moths that were frozen in fissures in the bark of red oaks (Crins 2002; Curry 2006; McIlwraith 1894; Weir 2008).

McPherson (1987) studied the winter fruit preferences of the Cedar Waxwing in Oklahoma. It consumed 3 species of hollies, 2 types of crabapples, mistletoe, red cedar, hackberry, and juniper. The order of preference for consumption of fruit was abundance, caloric content, and fruit size. Fruit 7-8 mm in diameter was highly preferred. It showed no preference for fruit colour. In late winter when fruit became scarce, it fed on elm seeds and flowers of hackberry, white elm, and cottonwood. In Texas, it fed on whichever fruit was most abundant, primarily juniper and mistletoe. During a winter of low fruit production, it was completely absent (Chavez-Ramirez and Slack 1996). Most authors concur that the staple winter foods of the Cedar Waxwing are berries of the red cedar (and other juniper species) and mountain-ash; buckthorn is important in the Ontario diet. Other fruits it has eaten in winter are those of barberry, cotoneaster, arbutus, crabapple, hawthorn, hackberry, and privet (Allen 1939; Campbell et al. 1997; Crouch 1936; Leighton et al. 2002; Tyler in Bent 1950).

The Cedar Waxwing seldom visits feeding stations. It may be attracted to feeders if fruits that it is already feeding on are put out. It is readily attracted by water and may accept raisins and apple slices (Dunn and Tessaglia-Hymes 1999).

Prior to a severe winter storm in Illinois, the density of Cedar Waxwings per km² was 31.6 in bottomland forest, 193.8 in upland forest, and 0 in urban residential areas. After the storm, none were present. Graber and Graber (1979) found no evidence of mortality and concluded that it emigrated from the area. Its nomadic habits may allow it to cope with adverse winter weather better than species that are more sedentary in winter.

James (1991) considered the Cedar Waxwing a common winter erratic in the south that occasionally occurred to northern Lake Superior. It is rare in winter in Algonquin Park (Tozer 2012) and possibly may not persist there all winter. It was detected on 8 of 13 Brighton CBCs, but sighted in only 2 winters at Presqu'ile (LaForest 1993). In Elgin County, large flocks gather where fruit is

abundant and there are flocks of about 100 birds most winters in the Aylmer Wildlife Management Area (Lancaster et al. 2004).

Freedman and Riley (1980) examined data from southern Ontario CBCs beginning in 1929 and found that the trend was toward more frequent irruptions and a higher overall population since about 1952. They concluded that the increase may have been a response to increasing availability of winter food due to planting of fruit-bearing shrubs. CBC data for Ontario indicate an annual increase of 2.77% 1970-21 and an annual decrease of 6.22% 2009-2021 (National Audubon Society 2022).

Red-breasted Nuthatch

Sitta canadensis

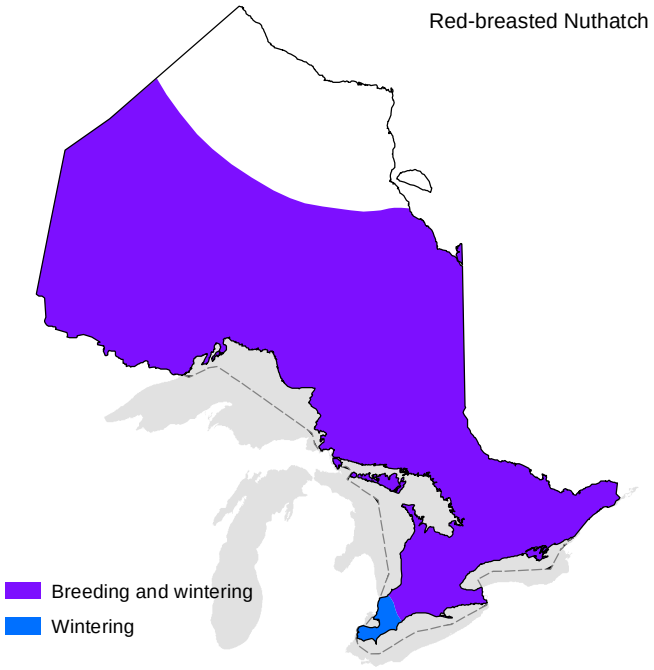
BREEDING SEASON

Habitat Requirements

In Ontario, the Red-breasted Nuthatch usually nests in mixed woods, occasionally in coniferous forests, and rarely in deciduous stands. More nest sites were in wet than dry habitats, possibly due to greater availability of dead trees for nesting. Some nests were at beaver ponds and most were near water, woodland edges, clearings, and roads, suggesting a preference for open areas near the nest (Peck and James 1987). Cheskey (1990) reported it nesting successfully in a backyard in the city of Waterloo. Although the yard was well wooded and part of a well-treed neighbourhood, it was not forest with most trees occurring in hedges and small groups.

In the Boreal Forest Region, the Red-breasted Nuthatch was associated with older, closed, mixed-wood forests and with areas with little interspersion of young and old forests. It and other species in this guild were associated with low amounts of edge and more intact forests (Rempel 2007; Rempel et al. 2007). Near Pickle Lake, highest densities occurred in mixed and coniferous forests (McLaren and McLaren 1981).

In the Canadian Shield in the Great Lakes St. Lawrence Forest Region, the Red-breasted Nuthatch commonly nests in mature and old-growth white pine forests. Its abundance in these forests is significantly correlated with the total basal area and the basal area of conifers (Kirk et al.



2012). It was rare in jack pine stands near Gogama, with the managed forests providing few nesting opportunities. It was absent until pines reached about 6 m in height. It was present in mixed forests because deciduous snags probably offered more potential nest sites (James and Peck 1995a). It occurred in 2 of 5 plots in jack pine forests in Parry Sound. Both were open stands with 25-50% crown closure and mixed with species such as trembling aspen, white birch, white pine, sugar maple, white spruce, and tamarack (James 1979a). In Algonquin Park, Martin (1960) considered it characteristic of hemlock. In wetlands, it nested in black spruce–white cedar stands, but was absent in pure black spruce and in bogs. In upland stands, it was present in white pine, fir-pine-hardwoods, hardwoods, and hemlock, and absent in poplar-birch, poplar-birch-fir-spruce, and fir-spruce. In immature white pine stands, it was tied for third in abundance with the Dark-eyed Junco.

In Durham Region in the Great Lakes–St. Lawrence Forest Region south of the Shield, the Red-breasted Nuthatch nested in an open-canopy young forest with poor drainage and a mature pine plantation. Speirs and Orenstein (1975) considered it a late-succession species associated with pine. During the first atlas in the Kingston region, breeding was reported only in squares containing coniferous and mixed woods where it particularly favoured white pine and red pine (Weir 2008).

The Red-breasted Nuthatch is strongly associated with coniferous tree coverage throughout its range. It typically nests in mature, diverse stands dominated by spruce, fir, pine, hemlock, tamarack, and cedar, and less frequently in pure stands of pine or hemlock. It also breeds in mixed forests, particularly where the dominant conifers are mixed with poplar or oak. It rarely nests in pure aspen stands. In the northeast, it regularly nests in coniferous plantations, northern hardwoods, lowland hardwoods, aspen-birch, natural pine forests, upland spruce-fir stands, lowland conifers (black spruce, tamarack, and white cedar), and mixed woods. In the Boreal Forest Region, it is most frequently associated with balsam fir stands, but is also present in stands dominated by spruce, pine, tamarack, and hemlock. In Quebec, it prefers mixed forests and deciduous woodlands with scattered conifers. In British Columbia, 44% of nests were in coniferous forests, 26% in mixed woods, and 11% in deciduous stands; 6% were in logged forests. It also occurred in lakeshores, riparian bottomlands, gardens, and parks; 13% were in treed urban, suburban, and rural areas (Back 1979; Bielefeldt and Rosenfield 1994; Campbell et al. 1997; Capen 1979; Crawford and Titterington 1979; Dawson 1979; Erskine 1977; Flack 1976; Ghalambor and Martin 2020; Hoffman 1989a; Niemi and Pfannmuller 1979; Noon et al. 1979; Rail in Gauthier and Aubry 1996; Samson 1979; Temple et al. 1979; Webb et al.

1977). The Red-breasted Nuthatch has variously been reported preferring pine, hemlock, spruce, and fir. This may be more a function of availability of coniferous species in different geographic areas. Spruce may be preferred wherever it is available and balsam fir may also be selected in the Boreal Forest Region. In certain areas, such as the Great Lakes–St. Lawrence Forest, pines are preferred and these are the dominant conifers. Hemlock is widely used, but may not be preferred where other conifers are present. In New Hampshire and Maine, it was associated predominantly with coniferous stands. It was most abundant in forests codominated by spruce and balsam fir, followed by those dominated by white pine and finally by balsam fir. In New Jersey, it was a facultative hemlock species. Approximately 5% of the population nested among hemlocks. The remainder nested in coniferous plantations dominated by Norway spruce. It may occasionally nest in tamarack and white cedar stands but these are not preferred species (Benzinger 1994; DeGraaf et al. 1998; Erskine 1977; Sinclair et al. 2003; Speirs and Orenstein 1975; Temple et al. 1979).

Near White River, the Red-breasted Nuthatch was significantly more abundant in mature forests than in clear-cuts 3-25 years old (Venier and Pearce 2005). In Pennsylvania, it was positively associated with old-growth forests. It occurred in 72.7% of old-growth forests compared with 4.1% of forests statewide and 6.4% of forests in the Appalachian Plateau (Haney 1999). In Alberta aspen stands, it was significantly associated with the density of coniferous species and was significantly more abundant in old-growth than in mature aspen stands. It was absent in young aspen stands (Schieck et al. 1995). In British Columbia, 76% of nesting habitats were mature stands (Campbell et al. 1997; Capen 1979; Erskine 1977; Kirk et al. 1996; Sinclair et al. 2003).

In New Hampshire and Maine, abundance of the Red-breasted Nuthatch was positively correlated with deciduous trees larger than 10 cm diameter at breast height (DBH), woody stems per ha, and total foliage volume of coniferous trees 2-10 cm DBH. It was negatively correlated with total foliage volume of deciduous trees (DeGraaf et al. 1998). In boreal forest habitat in New York, Vermont, Maine, Nova Scotia, and Newfoundland, it was positively correlated with the number of dead snags, canopy cover, and presence of deciduous trees. It occurred in a wide variety of spruce-fir habitat types (Ralston et al. 2019).

The Red-breasted Nuthatch is considered an area-sensitive species in Ontario (Coleman et al. 2000), but it requires relatively small woodlots of 10 ha or larger. In some cases, smaller woodlands may be used. Presence of suitable nest sites may be more limiting than forest size, and it may not actually be area sensitive in Ontario. It nested in a Waterloo backyard (Cheskey 1990) and a wooded area smaller than 0.5 ha in Aurora (personal observation), suggesting that it is not area sensitive in Ontario. In Minnesota, Howe (1979) observed it on 2 islands that were 0.9 and 1.1 ha in area, but did not positively confirm breeding. In Michigan, the presence of the Red-breasted Nuthatch was positively correlated with forest size (Crozier and Niemi 2003).

The Red-breasted Nuthatch is often considered a forest-interior species. In California, it showed a nonsignificant but substantial tendency for lower density close to forest edge. Density 400 m from edge was 1.71-2.64 times that at forest edge (Brand and George 2001). In Saskatchewan, it was more common in large forest fragments and in contiguous than fragmented forest. Hobson and Bayne (2000) considered it a forest-interior species. In Ontario, it is not a forest-interior species, frequently nesting along edges and near forest openings (Peck and James 1987) and even in urban yards

(Cheskey 1990). Strauss (2007) reported a Red-breasted Nuthatch nesting in a nest box on the eaves of a city residence in Victoria, British Columbia. In Newfoundland balsam fir stands, Whitaker and Montevecchi (1997, 1999) considered the Red-breasted Nuthatch a forest-interior specialist. It was significantly more abundant in forest interior than in riparian and nonriparian forest edges. In intact forests, it occurred in riparian areas 20-50 m from edge, but was absent in similarly sized buffer strips left adjacent to clear-cuts. In northeastern Quebec balsam fir–white cedar stands, there was no significant difference in its density in riparian and nonriparian stands (LaRue et al. 1995). Lindell et al. (2007) reviewed studies that examined abundance of the Red-breasted Nuthatch in relation to forest edge. One study found no response to edge; the other found that it avoided edge.

During incubation and brooding, the male and female roost together in the nest cavity. Females continue to roost overnight with the young until they fledge. Resident birds may use cavities for roosts year round (Ghalambor and Martin 2020).

The Red-breasted Nuthatch usually excavates its own nest cavity, but occasionally uses old woodpecker nests and natural cavities such as knotholes. Most Ontario nests were near the top of a dead tree stub, 3 were in dead or dying branches, and 2 were in living trees, one of which was dying. The DBH of 4 nest trees was 12.5-20.5 cm (average 15.8 cm). No preference was shown for nest orientation. It is a weak excavator, so most nests are in soft-wooded deciduous trees. Over 70% of nests were in deciduous trees, with poplar, birch, and spruce trees used most often. Nests were 1.5-15 m from the ground, with most 3-9 m up (Peck and James 1987). Cheskey (1990) reported a nest in a 20 cm diameter apple tree stump that was only 80 cm from the ground, one of the lowest ever reported. Two Ontario nests were in boxes designed for Black-capped Chickadees in white and red pine plantations near Long Point (Dunn et al. 1975).

Most nest cavities are excavated, with a few nests in old woodpecker and chickadee nests; use of nest boxes is rare. In Montana 52% of nests were in old sapsucker nests. Nest reuse is rare, but in British Columbia, 3 of 11 available old nests (27.3%) were used again. Most nests are in dead trees or dead portions of trees, but a few are in living trees and some are in posts and poles. Aspens and birches are the dominant nest trees, with lesser numbers of firs and pines and a variety of infrequently used species. The optimum DBH of nest trees has been estimated at 30 cm, but smaller trees (12.5 cm DBH) may be used and larger ones are often used. Nest heights of 0.5-36.6 m have been reported, with a mean of 10.2 m (Aitkin et al. 2002; Campbell et al. 1997; Evans and Conner 1979; Ghalambor and Martin 2020; Gunderson 1939; Leighton et al. 2002; Li and Martin 1991; Michael 1934; Sinclair et al. 2003; Tyler in Bent 1948).

The Red-breasted Nuthatch is highly aggressive early in the nesting season, particularly during excavation and nest building. During this period, any species that approaches the nest is attacked. Breeding territory sizes are variable, averaging from as small as 0.2 ha in Quebec hemlock forests to 10 ha in subalpine forests in New Hampshire. In the latter area, the large territory sizes appeared to be related to the scarcity of dead trees and suitable nesting cavities. In Algonquin Park, territory size averaged 0.49 ha (range 0.08-1.29 ha). In many areas, breeding territories are 1-3 ha, but snag density may affect territory size and breeding density. In Maine white spruce stands, mean territory size was 1.34 ha (Ghalambor and Martin 2020; Martin 1960; Morse 1977; Rail in Gauthier and Aubry 1996; Sabo 1980). No information on home range size is available.

No information is available on natal philopatry. Resident birds may maintain the same territory for years. It is not known if migratory or irruptive birds return to the same area to nest (Ghalambor and Martin 2020).

Limiting Factors

Eggs have been reported in Ontario nests from early May until mid-June, with most present from mid-May through the first week of June (Peck and James 1997). In Algonquin Park, nest cavity excavation occurs from mid-March to late May, nestlings are present from early June until early July, and dependent fledglings have been observed from early July to mid-August (Tozer 2012).

The time required to excavate a nest cavity varies depending upon hardness of the wood. Cavity excavation may take less than 5 days or as long as 18 days. As many as 4 cavities may be dug before the female selects one. Eggs are laid at the rate of 1 a day. At 1 nest, incubation began with laying of the penultimate egg; no other information is available. The incubation period at 1 Ontario nest was 13 days and it has been reported elsewhere as 12-13 days. Young left an Ontario nest at age 19 days, consistent with the overall reported range of 18-21 days. Young may leave the nest when they are as young as 15 days if the nest is disturbed (Cheskey 1990; Ghalambor and Martin 2020; Gunderson 1939; Kilham 1973; Michael 1934; Tyler in Bent 1948).

One brood is typically raised in a year. There is 1 record of a second brood in Ontario from Nipissing District; the second brood was raised in the same cavity. A pair of yearlings raised 2 broods in captivity in New Hampshire. In British Columbia, 6 pairs each raised 2 broods during years of outbreaks of the mountain pine beetle. Renesting occurs, usually in a newly excavated cavity. Clutches of 1-7 eggs have been reported in Ontario, mostly 5-6 eggs. Overall, clutches of 2-8 eggs have been reported (mean 5.8 eggs). In British Columbia, most clutches contained 6 or 7 eggs. Six-egg clutches were most common overall. During a year of high beetle abundance, some 9-egg clutches occurred (Campbell et al. 1997; Ghalambor and Martin 2020; Kilham 1973; Norris and Martin 2014; Peck and James 1987, 1997; Tyler in Bent 1948).

Both sexes first breed when they are 1 year old and birds breed every year thereafter. The mating system is monogamous. Resident birds remain mated for more than 1 year. Migratory and irruptive birds may only have seasonal pair bonds. Ontario residents may pair as early as December; nonresidents pair after spring return, usually in March and April (Ghalambor and Martin 2020; Kilham 1973).

Foraging occurs mostly in coniferous trees, primarily in live trees and less frequently in snags. The Red-breasted Nuthatch commonly forages in white cedar, balsam fir, hemlock, pine, and spruce. Most foraging was in live conifers in Oregon but live and dead trees were used according to their availability in Washington. In spring, it selected snags for foraging. Old-growth trees were selected in winter and second-growth trees were used for foraging in summer. Although foraging occurred in large-diameter trees (greater than 50 cm DBH) more than expected, smaller diameter trees (11-50 cm DBH) were used year-round. In mixed forests, foraging also occurs in deciduous trees such as poplars, basswood, beech, birches, and maples. It may use all portions of a tree for foraging, but usage of tree areas may vary seasonally. In winter, it forages significantly lower and closer to the trunk than in other seasons. Most foraging occurs on tree trunks and the upper and lower portions

of branches from their tips to the trunk. It walks up or down tree trunks and large branches and probes crevices in the bark for insects. It also forages on small branches by probing beneath flakes of bark, at bases of needle clusters on conifers, and on conifer cones where it extracts seeds. Foraging on twigs and foliage is common during the breeding season; foraging in winter is predominantly on bark of trunks and large limbs. Less commonly, it forages in leaf litter on the ground for arthropods and fallen seeds, in rocky outcrops, and on undersides of leaves. It occasionally flycatches and there is 1 record of it foraging on the back of a live white-tailed deer (Adams and Morrison 1993; Ghalambor and Martin 2020; Lundquist and Manuwal 1990; Sabo 1980; Tyler in Bent 1948; Weikel and Hayes 1999).

Nestlings are fed arthropods exclusively; young at 1 nest were fed large quantities of flying ants. Adults eat mostly arboreal arthropods in summer and large numbers of conifer seeds in autumn and winter. In Ontario in spring, it may feed on sugar maple sap icicles. In Oregon, the Red-breasted Nuthatch ate mostly weevils, leaf beetles, and other beetles during the breeding season; weevils, leaf beetles, ants, leaf bugs, earwigs, scarab and click beetles, and other insects postbreeding; and leaf beetles, weevils, sedge seeds, bark beetles, leaf bugs, and other insects during winter. It eats a wide range of beetles, but also caterpillars, spiders, ants, bugs, and flies. Its density is related to spruce budworm density in the Boreal Forest Region and northern New England. At low budworm density, it eats few budworms, but consumption increases exponentially as budworm numbers increase. In New Brunswick, there was no relationship between its abundance and budworms. During a spruce budworm outbreak in Maine, 16 stomachs contained 39% budworm larvae and pupae by volume (Crawford and Jennings 1989; Erskine 1977; Ghalambor and Martin 2020; Mitchell 1952; Morris et al. 1958; Simpson 2025; Sinclair et al. 2003; Tyler in Bent 1948). During bark beetle outbreaks in British Columbia, it excavated more new cavities instead of using existing ones, maintained a constant clutch size of about 6 eggs throughout the breeding season, and fledged as many as 100% more young than when beetles were scarce (Norris 2012). Norris and Martin (2014) studied the effects of an outbreak of the mountain pine beetle on the Red-breasted Nuthatch in British Columbia. Although this beetle does not occur in Ontario, infestations of the emerald ash borer have the potential to have the same effect. In areas and years where beetles were abundant, some second broods were produced, clutch size of replacement nests were as large as first nests instead of being smaller, and the number of fledglings produced per nest increased. Matseur et al. (2019) conducted a similar study on its response to forest disturbance by the mountain pine beetle and wildfires in South Dakota and Wyoming. Its abundance was negatively correlated with the coverage by 3-5-year-old wildfires. Densities increased as the percent cover of beetle-killed trees increased from 0% to 16%.

Brown-headed Cowbird parasitism of Red-breasted Nuthatch nests has not been reported in Ontario. There are only 2 records of parasitism in North America: one from Saskatchewan and one from Montana (Ghalambor and Martin 2020).

Logging or other factors that remove dead or diseased trees may have negative effects on breeding populations of Red-breasted Nuthatches. Results vary depending on the composition of the forest. In the Boreal Forest Region, its abundance did not change significantly when 30% or 50% of trees were removed, but it declined when 70% of trees were removed. It experienced a 25%

decrease when 50% of trees were removed, a 50% decrease when 70% of trees were removed, and a 75% decrease when 98% of trees were removed (Vanderwel et al. 2007, 2009). In the Canadian Shield of Ontario, there was no difference in its abundance in early successional and mid-successional clear-cuts compared with burns in the same seral stages. It was significantly less abundant in early successional and mid-successional stands than in mature stands (Zimmerling et al. 2017). In Algonquin Park, there was no difference in its abundance in control areas and sites where single-tree selection harvest had occurred. In California, burned coniferous forests supported vagrants only but unburned plots supported breeding pairs. In Montana, it continued to nest in areas that had been burned, but was absent in burns where salvage logging occurred. In Oregon, it decreased in response to fire but densities still remained higher in the forest that was burned than in the control forest. In New York northern hardwoods, it appeared to be unaffected by forestry operations, but it was rare overall due to the predominantly deciduous cover. In Vermont, it incorporated both logged and unlogged areas into territories. In Minnesota, it exhibited no significant response to timber harvesting in buffer strips, although its trend was positive. In Alberta, it decreased significantly in deciduous woodlands that were clear-cut and increased significantly when 25% of trees were removed in coniferous woodlands (Bock and Lynch 1970; Ghalambor and Martin 2020; Hanowski et al. 2005; Harrison et al. 2005; Hutto and Gallo 2006; Jobes et al. 2004; Lent and Capen 1995; Siegel and De Sante 2003; Stephens et al. 2015; Webb et al. 1977). In northern Ontario, Rempel et al. (2007) predicted a decline of the Red-breasted Nuthatch for all forest management scenarios: under silvicultural guidelines for replanting, tending, and harvest volume objectives; silvicultural guidelines plus application of timber management guidelines for marten, moose, caribou, and fish habitat; and silvicultural guidelines plus natural composition targets.

In Minnesota, blowdown of spruce-fir forest reduced canopy cover by 80% and increased shrub coverage by 100%. The Red-breasted Nuthatch bred in control plots, but was only a visitor to the blowdown area (Burris and Haney 2005).

In Quebec, abundance of the Red-breasted Nuthatch was not adversely affected by high densities of white-tailed deer. Its abundance was correlated with the amount of coniferous coverage (Cardinal et al. 2012).

Blewett and Marzluff (2005) studied the effects of urban sprawl on cavity-nesting birds near Seattle. Higher densities of Red-breasted Nuthatches occurred in areas with higher dispersion of land cover (more fragmented landscapes with less forest cover). Densities in built and forest areas combined were about 6 times less than those in natural woodlands. Productivity was highest where the percent of forest was low but aggregated, and where snag densities were high. Along the Michigan north shore of Lake Superior, it was significantly less abundant on cottage lots than in forest on the other side of the cottage road (Ford and Flaspohler 2010).

In Edmonton, noise was the second-most important factor in determining abundance of the Red-breasted Nuthatch. It has a low minimum song frequency that may be masked by anthropogenic noise, particularly from roads. It was less common in noisy areas (Proppe et al. 2013). In Alberta, it was significantly more abundant at quiet well pads than at noisy compressor stations. Sites distant from each of these structures supported significantly more nuthatches than sites close to them (Bayne et al. 2008). McClure et al. (2013b) created a phantom road during autumn migration

by playing traffic noise in an otherwise undisturbed forest. The Red-breasted Nuthatch declined with increasing noise activity. At 37 dB(A), 3.5 nuthatches were detected compared with less than 1 at 57 dB(A).

In Alberta, the Red-breasted Nuthatch was significantly more abundant at seismic lines than in adjacent forest interior and significantly less abundant at well pads than in adjacent forest interior (Bayne et al. 2016). There was no difference in its abundance at pipelines and adjacent forest interior.

Price (2004) concluded that the Red-breasted Nuthatch could disappear as a breeding species in southern Ontario if the average summer temperature increased by 2°C. In central Quebec and Labrador, it was strongly associated with stands having the warmest summer temperatures (DesGranges and LeBlanc 2012). This suggests that temperature increases may be beneficial near the northern extent of its breeding range.

Status

The Red-breasted Nuthatch undoubtedly bred throughout southern Ontario prior to forest clearing by European settlers. It probably was relatively uncommon in the south due to the predominance of deciduous tree cover. With forest clearing, it was locally extirpated as a breeding species in the south. McIlwraith (1894) knew of it only as a migrant in southern Ontario. In southern Quebec, populations declined after the 1850s due to extensive logging and it was a rare breeder there at the turn of the 20th century (Rail in Gauthier and Aubry 1996). In the Kingston area, there were only 3 summer records until 1968. It now breeds there regularly wherever red and white pines are common (Weir 2008). In Hamilton, the first documented nest was in 1956 and by the 1980s it was a regular breeder, predominantly in coniferous plantations (Curry 2006). Baillie and Harrington (1937) considered the Red-breasted Nuthatch a fairly common summer resident in nearly all of Ontario and certainly from Wellington, Peel and Renfrew counties north to southern Kenora District and Moose Factory. They had no records from more southerly areas of the province. Dunn et al. (1975) reported 2 nests at the St. Williams Forestry Station, and this was the southernmost breeding record for Ontario. At that time, the nearest breeding record was from Erindale from about 1950, about 130 km northeast of St. Williams. It is now a common and regular breeder in the St. Williams forest. In Elgin County, it was only a migrant in 1891 and 1954. By 2000, it was a rare breeder with records only from conifer plantations 60-70 years old (Lancaster et al. 2004). During the first atlas, it was widely distributed in the north to Attawapiskat and the Big Trout Lake area. It was well distributed in the south, but absent from many squares and all of Essex County. Breeding in Kent, Elgin, Middlesex, Huron, and Oxford counties occurred during the first atlas only in 1985 after a southward irruption (Mills in Cadman et al. 1987). James (1991) considered it an uncommon summer resident north to Big Trout Lake and Moosonee, but rare and local south of the Canadian Shield.

The second atlas indicated that the range of the Red-breasted Nuthatch was much the same as during the first atlas, except that it had become much more common and widespread south of the Canadian Shield. Its probability of observation increased significantly province-wide and in all regions. Largest increases occurred in the south, probably due to maturation of coniferous plantations. It was most abundant in the Great Lakes–St. Lawrence Forest Region in the Shield, and in the southwest portion of the Boreal Forest Region in Kenora District. Highest densities occurred

in the central and upper Ottawa valley, the Algonquin Highlands, and from the northwest shore of Lake Superior north to the Berens River and Sandy Lake (Cheskey in Cadman et al. 2007).

Long-term (1970-2021) Breeding Bird Survey data indicate annual increases of 2.1% in Canada and 2.3% in Ontario. The short-term (2011-21) trends were annual increases of 2.03% in Canada and 3.06% in Ontario. All results were of medium reliability except that the short-term Canadian trend was highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Most young are fully independent about 2 weeks after fledging, but others remain with their parents for extended periods and possibly all winter (Ghalambor and Martin 2020).

MIGRATION

The Red-breasted Nuthatch has a mixed migration strategy. Northern birds undertake regular migration and southern birds tend to be resident. All populations are irruptive and may move considerably south of their normal breeding and wintering ranges during irruption years. It is at least partially migratory in Ontario, but southern and central Ontario populations may be resident. Major irruption corridors occur at Point Pelee and along the northern shore of Lake Ontario, with birds flying south to Ohio and west toward Michigan. Significant migration movements are associated with fair weather, westerly winds, and high pressures. Movements are inhibited by adverse weather, low pressure, and fog (Ghalambor and Martin 2020).

Spring return flights are never as strong as autumn flights, but perhaps birds move on a broader front and are less concentrated. In the south, migrants appear in late April and are present until mid-May, with some stragglers remaining into early June. Timing of autumn migration varies depending on whether it is a normal migration year or an irruption year. In normal years, southward movement begins in late July or August and may continue into November. Most birds arrive south of the breeding range between the end of September and early November. Birds may appear along the southern shore of Lake Erie in Ohio as early as 20 August in a normal migration year. In Elgin County, autumn migrants arrive in late August some years, September other years, and often not until October. During irruptions, the timing of autumn migration is unpredictable, but it occurs much sooner than in normal migration years. Movement may start in early July; 1 family appeared to start southward migration the day after the young fledged. In the Kingston area, the average autumn departure date for irrupting birds is 19 October (Curry 2006; Ghalambor and Martin 2020; Lancaster et al. 2004; Weir 2008).

Irruptions of Red-breasted Nuthatches are frequent and fairly regular. Irruptive movements usually occur every other year, but may occur every 2-3 years, 2 years in a row, or with a 3-year gap. Southward invasions may coincide with irruptions of 7 other northern conifer seed-eating birds. Between 1901 and 1920 and 1951-80, there was high synchrony in the irruptions of the Red-breasted Nuthatch, Redpoll, and Pine Siskin, but no evidence of synchrony 1921-50. Invasion years are typically preceded by 1-2 years of bumper conifer seed crops, often resulting in exceptional reproductive success, followed by a collapse in seed production. In areas where Red-breasted Nuthatches do not breed, Christmas Bird Count (CBC) data show almost perfect cycles of abundance and absence. In Tennessee and Pennsylvania, cycles in peaks did not correspond to other areas and

may have been affected by local supplies of conifer seeds. Ontario CBC counts do not correspond well with irruption cycles, with peak numbers only 50% higher than lows. This is probably due to the presence of residents and migrants during normal migration years (Bock and Lepthien 1972, 1976b; Davis and Morrison 1988; Davis and Petersen 1995; Freedman and Riley 1980; Ghalambor and Martin 2020; Larson and Bock 1986; Yunick 1988).

During migration, the Red-breasted Nuthatch may occur in a variety of habitats, but it still prefers coniferous trees. In the nonbreeding seasons in British Columbia, it occurred in a diversity of habitats, but was most prevalent in older second-growth and old-growth forests dominated by conifers (Campbell et al. 1997; Ghalambor and Martin 2020). In oak savannahs in the Midwest, its abundance was correlated with tree density and was highest at tree densities of 500-600 per ha (Grundel and Pavlovic 2007b).

The Red-breasted Nuthatch begins caching food in autumn and continues throughout winter. Where it is resident, caching is probably critical to its winter survival. Most food items cached are conifer seeds, but it may cache some insects. Most caches are in crevices under bark, but occasionally in sapsucker wells, and rarely in the ground. About half of caches are covered with pieces of lichen or bark, and 1 ground cache was covered with small pebbles. In many cases, stored food is hammered into a crevice or pushed under a flake of bark. During autumn and winter in areas outside its normal range, it appears to be a short-term cacher. Food stored in the morning may be eaten in the afternoon of the same day or the next day. No information is available on how long food is stored by resident birds before it is retrieved (Dunn and Tessaglia-Hymes 1999; Ghalambor and Martin 2020; Grubb and Waite 1987; Hendricks 1995; Kilham 1974, 1975; Tyler in Bent 1948).

In autumn, the Red-breasted Nuthatch's diet consists of a mix of arthropods and seeds of conifers, but mostly conifer seeds. Seeds of pine, spruce, and hemlock are particularly favoured, as they are in winter. There is 1 record of nuthatches feeding on the entrails of a deer that had been dressed by a hunter. They may have been feeding on the tallow; suet is a favoured winter food (Ball 1945; Ghalambor and Martin 2020).

James (1991) considered the Red-breasted Nuthatch an uncommon to locally common migrant. Abundance varies considerably depending on whether or not it is an irruption year. At Prince Edward Point, none are seen during migration some years; hundreds may be seen other years (Weir 2008).

WINTER

The Red-breasted Nuthatch is associated with snow in winter. Length of the snow season is an important predictor of its presence (Keyser et al. 2022). For most populations, winter habitat is similar to breeding habitat, but a wider variety of habitats may be used. In addition to its typical habitat of coniferous and mixed woods, it may occur in deciduous forests, orchards, shrubby areas, riparian woodlands, parks, and shade trees and gardens in suburban areas. In winter, it is slightly more regular and abundant at rural than urban feeders. Data from Ontario Winter Bird-Population Studies revealed that it was associated with forests. The number of birds documented per km^2 was: 0 in farm, mixed rural, urban natural areas with open water, and city; 0.7 in urban natural areas, 1.0 in natural small urban areas, and 12.5 in forested areas. In suburban habitat in northern California, it

was positively associated with tall trees and negatively associated with roads and other human structures (Dunn and Tessaglia-Hymes 1999; Ghalambor and Martin 2020; Kalinowski and Johnson 2010; Smith 2003).

Resident pairs may maintain territories over winter. Migratory birds often join flocks of chickadees and other species and are nonterritorial. Some birds maintain winter home ranges of about 4 ha in winter, although these areas are not defended. In Ohio, where the Red-breasted Nuthatch does not breed, winter home ranges in deciduous forests were 0.9-4.5 ha. Home ranges may overlap; range overlap in Ohio for 2 males was 15%, but overlap was 50-60% for a group of 2 males and 1 female. As many as 3 male-male-female groups occurred in 1 woodlot. Some birds formed loose groups; others were solitary. Some emigrants set up home ranges and others do not, so that occasionally as many as 10 may visit a winter bird feeder. This number of nuthatches at a feeder is rare, with most northern feeders supporting a maximum of 2 birds compared with 1 in the south (Dunn and Tessaglia-Hymes 1999; Ghalambor and Martin 2020; Matthysen et al. 1992).

In winter, the Red-breasted Nuthatch relies heavily on conifer seeds and cached food, which is also predominantly conifer seeds. Northern populations rely more on cached foods than southern populations. Winter foods are mostly seeds of pine, spruce, and hemlock. It may eat insect eggs and larvae, bits of rotten apples and other fruit, sap from trees and stumps, and seeds of dock and giant ragweed as well as other weeds that extend above the snow. Feeding on hemlock seeds is affected by weather because hemlock cones open in dry, cold, and windy periods and close on warmer and more humid days. It often forages on conifer seeds that fall to the ground and this becomes more common as winter progresses (Ghalambor and Martin 2020; Kilham 1975; Tyler in Bent 1948).

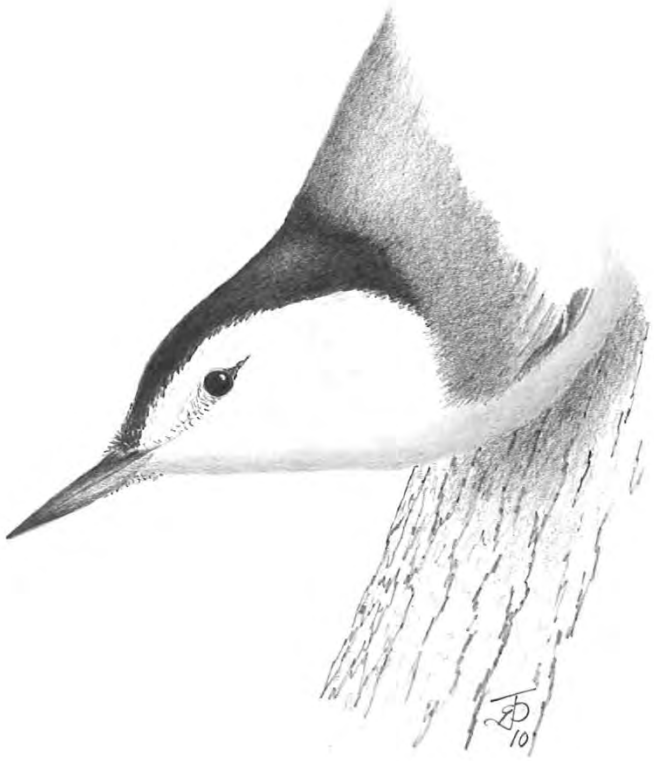
The Red-breasted Nuthatch frequently visits winter bird feeders, but the percentage of feeders visited declines steadily throughout winter. Frequently consumed feeder foods include suet, sunflowers, hulled peanuts and hearts, peanut butter mixes, and bird puddings. Infrequently consumed foods include mixed seeds, safflower, corn, niger, peanuts in the shell, meat scraps, baked goods, water, and oats (Dunn and Tessaglia-Hymes 1999). Participants in Canada and the United States recorded 7,258 Red-breasted Nuthatch foraging bouts. It preferred black oil sunflowers, 0.3-mm and 0.5-mm sunflower chips, and platform feeders (Horn et al. 2014).

James (1991) considered the Red-breasted Nuthatch rare to locally common in winter in the south, and occasional and rare in the north to Thunder Bay and Manitouwadge.

CBC data for Ontario indicate that the Red-breasted Nuthatch increased at annual rates of 5.03% 1970-2021 and 2.82% 2009-21 (National Audubon Society 2022).

White-breasted Nuthatch

Sitta carolinensis



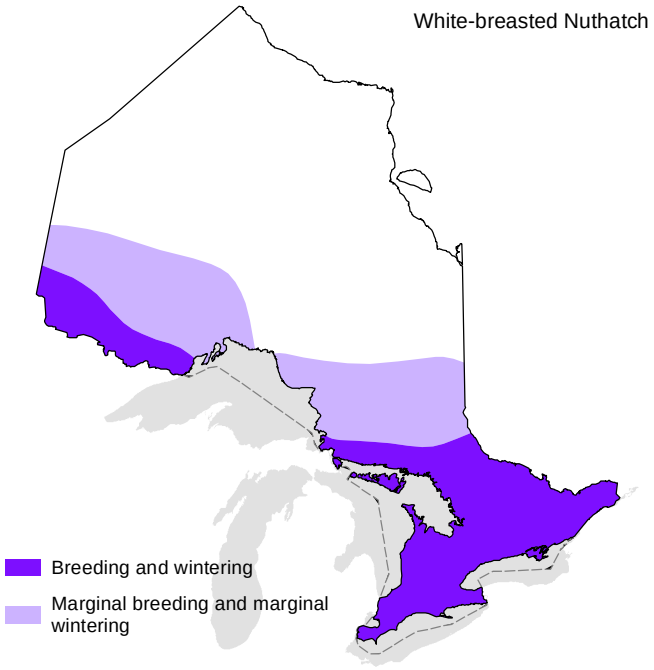
BREEDING SEASON

Habitat Requirements

In Ontario, the White-breasted Nuthatch nests mostly in mature deciduous woodlands, less frequently in mixed woods, and rarely in coniferous stands and residential areas. Forest edges are greatly preferred over interior. Most nests are near open areas such as watercourses or water bodies, roads, clearings, and fields (Peck and James 1987).

In eastern boreal forests, Erskine (1977) considered the White-breasted Nuthatch characteristic of transitional sugar maple–beech forests, but sometimes extending far into the Boreal Forest Region in mixed or deciduous habitats. Highest densities occurred in sugar maple or white ash stands, with low densities in poplar and birch stands. It was characteristic of deciduous forests in Algonquin Park. It occurred in hardwood stands but was absent in wet and dry bogs; coniferous forests dominated by pure or mixed stands of black spruce, white cedar, balsam fir, and hemlock; and birch-poplar stands and birch-poplar stands mixed with conifers (Martin 1960). In Durham Region, Speirs and Orenstein (1975) considered it a late-succession species. It was most abundant in mature beech–sugar maple and sugar maple–oak stands followed by a sugar maple–riparian area

of conifers, sugar maple and cedar-elm swamp, and a deciduous stand heavily damaged by a hurricane.



In the east, the White-breasted Nuthatch breeds most frequently in deciduous and mixed stands and is rare to uncommon in coniferous stands. In the west, it may be common in coniferous forests. In the western Boreal Forest Region, it was mostly associated with mesic mixed or deciduous forests and was absent in black spruce and species-poor jack pine stands (Kirk et al. 1996). In British Columbia, 78% of breeding records were from open but fairly contiguous forests, 20% were from human-influenced forests, and 2% from grasslands with scattered trees. In California, it was significantly more abundant in oak savannahs with grass and in montane hardwoods than in savannahs with shrubs. Its abundance in oak woodlands was intermediate between these habitat types. In eastern northern hardwoods, it was found on 90% of plots in mature, undisturbed habitats and 17% of plots in disturbed and successional areas. There are occasional records of it nesting in suburban areas throughout its range. It appeared to reach its highest densities in mesic stands and was least abundant in xeric stands in Wisconsin. Most authors concur that the White-breasted Nuthatch is usually associated with mature forest. In Quebec, clear-cuts in mixed or coniferous forest regenerating to hardwoods provided suitable habitat as did regenerating old fields. In Pennsylvania, it was negatively associated with old-growth forests. It occurred in 54.5% of old-growth forests compared with 82.8% of forests statewide, and 84.0% of forests on the Appalachian Plateau (Bancroft 1987; Beals 1960; Bent 1948; Bond 1960; Campbell et al. 1977; Capen 1979; Duyck and McNair 1991; Faanes and Andrew 1983; Haney 1999; Lanoue and Rail in Gauthier and Aubry 1996; McEllin 1979; Noon et al. 1979; Samson 1979; Temple et al. 1979; Wood et al. 2013).

At the landscape level, the White-breasted Nuthatch preferred areas that were 59-75% forested in North Dakota and 58-82% forested in New York. There were no areas with greater than 75% forest cover in North Dakota (Cunningham and Johnson 2019). In North Dakota 400-m landscapes, it increased with increasing tree cover within 100 m in landscapes with less than 30% tree cover, but its probability of occurrence declined when tree coverage exceeded 60% in landscapes with more than 30% tree cover. In wooded areas, it selected more edge-rich sites than in open landscapes (Cunningham and Johnson 2016).

Some information is available on microhabitat preferences of the White-breasted Nuthatch. In Tennessee, the most important habitat variables were related to understorey biomass (foliage, branch, and bole biomass of trees 1.2-8.4 cm diameter at breast height [DBH]) and the number and

size of trees in the lowest woody vegetation layer. It was present where there was lower biomass in the understorey layer and smaller than average understorey tree sizes (Anderson and Shugart 1974). In Michigan riparian swamps, it was most common in swamps closest to a river, with densities declining further from the river, and even fewer in upland forest beyond the riparian swamp (Inman et al. 2002). In Tennessee, there were more territories within 268 m of edge than 268-488 m from edge, but the difference was not significant (Kroodsma 1984). In Maryland, its presence was positively correlated with tree height (Lynch 1987). In Iowa, it was positively associated with sapling and tree richness and presence of deciduous trees (Stauffer and Best 1980). In the mid-Atlantic states, it was positively associated with forest area, number of trees, forest slope, and canopy height, and negatively associated with the percentage of forest cover within 2 km, the number of trees larger than 3 cm DBH, and the percent canopy cover by coniferous trees. Robbins et al. (1989) concluded that it was most likely to occur in greatly isolated and moderately isolated forests. In Vermont, it was associated with mid-successional habitats, increasing coverage by deciduous species, moderate density of dead trees, moderate amounts of poplar and white pine, low amounts of red maple, and abundant hophornbeam, sugar maple, and beech (Lent and Capen 1995).

The White-breasted Nuthatch was considered an area-sensitive species by some authors. In the mid-Atlantic states, it reached its maximum probability of detection in 300-ha forests. The size of forest at which detection decreased by 50% was 3.0 ha. The 3 smallest forests where it was detected on 2 or more visits were 4.2, 3.0, and 1.6 ha (Robbins et al. 1989). Blake and Karr (1987) considered it area sensitive in Illinois because its presence was positively associated with woodlot size, but gave no minimum forest size for it. In Missouri, Hayden et al. (1985) concluded that it required woodlands a minimum of 2.2 ha, but it reached 100% occurrence in forests 42-54 ha in size. Minimum size requirements were estimated at 4.7 ha in Illinois and 2.0 ha in New Jersey. Stauffer and Best (1980) concluded that it was restricted by patch size in Iowa and found that the minimum plot width for occurrence in riparian areas was 17 m. In Ontario, the White-breasted Nuthatch is occasionally considered an area-sensitive species requiring woodlots a minimum of 10 ha in area (Coleman et al. 2000). In southern Ontario, Austen et al. (2001) determined that the probability of observation of the White-breasted Nuthatch was negatively correlated with amount of forest 100 m or more from edge, amount of forest within 2 km, and amount of regional forest. It was negatively correlated with forest size. These relationships were not significant. Keller and Yahner (2007) found no relationship between forest size and its presence in Pennsylvania. In South Dakota, Gentry et al. (2006) found that its density was significantly lower in small (0.7-3.5 ha) isolated woodlots than in large riparian woodlands. It is likely that many of these woodlots were smaller than the typical territory size of this species. The White-breasted Nuthatch has a relatively large territory size and it seems unlikely that it is truly area sensitive. Its scarcity in woodlands smaller than 10 ha may simply be because these woodlands are smaller than the area required for a territory. In Ontario, it occasionally nests in isolated trees in non-forested areas (personal observation) and residential areas (Peck and James 1987).

Roosts are an important habitat component of the White-breasted Nuthatch. It uses roosts year-round, but they are most critical in winter. Winter roosts are frequently cavities excavated by Downy Woodpeckers. Roosts used throughout the winter by males may ultimately be taken over by the

female and used as the nest cavity. Nuthatches appear to prefer holes that are 2-3 times the size of their bodies for roosting. Although most roost in cavities in dead stubs, one roosted in a curl of bark hanging from a high, dead maple limb. Roosts are 2-12 m from the ground (Kilham 1971; Tyler 1916).

One pair of nuthatches was observed excavating or enlarging a cavity, but all other Ontario nests were in existing cavities, predominantly in trees. Two were in tree stumps and 4 were in bird boxes. Natural cavities were greatly preferred (87.1% of nests) to cavities previously constructed by woodpeckers or other species. Most nests were in living trees and, except for 2 nests in branch cavities, all were in trunks of trees. The DBH of 3 nest trees was 25.5-35.5 cm. Natural-cavity nests were in splits and knotholes and faced in random directions. Nests were occasionally used in successive or subsequent years. Eight-five percent of nests were in deciduous trees of 10 species compared with 2 species of conifers. The most frequently chosen nest trees were maples (18 nests), oaks (11), elms (7), and pines (5). Nests were 0.5-20 m from the ground, with most 1.8-9.0 m up (Peck and James 1987, 1997).

Most authors consider the White-breasted Nuthatch a secondary cavity nester, relying on natural cavities and old woodpecker holes for nest sites. In British Columbia, it is considered a primary excavator and has been observed excavating nest cavities elsewhere. In some areas, particularly the west, it readily uses nest boxes; usage of nest boxes in the east is less frequent. Most Ontario nests were in living trees, but use of snags and dead and living trees is variable elsewhere. In some areas, most nests are in snags; in others they are mostly in live trees or live portions of trees that are predominantly dead. Usage of type of tree is probably more dependent on availability of suitable nesting cavities rather than whether the tree is alive. Tree species used for nesting include elms, black cherry, pines, silver maple, hackberry, black walnut, aspens, oaks, and apple. Nest tree species may be defined by cavity availability; aspens were actively selected in an Arizona study area. One common characteristic of nuthatch nests is that they tend to be fairly low and in the main trunk of a tree. In Colorado, most nest entrances were immediately above a large branch and all entrances faced southward, away from the prevailing wind. Natural cavities appear to be preferred over woodpecker holes, with a high percentage of nests in knotholes where a dead branch has fallen off or in a cavity created by a lightning strike. The White-breasted Nuthatch has been known to evict chickadees from their nest and then use it. Most nests are 3-9 m from the ground. A wide range of tree sizes is used for nesting, with a minimum DBH of 25-30 cm. Abundance of nests appears unrelated to snag availability in most areas and, in Missouri, nests are highly correlated with increasing size and soundness of the nest tree (Bancroft 1987; Bent 1948; Bock and Fleck 1995; Brawn et al. 1984; Campbell et al. 1997; Cunningham et al. 1980; Duyck and McNair 1991; Evans and Conner 1979; Grubb and Pravosudov 2020; Lanoue and Rail in Gauthier and Aubry 1996; Li and Martin 1991; McEllin 1979; Rand 1972; Stauffer and Best 1980, 1982).

The White-breasted Nuthatch is territorial year-round, although boundaries of the winter and breeding territories may not be the same. Breeding occurs within the winter territory, but often at its edge. Evans and Conner (1979) reported a territory size of 0.8 ha, which is probably an underestimate. In New York, pairs nesting in wooded habitat had territories averaging 9.7 ha and in New Hampshire most territories were approximately 15 ha. In semi-wooded areas, territories may be as large as 20 ha. Certain density estimates and size of woodlands that it has been reported

breeding in suggest that territories may occasionally be as small as 3-5 ha. Territory size is probably determined by the amount of forest cover and the availability of suitable cavities for nesting (Butts 1931b; Grubb and Pravosudov 2020; Kilham 1972, 1981).

Nothing is known about natal philopatry, but it may be almost zero. Young leave their parents and the natal territory in July. In New York, young spent the winter near a feeder 0.8 km from their natal territory, but disappeared prior to the next breeding season. Adult site fidelity is extremely high. Once an adult breeds, it maintains the same territory for the rest of its life (Butts 1931b; Grubb and Pravosudov 2020).

Limiting Factors

Eggs have been reported in Ontario nests from the last week of April until the end of May, with most present in the first half of May (Peck and James 1987). In Algonquin Park, nests are under construction from early to mid-May, eggs are present in mid-May, nestlings are present from mid-May to late June, and dependent fledglings have been observed from mid-June to late July (Tozer 2012).

Nest building may continue a few days after the first egg is laid. Eggs are laid at the rate of 1 a day. The incubation period is 12-15 days. The nestling period is 21-26 days, and adults continue to feed the young for about 2 weeks after they fledge (Bent 1948; Butts 1931b; Duyck and McNair 1991; Grubb and Pravosudov 2020).

One brood is raised annually. Renesting usually does not occur after clutch loss, but there is 1 record of renesting from North Carolina. Ontario egg dates suggest that renesting does not occur, or is rare. Clutches of 5-8 eggs have been reported in Ontario, with most containing 6-8 eggs. Overall, clutch sizes of 5-10 eggs have been reported, but 6-9-egg clutches are typical with 8 eggs most frequent. Clutches may be smaller in the west, with most British Columbia nests containing 5-7 eggs. The average clutch size in North America was estimated at 7.3 eggs. The North Carolina pair that renested had an initial clutch of 7 eggs and a replacement clutch of 6 eggs (Bent 1948; Campbell et al. 1997; Duyck and McNair 1991; Grubb and Pravosudov 2020).

The age at first breeding is 1 year and birds apparently breed every year thereafter. The mating system is monogamous, and the pair bond is usually for as long as both birds remain alive. Due to the high mortality rate, only a few pairs remain mated for even 2 years. When a bird disappears, the survivor remains in the territory until a new mate shows up, regardless of the sex of the survivor. New mates usually appear within a week. In 1 pair, the male disappeared early in the breeding season and was replaced, and the new male nested with the female. The female disappeared during incubation and was replaced by a second female. This new pair nested together the following year (Bent 1948; Butts 1931b; Grubb and Pravosudov 2020; Kilham 1972).

Both members of a pair usually forage close together. The White-breasted Nuthatch typically forages on the bark of trees, either by moving upward on trunks or, more often, head-first downward. It chips the bark away with its beak to uncover food hidden in crevices. In a laboratory study, nuthatches were supplied with branches 0.5, 1.0, 2.5, 5.0, 10, and 20 cm in diameter. Branches 20 cm in diameter were used significantly more than expected; branches 1.0 cm in diameter and smaller were avoided. Males preferred to forage on the bottoms of branches; females preferred the

sides. In Ohio, no differences in foraging preferences of the sexes were evident. Both sexes relied on tree trunks and major limbs for foraging with the mean branch or trunk diameter used by males being 13.0 cm compared with 11.0 cm for females. Each bird in the pair mimicked their partner's foraging behaviour. As 1 bird moved higher, used larger branches, or branched further out from the trunk, so did the other. Birds started foraging high up in trees in the morning, descended toward midday, often searching the leaf litter for beechnuts, and moved up into the canopy again in late afternoon. In ponderosa pine forests in Colorado, there were significant differences in foraging behaviours between the sexes. Females foraged significantly higher (7.7 m) than males (2.8 m) with females foraging mostly on limbs and males feeding predominantly on trunks. Ground foraging may occur regularly, particularly if there is an abundant food source available. In Algonquin Park, foraging occurred from the ground to a height of 10 m; canopy height was 30 m. In Vermont, 55% of foraging was by gleaning, 43% by hammering, and 2% by hanging. Substrates used were 2% foliage, 40% branches, 56% trunks, and 2% twigs. Nuthatches rarely hawk for insects (Bent 1948; Brackbill 1950b; Grubb 1982; Grubb and Pravosudov 2020; Lent and Capen 1995; Martin 1960; Pierce and Grubb 1981).

The food brought to nestlings consists predominantly of invertebrates such as miscellaneous winged insects, caterpillars, grubs, moths, and spiders. During the breeding season, the White-breasted Nuthatch feeds almost exclusively on invertebrates, although it may drink from sapsucker wells in spring. The proportion of seeds in the diet has been estimated at 48% in spring, 0% in summer, 29% in autumn, and 68% in winter. During the breeding season, it feeds on stink bugs, beetles (weevils, and leaf, click, and metallic wood-boring beetles), earwigs, flying and wingless ants, book lice, adult and larval moths, spiders, millipedes, treehoppers, jumping plant lice, scale insects, gall midge larvae, aphid eggs, fall cankerworm eggs, and gypsy moth and forest tent caterpillars. One removed an egg from a Blue-gray Gnatcatcher nest and flew away with it. About 2 minutes later, it returned and took a second egg (Bancroft 1987; Bent 1948; Brackbill 1950b; Butts 1931b; Coggins 2002; Duyck and McNair 1991; Grubb and Pravosudov 2020; Lanoue and Rail in Gauthier and Aubry 1996). In New Brunswick, it did not exhibit any increase in populations associated with increasing numbers of spruce budworms (Morris et al. 1958).

White-breasted Nuthatch nests are rarely parasitized by the Brown-headed Cowbird. One of 26 Ontario nests (3.8%) was parasitized. No parasitized nests have been found in British Columbia. Parasitism has been documented in Illinois, but there are no records of any cowbirds being fledged (Campbell et al. 1997; Grubb and Pravosudov 2020; Lowther 1997; Peck and James 1997). Bent (1948) knew of only 4 cases of parasitism.

Extensive breeding habitat for the White-breasted Nuthatch was undoubtedly lost when European settlers cleared southern Ontario forests. It is still vulnerable to forest clearing and habitat fragmentation, with many residual woodlots being too small to support a pair. Some habitat is being regained as abandoned farmland evolves into forest.

The response of the White-breasted Nuthatch to timber harvesting and fire varies depending upon the intensity of the treatment. In the Boreal Forest Region, with special reference to Ontario, Vanderwel et al. (2009) reported no change in its abundance when 30, 50, or 70% of trees were removed. In the Carolinian Forest Region of Ontario, Holmes et al. (2004) found no significant

differences in its abundance in woodlots with no recent harvesting history and those where selection thinning and diameter-limit cuts had occurred. In New York, there were no differences in its abundance between control forests and forests where 25%, 50%, 75%, or 100% of merchantable trees were removed. These forestry practices left young trees and older trees with no value and are not comparable to clear-cuts (Webb et al. 1977). In Minnesota, it exhibited no significant response to tree removal in riparian strips along small watercourses (Hanowski et al. 2002). In Pennsylvania, it was significantly more common in cuts where snags were retained than in areas where snags were removed (Stribling et al. 1990). In the California Sierra Nevada, it occurred in both burned and unburned forest and was more abundant in the burned area. In the burn, it nested in burned stubs but foraged mostly in live trees that had been spared by fire (Bock and Lynch 1970). It is likely that nuthatch abundance would decline in burns where most trees were killed. In the Midwest, its density was highest where the frequency of fire was 0 within a 15-year period. It disappeared once the frequency of fires within 15 years reached 6 (Grundel and Pavlovic 2007b). In Montana, it was absent in burns where salvage logging occurred, but was present in unlogged burns; the difference in abundance was significant (Hutto and Gallo 2006). Fires or timber harvesting that remove a high proportion of snags and most of the canopy are detrimental to the White-breasted Nuthatch.

In North Carolina, the White-breasted Nuthatch increased in abundance with increasing numbers of houses and buildings within 200 m of the centre of the forest stand, but not significantly (Lumpkin and Pearson 2013).

In New Jersey and Pennsylvania over a 15-year period, hemlock declined from 56% of the total basal area to 46% due to the hemlock woolly adelgid; the amount of deciduous understorey increased. The White-breasted Nuthatch responded favourably to hemlock decline, possibly due to the increased prevalence of snags (Toenies et al. 2018).

Price (2004) predicted that the range of the White-breasted Nuthatch would contract in southern Ontario if the average summer temperature increased by 2°C. In Quebec, DesGranges and Morneau (2010) concluded that it was not very sensitive to climate change.

Status

McIlwraith (1894) considered the White-breasted Nuthatch a common resident. Baillie and Harrington (1937) reported it as a fairly common resident north to at least Temagami and Sudbury and had 1 record from the Lake of the Woods area. They concluded that it was much more common in the southern part of its range, becoming uncommon north of Parry Sound District and Ottawa. Mills (1981) stated that it reached the northern limit of its range in Muskoka and Parry Sound districts, becoming uncommon in the latitude of Lake Nipissing. During the first atlas, it was widespread in southern Ontario except for in Essex and Chatham-Kent, but was sparse in distribution in the Algonquin Highlands and south of Lake Nipissing. It occurred further north near Sudbury, Temagami, Sault Ste. Marie, Thunder Bay, and in the Kenora area (Mills in Cadman et al. 1987). Weir (2008) reported no change in status in the Kingston area since the 19th century, where it remains a common breeder and permanent resident. James (1991) considered the White-breasted Nuthatch an uncommon permanent resident in the south and occasional and rare in the north to Kenora, Thunder Bay, and Timiskaming District.

The second atlas indicated that the White-breasted Nuthatch had increased in abundance and extended its range somewhat since the first atlas. Its probability of observation increased significantly province-wide and in the Great Lakes–St. Lawrence Forest Region. The increase in the Boreal Forest Region was not statistically significant. There was a nonsignificant decline in the Carolinian Forest Region. Its range extended further north in northwestern Ontario and around Lake Nipigon. The greatest increase was in the southern Canadian Shield from Algonquin Park to Sault Ste. Marie, possibly due to increases in deciduous forest and canopy cover in this area. It also became more widespread in Essex County. It was most abundant in a wide band along the southern edge of the Canadian Shield from Kingston and Ottawa west to Georgian Bay (Bavrlic in Cadman et al. 2007).

Breeding Bird Survey data indicate annual increases of 1.76% in Canada and 1.65% in Ontario for 1970-2021. For 2011-21, there were annual increases of 0.417% in Canada and 0.428% in Ontario. The long-term trend for Ontario and the short-term trend for Canada were highly reliable; the other estimates were of medium reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

During the postbreeding period in Michigan, 60% of birds, including 75% of juveniles, were found in mature upland trembling aspen stands; 40% of birds and 25% of juveniles were found in riparian habitat that was a mix of alder, honeysuckle, and aspen (Akresh et al. 2009).

AUTUMN

The White-breasted Nuthatch is a predominantly permanent resident, with most birds remaining on their first breeding territory for the remainder of their lives. Birds may be found at the northern extreme of the range every winter. A 3-year study at Ithaca, New York, found no evidence of migration. The number of birds present remained the same and in most cases it was known that they were the same individuals. Over the course of the study, 3 birds were recorded only once, and these may have been migrants or wanderers without a territory. Portions of western and northern populations occasionally are irruptive. In Pennsylvania, 300 passed by a hawk watch in autumn 1968 compared with a total of 53 the 7 previous years. Irruptions may be very localized, with few birds observed in other areas near concentration sites. No information is available on the age of irrupting birds but it is possible that they are predominantly juveniles. There is little evidence of a return spring flight so it is unknown if wanderers breed near their natal area or elsewhere. At Point Pelee, numbers are small, with migrants arriving irregularly from the end of August until mid-September. Southern Ontario Christmas Bird Counts (CBC) indicated irregular cycles of abundance, with major irruptions in 1930 and 1961 and smaller numbers in 1937, 1942, and 1969. Rare irruptions have been documented in the Hamilton area between mid-September and 20 October. Numbers involved were typically 30-50, but there are 2 records of about 150 birds, 1 of 234 birds, and 1 of 275. Irruption years were 1966, 1968, 1975, 1977, 1989, and 1999. At Prince Edward Point, the White-breasted Nuthatch exhibited regular migration in spring and autumn in 1971 and 1972, with daily maxima of 10 in spring and 25 in autumn. The reasons for these irruptions are unknown. Data from Long Point Bird Observatory suggest occasional autumn irruptions and return movements in spring. A review of New York CBCs from 1960 to 1980 showed that there was little synchrony in the irruptions of the 2 nuthatch species. An analysis of CBCs over a more widespread area from 1931 to 1981 found that

the irruption patterns of White-breasted and Red-breasted nuthatches were similar. Until 1944, the fluctuations were irregular; from 1950 to 1964 there were 2 peaks at 3-year intervals and 4 peaks at 2-year intervals; the fluctuations became irregular again after 1970. From 1950 to 1955, the dates of high and low counts for White-breasted Nuthatch were close to those of the Red-breasted Nuthatch, and they were identical 1955-65 (Bent 1948; Brewer et al. 2018; Butts 1931b; Curry 2006; Davis and Morrison 1988; Freedman and Riley 1980; Grubb and Pravosudov 2020; Mills 1981; Weir 2008; Yunick 1988).

Autumn habitat is similar to that of the breeding season, although residents may shift their home ranges to include more open areas than those used during the breeding season. The White-breasted Nuthatch may appear in suburban areas or at rural residential lots, particularly if a feeder is available. In Pennsylvania, it was most abundant in forest interior, forest edge, and suburban forests followed by forest-agricultural edges and shrub-sapling stage forest. It was not observed in pole-stage forests (Rodewald and Brittingham 2002). During the nonbreeding season in British Columbia, it typically occurs in forested habitats, but may also be present in orchards, urban gardens, and where there are bird feeders (Campbell et al. 1997).

In autumn, the White-breasted Nuthatch maintains a territory that is retained throughout the winter. The nonbreeding territory is often a bit larger than the breeding territory and is in the same general area. Breeding and nonbreeding territories may be the same, but usually they are in slightly different locations with some overlap. Some authors stated that the autumn-winter territory was actively defended. Others stated that territories were not defended but that pairs had mutual respect for each other's territories. Occasionally territories overlap. Both members of a pair usually travel together within the territory but they occasionally split up. Members of a pair have been seen as far as 1 km apart. The territory and home range are often the same during autumn and winter, but birds may occasionally leave the territory to visit a distant feeder or other plentiful food source. The size of nonbreeding territories is variable and was only 2.9 ha in Ohio. In New York, 31 pairs had an average territory size of 19.4 ha. Where territories were entirely forested, they were 10.1-11.3 ha. Birds inhabiting territories that were only partially forested ranged over about 20 ha. In addition to territorial birds, there appear to be single birds without established territories that may range over a wider area (Bent 1948; Butts 1931b; Grubb 1982; Grubb and Pravosudov 2020; Tyler 1916).

Autumn and winter foraging techniques are similar to those used during the breeding season. During the nonbreeding season, nuthatches may forage in flocks led by chickadees and titmice. Nuthatches often follow other birds and supplant them from food sources. As a flock moves along, nuthatches drop out of the flock at the edge of their territory and are replaced by nuthatches in the adjoining territory (Grubb and Pravosudov 2020).

The diet changes in autumn with less reliance on invertebrates and greater consumption of mast. The winter diet is similar to that of autumn, but with more mast consumed as fruit and invertebrates become scarcer. Autumn and winter diet includes lesser amounts of animal foods (orthopterans, bugs, beetles, caterpillars, hymenopterans, and spiders) and more soft and hard mast (corn, cherry pits, sunflowers, hawthorns, wheat, grapes, beechnuts, acorns, hickory nuts, and walnuts). By winter, almost all food consists of hard mast but nuthatches also eat pine and hemlock seeds (Bent 1948; Grubb and Pravosudov 2020; Lanoue and Rail in Gauthier and Aubry 1996; Root

1988; Tyler 1916). It prefers acorns of pin oak and white oak over those of black oak. Black oak acorns have harder shells and it may have difficulty cracking them (Richardson et al. 2013).

During autumn and winter, the White-breasted Nuthatch is a scatter hoarder, storing food 10-100 m from where it is obtained, but mostly within 30 m. Food items are taken singly and stored individually. Virtually all caches are in trees where they are wedged under bark or into a furrow or crack in the bark. In Ohio and Arkansas, 69% of caches were on tree trunks larger than 8 cm DBH and 30% were on branches. Food was cached on the bottom of branches more than expected. No compass orientations were selected for caches on tree trunks. Eighty-one percent of caches were in the inner portions of trees, 12% in the middle, and 5% in outer portions. Forty percent were in a furrow or crack, 57% under bark, and the remainder at the end of a branch or in a bud, between 2 branches, or on a leaf. Males usually store food on the trunk of a tree but females may use a variety of sites for caching. Only 6-7% of caches were in trees with a DBH less than 15 cm, 10% in 15-23 cm DBH, 12% in 23-38 cm DBH, 20% in 38-53 cm DBH, and more than 30% in trees larger than 53 cm DBH. Caches averaged 8.0 m above ground (range 1-23 m). Caches are covered with bark or rotted wood (81%), lichens (15%), snow (3%), or moss (1%; Bent 1948; Grubb and Provosudov 2020; Kilham 1974; Petit et al. 1989).

In the United States, the White-breasted Nuthatch was among the most vulnerable species for striking residences 1-3 stories tall; it was 25.0 times more likely to suffer a collision than birds on average. It was not on the lists of the 20 most vulnerable species for striking low-rises or high-rises (Loss et al. 2014).

WINTER

Cold winter weather may affect White-breasted Nuthatch foraging strategies. In Ohio, the height at which it foraged was not significantly related to temperature or wind, but the distance that birds occurred from the windward side of woodlots was. It appeared to be wind sensitive when the temperature dropped below –6°C. On more than 62% of winter visits, it foraged only in the leeward half of woodlots, suggesting the potential for food depletion over winter. In other areas during cold and windy weather, it foraged significantly lower and on larger branches, used less exposed portions of the home range, and spent more time stationary (Dolby and Grubb 1999; Grubb 1982; Grubb and Pravosudov 2020). In New Jersey, it continued to be most common in oak woods even during cold, snowy weather, even though this cover type provided less shelter than some other habitats. It may have continued to use oak stands during adverse weather due to its high dependence on acorns for food (Brush 1989). In Missouri, temperature had a positive effect on its detection probability; wind had a negative effect. Its density increased 17% over the range of stocking from savannah to woodland to forest. It was essentially equally abundant at all levels of tree stocking (Kendrick and Thompson 2013).

Williams and Batzli (1979) examined the contents of 20 stomachs collected in winter in Illinois. The diet was comprised of 71.8% vegetable matter and 28.2% animal matter. The vegetation eaten consisted of 49.7% corn, 6.6% mast (mostly acorns), 5.7% wheat, 5.5% sunflowers, 3.8% unknown, 0.3% hawthorn, and 0.1% each grapes and other. The animal food included 7.2% adult hymenopterans, 6.5% adult beetles, 3.3% unknown, 3.3% bugs, 2.9% orthopterans, 2.7% caterpillars, 1.1% hymenopteran larvae, 1.0% spiders, and 0.2% other. The authors considered the White-

breasted Nuthatch moderately specialized in its winter diet. In New Jersey pine barrens, wintering birds were partly granivorous and ate acorns but not pine seeds. They were restricted to habitat with acorns and were common only in areas of tall oaks (oak and oak-pine forests); pine swamps and cedar swamps were not used (Brush 1989).

The White-breasted Nuthatch is a regular visitor to winter bird feeders, but the number using feeders declines as winter progresses. In some areas, it appears to prefer natural foods to feeders, but in other areas access to feeders improves the nutritional condition of birds. In Pennsylvania, feeders were provided at heights of 2, 4, and 6 m. Nuthatches foraged on 40.3% of visits at 6 m, 32.1% at 4 m, 27.6% at 2 m, and 0% on the ground. It was the only species that did not forage on the ground (although this often occurs elsewhere). Food taken consisted of 63.2% sunflowers, 35.3% corn, and 1.5% niger seed. No canary seed or millet was taken. According to Project FeederWatch, favourite foods at feeders were suet, sunflowers of any type, hulled peanuts or hearts, peanut butter mixes, and bird puddings. Infrequently taken foods included mixed seed, safflower, whole or cracked corn, niger, peanuts in the shell, meat scraps, baked goods, water, and oats (Bent 1948; Butts 1931b; Dunn and Tessaglia-Hymes 1999; Grubb and Pravosudov 2020; Nastase and Linville 1995). A total of 17,581 observations of White-breasted Nuthatch feedings were made by participants in Canada and the United States. It preferred black oil sunflowers, medium-sized (0.5 mm) sunflower chips, striped sunflowers, and whole peanuts. Tube and platform feeders were preferred over hopper feeders (Horn et al. 2014).

Forest fragmentation affected wintering White-breasted Nuthatches in Alberta and Quebec. They were unwilling to cross wide gaps (200 m) and presence of narrow hedgerows did not facilitate their movement among forest patches (St. Clair et al. 1998).

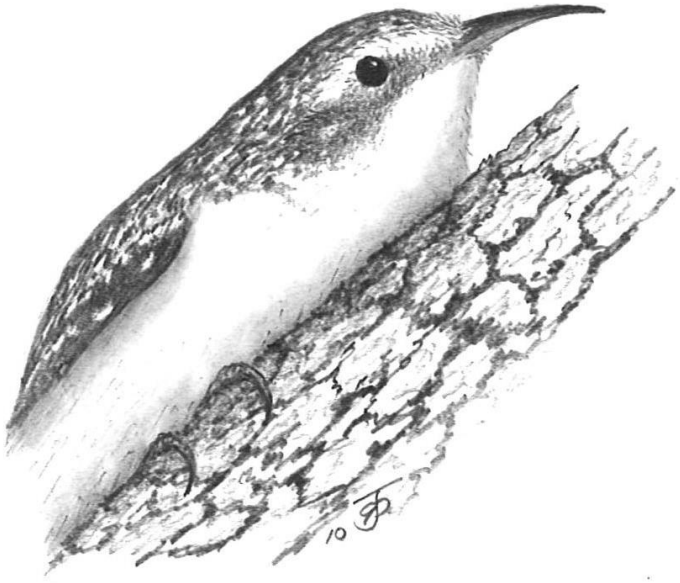
Severe winter weather may result in direct mortality of the White-breasted Nuthatch. In New Hampshire, populations declined sharply between the summers of 1969 and 1970. Holmes and Sturges (1975) attributed this to severe weather in the intervening winter and early spring. In Pennsylvania, Overlease and Overlease (1987) correlated local population fluctuations with severe weather and suggested that it was vulnerable to depth and length of snow cover, especially when accompanied by cold weather. In Illinois, Graber and Graber (1979) found no evidence of mortality after a particularly severe and prolonged winter storm. There was no overall change in density of birds, but many apparently moved from bottomland forests to upland forests.

Invasion by the emerald ash borer is having a positive effect on the White-breasted Nuthatch. The larvae of this beetle provide an abundant food source and the dead ash trees they leave behind supply potential nesting cavities (Bonter 2013; John 2013).

Southern Ontario CBCs indicated a significant increase from 1929 to 1977 (Freedman and Riley 1980). CBC data for Ontario indicate that the White-breasted Nuthatch increased at annual rates of 1.73% 1970-2021 and 3.84% 2009-21 (National Audubon Society 2022).

Brown Creeper

Certhia americana

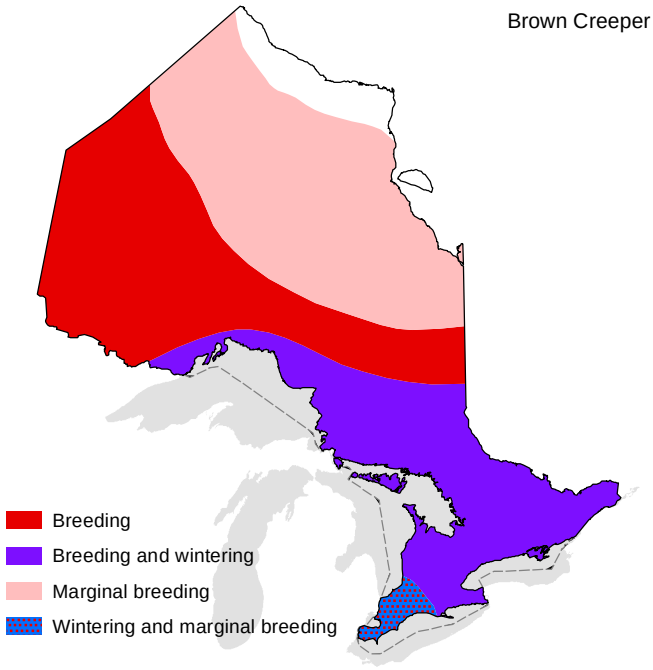


BREEDING SEASON

Habitat Requirements

In Ontario, the Brown Creeper breeds mostly in forests (72.5% of nests), including 33.3% in mixed woods, 25.4% in deciduous forests, and 13.7% in coniferous forests. Other habitats where nests occurred were beaver ponds with standing dead trees (15.7%), spruce bogs (7.8%), and edges of shrubby fields (3.9%). Most nests were found in wet rather than dry habitats which may be a reflection of the greater abundance of dead trees in wet areas (Peck and James 1987).

In the Boreal Forest Region of Ontario, the Brown Creeper was associated with older, closed, mixed-wood forests with little interspersion of young and old forest and a greater proportion of intact forest older than 80 years. It was not significantly correlated with average stand age, the percentage of hardwoods in stands, the amount of edge, or the percentage of total forest that was more than 80 years old (Rempel 2007; Rempel et al. 2007). Erskine (1977) considered it one of the most typical boreal species, characteristic of black spruce stands. In the Boreal Forest Region in western Canada, it was associated with dry, moderately rich, older, conifer-dominated stands. Kirk et al. (1996) considered it an old-forest species. In the Ontario portion of the Clay Belt, it was associated with mesic to wet stands with moderate to rich nutrient levels. It was most frequent in white or black spruce and jack pine stands, occasional in poplars, and was absent in tamarack and



cedar (Welsh and Lougheed 1996). From Pickle Lake north to the Manitoba border, McLaren and McLaren (1981) found it only in coniferous and mixed forests.

In the Canadian Shield in the Great Lakes–St. Lawrence Forest Region, the Brown Creeper nested in both mature and old-growth white pine stands. Its abundance was significantly correlated with stand age and density of pines larger than 40 cm diameter at breast height (DBH). It was 1.5 times more abundant in old-growth stands than in mature stands. Its probability of occurrence was 33% with 62 stems per ha (11.6 m^2 per ha) of medium-sized and large pine trees (Kirk et al. 2012). In Quetico Park, it was most common in 112-year old forests where it was the dominant species in the timber-gleaner guild. It occurred in nearly all communities from early succession following fire to old growth (Apfelbaum and Haney 1985). It was essentially absent in managed jack pine stands near Gogama, but occurred in adjacent pine stands that were more than 100 years old. Managed pine stands probably do not provide suitable nest sites until they are 70-80 or more years old when some larger dead or dying trees might occur (James and Peck 1995a). In jack pine stands in Parry Sound District, James (1979a) found the Brown Creeper along 1 transect of 10-15-m tall pines mixed with 5-15-m tall white birch, white pine, trembling aspen, white spruce, and tamarack; it was absent on 4 other transects. In Algonquin Park, Martin (1960) reported it in stands dominated by black spruce and white cedar, white pine, hardwoods, and hemlock. It was absent in bogs, white birch–poplar stands, and balsam fir–black spruce stands.

In Durham Region in the Great Lakes–St. Lawrence Forest Region south of the Shield, the Brown Creeper occurred in a young open-canopy forest, a black spruce bog with a fringe of red maple–poplar swamp, an open swamp, a mature white cedar–elm swamp, a mature sugar maple–oak forest, and a hilltop dominated by sugar maple with a swamp of white cedar–balsam fir–spruce at the toe of the hill. Speirs and Orenstein (1975) considered it characteristic of white cedar forest.

The Brown Creeper does not appear to favour any particular forest cover type but seems to use the cover types that are most prevalent in the landscape. In the north, it is most strongly associated with coniferous and mixed forests because these are the dominant types available. South of the Boreal Forest Region, it is found mostly in mixed and deciduous stands and even further south, mostly in deciduous forests. In northern hardwoods, it is most abundant in old stands dominated by sugar maple and yellow birch, with balsam fir snags. In western North America, it nests predominantly in coniferous stands. It has been reported nesting in sugar maple forests, maple–yellow birch–hemlock stands, white pine–white oak stands, red maple swamps, cedar swamps,

hemlock forests, white and black spruce stands, mixed swamps, flooded timber, aspen-dominated mixed woods, and balsam fir stands (Betts 1909; Chadbourne 1905; Golet et al. 2001; Hall and Laitsch 1963; Higgelke and MacLeod 2000; Inman et al. 2002; Kennard and McKechnie 1905; Mossman and Hoffman 1989; Palmer-Ball and Haag 1989; Poulin et al. 2020; Thompson et al. 1999).

The most critical habitat component for the Brown Creeper is presence of large trees and snags for feeding and nesting. Consequently, it is typically associated with mature or old-growth forests, or younger or more open habitats that have residual old trees. These latter areas may include early-succession forests with scattered large trees and snags that persist after a fire or, less frequently, a clear-cut. In these more unusual circumstances, nests may be in fairly open habitat, although it typically nests in closed-canopy forests. Near White River, it was significantly more abundant in mature forests than in clear-cuts 3-25 years old. It was only observed once in early successional habitats. In Alberta, at least 3 ha of mature to old-growth forest were required around the nest site. In Alberta aspen stands, it occurred only in old-growth forest and preferred areas with coniferous cover. In Quebec, it nested in recent burns with saplings shorter than 2 m, but with numerous snags; in young forests with saplings 5-11 m tall; and in mature forests 120 and 200 years old. It was not detected in clear-cuts where saplings were less than 5 m tall. It was significantly more abundant in mature forests than recent burns, but its abundance in young forests was not significantly different from either burns or mature forests. In New Brunswick, the probability of finding a nest declined significantly when there were fewer than 127 stems per ha of trees that were 30 cm DBH or larger. Stand structure (large trees and snags) and the presence of mature or old forest patches within a 250-m radius had a significant influence on the probability of the presence of a Brown Creeper nest. In black spruce forests, it is most common in stands older than 120 years. In burns, it is most frequent in moderate and severe burns in coniferous forests that leave a high number of snags and adjacent live trees for foraging. In the east, it is twice as abundant in old-growth forests as in mature second-growth forests. In the Appalachians in Pennsylvania, it occurred in 100% of old-growth forests compared with 23.1% of forests statewide and 32.4% of forests on the Appalachian Plateau. It was considered an obligate old-growth species. In eastern deciduous forests, it is seldom detected in woodlands younger than 60 years. In Washington, nests were found only in stands 60-120 years old and in old-growth forest; in British Columbia it was most abundant in stands older than 200 years (Bock and Lynch 1970; Campbell et al. 1997; Haney 1999; Higgelke and MacLeod 2000; Imbeau et al. 1999; Poulin 2008; Poulin et al. 2020; Schieck et al. 1995; Shaffer and Alvo in Gauthier and Aubry 1996; Tyler 1914; Venier and Pearce 2005; Wiggins 2005; Zarnowitz and Manuwal 1985).

Presence of breeding Brown Creepers appears to be correlated with the amount of forest habitat in the general area. In Alberta and the mid-Atlantic states, it was positively associated with the amount of forest within 2 km. In New York, it was found mostly in areas with at least 50% forest cover (Higgelke and MacLeod 2000; Robbins et al. 1989; Shaffer and Alvo in Gauthier and Aubry 1996). In Ontario, it regularly breeds in landscapes with 20-30% forest cover. In southern Ontario, its probability of detection was positively correlated with the amount of forest cover 100 m or more from edge, but negatively correlated with woodlot size, amount of forest cover within 2 km, and amount of regional forest cover; these relationships were not significant (Austen et al. 2001).

Several studies identified microhabitat requirements of the Brown Creeper. Many authors concluded that it needs a closed-canopy forest. In Alberta, canopy closure less than 20% was unsuitable habitat and 80-100% canopy closure was optimum (Higgelke and MacLeod 2000; Poulin et al. 2020; Thompson and Capen 1988; Wiggins 2005). It may require openings in the canopy to allow light penetration to the nest (Shaffer and Alvo in Gauthier and Aubry 1996). In a Michigan study area, light penetrated to each nest site due to the presence of dead trees, a road opening, swamp clearing, or the position of the nest tree on a stream bank (Davis 1979). In Idaho, canopy height and density were important predictors of Brown Creeper occupancy. Density of the upper canopy was the most important variable, although mean tree height and height variability were also important. The upper canopy was twice as dense at occupied sites as unoccupied sites (26.38 compared with 13.78 light detection and ranging hits). Mean tree height was almost 50% higher at occupied sites (12.17 m) than unoccupied sites (8.20 m; Vogeler et al. 2013). In northeastern mixed woods, the Brown Creeper's abundance increased with abundance of yellow birch and sugar maple (Temple et al. 1979). In South Dakota and Wyoming, its abundance was highest where spruce was the dominant tree. Its density increased as the percentage of spruce in the canopy increased from 0% to 80% (Matseur et al. 2019). In the mid-Atlantic states, its presence was positively associated with basal area (BA) and negatively associated with the density of trees smaller than 3 cm DBH and the number of trees near the detection site (Robbins et al. 1989). In Vermont, microhabitat characteristics included 42.7% ground cover, 9.1% of ground covered by slash, 84.4% canopy closure, 26.3 m canopy height, 14.5 m canopy depth, 12.6 m^2 BA of deciduous trees, 8.8 m^2 BA of coniferous trees, average DBH of deciduous trees 15.4 cm, and average DBH of coniferous trees 19.1 cm. Thompson and Capen (1988) considered the Brown Creeper typical of forest cover with moderate understorey coverage.

Presence of water may be a habitat requirement. Many nests have been in beaver ponds or flooded swamps, or close to a watercourse. All nests found in a Michigan study area were either in swamps with standing water or within 60 m of a stream. Wet conditions are more conducive to producing snags, so the Brown Creeper's affinity with water may be more a function of availability of nest sites. It does appear to prefer cool, moist microclimates (Davis 1979; Higgelke and MacLeod 2000; Palmer-Ball and Haag 1989; Poulin et al. 2020; Shaffer and Alvo in Gauthier and Aubry 1996).

The Brown Creeper is an area-sensitive species. In southern Ontario, anecdotal information suggests that it requires forests that are a minimum of 30 ha. It is possible that smaller woodlands may be used in heavily forested landscapes. Minimum forest sizes have been defined as 50 ha in Connecticut and 100 ha in Wisconsin and Wyoming. In Kentucky, the only known breeding area was in a 200-ha swamp, the largest swamp of its type in Kentucky (Palmer-Ball and Haag 1989; Poulin et al. 2020). In the Seattle area, it was most abundant at the 3 study sites with the highest percentages of forest cover and largest forest patches, and its abundance was correlated with snag density (Blewett and Marzluff 2005).

Most researchers consider the Brown Creeper a forest-interior species that avoids forest edges and openings. In Alberta, Higgelke and MacLeod (200) concluded that it was sensitive to the presence of clearings within 100 m of the nest, and reported that its probability of detection was inversely related to the amount of early successional habitat within 1 km. In California, it reached

highest densities 400 m from edge. It was estimated that the edge width for it was 85 m. In Oregon, it stayed further from forest edge (average 252 m) than any other cavity-nesting species. Another California study found that it was more abundant in sites with less high-contrast edges. It avoided soft edges (edges between patches of differing habitat quality for the species) and moderate edges. Average distance of nests from different edge types was 62 m for soft edges, 87 m for moderate edges, and 80 m for hard edges. Successful nests were in large-diameter trees and snags in forests with lower canopy volume and further from moderate and hard edges than unsuccessful nests. It showed clear negative responses to edges in terms of abundance, nest location, and nest survival. Nesting at forest edge has been observed in Ontario and Massachusetts (Brand and George 2001; Chadbourne 1905; Inman et al. 2002; Peck and James 1987; Poulin et al. 2020; Purcell et al. 2012; Wiggins 2005). Lindell et al. (2007) summarized studies that determined the abundance of the Brown Creeper in relation to forest edge. Two studies found that it demonstrated no response to edge; a third study found that it avoided edge. Nichols (1948) reported nesting in an unusual area in New York. Nests were in trees 1.8 m from the edge of a frequently used driveway. The habitat was an open area surrounded by lawns and scattered ornamental trees such as Norway spruce.

The habitat of the Brown Creeper may be summarized as large mature to old-growth forests with a closed canopy and numerous large trees and snags. There are exceptions including burns and clear-cuts where there are residual snags among new growth and some retained larger trees.

Limited information is available on Brown Creeper roost sites. In Michigan, a group of recently fledged creepers roosted on a tree trunk that was sheltered by other trees. They roosted in a tight circle with their bills pointing inward. A different tree was used as a roost each night and adults roosted separately from the young. Winter roosts may be used more permanently and human-made structures may be used as well as trees. In Colorado, creepers roosted during winter in groups of 2 or 3 in a Russian olive, where they squeezed into a crack or scar in the bark. The same tree was used 2 consecutive winters (Davis 1979; Poulin et al. 2020). In New York, 2 roosted for over a month beside the chimney of a house. The birds roosted beside a wasp nest that afforded protection, and pushed their bills straight up into the wood of the overhanging roof (Stone 1950). Other winter roost sites include on the rough stucco of a house near the front door (this roost was used by 2 birds for 2 winters); 1 roosted for 1 night in the rough bark of a large white ash; 11 roosted in a hollow beam at the end of a barn; 4 roosted regularly on the side of a building a short distance from a door and subsequently moved to the bole of a hollow elm 40 m away (Fitch 1958; Tyler in Bent 1948).

Most Ontario nests were in dead trees and stubs, although 1 was in a living tree, 2 were in fence posts, and 1 was behind a piece of tin under the roof logs of an outhouse. Most nests (91.3%) were in loose bark of trees, with 5.2% in cavities in tree trunks and 3.4% in splits in tree trunks. All but 1 nest were placed against the main trunk of a tree, with the other against a large limb. Most nests were built between loose bark and the tree trunk. Slightly more nests (54.9%) were in deciduous trees than conifers. The most common nest trees, in order of abundance, were elms, spruces, balsam fir, and pines. The DBH of nest trees was 15-41 cm. Nests were 0.6-12 m from the ground, with most 1.4-3.7 m up (Peck and James 1987, 1997). In Algonquin Park, small-diameter trees are occasionally used for nesting and nests are sometimes placed in cracks in tree trunks (Tozer 2012).

Of 248 North American nests, over 95% were in dead trees, nest height ranged from 0.2 to 22.5 m, and nest tree DBH varied from 15 to 103 cm. Of 273 New Brunswick nests, 72% were in balsam fir, 12% in maple, 6% in yellow birch, 5% in beech, 4% in spruce, and 1 was in white cedar. Ninety-eight percent of nests were in snags and the mean DBH of nest trees was 32.3 cm. In addition to the tree species used in Ontario, the Brown Creeper has nested in white cedar, large-toothed aspen, red and silver maple, and chestnut, black and white oak. It rarely uses bluebird boxes. In British Columbia, it uses artificial structures built especially for it, consisting of slabs of wood attached to a tree to create a cavity. Most natural nests are attached to bark that has pulled away from a tree trunk, but a few are in natural cavities created by lightning strikes or other stresses, or abandoned chickadee or woodpecker holes. Unusual nest sites include behind a wooden grill, in a stack of concrete blocks, under loose roof shingles, beneath a piece of channel iron on a wooden utility pole, and behind window shutters. These latter nests demonstrate that it does not always nest in forested habitat. It has been observed nesting in the same tree in 5 consecutive years, but all were in different locations. In California, 12 nest sites were reused in a subsequent year, but it was not stated if old nests were reused (Base 1989; Betts 1909; Bradbury 1919; Campbell et al. 1997; Chadbourne 1905; Cunningham et al. 1980; Davis 1979; Hall and Laitsch 1963; Higgelke and MacLeod 2000; Kennard and McKechnie 1905; Li and Martin 1991; Meyer 1913; Nichols 1948; Palmer-Ball and Haag 1989; Poulin et al. 2020; Purcell et al. 2012; Tyler 1914; Tyler in Bent 1948; Wiggins 2005; Zarnowitz and Manuwal 1985). In the Seattle area, the Brown Creeper nested in snags that were more decayed than random snags, and nested in snags with any kind of fungus less often than expected by chance (Blewett and Marzluff 2005).

Little information is available on territory size, on what areas are defended, or if territories are exclusive. In Ontario, average territory size was 1.0 ha (range 0.73-1.29 ha) in coniferous forest dominated by balsam fir and black and white spruce north of Lake Superior. Few observations were made of individual birds, and territories may have been as large as 2 ha. Territory size of 1 pair in Quebec was 0.47 ha. In northeastern Minnesota and adjacent Ontario, average territory sizes were 0.01-0.025 ha in postfire, mature, and old-growth mixed-woods. Small territories were related to high densities. In red spruce forests in Maine, mean territory size was 1.34 ha. In Michigan, territories were 2.3-6.4 ha. In northern hardwoods, the mean territory size was 4.2 ha (range 2.3-9.4 ha). In Massachusetts, adults rarely moved more than 10 m from the nest to obtain food for nestlings (0.03 ha), but in Michigan, territories were expanded as adults moved as far as 150 m to obtain food for nestlings. After fledglings leave the nest, the family may range 150-500 m from the nest, but it is unknown if any of this area is defended. No information on home range size is available (Chadbourne 1905; Kendeigh 1947; Morse 1977; Poulin et al. 2020; Shaffer and Alvo in Gauthier and Aubry 1996; Wiggins 2005).

No information is available on natal dispersal or philopatry, or on adult site fidelity to breeding or wintering sites (Poulin et al. 2020).

Limiting Factors

Eggs have been reported in Ontario nests from the last week of April until mid-July, with most present from the last week of May until mid-June. Young were present in a Nipissing District nest on 9 August, suggesting a later egg date (Peck and James 1997). In Algonquin Park, nests are under

construction from early May to late June, eggs are present from mid-May to early July, nestlings are present from late May to late July and rarely to early August, and dependent fledglings have been observed from early June to late July (Tozer 2012).

The female may take 6-30 days to build the first nest, but usually 7-14 days. Nests for second or third attempts are usually built in 6 or 7 days. Eggs are laid at the rate of 1 a day; laying may start the morning after the nest is completed. Incubation begins with the laying of the last egg. The incubation period at 1 Ontario nest was 13-14 days. Elsewhere, the incubation period has been reported as 11-17 days, with 15 days most frequent. All eggs typically hatch on the same day. The young fledge when they are 13-20 days old, but mostly at age 15-17 days (Davis 1979; Peck and James 1987; Poulin et al. 2020; Shaffer and Alvo in Gauthier and Aubry 1996; Tyler in Bent 1948; Wiggins 2005). Nesting activities within a given area may be highly asynchronous. In a small Michigan study area, 1 female had just finished building her nest while another was laying eggs, 1 female was incubating, and 1 nest contained 14-day-old nestlings (Davis 1979).

A single brood is raised annually. Earlier records of second broods were based on unmarked birds and probably represented different pairs. Renesting may occur about a week after the loss of the initial nest. Clutches of 4-8 eggs have been reported in Ontario, with most containing 4-6 eggs. This is typical throughout the Brown Creeper's range. The average size of North American clutches was 5.48 eggs; the mode was 6 eggs in Michigan (Campbell et al. 1997; Davis 1979; Nichols 1948; Peck and James 1997; Poulin et al. 2020; Tyler in Bent 1948; Wiggins 2005).

The age at first breeding has not been confirmed, but is thought to be 1 year. The mating system is monogamous and no cases of polygyny have been reported. Resident birds may remain paired year-round but migratory birds pair in early spring (Poulin et al. 2020; Wiggins 2005).

The Brown Creeper forages almost exclusively on the trunks of large trees and, to a lesser extent, on large branches. It occasionally forages on medium-sized and small branches and rarely on the ground. Although it forages on a wide range of tree sizes, larger trees are actively selected. Large tree trunks are more deeply furrowed and support a higher density of arthropods than smaller trees. Energy intake may be increased by foraging on 1 large tree instead of several small ones. In Washington, it was estimated that it would have to forage on 13 young trees (29 cm DBH) or 3.3 mature trees (67 cm DBH) to obtain the same amount of spiders as present on 1 old-growth tree (112 cm DBH). It was estimated that a minimum of 100 stems per ha of trees at least 25 cm DBH are required to support foraging Brown Creepers, but 500 stems per ha or more are necessary to support maximum densities. Its typical foraging strategy is to land at the base of a tree trunk and move upward either in a spiral pattern or straight up. When a branch is encountered, it may either move around it, or forage on the underside. Bases of dead limbs are favoured for foraging because they often support high densities of invertebrates. Most foraging occurs at heights of 9 m or less, but occasionally to the treetop. Once 1 tree has been scaled, it usually flies to the base of another large tree and repeats the process. Live and dead trees are typically used in proportion to their availability, and limbs that are used for foraging are usually larger than 5 cm in diameter. Tree species does not appear to be of importance, with tree size being more critical. In western North America, most foraging occurred on conifers. In Pennsylvania and Illinois, oaks, hackberries, elms, and pines are widely used, as are spruces and maples in Ontario (personal observation). It obtains most of its food

by probing, pecking, and gleaning. It rarely hawks insects (Adams and Morrison 1993; Franzreb 1985; Higgelke and MacLeod 2000; Lundquist and Manuwal 1990; Poulin et al. 2020; Tyler in Bent 1948; Weikel and Hayes 1999; Wiggins 2005).

Nestlings are fed small invertebrates exclusively. Ten-day-old nestlings in Michigan were fed click beetles, harvestmen, and mayflies. Invertebrates provided to young included ants, beetles, moths, spiders, and mayflies. Nestlings in New Brunswick were fed lepidopterans (mostly moths), spiders, and fly larvae, although smaller items could not be identified. During the breeding season, adults feed solely on invertebrates, especially insects, spiders, and pseudoscorpions. Most food items are less than 3 mm in length. In California, 62.8% of the diet consisted of beetles, 12.9% was unidentified, 9.7% was pseudoscorpions, 7.5% bugs, 1.0% flies, and 0.4% hymenopterans. Insects consumed included stink bugs, beetles (weevils and long-horned, bark, and leaf beetles), dark-winged fungus gnats, lepidopterans including caterpillars and codling moth pupae, lacewings, caddisflies, aphids, leafhoppers, scale insects, ants, sawflies, katydid eggs, and leaf skeletonizers (Davis 1979; Franzreb 1985; Poulin et al. 2020; Tyler in Bent 1948; Wiggins 2005). Crawford and Jennings (1989) examined 2 Brown Creeper stomachs in New Hampshire and Maine and found that they had not ingested any spruce budworms. In New Brunswick, there was no relationship between the abundance of the Brown Creeper and spruce budworms (Morris et al. 1958).

In 2005, a nest was found in Norfolk County that was parasitized by the Brown-headed Cowbird. This was the first record of cowbird parasitism of the Brown Creeper in Ontario. Parasitism is rare, with only 3 reports previous to the Ontario record (Davis 1979; Peck and James 1987; Peck and Peck 2006; Poulin et al. 2020).

Forest fragmentation and timber management may be the greatest limiting factors to the Brown Creeper. Due to its area sensitivity, it is vulnerable to forest fragmentation. In Wyoming, forest fragmentation resulted in greater declines of the Brown Creeper than any other species known to be old-growth specialists. It is sensitive to almost all types of forest management. Abundance decreases with decreasing canopy closure, lower density of large mature trees, and lower density of snags. Almost all types of logging, including fuelwood removal, have negative effects on all these factors. There may even be negative effects with selective thinning where snags are retained. In Pennsylvania, its density was higher in timber stand improvement areas where snags were retained than areas where snags were removed. No comparison was made to densities in areas where thinning did not occur. Without exception, paired comparisons of its abundance or presence in logged versus nearby unlogged forests indicated strong negative impacts from logging. Retaining large patches of forest with old-growth characteristics significantly increases habitat suitability. Patches of residual trees in clear-cuts are typically not used. Past logging may have affected populations and its distribution in eastern North America. The current range may be limited by where logging occurred between 1880 and 1930 (Franzreb 1985; Higgelke and MacLeod 2000; Poulin et al. 2020; Shaffer and Alvo in Gauthier and Aubry 1996; Stribling et al. 1990; Wiggins 2005). In the Canadian Shield of Ontario, there was no difference in its abundance in early successional clear-cuts and burns, but it was significantly less abundant in mid-successional clear-cuts than in mid-successional burns. It was significantly less abundant in early successional and mid-successional stands than in mature stands (Zimmerling et al. 2017). Vanderwel et al. (2007, 2009) summarized

studies that examined the effects of partial timber harvest in the Boreal Forest Region. Abundance of the Brown Creeper decreased when 30% and 50% of trees were removed, and it became locally extirpated when 70% of trees were removed. It experienced a 25% decrease when 20% of trees were removed, a 50% decrease when 35% of trees were removed, and a 75% decrease when about 50% of trees were removed. It was the second-most sensitive species to tree removal to the Ovenbird. Rempel et al. (2007) modelled the response of the Brown Creeper to forest harvesting in the Boreal Forest Region of Ontario. They predicted a population decline over 100 years even if all current forest management guidelines were implemented. They concluded that boreal forest management should create clustered areas of high edges separated by large areas of intact forest matrix to support the full suite of birds that inhabit the Boreal Forest Region. Intact areas are required to maintain Brown Creeper habitat. In Algonquin Park, Tozer et al. (2010) found that typical and intensive group-selection harvesting of trees had no effects on the Brown Creeper. Jobes et al. (2004) also found no significant effects on it due to partial harvesting in Algonquin Park. Geleynse (2013) observed contrasting effects of logging on the Brown Creeper in Algonquin Park. Its density was significantly lower in 4 silvicultural treatments, including intensive group-selection, typical group-selection, old single-tree selection, and recent single-tree selection. Nest trees were significantly closer to forested wetlands than randomly selected trees in all stands. In unlogged stands, it nested further from forested wetlands and in greater numbers in upland hardwoods than in logged stands. Densities declined in harvested upland hardwood forests due to loss of nesting habitat. In the Carolinian Forest Region of Ontario, the Brown Creeper was the only species that responded negatively to partial harvesting. It was absent in heavy cuts and rare in standard cuts (Holmes et al. 2004). In the Seattle area, its density in forests managed for timber production was 2.2 times higher than in suburban forests. Productivity was greatest where the percentage of forest was low but aggregated, and where snag densities were high (Blewett and Marzluff 2005).

The Brown Creeper often responds positively to fires that leave large snags, insect and disease outbreaks, and windthrow provided that these are not too severe. The positive response is usually short-lived and is related to bark-retention times on dead and dying trees. Overall, the loss of large trees to exotic insects and diseases and the eventual loss of snags could be a significant limiting factor in the east (Burris and Haney 2005; Mossman and Hoffman 1989; Poulin et al. 2020; Wiggins 2005). In South Dakota and Wyoming, its abundance was positively correlated with the percent area of 4-5-year-old wildfires. It also increased as the density of trees killed by beetles increased from 0 to 16% (Matseur et al. 2019).

Cold, wet weather during the breeding season may reduce reproductive success and some nests may become weakened and fall during prolonged rain. During the 1950s, the Brown Creeper was adversely affected by spraying of DDT to control Dutch elm disease, but there are no recent known impacts from pesticides or other contaminants (Davis 1979; Poulin et al. 2020; Wiggins 2005).

Status

It is probable that the Brown Creeper population declined with European settlement and subsequent forest fragmentation and lumbering. McIlwraith (1894) reported that it was observed in all seasons, but was rare during the breeding season. Baillie and Harrington (1937) stated that it bred sparingly from Middlesex and Welland counties north to the transcontinental railway line and

westward to Lake of the Woods. In Elgin County, it was only observed during migration in the 1890s, but was a rare breeder in 1954 and 2000 (Lancaster et al. 2004). During the first atlas, its distribution in the south was discontinuous due to its habitat requirements, and it was uncommon where it did occur. In the north, it appeared to be fairly common (Blomme in Cadman et al. 1987). James (1991) considered it a rare and local breeder in the agricultural south, uncommon north to Big Trout Lake and Moosonee, and rare north to Sutton Lake.

The second atlas revealed that there had been a range expansion and increase in abundance of the Brown Creeper since the first atlas. Its range extended much further northward to cover almost all of the Hudson Bay Lowland. It is uncertain if this represented a true range expansion or was an artifact of better coverage during the second atlas. Its probability of observation increased significantly province-wide and in the Canadian Shield and Hudson Bay Lowland. There was a nonsignificant increase in the Great Lakes–St. Lawrence Forest Region south of the Shield. There was a nonsignificant decline in the Carolinian Forest Region. In the south, there were noticeable increases in the number of squares occupied in the Sudbury to Sault Ste. Marie area and in the agricultural areas of Bruce, western Grey, Perth, and Middlesex counties. It was most abundant in Algonquin and Quetico parks, the Algoma highlands, and in northwestern Ontario from Woodland Caribou to Wabakimi parks. These are parks where logging is not permitted or are north of where logging occurs, so they support more mature trees (McLaren in Cadman et al. 2007).

Breeding Bird Survey data for 1970-2021 indicated annual increases of 0.74% in Canada and 1.71% in Ontario. Short-term (2011-21) trends included annual decreases of 0.828% in Canada and 2.01% in Ontario. All trends were of medium reliability except that the short-term trend for Ontario was of low reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Fledglings often split into 2 groups, with one following each parent. Parents continue to feed young 17-26 days after fledging. In Michigan, fledglings remained within 500 m of the nest site for at least 17 days postfledging. The family unit breaks down before autumn migration (Davis 1979; Poulin et al. 2020).

MIGRATION

In the east, the Brown Creeper is highly migratory. In the west, it tends to be a resident with seasonal movements related to changes in altitude. It occurs in Ontario during winter, but it is unknown if wintering birds are those that remained on their breeding grounds or those that retreated from more northerly sites. Northern populations appear to migrate longer distances than more southerly ones. Migration is known to occur at night, but it is possible that daytime movement may also occur (Poulin et al. 2020; Wiggins 2005). Banding records suggest that birds may fly directly over Lake Erie (Brewer et al. 2018).

Spring migration begins in Ontario in early April or very late March and continues until mid-May. Autumn migrants appear in the first week of September. Autumn migration is much more leisurely and birds may still be moving south in mid-November (Curry 2006; LaForest 1993; Lancaster et al. 2004; Mills 1981, 2005b; Weir 2008).

During migration, the Brown Creeper still prefers wooded areas, but has less stringent habitat requirements. While migrating, it may occur in most wooded areas that have intermediate-aged to mature trees, in suburban woodlands and treed lots, and in rural lots with large trees. When large numbers occur at Presqu'ile during migration, it may occur almost anywhere, including on the beach and in marshes. Small numbers (usually 1 or 2) may occur in flocks of chickadees, nuthatches, and kinglets (Campbell et al. 1997; LaForest 1993; Lancaster et al. 2004; Poulin et al. 2020). In Pennsylvania during autumn migration, it occurred at low densities with no significant differences among habitats. In order of decreasing abundance, it occurred in forest interior, suburban forest, forest edge, and forest-agricultural edge. It was absent in shrub and sapling-stage forests (Rodewald and Brittingham 2002). During autumn migration on 2 islands in the Gulf of Maine, it was significantly more abundant on a forested island than on one dominated by shrubs (Suomala et al. 2010).

Tall buildings and communication towers may be a significant source of mortality during migration. From 1993 to 1998, 434 collisions with Toronto office towers were reported, with 147 resulting in death. The Brown Creeper is one of the more common species that collides with Toronto office buildings. Collisions with tall towers are also common; 12 deaths occurred in an hour at 1 Illinois television tower (Poulin et al. 2020; Wiggins 2005). In the United States, the Brown Creeper was among the 20 most vulnerable species for striking any type of building, being 26.2 times more likely to suffer a collision than species on average. It was on the top 20 list of most vulnerable species to collide with each type of building: 81.1 times more likely than average to strike a residence 1-3 stories tall, 44.8 times more likely to strike a low-rise, and 44.3 times more likely to strike a high-rise than average (Loss et al. 2014).

Mills (2005b) examined spring and autumn migration timing for the Brown Creeper at Long Point 1975-2000 in relation to global warming. It arrived significantly earlier during this period at a rate of 4.1 days per decade and significantly delayed autumn migration at a rate of 5.8 days per decade.

In most of the province, the Brown Creeper is uncommon to common during migration, but it may be locally abundant in key migratory stopover areas. Daily spring counts may be as high as 500-650 at Prince Edward Point and Presqu'ile (James 1991; LaForest 1993; Weir 2008).

WINTER

The Brown Creeper is one of about only 45 species that winters in the Boreal Forest Region in Canada. Winter habitat is similar to breeding habitat, although younger forests, suburban forests, and treed rural and residential lots may be visited (Erskine 1977; Poulin et al. 2020). Densities of Brown Creepers per km^2 reported on Winter Bird-Population Studies in southern Ontario were 8.1 in rural forests, 3.8 in mixed rural habitats, 1.6 in urban natural areas and urban natural areas with open water, 0.4 in urban natural areas smaller than 10 ha, and 0.1 in cities. It was not reported from open farmland (Smith 2003). At Presqu'ile, it occurs most frequently in coniferous plantations (LaForest 1993). In California, wintering Brown Creepers were positively associated with tall trees and negatively correlated with human structures and roads (Kalinowski and Johnson 2010). In Missouri, its density increased with increased tree stocking. It was present in savannahs, woodlands, and forests, but its density increased 75% from the more open savannah habitats to forest cover

(Kendrick and Thompson 2013). In New Jersey pine barrens, it was more common in pine-dominated habitats than in those dominated by oaks, but not significantly (Brush 1989).

During autumn migration and shortly after arrival in the wintering area, the Brown Creeper may be gregarious. As winter progresses, it becomes solitary and agonistic and may defend a territory. Once settled into an area for the winter, individuals remain in the general vicinity and may be seen in the same tree for periods of days or weeks (Dunn and Tessaglia-Hymes 1999; Fitch 1958; Poulin et al. 2020).

Winter foraging may occur singly or in small monospecific flocks, but often in mixed flocks. The Brown Creeper frequently occurs in flocks of woodpeckers, chickadees, titmice, nuthatches, and kinglets. It is strongly associated with the Red-breasted Nuthatch and the Golden-crowned Kinglet (Fitch 1958; McIlwraith 1894; Poulin et al. 2020; Tyler in Bent 1948; Wiggins 2005). Webber (1986) studied winter foraging sites of the Brown Creeper. All tree species present were used for foraging, but not in proportion to their availability. Ash, oak, and walnut were selected over hackberry and maple. The size of trees it used was negatively correlated with temperature. As temperatures decreased, larger diameter trees were used almost exclusively for foraging; smaller trees were used as temperature increased. Birds ascended trees in the typical spiral pattern regardless of temperature and wind velocity. Kendrick and Thompson (2013) reported similar results in Missouri and found that its detectability increased with temperature and was negatively affected by wind.

The Brown Creeper's winter diet is similar to that of the breeding season, with a heavy reliance on insects. In Illinois, the diet consisted of 80% animal material, including 57.2% bugs, 12.4% adult beetles, 4.4% ants, 11.6% spiders, and 2.8% other groups. Vegetation consumed included corn and fragments of acorns. Small amounts of pine seeds and grass seeds may be eaten in winter (Poulin et al. 2020; Tyler in Bent 1948; Williams and Batzli 1979).

Only about 20% of winter bird feeders are visited by the Brown Creeper, and rural feeders are visited most frequently. Most food taken from feeders consists of tiny crumbs of seeds, including niger or suet that other birds have left behind. Favourite feeder foods are suet, bird puddings, and peanut butter mixes. Infrequently consumed items include pieces of sunflowers, water, and possibly peanut hearts and baked goods (Dunn and Tessaglia-Hymes 1999; Mills 1981; Tyler in Bent 1948).

Food caching appears to be a rare winter behaviour. Lima and Lee (1993) observed Brown Creepers caching small bits of sunflower kernels taken from a feeder. This occurred on 5 different dates and more than 1 bird was involved. Food items were carried singly to a nearby tree with a trunk diameter of 20-30 cm and carefully pushed upwards into a crevice in the bark. Caches were scattered 4-6 m from the ground in a single tree or a set of adjacent trees. Birds typically cached 3-10 items in rapid succession at the end of a visit to the feeder. No attempt was made to cover caches, but they were well concealed. This is the only case of caching that has been reported.

The Brown Creeper appears to be vulnerable to severe winter weather, which may result in poor overwinter survival and reduced populations the next breeding season. After a severe winter storm in Illinois, populations declined by 15.8% in bottomland forests and 38.1% in upland forests. Although no carcasses were found, it was suspected that higher than normal mortality occurred.

Declines in abundance in some habitats were not compensated for by increases in other habitats (Graber and Graber 1979).

James (1991) considered the Brown Creeper a rare winter resident in the south that occurred west to Thunder Bay.

Christmas Bird Count data indicate that the Brown Creeper increased in Ontario at annual rates of 0.41% 1970-2021 and 2.81% 2009-2021 (National Audubon Society 2022).

Blue-gray Gnatcatcher

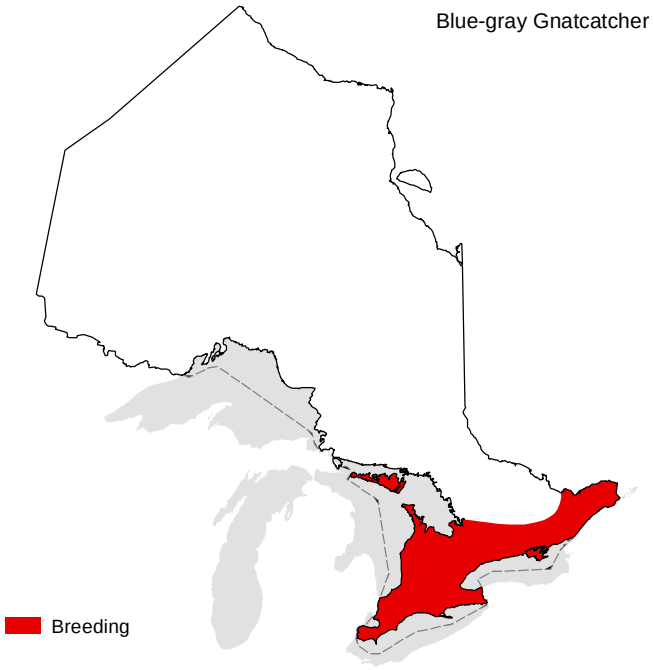
Polioptila caerulea

BREEDING SEASON

Habitat Requirements

In Ontario, the Blue-gray Gnatcatcher nests most frequently in deciduous forests (55.8% of nests) and mixed woods (27.9%), and less often in riverbank groves (9.3%), shrubby fields (4.7%), and swales (2.3%). It exhibits no apparent preference for upland or wetland habitat. Nests were often (41.9%) near openings such as paths, roads, clearings, streams, and lakes (Peck and James 1987). Lancaster et al. (2004) reported that it nested throughout Elgin County in woodlands, particularly along watercourses and in wooded swamps. McCracken (in Cadman et al. 2007) stated that it seemed to favour open-canopied deciduous swamps and floodplain forests.

Throughout its range, the Blue-gray Gnatcatcher nests predominantly in forested areas, but also in shrubby areas and rarely in suburban areas. It often nests in open shrubby habitat and forages in denser areas. It greatly prefers deciduous cover, but occurs in mixed woods less frequently. Conifers tend to be avoided except in the southeastern states where it may occur in pine stands. In the southeast, it is most abundant in forested river bottoms and upland pine woods with an understorey of oaks. In New Jersey, it was equally abundant in oak-pine forests and hardwood swamps. In Indiana, Illinois, and Kansas, it inhabits open shrub and woodland areas as well as lowland forests. In the northeastern states, it exhibits a marked preference for tall, mature trees in closed-canopy forests



along river floodplains. In the Midwest, its abundance was significantly associated with tree height. Its maximum density was at tree heights of 16 m, declining to about 70% at 22 m. In Illinois, it is most prevalent in riparian woods where it usually occupies the first level above the floodplain. Similar preferences were noted in Michigan where it was most abundant in the forested band adjacent to rivers. Densities decreased toward the upland forest further from the riparian habitat. When populations declined in Illinois, upland forests were deserted but densities in riparian woodlands remained constant suggesting that upland habitat was marginal. Kansas birds showed a preference for more open, drier situations, nesting in large honey locusts and elms in fields, in shrubby growths of chinquapin oaks and dogwoods, and less frequently in oak-hickory woodlands. In much of the mid-Atlantic states, it is strongly associated with oak and oak-hickory forests, predominantly white oak. Other habitats it has used for nesting include green ash and silver maple swamps in Vermont, silver maple–black ash and swamp white oak–black ash swamps in Wisconsin, white birch–basswood stands in Pennsylvania, red maple swamps in Rhode Island, and pine and oak barrens on river terraces in Wisconsin. Breeding habitat in Quebec included a silver maple–black ash swamp adjacent to a lake, a red oak stand beside a lake, a floodplain stand of swamp white oak, and a mature gray birch thicket in a field reverting to forest (Darveau in Gauthier and Aubry 1996; Fitch 1958; Golet et al. 2001; Graber et al. 1979; Grundel and Pavlovic 2007b; Inman et al. 2002; Kerschner and Ellison 2020; Mossman et al. 1991; Raynor 1964; Rich et al. 1994; Root 1967; Weston in Bent 1949).

Some studies documented microhabitat requirements of the Blue-gray Gnatcatcher. It appears to prefer more open-canopied forests with an open understorey layer. In Illinois, vegetation species composition, stem density, and basal area did not correlate with population abundance (Graber et al. 1979). In Utah, Whitmore (1977) considered the Blue-gray Gnatcatcher a habitat generalist, preferring moderate numbers of trees, shrubs, and ground cover. In Kansas, it was least frequent in oak-hickory woodlands that had a dense leaf canopy (Fitch 1958). In Vermont, it showed nonsignificant tendencies to select sites with lower basal area and tree density than in adjacent parts of the territory. Site characteristics were apparently more important than tree species (Kerschner and Ellison 2020). In Tennessee, Anderson and Shugart (1974) usually observed it in the upper canopy, but it selected habitat on characteristics of understorey biomass (foliage and branch biomass of trees 1.2-8.4 cm diameter at breast height [DBH] and bole biomass of trees 8.5-22.8 cm DBH) and the average size of canopy trees (foliage, branch, and bole biomass of trees larger than 22.8 cm DBH and stump biomass of trees 8.5-22.8 cm DBH). It occurred most frequently in areas with

an open understorey and large trees forming a canopy of approximately average biomass. Both conditions had to be satisfied for habitat to be suitable. In the mid-Atlantic states, its presence was positively correlated with canopy height and negatively correlated with slope and the number of dead standing trees larger than 3 cm DBH (Robbins et al. 1989). In Maryland, its abundance was negatively correlated with canopy closure and forest isolation (Lynch 1987). In Wisconsin, it occurred most frequently in intermediate stands on a moisture gradient and was not common in either mesic or xeric stands. This study was conducted entirely in upland areas. As the size of woodlots increased, its peak of abundance occurred in more xeric stands suggesting that there was a delicate balance between its response to woodlot size and vegetational conditions. It had a broader amplitude of habitat conditions than most species (Bond 1957). In California, it was significantly more abundant in oak savannahs with shrubs and montane oak stands than in oak savannahs with grass. Its abundance in oak woodlands was intermediate between these habitats. It was positively associated with coverage by hardwoods, shrubs, and conifers and negatively correlated with herbaceous cover and tree size (Wood et al. 2013).

The Blue-gray Gnatcatcher is typically considered an area-sensitive species, but not all studies support this. Hayden et al. (1985) did not consider it area sensitive, but had very few detections of it. In South Carolina, Kilgo et al. (1997) found no significant differences in detection rates in different-sized woodlots. Its probability of detection was 71% in hardwood stands as small as 0.5 ha. In Wisconsin upland stands, it was at least 50% more common in large than small woodlots and Bond (1957) concluded that it showed a preference for large woods. Frequency of occurrence was 6.2% in 6.1-14.2-ha woodlots, 17.4% in 16.2-32.4-ha woodlots, and 23.0% in stands larger than 32.4 ha. In Pennsylvania, its abundance was positively associated with larger woodlands. Robbins et al. (1989) considered it area sensitive in the mid-Atlantic states. Its probability of occurrence was greatest in forests larger than 3,000 ha and the probability dropped to 50% in 15.0-ha woodlots. The 3 smallest woodlots in which it was detected at least twice were 6.8, 10.1, and 23.0 ha. Kerschner and Ellison (2020) concluded that it may have specific microhabitat needs in upland forests, such as stream valleys and canopy openings that limit numbers rather than the species having requirements for large forests. They concluded that the area sensitivity of the Blue-gray Gnatcatcher needed further study.

Hodges and Krementz (1996) studied the abundance of the Blue-gray Gnatcatcher in riparian forests of different widths in Georgia. It was more abundant in medium-sized than narrow or wide corridors, but these differences were not significant. Its probability of observation was 82% in 50-m wide corridors, 83% in 100-m wide corridors, 86% in 200-m wide corridors, 92% in 500-m wide corridors, and 94% in 1,000-m wide corridors.

Somershoe and Chandler (2004) considered the Blue-gray Gnatcatcher a forest-interior species, but other authors considered it an edge or a forest edge–interior species (Golet et al. 2001; Harrison and Kilgo 2004; Hayden et al. 1985; Mossman and Hoffman 1989). In South Carolina, it was 6-7 times more abundant in small forest gaps or at forest edges during the spring migration, breeding, and postbreeding seasons than in forest. It occurred exclusively in edge and gaps during autumn migration. Bowen et al. (2007) considered it a forest edge species. In Tennessee, it exhibited regularly spaced peaks and lows of densities in relation to edge indicating that territories lined up parallel to

the edge of the forest. The density of territories was not significantly greater near edge than in deeper forest, although 18 territories were found within 268 m of edge compared with 6 territories 268-488 m from edge (Kroodsma 1984). Kerschner and Ellison (2020) concluded that it often occurred at or near habitat edges. In Ontario, the Blue-gray Gnatcatcher is not confined to forest interior. It may occur throughout forested habitat but is more prevalent at edges and forest openings, and may also occasionally breed in shrubby areas or small groves of trees (Peck and James 1987).

Most Ontario nests were in trees but 2 were in vines. Deciduous trees were selected for nest sites (94.1% of nests) over conifers and all but 1 nest tree was alive. Nest-tree species in descending order of abundance were oaks, ashes, maples, and birches. Nests were usually saddled on horizontal or near-horizontal branches (64.3%) and less frequently in crotches (35.7%). Eight nests were at knots, branch junctions, and vertical branches, or were under overhead branches or leafy twigs. The supporting limbs of 7 nests were dead. Nest limbs were 2.2-7.6 cm in diameter. One nest was at the trunk of the tree; 8 were 0.1-3.0 m distant, mostly 1.8-2.7 m from the trunk. Nests were 0.6-26 m from the ground, with most 6.7-12 m up (Peck and James 1987, 1997). Peck and James (1997) and Crins (2001) documented 4 instances of materials being taken from an old nest to build a new one. The nest reported by Crins (2001) was in a crack willow. A nest near London was 2 m from the ground on a branch close to the trunk of a hawthorn (Scott 1963).

Throughout its range, the Blue-gray Gnatcatcher nests predominantly in deciduous trees and occasionally in shrubs, rarely in conifers or dead snags. In Illinois, 98.6% of nests were in deciduous trees but in Florida pines may be selected over other tree species. In other areas in the north, oaks and elms are preferred nest trees, but nests have been reported commonly in sugar maple, sycamore, black walnut, sassafras, and honey and black locust and infrequently in ash, willow, hickory, hophornbeam, black cherry, crabapple, and alder. Most nests are saddled on horizontal branches (76% of Vermont nests), often built against a twig or side branch and also around a twig or knot for support. It also nests in outer branch forks but trunk forks are avoided as nest sites except in California. Nests are usually on limbs 2-5 cm in diameter, but occasionally on larger ones. Occasionally, nests may be among the forks of 3 or more branches. This is most likely to occur when the nest is in a shrub. In California, the height at which nests were situated was related to the height of the nest tree. Nests in oaks were always at least 0.9 m below the top of the tree; nests in shrubs were near the top. Individuals may build nests in very different situations. A female in California built nests in deciduous oaks, oaks that retained their leaves year round, and in shrubs, and nests were in shaded and unshaded locations and in vertical and horizontal nest forks. Nests have been reported at heights of 0.96-24 m with most 6-10 m up where trees are used for nesting. The same nest is not used again for replacement clutches or second broods, but the same nest site may be used later in the season or in subsequent seasons (Fitch 1958; Graber et al. 1979; Kerschner and Ellison 2020; Kershner et al. 2001; Nice 1932a; Nickell 1956; Raynor 1964; Root 1967, 1969b; Scott and McKinney 1994; Weston in Bent 1949). In Illinois, nest sites had significantly higher leaf density around nests than random sites at 1-m radius but there was no significant difference at 4-m and 11-m radii. Nest-tree species selection did not differ from availability. Nest height, distance to trunk, and leaf density did not differ significantly between first and subsequent nesting attempts (Kershner et al. 2001).

Early in the nesting season, the Blue-gray Gnatcatcher defends a territory. The entire territory is defended initially and boundaries become stable once nesting is underway. Later on, only favoured foraging areas are defended and there is a gradual decrease in territorial behaviour. Disputes later in the season are associated with shifts in territorial boundaries due to renesting activities. There is often a lack of synchrony in the nesting cycle of adjacent birds that allows pairs to move through undefended portions of neighbours' territories. It responds aggressively toward most vertebrates that approach within 6 m of the nest. In Illinois, territories were small and averaged 0.37 ha for 25 pairs observed within 26 ha of habitat. Nine territories in California averaged 1.8 ha (range 0.9-3.0 ha). Territories that contained large areas of open woodland tended to be larger, suggesting that territory size was related to the amount of tree foliage present. Four Vermont territories averaged 0.7 ha (range 0.5-1.1 ha). In Kansas, the territory used by 1 pair while feeding young was 0.49 ha, but outlying parts of the territory were rarely visited; another pair feeding young had a territory of 0.89 ha. Florida territories were 0.4 ha. In California, territorial boundaries were extended early in the fledgling period to include brood habitat and preferred foraging areas (Fitch 1958; Graber et al. 1979; Kerschner and Ellison 2020; Root 1967, 1969b).

Few data are available on home range size. Most pairs remain within 50 or 60 m of the nest once it is built. Others may forage as far as 150 m away in undefended areas. For the first few days, adults may forage near the brood which may be outside of the territory, or the territory may be extended to include these areas. In Florida, the home range size was 4.0 ha (Graber et al. 1979; Kerschner and Ellison 2020; Root 1969b).

No information is available on natal philopatry or dispersal. Very little is known about adult site fidelity. One instance of breeding site fidelity was reported in northern Florida (Kerschner and Ellison 2020).

Limiting Factors

Eggs have been found in Ontario nests from 6 May until 1 July, with most reported 25 May to 9 June (Peck and James 1997). The pair bond is established once pairs reach the breeding ground, but nesting may be delayed until arthropods become abundant. In Illinois, nest building began about a week after arrival. The time required to build a nest varies depending upon geographic location, whether it is a first or subsequent nest, and if material is used from a previous nest. One Kansas nest was built in a single day. Twenty-five Illinois nests took 3-5 days to build. In New Mexico, pairs averaged 4.8 days between abandoning parasitized nests and laying an egg in the next nest. In California, first nests took an average of 13.6 days to build (range 12-15 days), but only 8-10 days in Vermont. Second nests and replacement nests took an average of 4.8 days in California (range 3-6 days) and 5 or 6 days in Vermont. Second nests are started immediately after first nests produce young. In Illinois, the first egg was laid within 24 hours of completion of the nest. In the southeastern states, 5-10 days may elapse between nest completion and laying of the first egg. Nests are completed there before there is sufficient food to raise a clutch. Eggs are laid at the rate of 1 a day. Incubation starts with laying of the last egg, although full incubation may not begin until the next day. The incubation period of Ontario nests was 12 days at 2 nests and 15 days at another. Elsewhere, incubation periods of 11-15 days have been reported (mean 13 days). Young leave the nest when they are 10-15 days old, usually around 12-13 days, and the entire brood typically leaves the nest

within an hour. In Illinois, the nesting cycle from initiation of nest building until fledging was 33-38 days (Fitch 1958; Goguen and Mathews 1996; Graber et al. 1979; Kerschner and Ellison 2020; Peck and James 1997; Root 1967, 1969b; Scott 1993; Weston in Bent 1949).

In most areas, the Blue-gray Gnatcatcher raises only a single brood. Ontario egg dates suggest that second broods are not reared. In the southern states and California, second broods may be raised, but most pairs raise a single brood even in the south. In northern Florida, 1 of 22 pairs (4.5%) attempted a second brood and 1 of 60 pairs (1.7%) attempted a second brood in New Mexico. In Illinois, 69% of pairs that failed in their first brood renested and 21% of pairs attempted a second brood but only one was successful. In Vermont, 5 of 23 pairs (21%) attempted a second brood with only 3 pairs (13%) being successful in raising young in both broods. In Vermont, only pairs that started nesting the earliest attempted second broods. The gnatcatcher is a persistent renester and may make as many as 6 attempts in a year to raise a brood. In southern Illinois, renesting attempts ceased in early July. Ontario clutches contained 3-5 eggs, mostly 4 or 5. Mean size of 182 North American clutches was 4.5 eggs (range 3-6 eggs); 3- and 6-egg clutches are rare (Chamberlin 1901; Goguen and Mathews 1996; Kerschner and Ellison 2020; Kershner et al. 2001; Peck and James 1997; Root 1969b; Weston in Bent 1949).

Both sexes breed in their first year. The mating system is monogamous with no documented cases of polyandry or polygyny. Males and females share winter ranges and follow similar migration schedules suggesting the possibility of multi-year pair bonds, but there is no strong evidence that this occurs (Kerschner and Ellison 2020).

While foraging, the Blue-gray Gnatcatcher enters each tree that it encounters along a foraging route without exhibiting any avoidance or preference of any particular tree species. This study was done in California; it is uncertain if coniferous species are avoided in Ontario. An Illinois study determined that it was selective in the trees that it used for foraging. In order of preference, black gum, sycamore, pin oak, silver maple, shellbark hickory, and bitternut hickory were used more than their availability. In order of declining avoidance, pumpkin ash, red maple, blue beech, white elm, green ash, Shumard oak, and Manitoba maple were used less than their availability. Most foraging occurs near the tips of branches in broad-leaved foliage of trees and shrubs. Feeding is not confined to any particular level of trees and may occur in the herbaceous layer when adults are feeding young, where they search for grasshoppers and other large insects. It seldom forages around the trunk of trees or on large limbs where foliage is scarce. It typically forages on small-diameter horizontal twigs, but also on vertical twigs. It rarely perches on the upper surfaces of horizontal or diagonal limbs when twigs are absent. When feeding itself, the Blue-gray Gnatcatcher usually only gleans, but uses more varied tactics when feeding young. It hops rhythmically from perch to perch remaining only momentarily in 1 location (80 perches in 120 seconds counted) and fans its tail constantly which may assist in flushing prey. It rarely still-hunts by remaining in 1 location for more than 5 seconds. Three basic foraging techniques are used: surface gleaning, gleaning while hovering, and sallying after flushed prey. Hawking insects in flight or falling through the air is a rare foraging technique. Gleaning while hovering is used to capture prey on terminal sprigs of tree foliage or from tops of tall grasses and herbaceous plants (Gabbe et al. 2002; Kerschner and Ellison 2020; Root 1967).

Nestlings are fed larger food items than are consumed by adults. In California, grasshoppers were brought to young on nearly 20% of feeding trips but only 1 grasshopper was found in the stomach of an adult. In Florida, nestlings were fed mostly caterpillars. Optimal prey size appears to be 3-10 mm for adults; they rarely eat items smaller than 1 mm and larger than 10 mm. A sample of 287 stomachs from California revealed that the diet was predominantly insects but included spiders. Plants were found in stomachs on 3 occasions, but were thought to have been ingested incidentally. The diet consisted of 36.0% bugs, 32.3% beetles, 13.8% hymenopterans, 7.1% butterflies and moths, and 10.3% other. At least 70 families of arthropods were represented in the samples. In spring, plant bugs and lepidopterans formed a large proportion of the prey when these insects were abundant. In the summer, treehoppers and leafhoppers were more important in the diet. It avoided attacking late instar larvae of the tent caterpillar. In Vermont, half of 34 identifiable prey seen captured were adult and larval moths (Kerschner and Ellison 2020; Root 1967, 1969b).

The Blue-gray Gnatcatcher is one of the smallest regular hosts of the Brown-headed Cowbird. Parasitism rates vary considerably geographically. In Ontario, 4 of 33 nests (12.1%) were parasitized. Reported parasitism rates in other areas are 3.6% in Vermont, 27% in California, 56% in Illinois, 82% in Mississippi and Texas, and 77% in New Mexico. In New Mexico, parasitism was responsible for failure of 48 of 83 nests (58%). Individual pairs were inconsistent in their response to parasitism, both deserting and accepting parasitized nests. Nest desertion followed by renesting appeared to be an effective antiparasitism strategy but only 45% of nests parasitized during the egg-laying period were deserted. Two pairs buried a cowbird egg into the nest bottom. In both cases the cowbird egg was laid prior to completion of nest building before any gnatcatcher eggs were laid. Egg burying and nest desertion are the only rejection possibilities for the gnatcatcher because it is physically incapable of removing cowbird eggs. Cowbirds may remove gnatcatcher eggs and nestlings. Of 25 New Mexico nests where cowbird eggs were accepted during egg laying, 0 fledged gnatcatchers but 16 (64%) fledged cowbirds. Of 7 nests where cowbird eggs were laid during the incubation period, 2 were lost to predation, 3 fledged only gnatcatchers, 1 fledged only a cowbird, and 1 fledged 3 gnatcatchers and 1 cowbird. A later study in New Mexico found that no gnatcatchers fledged any of their own young in 54 parasitized nests. Gnatcatchers with a parasitized nest feed nestlings at the same rate as they would a normal clutch, but virtually all the food is consumed by the cowbird young. Brown-headed Cowbirds are able to fledge from gnatcatcher nests, but they do so at much smaller size and their survivorship to independence may be reduced. Gnatcatchers may exhibit an avoidance reaction to cowbirds when their populations are high. In Illinois in a bottomland forest that typically supported gnatcatchers, none were found in a year when the cowbird population was high (Ellison and Sealy 2007; Ellison et al. 2006; Goguen and Mathews 1996; Goguen et al. 2011; Graber et al. 1979; Kerschner and Ellison 2020; Kershner et al. 2001; Kilpatrick 2002; Peck and James 1997; Root 1969b; Scott and McKinney 1994; Weston in Bent 1949).

The response of the Blue-gray Gnatcatcher to forest management practices has been studied in Ontario, Pennsylvania, South Carolina, and Illinois. In Ontario in the Carolinian Forest Region, it was not observed in harvested woodlands. Holmes et al. (2004) concluded that it was a significant indicator of woodlands without a recent history of logging. In Pennsylvania, 1-ha plots were clear-cut in aspen and mixed-oak forests as part of a Ruffed Grouse management strategy. The Blue-gray

Gnatcatcher increased significantly due to this management, which resulted in a mosaic of forested plots of varying ages after the fourth cutting cycle (Yahner 2003). In South Carolina, Harrison and Kilgo (2004) compared its density in bottomland hardwood forests where patches of forest were left within a clear-cut with standard clear-cuts and leaving the forest intact. Densities in both types of clear-cuts were less than in control areas. Differences in density between standard clear-cuts and clear-cuts with patch retention were not significant. It was only 1 of 2 forest species that used clear-cuts in the second year of harvest. In Illinois, Robinson and Robinson (1998) cut openings of 0.02-0.4 ha in a 2,000-ha forest. The Blue-gray Gnatcatcher was significantly more abundant in recently cut compartments than in uncut areas and older cuts.

In Georgia, the Blue-gray Gnatcatcher increased in response to increasing fire severity. These responses were related to suppressed understorey, more open conditions, higher insect abundance, and improved foraging habitat (Klaus et al. 2010). In the Midwest, its greatest abundance occurred with fire frequency of 0 fires every 15 years, but this study was in oak savannahs where the canopy was already open (Grundel and Pavlovic 2007b). In North Carolina pine-oak forests, it responded positively to fire but only to those of high severity. Peak occupancy occurred 5-10 years after a severe fire. In this habitat, large patches of high-intensity fires may be needed to maintain populations (Rose and Simons 2016).

In urban woodlots in Chicago, the Blue-gray Gnatcatcher was positively correlated with coverage by nonnative honeysuckles and invasive-shrub stem density, particularly that of common buckthorn (Schneider and Miller 2014).

In New Jersey and Pennsylvania over a 15-year period, hemlock declined from representing 56% of the total basal area to 46% due to the hemlock woolly adelgid; the amount of deciduous understorey increased. The gnatcatcher responded favourably to hemlock decline and increased (Toenies et al. 2018).

The Blue-gray Gnatcatcher may be sensitive to severe winter conditions. Declines were observed in Maryland and North Carolina after the severe winters of 1977-78 and 1978-79 in the southeastern United States, with subsequent recovery (Kerschner and Ellison 2020).

In California, defoliation of trees by the tent caterpillar resulted in a general failure of nesting, probably due to the decline in food supplies (Root 1969b).

Status

McIlwraith (1894) concluded that the Blue-gray Gnatcatcher was a regular summer resident in southwestern Ontario, although it was locally distributed and not very abundant. In Elgin County in 1891 and 1954, it was considered a fairly common migrant that might breed; by 2000, it was an uncommon breeder (Lancaster et al. 2004). Baillie and Harrington (1937) considered it a very rare breeding species of extreme southern Ontario, south of Middlesex County and Durham Region. The most northerly records of its occurrence were Sault Ste. Marie, Goderich, and Sarnia. Curry (2006) reported only 4 records of the Blue-gray Gnatcatcher for the Hamilton area 1930-50. There were major flights of this species to the northeast in 1947 and 1954, and it has been observed in the Hamilton area annually since 1954 where it is expanding its range. Weir (2008) reported that the first birds appeared in the Kingston area as part of a major flight in 1953. Since then, it has been seen in

1954, 1958, and every year since 1959. Brewer (1994) noted that the Blue-gray Gnatcatcher was a regular but rather sparse breeder in southern Wellington County, but that it had become substantially more common in recent years. During the first atlas, Sutherland and Gartshore (in Cadman et al. 1987) concluded that it was an uncommon breeding species in southern Ontario. It was most abundant in the Carolinian Forest Region but absent from many squares there. Although there were some breeding records, it was still largely absent from southeastern Ontario. In the Great Lakes–St. Lawrence Forest Region south of the Canadian Shield, it was predominantly confined to the shores of Lake Ontario and the St. Lawrence River and in a band along the southern edge of the Shield. James (1991) considered it an uncommon summer resident in the Carolinian Forest Region; occasional and rare north to Bruce and Simcoe counties and the Ottawa area; and a vagrant to Manitoulin Island and in the north to Rainy River.

During the second atlas, the breeding distribution of the Blue-gray Gnatcatcher was similar to that reported during the first atlas. There was a bit of a northward range extension, with records from Manitoulin Island, the Bruce Peninsula, and considerably more records in the Great Lakes–St. Lawrence Forest Region south of the Shield. There was a significant increase in its probability of observation for the province as a whole due to infilling of its range in the Carolinian Forest Region and expansion in the Great Lakes–St. Lawrence Forest Region. It was most numerous along the north shore of Lake Erie with areas of moderate density near Grand Bend, along the north shore of Lake Ontario, and on the Frontenac axis (McCracken in Cadman et al. 2007).

Breeding Bird Survey data for Ontario indicate that the Blue-gray Gnatcatcher increased 1.78% annually 1970-2021 and decreased 3.37% annually 2011-21. The long-term trend was of medium reliability; the short-term trend was of low reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Fledglings may begin to feed themselves as early as 9 days after leaving the nest. Adults raising a second brood usually leave the young of the first nest to fend for themselves when they are about 18 days old. In California, fledglings start to move into areas unoccupied by territorial adults shortly after they are independent, but in the east family groups may remain together until mid-August (Kerschner and Ellison 2020).

Fledglings remain in dense foliage within 20 m of the nest for the first 3 days after leaving the nest. In California, young hatched in oak forest were led by their parents to shrub habitat when they were 1 or 2 days old. By the time fledglings are 4 days old, they begin to follow their parents. Adults raising a second brood may leave the brood in an area on the periphery or outside the territory while they attend to the second nest. The same stands of vegetation may be used by fledglings of different pairs at different times (Kerschner and Ellison 2020; Root 1967, 1969b).

In Missouri, Porneluzi et al. (2014) netted birds during the postfledging period in an oak-pine-hickory forest 2-15 years after it was clear-cut. The Blue-gray Gnatcatcher exhibited a significant curvilinear trend, peaking shortly after harvesting, declining to a low around 6-12 years after harvesting and then increasing somewhat.

MIGRATION

The Blue-gray Gnatcatcher is a diurnal migrant (Kerschner and Ellison 2020). Weir (2008) noted that gnatcatchers coming into the Kingston area appeared to be crossing Lake Ontario from the south. The sexes appear to migrate synchronously. Although loose aggregations may occur during migration, these seem to be fortuitous with gnatcatchers being more frequent as members of multi-species flocks (Kerschner and Ellison 2020).

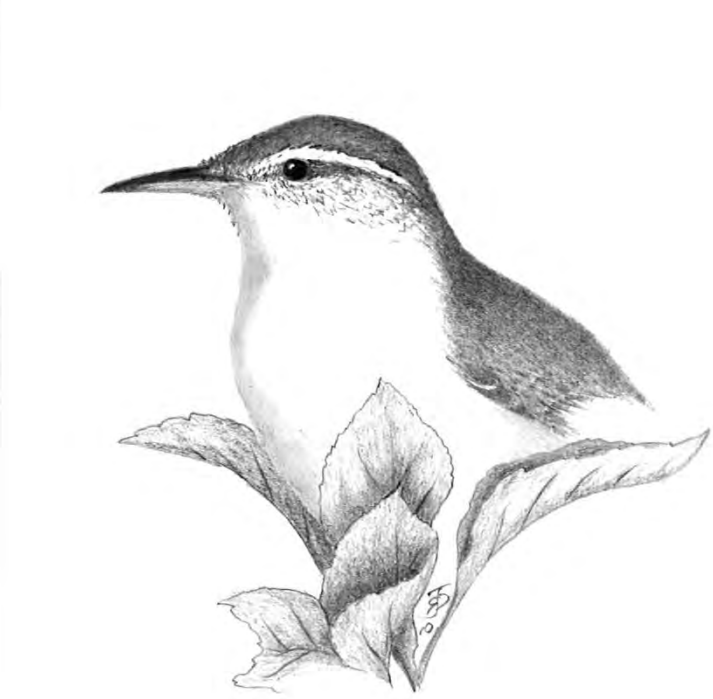
Spring migrants return to southern Ontario in mid-April with most moving through in the first 3 weeks of May. The Blue-gray Gnatcatcher appears to leave the breeding area shortly after the young are independent, usually in mid- to late August. Peak movement is in August. Most birds leave the province by the end of September, but stragglers may persist until late December (Cheskey 1985; Curry 2006; Lancaster et al. 2004; LaForest 1993; Weir 2008).

In Pennsylvania during autumn migration, the Blue-gray Gnatcatcher was most abundant at forest edge, followed by forest interior, suburban forest, forest-agricultural edges, and shrub-sapling-stage forest. It was not detected in pole-stage forest (Rodewald and Brittingham 2002). Also in Pennsylvania, it preferred larger woodlands during spring migration but had no relationship with forest size in autumn (Keller and Yahner 2007). In Minnesota and Wisconsin during spring migration, it was equally abundant in upland and floodplain forests (Kirsch et al. 2013).

James (1991) considered the Blue-gray Gnatcatcher an uncommon migrant in the province. Migration monitoring data from Long Point Bird Observatory indicated a significant increase of almost 5% per year since 1961, with the greatest rate of increase taking place since the late 1970s (McCracken in Cadman et al. 2007).

Bewick's Wren

Thryomanes bewickii



BREEDING SEASON

Habitat Requirements

In Ontario, the Bewick's Wren has nested only at Point Pelee National Park. All nests were in open habitat in wooded parkland and were in picnic pavilions or under a cottage (Peck and James 1987).

Where the Northern House Wren is absent, especially in the east, the Bewick's Wren prefers to nest near dwellings and outbuildings near shrubby or wooded areas. In the west, the 2 wren species may coexist but in the east the presence of house wrens forces Bewick's Wrens to nest in woodlands where there is dense shrub cover. The Bewick's Wren may nest in deciduous, mixed, and coniferous stands. Dominant tree species in breeding habitat include chestnut oak and other oaks, ashes, and pitch pine. In addition to open, brushy woodlots and suburban and rural residential areas, it nests in lowland riparian forests, shrubby thickets, hedgerows, orchards, and farmland at edges of forested areas. Forests with dense overhead canopy are usually avoided as are grassy areas devoid of shrubs. A Utah study concluded that it was a habitat generalist confined to areas of dense thickets; the Northern House Wren was associated with lower shrub density and increasing amounts of grass. In Washington, the Bewick's Wren nests in deciduous and riparian woodlands, shrubby thickets, parks, and gardens. It preferred higher foliage-height diversity and more complex and dense habitats than the Song Sparrow. In many areas, particularly in the west, the Bewick's Wren is strongly associated

with junipers (Bent 1948; Campbell et al. 1997; Gorton 1977; Graber and Graber 1963; Kennedy and White 2020; Kroodsma 1973; Miller 1941; Pogue and Carter 1995; Smiley and Stapleton 1976; Sutton 1930; Whitmore 1977). In grassland areas of Oklahoma, it was absent where there was no shrub cover and increased in abundance with increasing density of red cedar. It was associated with shrub and woodland cover (Chapman et al. 2004). In California, it was significantly more abundant in oak savannahs with shrub cover and montane hardwoods than in oak savannahs with grass cover and oak woodlands (Wood et al. 2013). In Texas, its highest probability of occurrence was at 40-60% woody canopy cover within a radius of 250 m (Plappert et al. 2024).

During the breeding season, adults roost individually in cavities in trees and posts, among vines and dense conifer foliage, and in buildings and nest boxes. Young roost together for about a month, sometimes in old nest cups (Kennedy and White 2020).

All Ontario nests were on or under buildings at Point Pelee. The first was on a beam under a cottage and the others were on beams under the eaves of picnic pavilions. Two nests were 1.8-2.4 m above ground (Baillie 1962; Peck and James 1987).

The Bewick's Wren is a secondary cavity nester that uses a wide range of natural and artificial sites. Nests in natural situations may be in tree cavities or old woodpecker holes. Less frequently, nests are in burrows in the sides of banks, in holes in the ground under shrubs or rocks, at the mouth of vacant rodent holes, in crevices of rock ledges, in interstices between small boulders, in holes in the floor of small caves, in upturned roots of fallen trees, and in the centre of dense brush piles. Most nests in artificial situations are in openings under, on, or in abandoned or occupied buildings. Nests have been reported in rock walls, piles of boxes, under roof tiles, in nest boxes, in tin cans at a landfill site, in old cow skulls in pastures, on beams under buildings or under eaves of open structures, in a truck glove compartment box (the truck was used daily), in empty cartons, among saddles and harness, in rubber boots, on plates or exposed shelves in buildings, in garage drawers and cupboards left ajar, behind a frying pan hanging on a post, in hay in barns, in holes in fence posts, in empty barrels, in discarded clothing hung in buildings, in baskets and empty flowerpots, in deserted automobiles and machinery, in oil wells, in mail boxes, in old phoebe and Barn Swallow nests associated with buildings, in old oriole and mockingbird nests, in a hanging sack, in woodpiles, in a paper bag half filled with nails, and in a fishing creel. In British Columbia, 47% of nests were in buildings, 5% in posts and poles, 4% in abandoned automobiles, and 40% in trees. Overall, 42% of

nests were in artificial cavities, containers, or nest boxes; 34% were in natural cavities or crevices; and 15% were in rafters or other supports in buildings. Nearly 80% of nests were in backyards, on farms, or in gardens. In West Virginia, 12% of nests were in natural or woodpecker cavities and the remainder were associated with buildings. It is much less inclined to nest in nest boxes than the Northern House Wren and Bewick's Wren's nests tend to be placed closer to the ground. Nests have been reported from below the ground to 10 m above ground, but most are 1-3 m up. In British Columbia, nests were 0.3-6.0 m from ground with most 0.9-1.8 m up. One California nest extended horizontally about 45 cm into a hillside (Beemer 1947; Bent 1948; Campbell et al. 1997; Kennedy and White 2020; Miller 1941; Pogue and Carter 1995; Root 1969a; Smiley and Stapleton 1976; Verner and Purcell 1999).

The male defends the territory and resident pairs may retain their territory year-round. Territories may overlap those of Carolina and Northern House wrens but in some areas Bewick's and house wren territories may be exclusive. In Oregon, 3 of 6 house wren territories were completely within Bewick's Wren territories and the other 3 overlapped Bewick's Wren territories. Bewick's Wren territories that did not overlap Northern House Wren territories averaged 2.0 ha (range 1.3-3.8 ha). Territories overlapping those of Northern House Wrens were larger and averaged 3.8 ha (range 2.5-4.8 ha). The larger territories may have been due to the extensive open areas in them or possibly due to interspecific competition. In northeastern Kansas, territories averaged 1.58 ha (range 1.17-2.14 ha); territories that overlapped those of Northern House Wrens in California averaged only 0.34 ha (range 0.17-0.45 ha). Territory size and shape vary with the distribution of vegetation and open space and the number of birds (Kennedy and White 2020; Kroodsma 1973; Miller 1941; Sutton 1930).

The rate of natal philopatry in migratory populations is uncertain. In resident populations, most young leave the natal territory at age 5 weeks, although some may remain until the following spring. Young males may establish a territory in July or August of their first year. One male established a territory at age 60 days and a female was mated to an adult male at age 75 days. Of 17 fledglings in a resident Oregon population, 11 males dispersed an average of 1.2 km (range 0.1-3.2 km), 2 females dispersed 0.8 km, and 4 females remained in the natal territory 10-27 weeks but did not breed there. In Kansas, 2 birds banded as nestlings returned to nest the following year (Kennedy and White 2020).

Resident adults may maintain their territory as long as they live. Limited evidence suggests that migratory adults have fairly high site fidelity. In Kansas, 2 males that bred in 3 successive years (4% of birds), and 3 males and 3 females that bred in 2 successive years (15% of birds) all returned to nest within 100 m of the nest where they were originally banded. It was thought that the percentage of returning birds was an underestimate. In California, 1 nest site was used in 10 consecutive years, but it was unknown if the same birds were involved (Kennedy and White 2020; Miller 1941).

Limiting Factors

Eggs have been found in Ontario nests from 9 to 24 May (Baillie 1962; Peck and James 1987). All Ontario nests failed; first nests that went full term would probably contain eggs into early June. In other areas, the Bewick's Wren may nest late into the season: a specimen taken 12 December in California exhibited evidence of breeding. In resident populations, the nest may be started very early in the season and construction may take as long as 1 month. The median time to build a nest is 7 days and 66% of nests are completed in less than 8 days. A pair renesting in a new cavity built a nest

in a single day. The first egg is usually laid sometime between the first and third morning after the nest is complete. One egg is laid per day, although a day may occasionally be skipped in larger clutches. Incubation is initiated with laying of the penultimate or last egg. Early studies reported the incubation period to be 10-14 days, mostly 14 days. It appears as though reports of shorter incubation periods are incorrect, and that the incubation period is 14-16 days. Second broods may have slightly shorter incubation periods. The nestling period is 14-22 days and appears to be shorter in the southern portion of its range. In British Columbia, the nestling period is 18-22 days compared with 14-17 days in the south where 14 days is most frequent. The young remain together and continue to be fed by the adults for about 2 weeks after fledging (Bent 1948; Campbell et al. 1997; Kennedy and White 2020; Koenig and Stahl 2007; Miller 1941).

Most pairs raise 1 brood annually, but 2 broods are commonly raised. Although most cases of second broods are from more southern portions of its range, second broods are common in British Columbia. Only birds with early first clutches (13 April to 15 May) initiate second broods, usually 1-10 days after the first brood fledges. One Oklahoma pair raised 3 broods in a season. Renesting occurs if loss occurs early in the season. Some birds lay 3 clutches in order to raise 2 broods: the initial clutch, a replacement clutch, and the second brood. Clutches of 4-6 eggs were found in Ontario. Clutches of 3-8 eggs have been documented, with a mean clutch of 5.6 eggs for clutches started prior to 1 June and 5.2 eggs for later clutches. Mean clutch sizes are larger in the east than west. Clutches of 9-11 eggs were reported historically, but clutches this large have not been documented recently (Baillie 1962; Bent 1948; Campbell et al. 1997; Kennedy and White 2020; Pearse et al. 2004; Peck and James 1987).

Both sexes breed in their first year and continue to breed in successive years. In some populations, many males remain unmated with as many as 24% not breeding. These males tend to have inferior territories. The mating system is predominantly monogamous. Rare cases of polygyny and polyandry have been observed or suspected. One polyandrous female laid the first egg of her second clutch when the young of the first brood were 15 days old, 2 days before fledging. Resident birds may remain paired long term. Migratory birds may pair early each spring (Kennedy and White 2020; Kroodsma 1972; Pearse et al. 2004).

The Bewick's Wren feeds primarily by gleaning invertebrates from leaves, branches, and twigs of the lower strata of herbaceous species, shrubs, and trees. Much foraging is done in dense vegetation, but it also ventures into open areas to forage on tree trunks. On small branches and twigs, it sometimes clings to the lower sides and hangs upside down. In dense vegetation, it moves quickly among the lower branches. On tree trunks, it usually begins at the base and hops upward, often in a spiral fashion similar to that of the Brown Creeper. It removes insects imbedded in bark by a rapid series of pecks resembling those of a woodpecker. Occasionally it hops on the ground and picks food from it or turns over leaves with its bill. It rarely hawks or hovers for food. In early spring, the sexes may segregate with the female foraging near the ground and the male in trees. After nest building and later in the season, there are no sexual differences in foraging. Seasonal differences in foraging techniques were observed in Arizona: 77-82% probing and 17-18% gleaning in May and June; and 35-46% probing and 54-64% gleaning in July. Gleaning in July was mostly on the ground, possibly in response to new plant growth. A New York pair foraged for food for nestlings in more

open forest; adults with fledglings foraged in dense undergrowth (Kennedy and White 2020; Miller 1941; Smiley and Stapleton 1976).

Males bring food to incubating females. Supplemental feeding experiments have demonstrated that food was limited to incubating females. Initially, 1-cm-long caterpillars are brought to nestlings but, as the young age, they are brought larger items (2-3 cm) that include butterflies and some hard-bodied arthropods. Food brought to Kansas young consisted of 51% caterpillars with some adult butterflies and moths, 13% spiders, 6% grasshoppers, 6% insect pupae, 4% beetles, and unidentified arthropods. An examination of 146 stomachs from all months in California determined that the adult diet consisted of 31% bugs, 21% beetles, 17% bees and wasps, 12% caterpillars with some adult butterflies and moths, 6% flies and other insects, less than 5% spiders, 4% grasshoppers and crickets, and less than 3% vegetation (fruit pulp, seeds, and plant rubbish). Most vegetable matter was eaten in December and January. The same study determined that nestlings were fed predominantly caterpillars, but also spiders, grasshoppers, insect pupae, and various small arthropods (Bent 1948; Kennedy and White 2020; Pearse et al. 2004; Smiley and Stapleton 1976).

The Bewick's Wren is rarely parasitized by the Brown-headed Cowbird. Only 15 cases of parasitism have been documented: 5 In Texas, 5 in British Columbia, and 1 each in Ohio, Tennessee, Missouri, Oklahoma, and Kansas. In most cases, wrens either deserted the nest or removed the parasitic egg. In 1 British Columbia nest, the adults raised 1 cowbird but none of their own young (Campbell et al. 1997; Kennedy and White 2020).

One of the greatest limiting factors to the Bewick's Wren is interspecific competition. Interspecific competition has been reported with the Northern House Wren, Carolina Wren, and Song Sparrow. The most significant competitor is the house wren. In some areas, the 2 species coexist peacefully with overlapping territories. In other areas, the 2 species coexist but with much territorial conflict with the house wren being dominant. In some areas, the house wren has resulted in local extirpation of the Bewick's Wren. Peaceful coexistence occurs mostly near the west coast where the 2 species have been in contact for a long time. In some areas, resident populations of Bewick's Wrens are often able to raise a brood before the migratory house wrens arrive. Once house wrens appear, Bewick's Wrens are frequently relegated to suboptimal habitats. Competition is most extreme in eastern populations where both species are migratory because the Bewick's Wren does not have the benefit of an earlier start to breeding. The house wren moved into much of this area fairly recently so that the 2 species have not adapted to coexistence. Where the 2 species compete, the house wren is more aggressive and dominant and excludes the Bewick's Wren from the best habitats. The house wren frequently punctures and removes Bewick's Wren eggs from nests, or covers up their nests with twigs; occasionally it kills Bewick's Wren nestlings. In Kansas, 35.6% of Bewick's Wrens' nests failed as a result of house wren activity and 81% of nest losses were due to the house wren. Nest-box programs for Bewick's Wrens usually fail where house wrens are present. Not all authors agree that declining Bewick's Wrens are a result of the house wren, but there is very strong circumstantial evidence for this being the case in the east where declines in the Bewick's Wren are strongly correlated with increases in the house wren. In winter, the Bewick's Wren avoids Florida and southern Louisiana and shows a depression in numbers in southern Texas. These are the locations where the house wren is most abundant. There is some evidence that the 2 species are

becoming more tolerant of each other. In West Virginia, the Bewick's Wren reoccupied areas where it was formerly common and subsequently disappeared after the arrival of the house wren (Bent 1948; Brooks 1947a; Kennedy and White 1996, 2020; Kroodsma 1973; Root 1969a, 1988; Sutton 1930; Verner and Purcell 1999; Whitmore 1977).

Occasionally territorial interactions occur with the Carolina Wren, but the 2 species often coexist with no apparent conflicts (Sutton 1930). In winter, the Bewick's Wren appears to avoid the southern grasslands and eastern part of the tree and shrub savannah habitat where the highest concentration of Carolina Wrens occurs (Root 1988).

In Washington, territories of Bewick's Wrens and Song Sparrows overlapped in forage behaviour, heights, and techniques. The Song Sparrow showed some territorial aggression to the Bewick's Wren, but this declined as the season progressed. The 2 species appeared to divide the habitat vertically. Presence of Song Sparrows does not appear to be a significant limiting factor to the Bewick's Wren (Gorton 1977).

Nest sites may be limiting in some parts of the Bewick's Wren's range. Addition of nest boxes in Arizona and Mexico significantly increased its density but nest boxes have the potential to increase local house wren populations (Kennedy and White 2020).

Near Seattle, the Bewick's Wren strongly avoided areas within forest patches that were rich in a single predator species, but co-occurred with nest predators at larger scales (Marzluff et al. 2007).

Severe winter weather may result in significant mortality. Significant declines occurred throughout the Bewick's Wren's range after severe winters in the 1970s. A localized decline of 62% occurred in California after the exceptionally cold winter of 1990-91 (Kennedy and White 2020; Verner and Purcell 1999).

DDT has been suggested as a potential cause of this species' decline. A possible significant limiting factor is the increased abundance of feral and domestic cats (Campbell et al. 1997; Kennedy and White 1996, 2020).

Price (2004) concluded that the breeding range of the Bewick's Wren might expand northward to include southern Ontario if the average summer temperature increased by 2°C.

Status

The first record of the Bewick's Wren nesting in Ontario occurred in 1950 when a nest was found at Point Pelee. Nesting occurred at the same location in 1956 and 1957. Five nests have been found in Ontario and all were at Point Pelee. There has been no evidence of breeding in the province since 1957 (Baillie 1962; James 1991; Peck and James 1987).

The Bewick's Wren has experienced large fluctuations in its abundance and range. It responded favourably to the extensive deforestation due to European settlement. Most of its initial range extension occurred from about 1890 to 1910. As early as the 1920s significant declines in breeding populations occurred, especially in the east at the same time that the Northern House Wren was extending its range. Despite this decline, in the 1940s the Bewick's Wren was steadily increasing its range northward into Illinois, Michigan, Pennsylvania, Ohio, and Indiana where it was unknown 50 years previously. It was near the end of this range expansion that it occurred in Ontario. The decline

of the Appalachian Bewick's Wren, the eastern subspecies that probably nested in Ontario, was first noted in the 1930s. The Bewick's Wren has declined steadily since the Breeding Bird Survey was initiated in 1966. It has declined significantly throughout its range, but has almost disappeared east of the Mississippi River. During the 1980s, it was estimated that there were only 20 breeding pairs in Maryland, Virginia, and West Virginia combined (Bent 1948; Kennedy and White 1996, 2020).

MIGRATION

West coast birds are resident whereas eastern birds are short-distance migrants. Spring migration in the east occurs from mid-March to mid-April. Males arrive a week prior to females. Autumn migration in the east extends from late September to early November. In Ontario, the Bewick's Wren has been recorded until late October (James 1991; Kennedy and White 2020; Miller 1941).

It is unknown whether the Bewick's Wren is a diurnal or nocturnal migrant. There are 4 records of it striking towers, suggesting some nocturnal migration. During migration it typically forages and travels singly, but may occasionally occur in mixed-species flocks (Kennedy and White 1996, 2020).

During migration, the Bewick's Wren occurred in lowland riparian forest in Colorado (Kennedy and White 2020). Campbell et al. (1997) summarized its nonbreeding season habitat in British Columbia, but the species is a permanent resident there. They described it as a species of edge habitats where shrubby areas abutted coniferous forest, and of shrubby areas at edges of fields, along power-line cuts, around swampy ponds and sloughs, along roads, and on shorelines of creeks and lakes. It also occurs in shrubby parks and residential gardens.

The Bewick's Wren is a vagrant in Ontario that exhibits no regular migration. It is absent in the province most years.

Carolina Wren

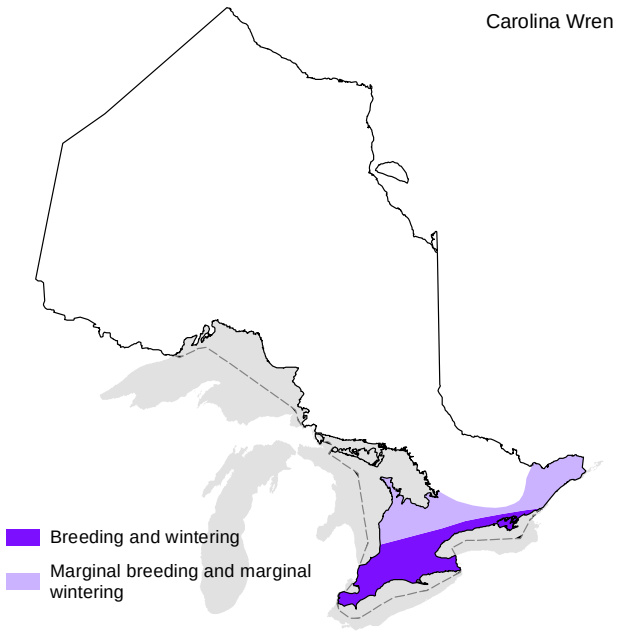
Thryothorus ludovicianus

BREEDING SEASON

Habitat Requirements

In Ontario, the Carolina Wren nests mostly in buildings in residential and wooded areas, but also in deciduous woodlands. There is 1 record of it nesting in duck-trap gear in a marsh (Peck and James 1987, 1997). In Elgin County, it occurs most frequently along Lake Erie, in shoreline woodlots, and in villages and towns (Lancaster et al. 2004). At Presqu'ile, all nesting records are from the campground (LaForest 1993).

The most important habitat requirement of the Carolina Wren is dense shrubs or brushy cover. It may frequent brush piles, fallen treetops, and rocky places in woods. In the northern portion of its range, it is most frequently associated with rural dwellings and residences in villages and towns, although it also inhabits woodlands. In the south, it tends to occur more frequently in woodlands than around residences. Within woodlots, it is often found along watercourses and in ravines with steep, bare banks. Areas with exposed tree roots or uprooted trees are preferred. It often occurs in disturbed woodlands and is more frequent in younger than older stands. In Tennessee, it selected areas with large numbers of canopy and subcanopy trees. These trees were smaller than those



found in the general area. It appears to prefer moist woodlands over upland hardwoods. In Alabama, it was most likely to occupy floodplain forests during the breeding season. It is not area sensitive and is more likely to be found in isolated woodlots than in areas of contiguous forest. Its presence is not associated with width of riparian forests. Although 1 study suggested it required 10 ha of forest cover, it used significantly smaller woodlands in South Carolina. Its probability of detection in South Carolina woodlots surrounded by fields was 84% in 0.5-ha woodlots, 90% in 1-ha woodlots, 98% in 2.5-ha woodlands, and 100% in 5-ha and 10-ha woodlots. Its probability of detection was lower in hardwood woodlots surrounded by pine forest: 14-15% in 0.5 ha, 21-22% in 1.0 ha, 43-50% in 2.5 ha, 70-94% in 5 ha, and 72-100% in 10 ha (Anderson and Shugart 1974; Bannon and Rail in Gauthier and Aubry 1996; Bent 1948; Fitch 1958; Haggerty and Morton 2020; Keller et al. 1993; Kilgo et al. 1997; Lynch 1987; McClure et al. 2013a; Noon et al. 1979; Robbins 1979; Sutton 1930).

In Texas pine and pine-hardwood forests, abundance of the Carolina Wren was positively correlated with the number of shrub species and stems, foliage density 1 and 3 m from the ground, and percent coverage by hardwoods 5-16 cm diameter at breast height (DBH). It was negatively correlated with percent coverage by pines 17-32 cm DBH and the number of tree stems 17-32 cm DBH (Conner et al. 1983).

In South Carolina, the Carolina Wren was most frequent in forest edge habitat during spring migration and the breeding and postbreeding seasons. Usage of forest gaps was consistent from spring through autumn and was typically lower than for other habitat types (Bowen et al. 2007). Kroodsma (1984) found no edge effect for it in Tennessee. It occurred in low density at forest edge to approximately 100 m from edge, was most abundant 100-220 m from edge, and occurred in low density beyond 220 m from edge. All birds seen were within 268 m of edge and none were present 268-488 m from edge.

Roosts are an important habitat component for the Carolina Wren. During the incubation period, the male roosts in shrubs, usually within 50 m of the nest. Both adults roost in shrubs during the nestling period. A Florida pair roosted together in a hanging plant basket 2.4 m from the nest during nest construction through laying of the first egg (12 nights) and also on the day that the fourth egg was laid. It is extremely vulnerable to cold, so roosts are important even on cool summer nights. There is 1 record of 4 fledglings roosting together in a newly constructed Northern Cardinal nest on a night when there was frost. In winter, roosts are critical in keeping wrens warm. Birds may roost in their own nests and 1 pair used an old Eastern Phoebe nest under the eaves of a building

as a winter roost. There are a few records of Carolina Wrens enlarging the hole in hornets' nests and using the nest as a roost site. Other reported roost sites include in bird boxes, old coat and shirt pockets, hanging ferns, garages, barns, squirrel dreys, vine tangles, decaying logs, small cavities in snags of trees, and on the ground under ferns. Members of a pair may roost together or singly (Bent 1948; Brooks 1932; Fitch 1958; Haggerty and Morton 2020; Jawor and Gray 2003; Labisky and Arnett 2006; Laskey 1948; Ramsay 1987).

Twenty-five percent of Ontario nests were in natural habitat, mostly in cavities in stumps and fallen trees; 1 was in a brush pile. Nests in buildings and other artificial sites were on shelves, electrical boxes, and beam ledges; in washbasins, 6-quart baskets, empty boxes, nail barrels, travel bags, funnels, hanging flower pots, bird boxes, and in duck-trap gear in a marsh; under eaves of a building; and under an overturned canoe between a seat and a seat-pad (LaForest 1993; Lancaster et al. 2004; Peck and James 1987, 1997). Nests are hidden at depth in a recessed area and may be used for subsequent nestings in the same year or in following years. Nests were 0.5-4.5 m from the ground, with most 1.2-2.2 m up (Peck and James 1987, 1997).

Nests in natural habitats elsewhere were under decayed wood among stump roots, among exposed roots of a walnut tree, between the divided stem of a young cedar tree, in a 3-point fork of a white elm in a woodland, in a hole in the ground, in tree cavities, in a black walnut on a partially broken-off limb, in tangles of vines, in conifer branches, and in a hole in a bank. First nests of the season are often on the ground under dense, fresh vegetation. Most reported nests are in or on artificial features, but these nests are much easier to find and may be over-represented in the sample. Many nests are in buildings; wrens may gain access through very small openings such as a hole in a cracked window pane or a partially open window. Ledges and eaves around buildings are favoured nesting areas. Nests have been in hanging baskets and flower pots, in a paper bag on a shelf, between the rafters of a porch, on the top of a cupboard in a bedroom, in hornets' nests, behind a picture in a bedroom, in bluebird boxes, on shelves among cans and jars, in a sack of old clothes, in a sack of seeds, in the fold of a hanging quilt, in a crevice between a house wall and a downspout, in a mail box, in a tin cylinder for newspapers, in a dust mop, in window boxes, in cardboard boxes, in a pair of pants hanging from a hook, in glove compartments of abandoned cars, in grain sheaves, in a cavity in a stone wall, in old shoes, in tin cans, on top of propane tanks, in the back of a sofa in a house, and in discarded hats. One successful nest was on a tractor that was used daily. Nest height extremes of from below the ground to 9 m have been reported but most nests are 1-2 m up; the mean height of 393 nests was 1.8 m (Bent 1948; Brooks 1932; Chapman 1947; Grzybowski 1995; Haggerty and Morton 2020; Laskey 1948, 1950a; Luther 1974; McGaha 1998; Nice and Thomas 1948; Ramsay 1987; Sanborn 1932; Sutton 1930; Tinker 1909; Turcotte 1989).

The Carolina Wren is territorial year-round, and territorial aggression is highest outside the breeding season. The size of the territory is defined by resources required for winter survival rather than breeding. Territory size decreases with increasing wren density, but boundaries may overlap slightly and shift with changes in density. All nesting, foraging, and feeding of young occurs within the territory. In Illinois, the mean size of 3 territories was 0.12 ha (range 0.049-0.25 ha). In Tennessee, mean territory size was 4.1 ha (range 2.1-8.1 ha); mean territory size was 1 ha in North Carolina. The year-round range of Alabama birds averaged 0.7 ha (range 0.38-1.72 ha). In Kansas, 1 territory

measured 2.3, 3.7, 1.6, and 3.1 ha over 4 years. Although this territory was occupied in 6 years, the individuals using it changed (Brewer 1955; Fitch 1958; Haggerty and Morton 2020; Haggerty et al. 2001; Morton and Shalter 1977).

The Carolina Wren is nonmigratory and very sedentary. Some limited diurnal movement may occur. Little information is available on natal philopatry and juvenile dispersal. In most cases, juveniles are precluded from breeding in their natal territory due to the territorial activities of their parents. In Alabama, 4% of fledglings remained to breed in the study area. All nested on or very close to a territory adjacent to the natal territory and within 150 m of their natal territory. Once a bird establishes a territory, which may be in the autumn after fledging, it typically remains in the same territory for its lifetime. Exceptions may be females that lose their mates and are unable to continue to defend the territory. These females may be forced to move and find an unmated male holding a territory (Haggerty and Morton 2020; Laskey 1948, 1950a).

Limiting Factors

Eggs have been found in Ontario nests from early April until early August, but the presence of 3 young in an Essex County nest on 29 August suggests a later egg date. Most nests with eggs were reported 10-29 May (Peck and James 1997). The Carolina Wren has a long egg-laying period that may extend from very late March into September even in northern, cool climates such as Vermont. This is due to its propensity for multiple brooding and replacement of lost clutches. One nest was almost completely built within 2 hours, but 4-7 days is more typical for nest completion. Eggs are laid at the rate of 1 a day. Although the female may start staying in the nest at night after she lays the first egg, full-time incubation does not start until laying of the last, or occasionally penultimate, egg. Incubation periods in Ontario were 14-15 days. Overall, incubation periods of 12-16 days have been reported (averages 14.8 and 15.8 days). Young fledge when they are 10-16 days old, but mostly at 12-14 days; the mean nestling period is 13.3 days (Bent 1948; Gill and Haggerty 2012; Haggerty and Morton 2020; Laskey 1948, 1950a; McGaha 1998; Nice and Thomas 1948; Peck and James 1997; Turcotte 1989).

Two broods are commonly raised in a season including in Ontario. Either a new or the old nest may be used for the second brood. In the southern part of the Carolina Wren's range, 3 broods are occasionally raised. Renesting may occur if a clutch is lost. The renesting interval after Alabama nests failed averaged 9.3 days compared with 11.0 days following successful nests. Females averaged 3.7 nesting attempts per breeding season. Clutches of 3-9 eggs have been reported in Ontario, with most containing 5 eggs. The normal clutch size is 3-5 eggs, with a mean of 4.3 in Alabama and a mode of 4 eggs. Further north in Tennessee, 5-egg clutches were most frequent. Of 255 nests throughout North America, mean clutch size was 4.8 (mode 5 eggs, range 3-7 eggs). There is 1 record of 8 eggs as well as the 9-egg clutch for Ontario. There is no significant decline in clutch size as the season progresses (Bent 1948; Haggerty and Morton 2020; Laskey 1948, 1960; Peck and James 1987, 1997; Sanborn 1932; Turcotte 1989).

The age at first breeding is 1 year. The mating system is monogamous and permanent pair bonds are maintained year-round. There are 2 records of possible polygyny occurring when 2 females nested on a single male's territory. The male assisted only at the nest of the primary female. Birds may establish pair bonds as early as July of their hatching year. Although pair bonds are

permanent for the lives of pair members, a deceased mate is quickly replaced. Divorce is rare and there are no reported cases of intraspecific nest parasitism or extra-pair fertilizations (Haggerty and Morton 2020; Haggerty et al. 2001; Laskey 1950a; Morton and Shalter 1977; Nice and Thomas 1948).

The Carolina Wren usually forages on the ground or close to it in leaf litter, around fallen trees and upturned roots, and in tangles of vegetation. It occasionally forages on vines, in squirrel dreys, and bark crevices. Occasionally it hitches up tree trunks and branches similar to a creeper or nuthatch, probing its bill into cracks. It obtains most food by gleaning but often turns over decaying vegetation with its bill to expose prey. In Louisiana, 83% of observations of foraging birds were 0.5-7.6 m from the ground (Haggerty and Morton 2020; Morton and Shalter 1977).

During incubation, the male feeds the female on the nest and she is given mostly caterpillars. Both adults feed the nestlings caterpillars, spiders, moths, crickets, grasshoppers, worms, and beetle larvae and adults. At 1 nest, young were initially fed very small spiders. After 7-10 days, nestlings were fed grasshoppers from which the legs had been removed. In the final stages of nesting, large grasshoppers complete with legs were the staple food items. An examination of 291 stomachs found that 94% of food consisted of animal matter and 6% was vegetation. Animal material included 22% caterpillars and a few moths, 19% bugs (leafhoppers and stink, soldier, leaf-footed, and chinch bugs), 14% beetles (weevils and ground, leaf, bean leaf, and flea beetles), 13% orthopterans (grasshoppers, crickets, and cockroaches), 11% spiders, 5% hymenopterans (ants, bees, and wasps), and 3% flies (crane flies). Miscellaneous animal material in the diet included millipedes, isopods, katydids, snails, and remains of lizards, frogs, and snakes. Vegetable matter eaten consisted of seeds of bayberry, sweet gum, poison ivy, sumac, smartweeds, and acorns. The proportion of plant food increases to 11% in winter and declines to 1% in summer. It has also been reported eating the fruit of mulberries (Beal et al. 1916; Chapman 1947; W.E. Davis 1991; Haggerty and Morton 2020; Holt 1918; Laskey 1948; Neudorf et al. 2013; Nice and Thomas 1948; Tinker 1909).

Brown-headed Cowbird parasitism of the Carolina Wren has yet to be reported in Ontario. Although the Carolina Wren is an uncommon host, it readily accepts cowbird eggs and young. Parasitism rates from various states range from 0% to 33.3%. Both cowbirds and wrens may be raised from parasitized nests. If there are 2 or more cowbirds in a nest, there is little likelihood of wrens fledging. The young wrens cannot compete for food and eventually become weakened and subsequently trampled or smothered to death by the young cowbirds (Grzybowski 1995; Haggerty and Morton 2020; Hahn and Hatfield 1995; Kilgo and Moorman 2003; Laskey 1948; Lowther 1991, 1997; Luther 1974; Messerly 1998).

Young of early nests may die of exposure during cold or wet weather. At a Tennessee nest, 1 of 3 9-day-old nestlings died when the temperature dropped to 16.7°C (Laskey 1948).

Habitat loss or degradation is not an issue for the Carolina Wren. Throughout its range, forest fragmentation and abandonment of marginal farmland has probably been beneficial (Haggerty and Morton 2020). In Illinois, Robinson and Robinson (1999) created 0.02-0.4-ha openings in contiguous forest. Numbers of wrens increased significantly in openings and they were significantly more abundant in recent cuts (1-5 years old) than in 10-15-year-old cuts. In South Carolina, Harrison and Kilgo (2004) studied the effects of small clear-cuts on Carolina Wrens. Plots were 11-13 ha; some

were completely cut but 0.2-ha and 0.61-ha patches were retained in other plots. In clear-cuts, wrens were absent the first year after cutting but increased the next year. Numbers were lower than prior to cutting, but not significantly. In the patch-retention areas, numbers of wrens declined significantly the first year, but were higher than pre-cutting the second year.

Jackson et al. (2011) monitored the reproductive success of Carolina Wrens breeding in forested floodplains of 2 mercury-contaminated rivers in Virginia. Nesting success was 34% lower on contaminated sites than on reference sites. Blood mercury concentration of the female was a strong predictor of nest success. A 10% reduction in nest success corresponded with 0.7 µg per gram mercury in the blood, 2.4 µg per gram mercury in body feathers, 3.0 µg per gram mercury in tail feathers, and 0.11 µg per gram mercury in eggs. These represented relatively low concentrations of mercury in the environment. Wrens exhibited high rates of nest abandonment and those nesting in floodplains adjacent to watercourses subject to mercury fish-consumption advisories may be adversely affected. Carolina Wrens accumulate mercury to higher concentrations than other songbirds due to their heavy reliance on spiders in their diet.

In pine-oak forests in North Carolina, the Carolina Wren responded positively to fire. It occurred more frequently immediately following fire regardless of its severity. Peak occupancy occurred in locations that had experienced high-severity fires 0-5 years previously (Rose and Simons 2016).

Price (2004) predicted that the range of the Carolina Wren might expand in southern Ontario if the average summer temperature increased by 2°C. In North Carolina, its abundance was correlated with temperature, suggesting that it would benefit from climate change (Lumpkin and Pearson 2013). Near Ann Arbor, Michigan, Job and Bednekoff (2011) demonstrated that the winter range limits for the Carolina Wren were more directly related to food supply and presence of bird feeders and were only indirectly related to temperature. Thus, it may not respond as predicted by some climate models.

Status

The Carolina Wren is a recent arrival to Ontario, particularly as a breeding species. The first record was from Mount Forest during the winter of 1890-91. In 1905, a fledgling was found at Point Pelee, which represented the first breeding record for Ontario and Canada (Baillie 1967; McIlwraith 1894). Baillie and Harrington (1937) considered it an uncommon and irregular resident in the south, north to Lambton County and east to Victoria and Northumberland counties. The first record in Elgin County was in 1930 where it is now a rare local resident (Lancaster et al. 2004). In the Kingston area, the first Carolina Wren was seen in 1923, but the next record was not until 1949. It has been observed every year since 1970 (Weir 2008). Only 39 pairs were estimated breeding in the province during the first atlas, which followed a period of severe winters (Austen et al. 1994; Richard in Cadman et al. 1987). In 1989, at least 100 birds were present at Point Pelee during the breeding season, but the population dropped to 25-30 in 1992 and 10 in 1993 (Austen et al. 1994). James (1991) considered it a rare permanent resident in the Carolinian Forest Region, nesting occasionally as far north as Simcoe County. Since the 1970s, its population and range have continued to expand. Numbers in Niagara Region began to increase in the late 1980s (Black and Roy 2010).

The second atlas demonstrated that the range of the Carolina Wren had expanded northward and eastward since the first atlas. It was documented throughout most of the Carolinian Forest Region and along the north shore of Lake Ontario and the St. Lawrence River, with records in the Ottawa area, near Lake Simcoe, and at the base of the Bruce Peninsula. There were 3 scattered records in the southern portion of the Canadian Shield. Its probability of observation increased significantly south of the Shield and notably in the Carolinian Forest Region. Densities were low with highest densities in Essex County and the Regional Municipality of Niagara (Read in Cadman et al. 2007).

The North American Carolina Wren population began to increase and expand northward in the late 19th and early 20th centuries. The typical pattern is that the range extends northward for several years, then contracts suddenly due to severe winter weather, then gradually recovers and usually surpasses its previous northern range. Cold weather with ice and snow decimates populations, but they often recover in a few years. The overall increase in range and population has been attributed to less severe winters, reforestation, abandonment of marginal farmland, and winter bird feeding (Bannon and Rail in Gauthier and Aubry 1996; Bent 1948; W.E. Davis 1991; Haggerty and Morton 2020; Overlease and Overlease 1987; Sutton 1930).

Breeding Bird Survey data indicate that the Carolina Wren increased in Ontario at annual rates of 4.55% 1970-2021 and 4.32% 2011-21. The long-term results were of medium reliability; the short-term results were of low reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Some fledglings may disappear from the nesting area in 1-2 days, but most remain nearby for 22-37 days with stragglers persisting for 48-79 days (Haggerty and Morton 2020).

In Ohio, Vitz and Rodewald (2006) captured 4 adult and 47 juvenile Carolina Wrens in regenerating hardwood clear-cuts. Dense woody vegetation in clear-cuts may be important in providing cover and food for it. In Missouri, Porneluzi et al. (2014) netted birds during the postfledging period in an oak-pine-hickory forest 2-15 years after it was clear-cut. The Carolina Wren was among the more common species captured. Peak numbers occurred 2-4 years after cutting with a gradual decline thereafter.

WINTER

The Carolina Wren is a snow avoider. Important predictors of its presence are a short snow season and presence of frozen ground without snow (Keyser et al. 2022).

In Alabama, the Carolina Wren occurred most frequently in areas with dense ground cover in winter. Sites that had dense vegetation taller than 7.6 m that were used regularly during the breeding season were typically abandoned in winter (McClure et al. 2013a). In Missouri, the level of tree stocking had no effect on its abundance. It was equally abundant in savannahs, woodlands, and forests (Kendrick and Thompson 2013). In Arkansas, Kentucky, and Mississippi, it was equally abundant in row-crop fields with and without buffers of native grasses and forbs (Evans et al. 2015).

Severe winter weather is the most significant limiting factor for the Carolina Wren. Because it forages chiefly on the ground, prolonged periods of snow cover confine it to foraging under

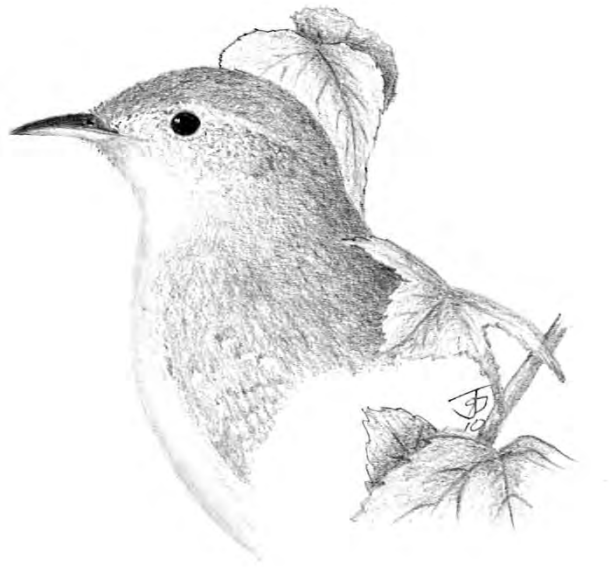
windfalls and other areas sheltered from snow. Over a 47-year period in the United States, the centroid of its distribution shifted northward during years with mild winters and few snow-cover days when snow depth exceeded 5 cm. It shifted southward dramatically in the late 1970s, early 1990s, and late 2000s during severe winters with extended snow-cover days. Northern populations experienced a 1.1% decrease for every day with 4 cm of snow cover. In southeastern Michigan, snow cover rather than temperature correlates with historical range expansions and fluctuations. Although snow cover may be more critical, it also appears vulnerable to cold weather, but there are cases of it being unaffected by long cold snaps. Christmas Bird Count (CBC) data suggest that it is absent where the average minimum January temperature is below −12°C, and regular sightings occur where the minimum January temperature is above −7°C (Bent 1948; W.E. Davis 1991; Haggerty and Morton 2020; Huang et al. 2016; Job and Bednekoff 2011; Morton and Shalter 1977; Root 1988).

Severe winter weather may be devastating to local or even continental populations. The first to succumb are those that were unsuccessful in establishing a territory because they are excluded from prime food resources. Winter mortality under poor conditions is commonly 80-90% and occasionally 100%. The Carolina Wren was documented on every Hamilton CBC from 1951-62, was absent 1963-69, and was present again 1970-75, apparently in response to weather conditions. After periods of absence, the next birds seen were invariably in autumn suggesting that these were hatch-year birds colonizing from the south. In a Tennessee area where it was common, no breeding birds were detected in 1940 after a severe January storm. A severe storm in Illinois appeared to result in 100% mortality in 1979. After a severe winter in the late 1970s in Ohio, numbers at 1 site dropped from 537 to 1. During the winter of 1935-36, temperatures in West Virginia ranged from −27°C to −34°C. Several birds were found dead and, although previously one of the most common permanent residents, the Carolina Wren practically disappeared. Following the 2 severe winters of 1976-77 and 1977-78, the population declined significantly in most of eastern North America. Due to the effects of winter conditions, populations oscillate, increasing during warm periods and decreasing abruptly after severe winters. An increase in Carolina Wrens observed at winter feeders has been reported in Ontario suggesting a response to warmer winters (Austen et al. 1994; Bent 1948; Curry 2006; Dunn and Tessaglia-Hymes 1999; Fitch 1958; Graber and Graber 1979; Haggerty and Morton 2020; Laskey 1948, 1950a; Morton and Shalter 1977; Overlease and Overlease 1987; Strain and Mumme 1988; Wilcox 2006).

The Carolina Wren is the only wren that regularly visits bird feeders. At the northern extent of its range, feeders may be essential for winter survival. The increase in popularity of bird feeding is probably a major contributor to its northward range expansion. Food is a greater limiting factor than temperature in the winter. It tends to be slightly more frequent at rural feeders than those in suburban and urban areas. Feeders with nearby shrubbery are more likely to attract it. Favourite feeder foods include bird puddings, hulled peanuts and peanut hearts, chopped walnuts and other nuts, suet, and peanut butter mixes. Infrequent choices include mixed seeds, millet, all types of sunflowers, safflower, cracked corn, milo, peanuts in the shell, pet food, fresh or dried fruit, baked goods, water, meat scraps and bone marrow, and popped corn. Away from feeders, the winter diet is similar to that of the breeding season, being predominantly insects and spiders (Bannon and Rail in Gauthier and Aubry 1996; Bent 1948; W.E. Davis 1991; Dunn and Tessaglia-Hymes 1999; Haggerty and Morton 2020; Job and Bednekoff 2011; Lancaster et al. 2004; Sutton 1930).

Northern House Wren

Troglodytes aedon

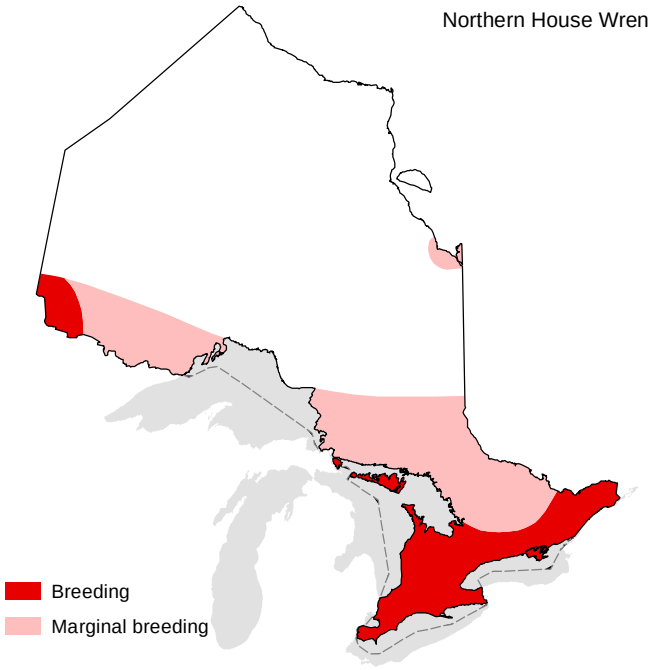


BREEDING SEASON

Habitat Requirements

In Ontario, the Northern House Wren nests in farmland, overgrown fields and pastures, orchards, fencerows, young plantations, and limestone savannahs (38.7% of records); woodlands, swamps, bogs, and beaver ponds (23.4%); rural and urban gardens, farmyards, cottage areas, and parkland (23.0%); river, lake, and pond shorelines and road and railway rights-of-way (14.1%); and treed sand dunes (0.8%). In woodland sites, the canopy was either open or nests were at the edge or in clearings. Deciduous and mixed woods were greatly preferred to coniferous woods. There appeared to be a slight preference for dry areas over wet areas (Peck and James 1987).

There are 2 consistent components of the Northern House Wren's habitat. It is strongly associated with the presence of shrubs and it prefers open habitats with some tree or shrub cover. Although shrubs are almost essential to the house wren, it avoids areas of very dense shrubbery. At Presqu'ile and Mer Bleue, nest boxes placed in sparse vegetation were selected over those in dense vegetation; nests in sparse vegetation were more successful (Belles-Isles and Picman 1986a). In Wyoming, Vermont, and Utah, it selected nest boxes in areas with smaller trees, fewer but larger shrubs, fewer saplings, and more herbaceous ground and understorey cover than areas containing unused boxes. Boxes in habitats with dense sapling or small shrub understories were avoided, but it frequently nested at sites with herbaceous cover and dispersed large shrubs. Nests in more open



areas were more successful, especially in areas with open canopies and surfaces and few decaying logs or dwarf shrubs (Finch 1989a; Parren 1991; Whitmore 1977). In Oregon, where the Bewick's and house wrens coexisted, the house wren was absent in riparian oak-ash forest with dense underbrush, but occurred where the denser shrubby understorey was replaced by grasses. It also nested in open pastures where a single tree provided a nest site and rose thickets provided foraging habitat (Kroodsma 1973). In California, occupancy rates of boxes were significantly correlated with riparian vegetation and negatively correlated with the percentage of grassland in the landscape. These broad-scale habitat features were also a good predictor of nest success (Milligan and Dickinson 2016). In Maryland suburbs, presence of the Northern House Wren was correlated with presence of shrubs as tall as 6 m, but decreased with increased tree volume at heights of 15.5-16.5 m (Thomas et al. 1977). In Manitoba, sites that were used were characterized as shrub pasture. The presence of a tree near the nest site was the most important variable; distance to the nearest tree was the only variable that differed between used and unused nest boxes. Average distance of nests from a tree was 12.1 m (Munro and Rounds 1985). Near Kingston, all occupied boxes were within 30 m of a forest; the mean distance was 13.9 m (Rendell and Robertson 1990). In Vermont, only 1 wren used a box more than 10 m from a perch taller than 3 m (Parren 1991). In Wisconsin upland forests, it is confined to shrubby woods and edges, especially if rock or wood piles are present (Mossman and Hoffman 1989). Taylor and Taylor (1979) considered it a species of small woodland openings and edges. In Wyoming, it used habitats where 50% of the ground was bare and shrub coverage was less than average. Areas with short shrubs were selected over those with tall, spreading shrubs (Finch 1989b, 1991a). In Iowa, it was positively associated with tree and shrub richness and size, vertical patchiness of vegetation, and snag density. It was positively associated with increasing diameter at breast height (DBH), but negatively associated with the number of snags smaller than 25 cm DBH (Stauffer and Best 1980). In California, it was equally abundant in oak savannahs with grass cover, oak savannahs with shrub cover, montane hardwoods, and oak woodlands (Wood et al. 2013). In Chicago, it was negatively associated with distance from edge in woodlots and the amount of urban cover (Schneider and Miller 2014).

The Northern House Wren is frequently considered a habitat generalist, but this is more a function of the fact that its preferred microhabitats occur within a wide range of areas. Knowledge of its true habitat preferences are confounded because a high proportion of studies have been conducted on populations breeding in nest boxes. In British Columbia, 79% of nests were reported from human-altered habitats and 12% from forest, but results were biased by a predominance of

nests studied at a single residence (Campbell et al. 1977). It may occur wherever there is shrub habitat with suitable nesting cavities. This may include urban and rural residential areas, hedgerows, shelterbelts, orchards, overgrown fields and pastures, shrubby rights-of-way, young burns and clear-cuts, shrub thickets and young forests, savannahs, and edges of woodlands. Aspen forests are important in the west, but seldom used in the east. Riparian and upland woodlands are inhabited, as are those fronting on lakes. In Ontario and Quebec, it is most abundant south of the Canadian Shield where extensive agriculture and urban development have fragmented the forest cover and provided its favoured thicket and shrub habitat. Several studies demonstrated that its abundance is correlated with the number of snags present (Back 1979; Beals 1960; Campbell et al. 1997; Evans and Conner 1979; Faanes and Andrew 1983; Flack 1976; Johnson 2024; Kirk et al. 1996; Kroodsma 1973; Lancaster et al. 2004; Leighton et al. 2002; McNicoll and Robert in Gauthier and Aubry 1996; Niemi and Pfannmuller 1979; Noon et al. 1979; Samson 1979; Temple et al. 1979).

In a Connecticut woodlot over a 59-year period, there was a progressive shift to larger trees, a sparser shrub layer, and a less diverse tree canopy. The Northern House Wren declined in the woodlot probably due to the decrease in coverage by shrubs (Buchanan et al. 2016).

The Northern House Wren is an early successional species that may move into previously unoccupied habitat after it is disturbed. Near Thunder Bay, it nested where a forest fire had occurred 5 years previously. By then, the understorey had developed to a height of 4 m and was dominated by poplar, willow, and alder with taller dead trees (Escott 2004). It commonly appears in burns or clear-cuts in early stages of succession. In California, it occurred in burned forests but was absent in adjacent unburned forests. In burned pitch pine stands in the northeast, densities were highest 1-12 years after fire. It was rare 20 years after fire (Bock and Lynch 1970; Capen 1979; Erskine 1977). It is a common inhabitant of old fields provided that suitable nest sites are available. In New Jersey, it occurred in the youngest (10 years) old-field habitats studied, and was also present in second-growth and climax forests that had been logged (Suthers 1988). In Wisconsin, it occurs in a wide range of pine and oak barren habitats (Mossman et al. 1991).

In North Dakota in open habitats, the Northern House Wren's probability of occurrence increased linearly with an increase in tree cover within 100 m to a maximum of 60%. In wooded landscapes, its probability of occurrence increased to about 50% tree cover and levelled out with increasing tree cover. It preferred landscapes that were 35-75% forested; no areas were present that had more than 75% forest cover (Cunningham and Johnson 2016, 2019).

The Northern House Wren is an obligate edge species. In large woodlands, it is confined to edges and openings such as margins of beaver ponds or areas affected by logging or fire. Densities in small, isolated woodlands may be 2-3 times greater than in unfragmented woodlands. It occurs more frequently in isolated, fragmented woodlands than expected and avoids large, contiguous forests. In Maryland, frequency of occurrence was 80% in 0.1-ha woodlands, 50% at 3 ha, 10% at 100 ha, and less than 0.5% in 3,200-ha woodlands. In the mid-Atlantic states, frequency of occurrence was 70% in a 0.3-ha woodlot, 50% in 3.2 ha, 15% in 100 ha, and 5% in 3,200 ha. Its abundance was negatively associated with forest area, the amount of forest within 2 km, and the number of trees at the point count location (Askins et al. 1987; Blake and Karr 1987; Brush 1994; Hobson and Bayne 2000; Lynch 1987; Johnson 2024; Robbins et al. 1989). In southern Ontario, its probability of

detection was negatively correlated with the amount of forest 100 m or more from edge and forest size, and positively correlated with the amount of forest cover within 2 km and regionally. None of these relationships were significant except for the amount of regional forest cover (Austen et al. 2001).

The female may begin roosting in the nest before or after laying begins, but always before it is finished. Both sexes roost in cavities at night, usually singly but occasionally together. Roost sites include old woodpecker holes, natural cavities in trees and posts, short burrows in banks, in the eaves of houses, between the tiles on a roof, in a gourd, and in the hollow end of a garden trellis. Fledglings roost together and occasionally with the female. They rarely return to the nest to roost, but other nest boxes may be used for roosting. Young frequently roost in more open situations such as in dense foliage or on the platform of an old American Robin, Gray Catbird, American Redstart, or Chipping Sparrow nest (Baillie and Hope 1947; Gross in Bent 1948; Johnson 2024; Skutch 1953).

Seventy-five percent of Ontario nests Ontario were in nest boxes; 12.8% were in cavities in trees, snags, and stumps; 7.1% were in holes or openings in fence posts, utility poles, and pipes; 2.7% were in holes and recesses in buildings, often under eaves; 0.9% were inside metal cans, tool boxes, kettles, and mail boxes; 0.5% were in old Barn Swallow nests; 0.2% were in old robin nests; 0.2% were in hanging fabric and paper bags; and less than 0.1% were in an old Baltimore Oriole nest, under sawdust in an icehouse, under a log pile, on the side of a flagpole float, in a broken light standard, in the head of a ceramic owl mounted on a post, in a metal can buried in the ground, and between 2 robin nests built on top of each other. Nest boxes constructed for Eastern Bluebirds, Tree Swallows, Purple Martins, and Black-capped Chickadees were used, often in the same season after the other species raised a brood. Of 180 nests in trees, 88.3% were in natural cavities and the remainder were in old woodpecker holes. Nests were in both dead (76.7%) and living (23.3%) trees; deciduous trees (85.3%) were preferred to conifers (14.7%). Tree species most frequently used for nesting were birch (19 nests), elm (13), white cedar (11), and apple (9). Three nests were on or near the ground. Excluding nests in bird boxes, nests in trees were 0.3-23 m from ground with most 1.2-3 m up; nests in buildings were 0.6-3.7 m from the ground, mostly 1.8-2.7 m (Peck and James 1987). One Algonquin Park nest was in an old Barn Swallow nest inside a building and another was in an old boot attached to a telephone pole (Tozer 2012).

A high proportion of nests reported elsewhere were in nest boxes. In addition to standard nest boxes, the Northern House Wren has nested in cardboard milk cartons, plastic gallon milk jugs, cigar boxes, gourds, bat boxes with slits on the top, and hanging coconut shells. Nest boxes that have been previously used are highly preferred over clean nests, possibly because previous use is indicative of success or good-quality habitat. Males remove old nests prior to constructing a new one and this may reduce ectoparasite loading. Unusual nest sites include old cow skulls, fishing creels, old boots, tin cans, inside old paper nests of wasps and hornets, in water pots, in teapots, in flowerpots, on shelves in sheds, in a soap dish, in a bag of feathers, in pump nozzles, in hats or pockets of scarecrows, in holes in iron pipe railings, in weathervanes, in holes in walls or buildings, in a coat hung up at a campsite, in tobacco boxes, and in mailboxes. One nest was on the rear axle of a car that was used daily. The birds went with the car when it was driven and the nest was successful. There are several reports of it using old nests of other species. It nests fairly frequently in Baltimore Oriole and robin nests, and less frequently in other species' nests. Robin nests tend to be

used when there are 2 adjoining nests available. One nest was in a Cliff Swallow nest on the bank of a river; the nest was without a neck and 4 other swallow nests appeared to have been used. The house wren has also nested in old Barn Swallow and Eastern Phoebe nests, 1 nest was in an old Belted Kingfisher nest in a sand bank, 1 was in a Bank Swallow burrow, and another was deep in the interstices of an Osprey nest. Most studies report no preference for orientation of the cavity entrance for either nest boxes or natural nests. In Alberta, 68% of nests were oriented east to south, and the orientation of successful nests was significantly different from failed nests. Successful nests were oriented in an east-southeast direction (Benton 1950; Black 1983; Brush 1994; Common 1948; Dales 1926; Finch 1989a; Fletcher 1944; Gillespie 1946; Grauman and Kuyt 1999; Gross in Bent 1948; Gutzwiller and Anderson 1986a; Johnson 1996, 2024; Kaluthota and Rendall 2017; Kennedy and White 1992; Lancaster et al. 2004; Leighton et al. 2002; Mills 1981; Pacejka and Thompson 1996; Pribl and Picman 1997; Skutch 1953; Thompson and Neill 1991). In Ohio it nested in polyvinyl chloride tubes 27.5 cm long with a 9.5-cm inside diameter. These were hung horizontally, both ends were capped, and an entrance hole of 5.1 cm diameter was drilled in 1 end (Tyson et al. 2011).

In natural cavities and cavities made by primary excavators, the Northern House Wren typically uses cavities closer to the ground and with smaller entrances than other cavity nesters. No preference appears to be shown for cavity entrance orientation, or snags versus live trees. In Arkansas, it appeared to prefer aspens; 83% of nests were in aspens which were only 12% of the available trees. In Alberta, all 91 nests in natural cavities were in trembling aspen, which was the most abundant tree species. In Iowa, snags that were soft or intermediate in hardness were selected; hard snags were used less than their availability. In Colorado, non-knothole cavities were used more frequently than cavities created by knotholes. It nests mostly in small, dead limbs and frequently uses old Downy Woodpecker nests. Optimum DBH of nest trees has been estimated at 20 cm, but trees as small as 15 cm DBH are used, and limbs as small as 7.5 cm in diameter may be used for nesting. Height of natural nests ranges from 0.9 to 50 m, with most 1.8-5.4 m from the ground. In Arkansas, nests averaged 9.0 m from the ground. In Montana burns, it nested in trees with 90% bark cover that averaged 12 m tall with an average DBH of 30 cm. In Alberta, natural nest cavities were often reused within breeding seasons and in subsequent years (Campbell et al. 1997; Evans and Conner 1975; Flack 1976; Gross in Bent 1948; Gutzwiller and Anderson 1986b; Hutto and Gallo 2006; Johnson 2024; Kaluthota and Rendall 2017; Li and Martin 1991; Munro and Rounds 1985; Sedgwick and Knopf 1980; Skutch 1953; Stauffer and Best 1980, 1982).

The Northern House Wren is a vigorous defender of its territory. The male builds 2-3 nests within the territory, rarely as many as 7. Only 1 nest is subsequently finished by the female, but the dummy nests assist in establishing the territory. It is notorious for destruction of other nests. Holes are pecked in eggs, and the eggs are often thrown out of the nest onto the ground. Nestlings may also be pecked and ejected from the nests and there is circumstantial evidence of house wrens killing other adult wrens in the nesting cavity. Nests of all bird species within the territory may be attacked and those as far as 100 m from an active house wren nest may be destroyed. Territorial intrusions by other house wrens, mostly males, are common. In some cases, these are attempts at extra-pair copulations. Floater males often intrude and take away surplus nest sites and attempt to take over active nests. Replacement males that pair with females with eggs or nestlings frequently kill the first brood (Belles-Isles and Picman 1986b, 1987; Brush 1994; Dales 1926; Finch 1990; Horn et al. 1996;

Johnson 2024; Kendeigh 1941; Kennedy and White 1996; Kermott et al. 1990, 1991; McNicoll and Robert in Gauthier and Aubry 1996; Parren 1991; Pribl and Picman 1991; Quinn and Holroyd 1989; Rendell and Robertson 1990). Nests are typically a minimum of 30-35 m apart; closer nests usually have a visual obstruction between them. Early arriving males have a large territory that shrinks as more birds arrive. Late-arriving males must squeeze in between established males to claim a territory. Late-arriving birds are almost always juveniles. In Oregon, the mean size of 14 territories was 0.9 ha (range 0.4-1.8 ha). These birds were nesting in natural cavities rather than boxes. In Ohio, 178 territories of birds nesting in boxes averaged 0.4 ha (range 0.03-1.44 ha); most territories were 0.2-0.5 ha. Territory size decreased with increasing density of birds (Johnson 2024; Kendeigh 1941; Kroodsma 1973; Muller et al. 1997).

Natal philopatry is low, with most information from Ohio. Of 7,375 nestlings, 2.1% returned to breed. It was estimated that 11.5% of surviving birds returned. In another study, 2 of 356 banded chicks (0.6%) returned to breed the following year. Also in Ohio, 71.5% of returning nestlings first bred when nesting was initiated in the spring. The remainder first nested when other birds were initiating their second broods. Many nestlings skipped 1 or less commonly 2 years before returning to breed. In Illinois, return rates of nestlings was significantly less than for adults, and significantly more male nestlings (3.6%, range 1.9-11.0% per year) returned than females (2.0%, range 0.6-3.7% per year). In Ohio, 62.9% of returning nestlings were male and 37.1% were female. Significantly more chicks (3.9%) from early nests returned than those from late nests (1.1%). There was no significant difference in the distances yearling males (607.5 m, range 120-1,707 m) and females (674.0 m, range 124-1,728 m) nested from their natal box. The median distance moved by early-season yearlings (661 m) was significantly greater than for late-season yearlings (493.5 m). At another Ohio site, yearlings nested as far as 3.0-3.3 km from their natal nest (Drilling and Thompson 1988; Kendeigh 1941; Kendeigh and Baldwin 1937; Payne 1990; Robinson and Rotenberry 1991).

Drilling and Thompson (1988) studied adult Northern House Wren site fidelity in Illinois. Significantly more male (38.1%) than female (23.3%) adults returned to breed the following year. A total of 36.6% of adult males returned to breed for at least 2 years compared with 20.6% of females. Many females returned 3-4 years to breed, and a few 5-6 times. Ten females and 7 males were not recaptured in the year between their first and second captures. Adult females moved significantly further (134.0 m, range 0-1,634 m) between successive nests than males (67.0 m, range 0-684 m). Females that were unsuccessful at their previous nesting moved significantly further (215.0 m, range 0-1,368 m) than those that were successful (134.0 m, range 0-1,634 m), but there was no difference in distances moved by previously successful (62 m) and unsuccessful (85.0 m) males. The outcome of the previous year's nesting attempts did not affect return rates, but returning females produced more offspring than non-returning females. The return rate of males was not influenced by breeding success or number of young raised. Previously unsuccessful females tended to be more successful if they moved 2 territories or further from their previous nest, but distance moved by males did not affect success. In Ohio, 631 of 1,831 adults (34.5%) returned to breed in a subsequent year. Most settled in a territory that overlapped their previous territory (58%) or was adjacent to the previous territory (12%). The percentage of females returning did not differ significantly from that of males, although there was a greater tendency for females to wander. Of returning males, 31% nested in the same box compared with 26% for females. An additional 53% of males and 44% of females

nested within 300 m of their former nest box. Maximum distance that a returning male nested from his previous nest was 1.8-2.1 km compared with 2.7-3.0 km for females (Kendeigh 1941; Kendeigh and Baldwin 1937). In Wyoming, return rates of females were 29% for birds raising 1 brood, 38% for birds raising 2 broods, 29% for monogamous females, and 38% for primary females in a polygynous relationship. There were no significant differences among these return rates (Czapka and Johnson 2000). In Ohio, the return rate of adult females was 10% (Robinson and Rotenberry 1991). In New Jersey, 5 of 127 adults (3.9%) returned the following year and there was 1 multiple return (Suthers 1988).

Limiting Factors

Eggs have been reported in Ontario nests from the first week of April until 1 September, with most present in the last 3 weeks of June (Peck and James 1987, 1997). Females begin choosing mates within a few days after their arrival. The male begins building nests in empty cavities as soon as he arrives and claims a territory within hours of arrival. The female begins completing the nest as soon as pairing occurs. In New Jersey, nests initiated before 14 June took 13.9-15.0 days to build compared with 10.0-12.0 days for later nests. In Wyoming, timing of nest construction varied annually depending on flooding severity because wrens waited until flood waters receded to build their nests. The mean length of time required to build a nest was 5.0-13.3 days. Late in the breeding season, the female may initiate egg laying before she completes the nest lining. One egg is laid per day, but there was a 2-day interval between the third and fourth eggs at 1 Ontario nest and a 3-day interval between the fourth and fifth eggs at another. In some clutches, eggs are incubated slightly beginning with laying of the first egg. Initiation of daytime incubation may be delayed until the penultimate or final egg in other clutches. The incubation period was 10-19 days in Ontario, mostly 12-14 days. The short Ontario incubation periods indicate clutches where incubation occurred before the clutch was complete. In the longest incubation periods, there was a delay in incubation of 6-10 days after the clutch was completed. In British Columbia, incubation periods of 14-15 days have been reported; elsewhere incubation periods of 12-13 days are typical. The incubation period shortens as the breeding season progresses. In Illinois, the incubation period for clutches completed by mid-June averaged 12.7 days compared with 12.2 days for later clutches. Depending upon when incubation is initiated, hatching may be synchronous over a 24-hour period or asynchronous over 2-4 days. Nestling periods of 12-20 days have been reported, with 17-18 days most typical; young usually fledge earlier than this only if the nest is disturbed (Baldwin 1921; Brackbill 1960a; Campbell et al. 1997; Dunn 1976; Finch 1991b; Gross in Bent 1948; Harper et al. 1994; Johnson 2024; Kendeigh 1941; Kennedy and White 1992; Peck and James 1987; Quinn and Holroyd 1992; Skutch 1953).

The Northern House Wren commonly raises 2 broods a year, depending upon latitude and when the first clutch was initiated. There are reports of 3 broods per year from the south, but references to third broods may be renesting attempts. At lower latitudes, almost all females that begin breeding in May or early June attempt a second brood. At higher latitudes only the females that bred the earliest raise a second brood. Second broods are common in Ontario. In Ohio, 89% of males involved in second broods retained the same territory. Territories were changed only due to pressure from other males or to accommodate new mates. At the end of the first nesting period, 23% of males left the study area and 24% of males present for the second nesting were new to the site; 41% of females disappeared and 27% of females present for the second nesting were new. Of

the new birds, 95% of males and 92% of females were yearlings. In Illinois, 50-60 days elapsed between laying of the first egg of the season and production of the second clutch. In Wyoming, there was an average of 36-60 days between the laying of the last egg of the first clutch and the laying of the first egg of the second clutch. In Ohio, females that laid clutches of 6 or 7 eggs were more likely to lay a second clutch than those that had smaller or larger first clutches. Renesting is common if a clutch is lost; 3 renestings occurred at 1 Ontario nest. Clutches of 2-9 eggs have been reported in Ontario, with 6 and 7 eggs most frequent. In eastern Ontario, house wrens regularly laid 4-7 eggs (mean 6.1). Ontario clutch sizes are typical. Usually 4-7 or 8 eggs are laid; larger and smaller clutches are rare. Clutch size increases northward and decreases as the season progresses. Mean clutch sizes of 6.2-6.5 eggs have been reported. Clutches laid before mid- to late June usually contain 6-8 eggs; later clutches have 4-6 eggs. In Ohio, first clutches averaged 6.3-6.5 eggs compared with 5.2-5.7 eggs for second clutches. Most females laid 5 or 6 eggs in their second clutch regardless of the size of their first clutch (Campbell et al. 1997; Finch 1991b; Gross in Bent 1948; Kendeigh 1941; Kennedy and White 1991; Johnson 2024; Palmer-Ball 1992; Parren 1991; Peck and James 1987; Picman and Belles-Isles 1988b; Robinson and Rotenberry 1991; Thompson and Neill 1991; Whittingham et al. 2002; Young 1994).

Both sexes are capable of breeding when they are 1 year old. Yearlings nest later in the season than adults, typically initiating nests when adults are starting their second broods. It is uncertain if yearlings are late migrants or unpaired floaters until they initiate nesting. In Ohio, 12-18% of Northern House Wrens did not breed in their first year (23.4% of males and 6.7% of females). Less than 5% of experienced breeders do not breed in a given year. In most populations, there appears to be a surplus of unmated males and females; lost mates are typically replaced within 3 or 4 days (Drilling and Thompson 1988; Gross in Bent 1948; Johnson 2024; Kendeigh 1941; Kendeigh and Baldwin 1937; Kermott et al. 1990, 1991).

The mating system is predominantly monogamous, but considerable numbers of males are polygynous. Females select mates and appear to reject those that do not have more than 1 potential nest site in their territory. Polygyny is enhanced by provision of surplus nest boxes in a territory. In Wyoming, 53.3% of males were polygynous when nest boxes were provided compared with 9.6% that had only natural cavities within their territory. Eighty-three percent of males with boxes and 47% of males with natural cavities consistently attempted to attract a second mate. In Illinois, 24.2% of males were bigamous and one (0.2%) was trigamous; 2.8% of males had 2 bigamous matings in a season and one had 3 bigamous matings. In Alberta, 21.7% of males were polygynous and 35.7% of females were mated to a polygynous male. At another Alberta site, 18 males nested polygynously and 6 of them did so while the first nest was active. The others were sequentially polygynous within the breeding season, changing mates for the second brood. In Ohio, only 6% of matings were polygynous, but 2 populations nesting in nest boxes in New York had polygyny rates of 13-40% (average 20%). In a Wyoming population where only natural cavities were present, 9.6% of males attracted a second mate; 15-35% of males were polygynous in subsequent years when each male was provided 2 nest boxes. Polygyny is usually asynchronous with the secondary female initiating egg laying after the primary female. Secondary females tend to lay smaller clutches because they nest later. Mate sharing does not appear to affect the reproductive output of the primary female's first clutch, but these birds are much less likely to attempt a second clutch and may have lower

overall reproductive output than females mated to monogamous males. If a primary female suffers nest loss, she may renest with the same male and become the secondary female in the relationship. Polygynous males rarely retain both mates for a second brood, but produce 4 broods in a season when they do. In Wyoming, 94% of monogamous and primary females fledged at least 1 young compared with 69% of secondary females. Both sexes solicit extra-pair copulations, but the rate of extra-pair copulations is diminished by the territoriality of males. In Illinois, 8.4% of nestlings were unrelated to their putative father. The proportion of extra-pair nestlings was significantly higher in nests defended by polygynous males (10.2%) than monogamous males (7.4%). The incidence of extra-pair nestlings increased as the breeding season progressed. The frequency of broods containing extra-pair nestlings was greater for secondary broods of polygynists (42.9%) than for primary broods of polygynists (17.2%), or for monogamists (26.0%). The pair bond is very temporary and frequently lasts for only a single brood. Although pairs may occasionally stay together to raise 2 broods, usually a different mate is selected for the second nesting. A different mate may also be selected when renesting. In Illinois, 45.3% of birds with 3 nests in a year had a different mate for each nest. For monogamous pairs, 55.4% switched mates for the second nest and 44.6% remained paired. About half of males that care for their first young lose their territory and consequently their mate; over 90% of non-caring males retain their territory. In Ohio, 13% of males remated with their mate of a previous year compared with 22% of females. One pair was mated in 3 years, but only for 1 nesting during each of these years. Based on returns, 58% of pairs that had the opportunity to remate in subsequent years did so. In all cases when birds remated in a subsequent year, they returned to an area that overlapped the territory they held the previous year (Baldwin 1921; Bart 1990; Czapka and Johnson 2000; Drilling and Thompson 1991; Gross in Bent 1948; Johnson 2024; Johnson and Kermott 1991; Kaluthota and Rendall 2017; Kendeigh 1941; Llambías et al. 2012; Quinn and Holroyd 1992; Soukup and Thompson 1997). Picman and Belles-Isles (1988b) observed 5 probable cases of intraspecific parasitism in 23 nests at Presqu'ile and Mer Bleue. In 3 cases, 2 eggs were laid in the nest in a single day and in the other 2 cases an egg was laid after the original clutch was completed.

In Manitoba, most food was obtained by gleaning (82.5% of observations), 12.5% by hovering, and 4.7% by other techniques. There was a large variation in foraging behaviour at different nest sites, with birds using foraging substrates similar to their availability. Ground foraging occurred least, with dead and live limbs preferred for foraging. Most foraging occurred in the subcanopy, in saplings and shrubs, and in herbaceous ground cover. Peach-leaved willow was selected for foraging; green ash was used less than its availability. Manitoba maple and sandbar willow were important species for foraging (Guinan and Sealy 1989). In southern California, 26% of foraging activities occurred on leaf litter, 49% in shrubs, and 26% in trees (Johnson 2024).

The male may feed the female while she is incubating, but this behaviour may be rare in some populations. In the first third of the nestling stage, the female spends much time brooding, so feeding by the male is essential to prevent starvation of the young. Juveniles from the first brood may help to feed nestlings in the second brood. Nestlings are fed small invertebrates including spiders, hairless caterpillars, grasshoppers, cockroaches, moths, mosquitoes, grubs, flies, butterflies, horse flies, beetles, monarch butterflies, underwing moths, harvestmen, soldier bugs, owlet moths, leafhoppers, crickets, and ants. Of 40 gizzards removed from 15-day-old nestlings, 100% contained

adult or larval beetles, 70% had leafhoppers, 62% had crickets or grasshoppers, 50% had flies, 43% had spiders, 40% had caterpillars, 23% had earwigs, and 45% contained fragments of land snails. Young are also fed significant amounts of grit. A video of 755 trips to Illinois nests revealed that nestlings were fed 29.5% grasshoppers and crickets, 22.5% caterpillars, 13.2% spiders and harvestmen, 5.3% bugs, and 3.8% flies, bees, and wasps. In New York, adults captured spiders, beetles, adult lepidopterans, spiders, and harvestmen in proportion to their availability. Orthopterans and caterpillars were captured more than expected and flying insects were selected less than expected. Slugs were readily available but fed to nestlings only in a drought year. Adults eat invertebrates almost exclusively and have a diet similar to the young. Fairly immobile prey such as spiders, beetles, bugs, and various types of larvae are overrepresented in the diet compared with their availability. More mobile invertebrates such as small flies, leafhoppers, and springtails are underrepresented. In Manitoba, midges were present in 84.2% and 82.0% of stomachs over 2 years and accounted for 51.9% and 29.5% of food items. Beetles and flies other than midges were taken early in the season. Other adult insects, mostly butterflies, moths, and hymenopterans, were consumed in late July and early August. Spiders and beetles were taken consistently. Wrens appeared to select for beetles in addition to midges and bugs. No prey items were represented in stomachs in proportion to their availability. Most prey was 3-9 mm in length, but occasionally larger and smaller invertebrates were eaten. Other items infrequently consumed included mites, book lice, large mayflies, and mosquitoes. Another study examined stomachs from a wide geographic area and found the diet to be comprised of 29.3% bugs (stink and ebony bugs and leafhoppers); 17.6% grasshoppers, crickets, and locusts; 13.9% moths and caterpillars; 13.8% beetles; and 8% ants. Small numbers of millipedes, ticks, lice, aphids, snails, and small crustaceans were eaten. The food of 68 birds from the southeastern states was examined and animal food was eaten exclusively: 29.3% bugs (predominantly stink bugs, but also ebony bugs and leafhoppers), 17.6% orthopterans, 13.9% lepidopterans (including many adult moths), 13.8% beetles (weevils and ground, lady, and leaf beetles), 8.2% ants, 3.3% bees and wasps, 10.5% spiders, 2.8% millipedes, and trace amounts of snails and isopods. Another study examined 52 stomachs from the United States and determined that the diet consisted of 98% animal matter and 2% vegetation. The vegetation included bits of grass and similar matter and was probably ingested incidentally. Half the food consisted of grasshoppers and beetles and the rest was caterpillars, bugs, and spiders. In a Utah population, nestlings were occasionally fed small fish and fish appeared to be a regular but rare component of the diet (Beal 1897a; Beal et al. 1916; Common 1948; Gross in Bent 1948; Guinan and Sealy 1987; Johnson 2024; Johnson et al. 1992; Mayoh and Zach 1986; Pearse et al. 2004; Skutch 1953; Williams and Pennock 1995).

Cowbird parasitism of the Northern House Wren is rare. In Ontario, 5 of 1,214 nests (0.4%) were parasitized. Parasitism has not been reported elsewhere in Canada and there are currently only about 5 other records of parasitism. Both cowbird and wren young may fledge from parasitized nests. The house wren appears to be a suitable host, but it may reduce the incidence of parasitism by selecting small cavity entrances. Cowbirds cannot access cavities with an entrance diameter smaller than 38 mm (Campbell et al. 1997; Gross in Bent 1948; Hamerstrom 1947; Hodges 1949a; Johnson 2024; Lowther 1985, 1991; Peck and James 1997; Pribl and Picman 1997).

In Iowa, a Prothonotary Warbler parasitized a house wren nest. The nest initially contained 3 wren eggs and 1 warbler egg. One wren egg disappeared and the other 2 did not hatch. The wren successfully fledged the warbler (Dodson et al. 2024).

Although presence of suitable nesting cavities may be a limiting factor in some localized areas, habitat loss is not a major factor for the Northern House Wren. There may be some limited competition for cavities from European Starlings and House Sparrows, but this wren prefers cavities with smaller entrance diameters so this is not a significant limiting factor. Deer mice and white-footed mice may be more significant competitors for nesting cavities than other bird species. The house wren benefits from forest clearing and habitat fragmentation, and increased its range significantly once forest clearing began. The more recent abandonment of marginal agricultural land has provided additional breeding habitat, at least temporarily. Provision of nest boxes has resulted in large increases in populations (Johnson 2024; Kendeigh 1941; McNicoll and Robert in Gauthier and Aubry 1996).

Extreme weather may affect abundance of the Northern House Wren. Population declines often occur after unusually cold winters. In California, it declined significantly during a 5-year drought and recovered dramatically at the end of the drought. Prolonged hot temperatures may depress populations or reduce reproductive success. If weather is unfavourable when first clutches are usually initiated, some birds may not breed. Reproductive effort declines when the average night temperature for May, June, and July drops below 17°C or when the average night temperature in May or June is less than 14°C. In Ohio, mean daily temperatures above 26.7°C appeared unfavourable. Excessive rain during the breeding season may reduce nesting success (Johnson 2024; Kendeigh and Baldwin 1937; Verner and Purcell 1999).

In the Carolinian Forest Region of Ontario, abundance of the Northern House Wren was negatively correlated with basal area. It was most abundant in heavily cut forests (diameter-limit cuts) followed by woodlots harvested by single-tree selection and by unharvested stands (Holmes et al. 2004). In Montana, it was more abundant in burns where logs had not been salvaged than where postfire logging occurred (Hutto and Gallo 2006). Kronland and Restani (2011) reported similar results in the same state, although differences in abundance in the control and logged areas were not significant. In Oregon, it responded positively to fire and increased with increasing severity of the burn (Stephens et al. 2015).

Doherty and Grubb (1998) examined breeding success of the Northern House Wren under high-voltage lines (69kV and 765 kV) in Ohio. There was no effect due to electromagnetic fields on any measure of reproductive success. At a nuclear research establishment in southeastern Manitoba, it avoided adverse effects of radiation by selecting boxes that were not exposed to high radiation. Birds abandoned some boxes with high exposure rates before laying eggs. Radiation did not affect the number of fledglings produced or clutch size, hatching success, incubation time, and nestling time. At higher breeding densities, some birds may use high-exposure boxes where breeding success or growth of nestlings may become reduced due to radiation (Zach and Mayoh 1982).

No significant difference in reproductive success has been identified in Northern House Wrens nesting in natural cavities and nest boxes. Mortality rates were lower in boxes and birds using boxes laid larger clutches, hatched more eggs, and fledged more young than those using natural cavities.

Although the differences were not significant at individual study areas, they may be at a population level (Johnson and Kermott 1994; Purcell et al. 1977). Nest boxes have contributed significantly to the House Wren population by providing nest sites where none previously existed.

In Washington, DC and Baltimore, Maryland there was no difference in clutch size of suburban and rural birds, but suburban nestlings weighed less and had smaller body size than rural birds prior to fledging. It appeared as though the average quality of prey for nestlings may be lower at suburban sites. Suburban birds fledged more young than rural birds due to higher rates of predation on rural nests (Newhouse et al. 2008).

The Northern House Wren was vulnerable to the West Nile virus. It experienced a several-year decline following the spread of this disease in the 2000s, but appeared to have recovered by 2005 (Johnson 2024; Kilpatrick et al. 2007).

Elliott et al. (1994) studied reproductive success and accumulation of organochlorines in Northern House Wrens breeding in British Columbia orchards. Wrens nesting in orchards had 106 times more DDT, 5.5 times more DDE, and 15 times more DDD in their eggs than those nesting in other habitats. There was no difference in nesting success between orchard-nesting birds and birds nesting in other habitats. The organochlorine burdens were acquired locally in orchards rather than on the wintering grounds. Beginning mostly in the 2000s, house wren eggs and tissues have been monitored as indicators of bioaccumulation of toxins such as PCBs, polychlorinated dibenzofurans, polychlorinated dibenzo-p-dioxins, cholinesterase inhibitors, and heavy metals (Johnson 2024).

Nestlings may be subjected to parasitism by blowfly larvae, but the effects of this are fairly minor. Parasitism may slightly delay development of the young which could potentially increase nestling or fledgling mortality. Parasitism did not appear to affect nestling survival if it occurred after young were 6 days old. Infestations occurring very early in a nestling's life may be fatal, but infestations at this age occurred in only 12% of Wyoming nests. Parasitized nestlings showed normal haemocrit levels but had significantly reduced (less than 25%) concentrations of haemoglobin in their bloodstreams. This may have a profound effect on survivorship of fledglings because anaemic birds have a reduced ability to sustain flight (Eastman et al. 1989; L.S. Johnson et al. 1991; O'Brien et al. 2001).

In North Carolina, abundance of the Northern House Wren was significantly correlated with the number of houses and other buildings within 200 m (Lumpkin and Pearson 2013). In subdivisions in Rhode Island, abundance declined with increasing amounts of retained forest (Johnson 2024).

At noisy urban sites, Northern House Wrens sang songs with a narrower frequency range and faster rate than in quieter rural areas. It modified its trill structure to reduce sound masking and improve signal transmission. Wren songs had similar minimum frequencies at both sites, but frequency was increased as noise levels increased (Redondo et al. 2013). Urban house wrens inhabiting noisier territories had smaller song repertoires. Those in the noisiest locations tended to include more high-frequency elements in their songs. Not all males modified their songs to reduce masking effects of noise (Juárez et al. 2020).

DesGranges and Morneau (2010) considered the Northern House Wren sensitive to climate change because its presence was correlated with the mean number of annual degree-days equal

to or greater than 10°C in May, June, and July. Price (2004) predicted that the breeding range of the house wren would contract northward in southern Ontario if the average summer temperature increased by 2°C.

Status

The Northern House Wren is probably much more common now than prior to European settlement and subsequent forest clearing. It was not known to occur in Ohio in the 1830s but moved in quickly after the settlers arrived (Mayfield 1988). A similar pattern probably occurred in Ontario, where it was common by the turn of the 20th century and continues to be common (Lancaster et al. 2004; Mills 1981; Weir 2008). Baillie and Harrington (1937) considered it a common breeding species from the southern border north to at least Lake Abitibi and west to Lake of the Woods, but present more sparingly in the north. Mills (1981) noted that it was not as common in Muskoka and Parry Sound districts as it was historically, but that populations were recovering from a low in the 1960s. The decline may have been due to forest maturation. During the first atlas, it was ubiquitous south of the Canadian Shield, with density estimates of more than 1,000 pairs in some squares. Previously common in Algonquin Park (MacLulich 1938), it disappeared there due to in-growing of forest openings and removal of dwellings. It occurred sporadically in the Canadian Shield during the first atlas (Gould in Cadman et al. 1987). James (1991) considered it common north to Georgian Bay and Ottawa, locally rare and occasional to Sioux Lookout and Timmins, and a vagrant north to James Bay.

The second atlas demonstrated that there had been no change in the breeding range of the Northern House Wren since the first atlas. It was found in virtually every square south of the Canadian Shield and had a scattered distribution in the southern Shield and the Boreal Forest Region. There was no change in its probability of observation province-wide, but there was a significant increase in the Great Lakes–St. Lawrence Forest Region in the Shield. It was most abundant south of the Shield, particularly from Huron to Haldimand counties and in a band along the edge of the Shield from Georgian Bay to Brockville. Lower densities occurred in the intensive agricultural areas in the southwest and in the dense urban areas of the Greater Toronto Area (Brewer in Cadman et al. 2007).

Breeding Bird Survey data for 1970-2021 indicate that the population increased at annual rates of 0.587% in Canada and 1.22% in Ontario. For 2011-21, the annual rates of increase were 1.6% in Canada and 1.52% in Ontario. All results were highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Some young become independent approximately 10 days after fledging whereas some may still be receiving food from their parents 2 months later; independence usually occurs 12-13 days after fledging (Johnson 2024). One adult led its 5 fledglings back to the nest for 2 consecutive nights. Temperatures were below freezing (–2°C and –3°C) those nights. The first day after fledging, young remained within 7-12 m of the nest, but wandered 40-104 m from it the following day (Scholer 2015). Typically fledglings do not return to the nest because they are particularly vulnerable to predators within the nest and nests are often infested with ectoparasites.

MIGRATION

Northern House Wrens that breed in Ontario migrate through the southeastern United States and winter as far north as Maryland. One banded at Long Point was recovered in Texas; one banded in

Pennsylvania was recovered in the Dunnville Marshes (Brewer et al. 2018). It is unknown if individuals migrate singly or in flocks (Johnson 2024).

The Northern House Wren is a nocturnal migrant that arrives in the province near the end of April, with migration continuing until mid-May or even June. Occasionally birds arrive as early as the end of March. Males arrive on the breeding grounds a few days before females; in Ohio, females arrived about 9 days after males. Older, experienced birds tend to arrive before yearlings, although some first-time breeders also arrive early. Some first-time breeders do not appear on territories until mid- to late June. Autumn migration occurs predominantly in September with most birds gone by the end of September or early October, with occasional stragglers to mid-October. There are a few records from late December or very early January (Black and Roy 2010; Curry 2006; James 1991; LaForest 1993; Lancaster et al. 2004; Weir 2008).

During migration, the Northern House Wren occurs primarily in edge and shrubby habitats. It prefers woodland edges, gullies, thickets, ravines, open forest stands, hedgerows, raspberry patches, shrubby roadsides and power-line rights-of-way, and thickets around ponds, orchards, gardens, and abandoned buildings (Campbell et al. 1997; Fitch 1958). During spring migration in Minnesota and Wisconsin, it was significantly more abundant in floodplain forests than in upland forests (Kirsch et al. 2013).

The Northern House Wren shows considerable site fidelity during migration and some birds probably follow the same route every year. Taylor et al. (1983) examined 2,218 recoveries of house wrens and found that 97% of them were at or near the place of banding. There were 207 cases (9.3%) of the same bird repeating at the same site at least 1 year after being banded; 80.1% repeated once after the first recovery, 13.0% repeated twice, 6.3% repeated 3 times, and one repeated 4 times. Somershoe et al. (2009) also demonstrated house wren site fidelity during migration in Florida.

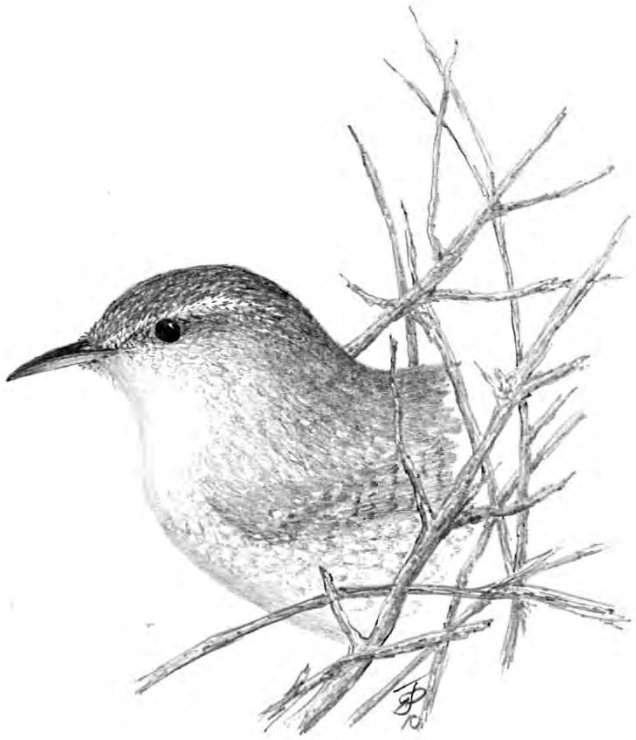
During migration, the Northern House Wren is vulnerable to being killed due to collisions with tall structures. It frequently collides with television towers, lighted buildings, and lighthouses (Gross in Bent 1948; Johnson 2024; Taylor et al. 1983).

In New York, Zelt et al. (2017) compared spring arrival dates, autumn departure dates, and length of the breeding season during 1888-1939 and 1967-2012. There was little climate change during the first period but significant warming during the second period. Spring arrival dates of the Northern House Wren were significantly earlier during the second period, but there were no significant differences in autumn departure dates or length of the breeding season.

The Northern House Wren is uncommon during migration in Ontario (James 1991).

Winter Wren

Troglodytes hiemalis



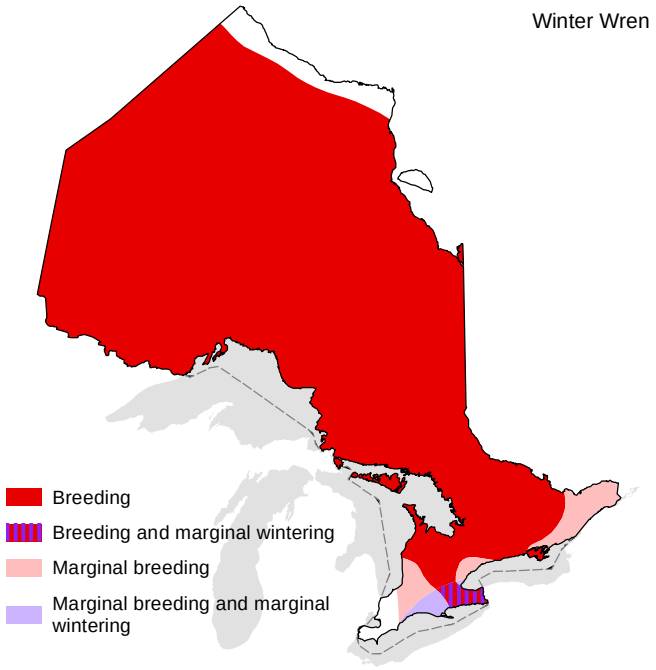
BREEDING SEASON

Habitat Requirements

In Ontario, the Winter Wren breeds in deciduous, mixed, and coniferous forests. It nests predominantly in swamps or near bodies of water. Two nests were in bogs treed with conifers and one was in a mixed forest near buildings (Peck and James 1987).

The Winter Wren was common in a black spruce swamp south of Moosonee and was likely to be found anywhere in the Hudson Bay Lowland where there was substantial forest (Wilson and McRae 1993).

In the Boreal Forest Region, the Winter Wren was associated with older coniferous mixed-wood forest with lower edge ratios and more intact forest cover. Rempel et al. (2007) predicted its habitat would be maintained under natural conditions as well as timber harvesting that adhered to the forest management guidelines for key species. It occurred in older, closed, coniferous forests in a mature forest matrix (Rempel 2007). Near Pickle Lake, it occurred in small numbers in black spruce forests at widely scattered areas (James 1980). In northwestern Ontario, it was most abundant in



coniferous forest, was present in mixed shrub communities, and absent in other habitat types (McLaren and McLaren 1981). Near Hearst, it nested in clear-cuts 5-24 years old and in uncut upland mixed stands (Welsh and Fillman 1980). Near White River, it was more abundant in mature forests than in clear-cuts 3-25 years old, but not significantly (Venier and Pearce 2005).

In white pine stands in the Canadian Shield in the Great Lakes–St. Lawrence Forest Region, abundance of the Winter Wren was significantly correlated with presence of medium and large pine trees. It was more common in old-growth than mature stands, but not significantly (Kirk et al. 2012). In Quetico Park, it nested in all stages of succession following forest fire with no significant differences in abundance from early successional to old-growth forest (Apfelbaum and Haney 1985). It was rare in jack pine and jack pine mixed stands near Gogama. Forest type was not as important as local conditions. It was associated with damp depressions in the sandy soils that were mostly too dry to support suitable habitat for it (James and Peck 1995a). In Algonquin Park, it nested in black spruce and black spruce–white cedar wetlands and in upland hemlock forests and was absent in other forest types (Martin 1960). In Muskoka and Parry Sound districts, it nested in dense, moist forests of many types (Mills 1981).

In Durham Region in the Great Lakes–St. Lawrence Forest Region south of the Shield, the Winter Wren nested in wet habitats including a black spruce bog, a riparian forest of white cedar–balsam fir–spruce, and 2 flooded woodlands with considerable hurricane damage and downed timber. Speirs and Orenstein (1975) considered it a mid-succession species associated with white cedar. At Presqu'ile, nesting occurred in coniferous forests and wet hemlock–grey alder forests (LaForest 1993).

In the Carolinian Forest Region near Hamilton, McIlwraith (1894) reported the Winter Wren nesting in cedar swamps made impenetrable by fallen timber. It is still present in these swamps as well as other extensive swamps in the Hamilton region (Curry 2006). In Elgin County it breeds in deeply shaded ravines that support hemlock (Lancaster et al. 2004). Baillie and Harrington (1937) stated that the Winter Wren bred in Ontario in deep woods and swamps.

Many studies concluded that the Winter Wren is an obligate old-growth forest species. In Alberta, it was associated with conifers in aspen stands and was significantly more abundant in old-growth stands than in mature and young stands (Schieck et al. 1995). In Saskatchewan, it occurred only in forests that were 140 years old or older (Cumming and Diamond 2002). Hejl et al. (2020) stated that the Winter Wren was unique among wrens in its association with old-growth forests.

Old-growth structure (snags, downed logs, and large trees) are used for nesting, foraging, and roosting. Nonetheless, it nests in a wide range of habitat including treeless islands, cliff faces, clear-cuts, and logged forests, although habitat suitability is lower in these habitats. In Quebec, it nested in young and mature black spruce forests, but not in clear-cuts or burns. It was equally abundant in forests with sapling growth 5-11 m tall and in those that were 120 and 200 years old (Imbeau et al. 1999). In Pennsylvania, it had a positive affinity for old-growth forest. It was present in 90.0% of old-growth forests, in 7.7% of forests statewide, and in 14.7% of forests in the Appalachian Plateau (Haney 1999). In the Yukon, it is regularly encountered only in dense old-growth riparian white spruce forests with a complex understorey, abundant leaf litter, and large fallen trees (Sinclair et al. 2003). In southern agricultural Quebec, it nests mostly in mature isolated woodlots with some conifer growth, or in peatlands. Further north, it nests mostly in coniferous and mixed forests, but also in mature dense deciduous and hemlock stands (Gagnon and Robert in Gauthier and Aubry 1996).

Despite the Winter Wren's apparent affinity for old-growth forest in certain areas, it nests in much younger stands and even clear-cuts. It is strongly associated with dense shrubbery, upturned root wads, and old logs. These preferences result in it inhabiting a wide range of forest ages from recent clear-cuts to old-growth forest. It may occur in clear-cuts or blowdowns where there is residual slash or upturned roots for cover, but is absent in burns where there is limited retained undergrowth. Near Hearst, it nested in clear-cuts 5-24 years old (Welsh and Fillman 1980). In New York, it nested near or within hemlock blowdown in a forest, but disappeared after the blowdown was cleaned up. In Alberta, retention of trees in clear-cuts allowed it to remain in the open areas. Its abundance increased with increasing basal area of trees left starting 3 years after cutting. In central Quebec, its density was 1.5 times higher in birch stands than black spruce–moss stands and more than twice as high as in old burns and shoreline ecotones in coniferous forests. In British Columbia, it occurred in mixed forests with a dense understorey, deep ground litter, and numerous fallen trees in various stages of decomposition. In subalpine areas of New Hampshire, it demonstrated a specialty for fallen logs. In New England, its presence was affected both by size class of timber and forest type. It occurred only in sawtimber-sized forests, the largest size-class of trees, and in stands dominated by red maple and hemlock. In the Boreal Forest Region, the Winter Wren was in a guild that was primarily associated with conifers and it occurred in rold stands. In subalpine areas of New Hampshire and Maine, its abundance was positively correlated with the percent ground cover and the total foliage volume of deciduous trees larger than 10 cm diameter at breast height (DBH). It was negatively correlated with canopy closure, the number of woody stems per ha, the number of snags larger than 10 cm DBH and taller than 5 m, and the total foliage volume of coniferous trees larger than 10 cm DBH (Burris and Haney 2005; Campbell et al. 1997; DeGraaf and Chadwick 1987; DeGraaf et al. 1998; Hejl et al. 2020; Gagnon and Robert in Gauthier and Aubry 1996; Holmes and Robinson 1988; Kirk et al. 1996; Sabo 1980; Sinclair et al. 2003; Tittler et al. 2001; Yunick 1990; Zarnowitz and Manuwal 1985).

The Winter Wren is frequently associated with water or with wet to damp habitats. In southern Quebec, it is often found near streams or lakes or in poorly drained or swampy forests (Gagnon and Robert in Gauthier and Aubry 1996). Streams were an important component of territories in

subalpine areas of New Hampshire (Sabo 1980). Hejl et al. (2020) stated that it frequently nests and forages near water, especially streams, but also bogs, swamps, and lakes. It is more restricted to riparian areas in the drier parts of its range, but water appears to be important to it throughout. Territories are preferentially established along watercourses or other sources of water, resulting in a patchy distribution.

In many areas, the Winter Wren is strongly associated with coniferous trees. Coniferous forest was most frequently inhabited throughout British Columbia (Campbell et al. 1997). In New Jersey, Benzinger (1994) considered it a facultative hemlock species. He estimated that 70% of the New Jersey population nested in hemlock growth and 30% in hardwoods containing pines. The most frequently occupied areas included ravines, stream valleys, and slopes, most of which supported hemlock. It was restricted to heavily wooded sites suggesting that microclimate might be a factor. Hemlock cover may result in lower air temperatures and higher humidity. Hejl et al. (2020) concluded that highest nesting densities occurred in coniferous forests. In an extensive forest near Richmond, Ontario, the Winter Wren was common in mixed swamps and coniferous forest. Over a 4-year period, it occurred in only 1 deciduous stand where there was extensive American yew in the understorey (personal observation).

Although the Winter Wren is strongly associated with coniferous stands, it occurs in a variety of forest types. In addition to mixed forests, cedar and spruce swamps, and upland and lowland fir communities, it has nested in many other forest types. These include sugar maple–beech–yellow birch hardwoods, dry boreal forests rich in nutrients, northern hardwoods, lowland hardwoods, and aspen-birch stands (Back 1979; Crawford and Titterington 1979; Dawson 1979; Holmes and Robinson 1988; Kirk et al. 1996; Noon et al. 1979; Samson 1979; Temple et al. 1979). Forest type may not adequately describe the microhabitats within the forest that it is selecting. Habitat features higher than 3 m may be relatively unimportant because it forages and nests close to the ground (Benzinger 1994).

The Winter Wren is often considered a forest-interior species. In southern Ontario, its probability of detection was positively correlated with the amount of forest cover 100 m or more from edge, forest size, and the amount of regional forest cover, but it was negatively correlated with the amount of forest within 2 km. These relationships were not significant (Austen et al. 2001). In a forest near Richmond, Ontario, it was significantly more abundant 180 m from edge than at 120, 60, or 0 m (Gore & Storrie Limited 1992). Lindell et al. (2007) summarized studies that determined its abundance in relation to forest edge. One study found that there was no relationship between its distribution and edge; 2 showed an avoidance of edge. In Newfoundland balsam fir stands, it was equally abundant in riparian edges, nonriparian edges, and forest interior. It was also equally abundant in 20-50-m wide riparian buffer strips retained between clear-cuts and water bodies and watercourses (Whitaker and Montevecchi 1997, 1999). In eastern Quebec forests, there was no difference in its density in riparian and nonriparian balsam fir–white cedar stands (LaRue et al. 1995).

Hejl et al. (2020) stated that Winter Wren abundance was higher in forests larger than 20 ha and in more continuous habitats surrounded by late successional forest than in smaller habitats and areas surrounded by edge, particularly clear-cuts. Size of clear-cuts may be important because it will nest near forest edge in small clear-cuts but may not nest in large clear-cuts or in the interior of

clear-cuts (Hejl et al. 2020). In Wisconsin, it was not present in linear tracts less than 100 m wide (Hejl et al. 2020). In Michigan, its abundance was positively correlated with patch size (Crozier and Niemi 2003). Drolet et al. (1999) studied its occurrence in 100-ha landscapes where forest cover ranged from a few remnant hectares to over 90 ha. They found no significant correlation between Winter Wren abundance and the amount of coniferous forest, mixed forest, mixed regeneration, clear-cuts, or windthrow within 100-ha squares, or with presence of budworm outbreaks.

In Ontario, there are some components of the Winter Wren's habitat that are consistent throughout its range, but other habitat requirements may vary from areas south of the Canadian Shield to in the Shield. Throughout Ontario, it is strongly associated with large, fallen logs and tangled undergrowth. South of the Shield, it is restricted to forested habitat where it appears to be area sensitive, seldom occurring in forests smaller than 20-30 ha. Exceptions occur, and it nests in wooded ravines with hemlock cover. In the south, it is most often found in mature and old-growth coniferous and mixed swamps containing white cedar, balsam fir, and spruce. These areas provide the cooler microhabitat that it appears to prefer as well as downed timber, upturned root wads, and the dense undergrowth that it requires. Deep, wooded ravines also provide these microhabitats. It may also nest in wet forests with dense shrub growth and windfalls, and these may have limited canopy closure due to high wind damage. South of the Shield, it is found mostly in forest interior, probably because cool moist habitats, fallen logs, and upturned roots seldom occur in forest-edge habitats. In the Shield, it appears to be less exacting in its habitat requirements. Complex understorey structure in the form of fallen logs, root masses, and shrubs is still necessary. Its presence is often strongly associated with water and it may occur at forest edges along beaver ponds, rivers, and lakes. While associated mostly with conifers in the south, understorey characteristics and presence of water appear more important in the Shield. Forest maturity is also not as important in the Shield, and it may nest in all successional stages of forest provided that the understorey structure is suitable and there is water nearby.

Early in the breeding season, the male occasionally roosts in his own dummy nest and also in hollow logs while the female roosts in the nest that is ultimately used for nesting. Both members of the pair roost alone at this time. Once the young fledge, the brood roosts together, and the female may lead the young to the roost for about 2 weeks. Some nests may be used for brooding but not for nesting (Hejl et al. 2020).

All Ontario nests were well hidden and shaded. Most were in fallen tree roots and in holes in tree stumps and fallen logs. Single nests were found under live birch roots growing under a building, under a bank of a ditch, in moss on a rock, and on a rock ledge. Nests were 0.08-2 m from the ground, but mostly 0.3-1.1 m up. One nest was in an old phoebe nest on a ledge (Peck and James 1987, 1997). In Algonquin Park, 1 nest was in a woodshed between a beam and the roof of the building. One nest was on a cottage above a window between the rafters of an overhanging roof. Later the same year, another nest was found at the same cottage in a sand-sifting box hanging on the outside wall of a shed. One of these nests was 2.1 m from the ground (Tozer 1996).

Throughout North America, the Winter Wren is a secondary cavity nester that nests primarily in natural cavities or old woodpecker holes, occasionally in cavities that it excavates in creek banks, and rarely in or on human-made structures or in a free-hanging nest constructed in a tree (Hejl et al.

2020; Zarnowitz and Manuwal 1985). In British Columbia, 52% of nests were in living or dead coniferous or deciduous trees and 24% were in banks and cliffs. Most were in a cavity: 33% in natural cavities and woodpecker holes, 26% among roots of overturned trees, and 26% under an overhang in a soil bank or cliff or an overhang of a building (Campbell et al. 1997). Bent (1948) reported most nests in cavities in the soil of upturned roots, but also some in rotten stumps, under roots of standing trees, in woodpecker holes, in rolls of bark of large trees, in logs, suspended from tree limbs, and in soil banks. Evans and Conner (1979) reported that the optimum size of snag for nesting was 20 cm DBH and that cavity entrances should be a minimum of 3 cm. It occasionally nests in nest boxes and other artificial features. Nests have been in and on buildings, in hanging flower planters, in old stoves left outside, in an air vent in a suburban house, in shrubs, on a bridge, in an abandoned automobile, and in a pair of snowshoes (Bent 1948; Campbell et al. 1997; Gagnon and Robert in Gauthier and Aubry 1996; Yunick 1990).

The territory size of the Winter Wren varies depending upon habitat type, food availability, density of breeding pairs, and whether the male is monogamous or polygynous. North of Lake Nipigon, 3 territories were 0.49-1.13 ha (average 0.89 ha; Kendeigh 1947). Average territory size in Algonquin Park was 0.49 ha (range 0.06-1.17 ha). The average depth of territories was 4.3 m (Martin 1960). Average territory size was 0.9 ha in a mature hemlock stand near Mirabel, Quebec (Gagnon and Robert in Gauthier and Aubry 1996). In subalpine areas of New Hampshire, territories averaged 1.6 ha (Sabo 1980). In Maine red spruce forest, Morse (1977) reported a territory size of 3.64 ha. In British Columbia, the average size of territories was 0.68-1.46 ha over 3 years (Hejl et al. 2020). Territory densities may be low and territory sizes larger when physical barriers and unsuitable habitat preclude the presence of neighbours. Territory size is affected by habitat structure and composition that determine the number of nest sites and singing posts and availability of food. When density of breeding birds is low, the most favourable habitats are occupied. Less favourable sites are occupied only when the population is high (Hejl et al. 2020). Where Winter Wrens are resident, the male defends the territory year-round, but the size of the territory may shrink after the breeding season. Females occupy a home range of 0.2-1.4 ha during the breeding season. These home ranges are usually non-overlapping, although limited overlapping may occur. Ranges of females mated to the same male do not overlap (Hejl et al. 2020). Near Quebec City, territories were not clumped with no evidence of coloniality (Bourque and Desrochers 2006).

The rate of natal philopatry is unknown (Hejl et al. 2020). Limited data suggest that adult site fidelity is high. In British Columbia, 16 of 44 nests (36.4%) were reused the following year, and 5 were used by the same male (Hejl et al. 2020).

Limiting Factors

Eggs have been found in Ontario nests from late May to mid-July, mostly during the first 3 weeks of June (Peck and James 1987, 1997). The length of time required to complete a nest is unknown. The interval between the beginning of nest building and the initiation of egg laying is 3-22 days. Eggs are laid at the rate of 1 a day, although a day is occasionally skipped. Incubation often starts with the laying of the last egg, but may start as early as when the first egg is laid. It has been suggested that incubation starts with the last egg in clutches laid in April and May and with the first egg in later clutches. The incubation period is 14-16.5 days. The young leave the nest when they are 15.5-19

days old, typically 16-17 days. The family group remains within the male's territory for 6-36 days after the young from first brood fledge and then the family unit dissolves (Bent 1948; Campbell et al. 1997; Hejl et al. 2020).

The lengthy egg-laying period suggests that 2 broods may be raised in Ontario (Hejl et al. 2020; Peck and James 1997). Renesting almost always occurs after failure of the first nest; 2 attempts at renesting may be made. There is a strong correlation between the number of nests completed and the number of breeding attempts a male makes each season (Hejl et al. 2020). Clutches of 4-6 eggs have been reported in Ontario, with 5-6 eggs most frequent (Peck and James 1997). Clutches of 1-9 eggs have been reported with most containing 5-6 eggs, or occasionally 7 eggs. Clutch size increases with latitude (Bent 1948; Campbell et al. 1997; Hejl et al. 2020).

The age at first breeding has not been documented. Both sexes presumably breed in their first year and every year thereafter similar to other North American wrens. Some adult males remain unmated during at least part of the breeding season (Hejl et al. 2020). The mating system is predominantly monogamous, but bigamy occurs and trigamy is rare. Polygyny appears to be more prevalent where food or nest sites are abundant but unevenly distributed. There appears to be no difference in nesting success between monogamous and polygynous males (Hejl et al. 2020).

The Winter Wren's foraging techniques have been considered similar to those of the Black-capped Chickadee, except that the wren almost never forages above heights of 3 m. In Algonquin Park, the Winter Wren had the lowest territory of any bird species, where it was not observed over 2.4 m from the ground. Average foraging heights in other regions were 0.7 m in subalpine communities and 1.7 m in northern hardwoods. Within this vertical range, it may forage on all available substrates including the ground, logs, root masses, shrubs, and trees (Hejl et al. 2020; Holmes and Robinson 1988; Martin 1960; Sabo 1980). The foraging substrate that is used most frequently varies depending upon the habitat and availability of food. In northern hardwoods, it foraged most frequently in the shrub layer on bark and leaves, followed by on the ground and around the bases of living trees, in herbaceous or fern cover, and in the air. In subalpine communities, it foraged most on the forest floor (81.5%) and seldom on coniferous (6.3%) and deciduous (4.5%) tree foliage (Hejl et al. 2020; Holmes and Robinson 1988; Sabo 1980). It occasionally forages underwater along ditches and stream banks by immersing the upper half of its body to capture aquatic invertebrates or small fish (Bent 1948; Heck 1994). Hawking and aerial foraging are rare foraging techniques (Holmes and Robinson 1988). Occasionally it forages on tree trunks in a fashion similar to that of the Brown Creeper (Hejl et al. 2002). In New Hampshire, foraging techniques were 24.9% probing, 61.3% gleaning, 2.5% jumping to hover, 6.8% hovering, and 4.5% hawking. Slightly more than 50% of foraging manoeuvers were directed towards prey on bark: 50% of these were on tree trunks and exposed roots; 41% on dead logs and branches laying on the ground; and 9% on the bark of twigs or branches near the ground. It was primarily a gleaner in all substrates, but it also probed bark extensively on fallen dead wood and less frequently in the ground litter. While searching for food, it also hopped into knotholes and cracks between upturned roots. It mechanically searched low substrates for prey by hopping slowly and examining crevices. It also probed clusters of dead leaves suspended in shrubs (Holmes and Robinson 1988). In subalpine New Hampshire communities, foraging strategies were 63.3% fallen log manoeuvers, 14.3% gleaning

from the litter, 11.5% pecking at the litter, 5.2% gleaning from leaves, 2.8% pecking at twigs, 1.4% gleaning from tree trunks, 1.0% hawking from leaves, and 0.3% gleaning from twigs (Sabo 1980).

Both adults feed the nestlings; the male rarely brings food to the female as she incubates (Hejl et al. 2020). Bent (1948) reported that nestlings were fed a variety of moths, including spruce budworm moths and geometer moths; crane flies; cutworms; caterpillars; a variety of small insects; and spiders.

The adult Winter Wren's diet is similar to that of nestlings; it feeds predominantly on invertebrates. It is an opportunistic or weakly selective forager, and the quantity of available food is a factor in its habitat selection and dispersion. Insects and spiders are staples in the diet. The major invertebrate groups consumed include beetles, bugs, caterpillars, ants, fleas, mites and ticks, pseudoscorpions, millipedes, spiders, and harvestmen. In a sample of 122 British Columbia stomachs, 66% contained beetles, 51% spiders, 30% moth and butterfly caterpillars, 23% mites and ticks, 10% millipedes, 10% harvestmen, and 2% snails. The abundance of soft-bodied invertebrates was probably underestimated. Other food items included centipedes, springtails, bristletails, lacewings, and unidentified seeds. Consumption of certain foods varied seasonally: millipedes occurred in 2%, 28%, and 50% of stomachs during the breeding season, autumn, and winter, respectively, compared with 5%, 4% and 17% for springtails and 3%, 52%, and 0% for seeds during the same periods (Hejl et al. 2020). Bent (1948) reported the diet to consist almost exclusively of invertebrates: beetles, bugs, spiders, caterpillars, and ants and other small hymenopterans. Forest insects consumed included beetles (weevils and long-horned and leaf beetles), leafhoppers, aphids, lacewings, sawflies, and caterpillars. Grasshoppers, crickets, crane flies, millipedes, and snails were minor components of the diet; dragonflies, harvestmen, mites, pseudoscorpions, and isopods were rarely eaten. In New Hampshire, Holmes and Robinson (1988) observed adults taking spiders, harvestmen, and a variety of insects. In New York, one captured 3 small trout fingerlings by dashing through several metres of 1-cm-deep water to grab the fish (Heck 1994). It has been observed eating red cedar berries in October. Near Manitouwadge, there was no correlation between the abundance of the Winter Wren and spruce budworm (Venier et al. 2009). In New Brunswick, Morris et al. (1958) found an inverse relationship, with the Winter Wren decreasing with increasing budworm abundance. Mitchell (1952) examined the contents of 9 stomachs during a spruce budworm outbreak in Maine. Over 2 years, the diet consisted of 3% and 11% budworm larvae and pupae by volume.

The Winter Wren has not been documented being parasitized by the Brown-headed Cowbird (Hejl et al. 2020).

Forest fragmentation and logging are the greatest limiting factors to the Winter Wren. In Ontario south of the Canadian Shield, activities that reduce forest sizes below 30 ha are likely to result in the loss of breeding Winter Wrens. Even larger forest remnants may become unsuitable habitat if they become drier or less complex in structure. In Maine, it was more abundant distant from a highway even when habitat was taken into account. Ferris (1979) concluded that the highway was having a negative effect on the Winter Wren. It was not determined if the aversion to the road was due to a response to predators, noise, edge, or other factors. In the Canadian Shield of Ontario, it was equally abundant in early successional and mid-successional clear-cuts and burns in the same seral stages.

It was significantly less abundant in early successional and mid-successional stands than in mature stands (Zimmerling et al. 2017). Hejl et al. (2020) stated that it was one of few species that was clearly harmed by forest fragmentation in the west. There is concern for it in certain areas due to declines in snags, downed trees, large trees, and old-growth forest. Hejl et al. (2020) predicted that a combination of forest fragmentation and simplification of forest structure through even-aged management would probably result in its decline. It may be somewhat more resilient to forest-management practices in the east, where it occasionally nests among residual trees and slash in clear-cuts. Vanderwel et al. (2007, 2009) summarized studies that examined the effects of partial timber harvesting in the Boreal Forest Region, with particular reference to Ontario. There was no change in its abundance when 30%, 50%, or 70% of trees were removed. It experienced a 25-75% decrease in abundance when about 85% of trees were removed. In Algonquin Park, group-selection and single-tree harvesting of tolerant hardwoods had no significant effect on the Winter Wren (Jobes et al. 2004; Tozer et al. 2010). In New York, Webb et al. (1977) studied the response of Winter Wrens when 25%, 50%, 75%, or 100% of merchantable trees were removed in diameter-limit forest management. A declining trend in wrens was observed with increasing logging intensity, but the trend was not significant. It appeared to be negatively affected only when logging approached being a clear-cut. In Minnesota, tree removal in residual riparian buffer strips did not negatively affect it. It responded positively when trees were cut-to-length on site rather than being removed whole. The cut-to-length harvest resulted in greater amounts of slash being left within the forest (Hanowski et al. 2002, 2005). In Maine, the Winter Wren was associated with all seral stages resulting from clear-cuts of spruce-fir forests. Highest density occurred in the first 2 years after cutting when the habitat was characterized by dense slash and abundant open ground. Numbers remained high 3-12 years after clear-cutting as the habitat evolved through dense raspberries and regenerating hardwoods less than 2 m tall to hardwood regeneration taller than 2 m with a well-developed coniferous regeneration stratum. Density declined by approximately 50% as the habitat changed to hardwood regeneration taller than 4.5 m with trees with a DBH of 10-15 cm (Titterington et al. 1979). In Vermont, the territory of a Winter Wren included mostly a clear-cut area but also adjacent hardwood forest (Lent and Capen 1995).

In Alberta, the Winter Wren was equally abundant near noisy compressor stations and quiet well pads. It appeared to be unaffected by chronic noise (Bayne et al. 2008). It exhibited no response to energy sector disturbances. There was no difference in its abundance at seismic lines, pipelines, well pads, or forest interior adjacent to these features (Bayne et al. 2016).

Price (2004) concluded that the Winter Wren might disappear as a breeding bird from southern Ontario if the average summer temperature increased by 2°C.

Status

The Winter Wren was probably more abundant south of the Shield prior to European settlement than it is at present. McIlwraith (1894) stated that it was predominantly a migrant in the Hamilton area, although a few remained to breed in large swamps in Flamborough Township, where it still nests (Curry 2006). Baillie and Harrington (1937) concluded that it bred in small numbers from Middlesex and Leeds counties north to Moose Factory and west to Manitoba. In Muskoka and Parry Sound districts, it is the most common breeding wren (Mills 1981), but it is much less common than

the Northern House Wren south of the Shield (Richard in Cadman et al. 1987). James (1991) reported that the Winter Wren was a common resident throughout the province south to Rondeau Park, but becoming rare in the northern Hudson Bay Lowland and south of Georgian Bay and the Shield.

The second atlas demonstrated that the range of the Winter Wren had not changed significantly since the first atlas, although it was found in many more squares on Manitoulin Island and in a band south of the Canadian Shield. Its probability of observation increased significantly province-wide and in every region except the Carolinian Forest Region, where the trend was positive but not significant. It was most abundant in the Shield, particularly in the Boreal Forest Region in Thunder Bay and Cochrane districts. South of the Shield, it was considerably less abundant and absent from intensive agricultural areas in the southwest (Brewer in Cadman et al. 2007).

There are insufficient Breeding Bird Survey data to determine population trends of the Winter Wren (A.C. Smith et al. 2023).

MIGRATION

In North America, different populations of Winter Wrens have different migratory strategies. Some are completely migratory whereas others are partially migratory or resident (Hejl et al. 2020). It appears as though most of Ontario's population is migratory. Although some birds overwinter in the extreme south, it is likely that most of these have migrated from further north. Most areas where it is observed in winter are not suitable breeding habitat, or are areas where it is not known to breed. There are a few locations where it breeds and also occurs in winter. These birds may be maintaining their territory year-round.

Average spring arrival is in late March to early or mid-April in the south, but not until mid- to late April in the southern Shield. The peak of migration in the south is in the last half of April. Autumn migrants may arrive in the south in the last third of August, but the peak of migration is from mid-September until mid-October. In the south, migrants may continue to move southward through December in response to adverse weather conditions. Most of the population is gone by late October or early November (Curry 2006; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008).

During migration, the Winter Wren prefers dense tangles of shrubs and undergrowth, as well as brush piles. It is not confined to habitat that it uses during the breeding season and may occur in city parks and gardens, rural residential lots, thickets at edges of wetlands, cool gullies along watercourses, power-line rights-of-way, logging slash, riparian areas, and a variety of woodland types with brushy areas (Campbell et al. 1997; Hejl et al. 2020; McIlwraith 1894).

In British Columbia where the Winter Wren is resident, females leave their breeding territory after the breeding season, but males remain in the general area. Autumn territory size of males in British Columbia ranged from 0.42 to 1.31 ha (Hejl et al. 2020). It is unknown if males maintain autumn territories in Ontario.

During the nonbreeding season, the Winter Wren may roost nocturnally during periods of low temperatures or cold, rainy weather. Those that remain near the breeding grounds may roost in

their own or Carolina Wren dummy nests. Birds may also huddle close together on a branch to preserve heat (Hejl et al. 2020).

During the day, the Winter Wren may occasionally be observed in mixed flocks with other species. Migration is predominantly nocturnal, and it is commonly killed by striking towers and other illuminated tall structures at night (Hejl et al. 2020; Taylor et al. 1983).

The Winter Wren is common during migration (James 1991).

WINTER

Christmas Bird Count data indicate that the Winter Wren winters only in areas that receive over 81 cm of precipitation annually (Root 1988). It was most often found during winter in Elgin County in woodlands where there was a coniferous component and where streams stay open all winter (Lancaster et al. 2004). Throughout its range, it is often found in riparian areas during winter (Hejl et al. 2020). In winter, it may use a variety of habitats, including any type of woodland and occasionally around houses and gardens in villages and towns (Bent 1948; Hejl et al. 2020).

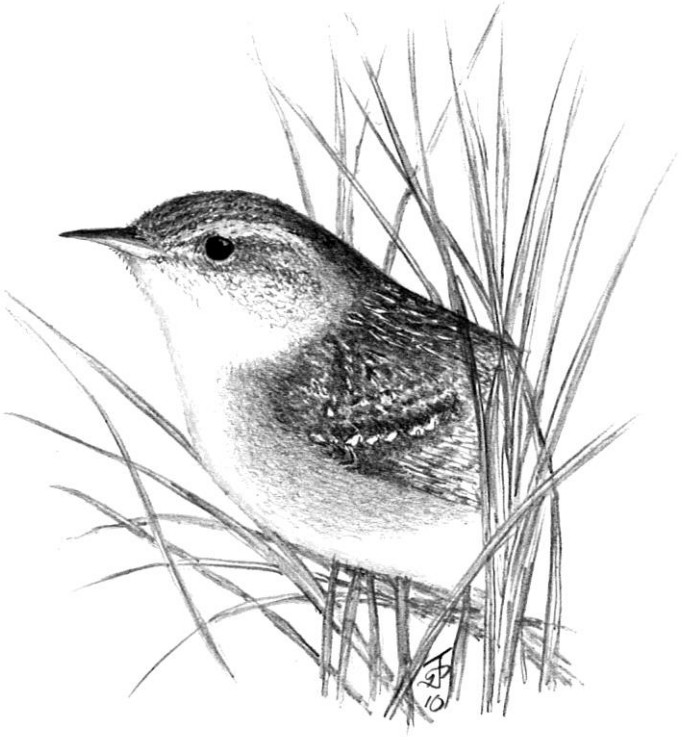
Roosts are an important winter habitat component. Winter Wrens may roost in nest boxes, in woodpecker holes, nests that were not used for breeding, mammal burrows, abandoned or open outbuildings, and crevices in occupied houses. There is 1 record of 4 or 5 roosting together on a pine limb under an accumulation of needles. Males, females, and hatch-year birds roost together communally (Bent 1948; Campbell et al. 1997; Hejl et al. 2020).

The greatest limiting factor in winter is severe weather. During exceptionally cold and snowy weather, many Winter Wrens die. Marked declines in breeding populations often occur after severe winters. Severe winters in the southeastern states several years between 1966 and 1978 resulted in significant population declines (Bent 1948; Hejl et al. 2020).

The Winter Wren is rare in winter, occurring primarily along the northern shore of Lake Erie, but also north to Hamilton and occasionally to Presqu'ile Park and Kingston. One early March record from Muskoka suggests overwintering (Curry 2006; LaForest 1993; Lancaster et al. 2004; Mills 1981; Weir 2008). It is possible that it is more common during winter than it was historically. McIlwraith (1894) knew of no winter records for the Hamilton area or the province. It occasionally overwinters in the Hamilton area now (Curry 2006). In Elgin County, it was not known to occur in winter in 1891 but by 1954 a few remained in winter (Lancaster et al. 2004).

Sedge Wren

Cistothorus stellaris

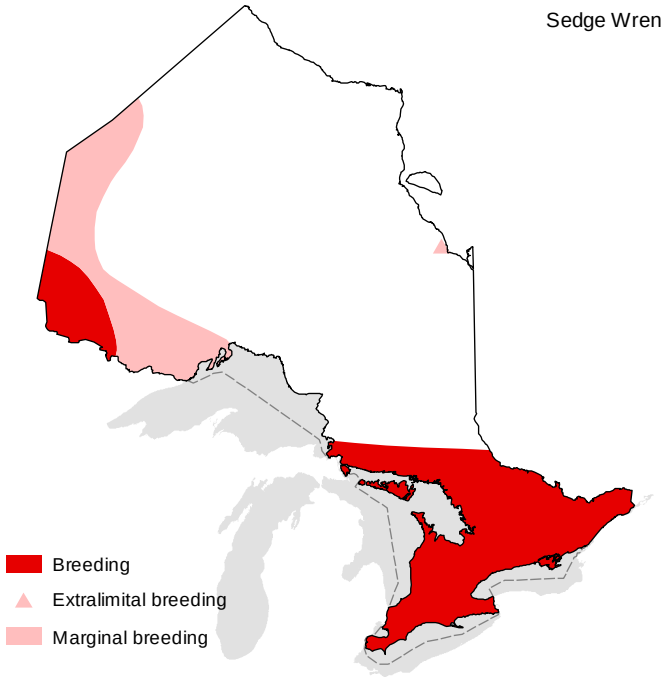


BREEDING SEASON

Habitat Requirements

In Ontario, the Sedge Wren nests in sedges or cattail meadows and marshes (48.6% of nests); in cultivated and uncultivated tallgrass fields and pastures (42.9%), including 2 nests in strawberry patches; in bogs (5.7%); and in an old, overgrown, wet gravel pit (2.9%). Wet habitats were slightly preferred (54.3%) to upland habitats, but nests were rarely over water. Most habitats used for nesting were open, although scattered trees and shrubs were occasionally present (Peck and James 1987). Breeding has occurred in Ontario in marshes (especially those dominated by sedges), bogs, fens, old fields with tall rank growths of grass, wet meadows, and hayfields (LaForest 1993; Lancaster et al. 2004; MacLulich 1938; McIlwraith 1894; Sandilands 1984; Weir 2008).

Typical Sedge Wren habitat consists of damp or wet areas dominated by sedges or grasses, often in the interface between wetlands containing standing water and upland meadows. Nesting habitat is often bounded by cattail marsh on 1 side, which may be occupied by the Marsh Wren, and dry habitats. There is usually very little and often no water where it nests, although it may occasionally nest where water is as deep as 50 cm. The territory is usually dominated by graminoids early in the season, but goldenrods, asters, blue vervain, and other herbaceous species may be



prevalent later in the season. Most territories support 2 or 3 small trees or shrubs such as willows, meadowsweet, chokecherry, and hawthorns that are used as singing perches by the male. Occasionally shrubs may be fairly dense, particularly at edges of bogs and fens and more upland borders of marshes, but it tends to avoid cropland and areas of extensive woody vegetation. Height of vegetation may be important. It may wait to initiate nesting until vegetation is 1-2 m tall and it seldom nests in vegetation shorter than 0.5 m. It selects dense vegetation. Higher breeding densities occur in denser cover of similar vegetation types. In tallgrass prairie, it prefers tall dense vegetation, usually with a well-developed litter area. In the Boreal Forest Region, the Sedge Wren nests predominantly in fens. In other regions, it nests in wet prairie-sedge meadows; lake-edge marshes; restored prairies of big bluestem, switch grass, and Indian grass; fields of smooth brome and reed canary grass; cultivated rice fields; cordgrass sloughs; sedge meadows; beaver meadows; natural tallgrass prairies; stands of river bulrush in semipermanent ponds and lakes; common reed stands; dry depressions or sloughs in upland fields that contain water only after storms; damp hayfields and old fields; drier margins of marshes; lightly grazed pastures; and fields managed for waterfowl production. It selects soils and vegetation that are highly vulnerable to drying or flooding caused by annual and seasonal variation in rainfall so that habitat suitability may constantly be changing. It nests in tall, dense growths of sedges (especially fens in the Shield) and usually avoids short, sparse, or open vegetation, flooded areas, and wetlands dominated by cattails. In Minnesota, average characteristics of territories were 303 sedge stems, 16 forb stems, and 50 shrub stems per m^2 and a predominant vegetation height of 1.1 m. Higher densities occurred in areas of medium shrub densities (11-32 stems per 25 m^2) than in areas with more or less shrub growth. In Wisconsin, its density was positively correlated with cover of woody vegetation, maximum vegetation height, vegetation density, cover of herbaceous vegetation, and cover of residual vegetation. North Dakota populations were lower during a drought than during a wet period. Its abundance was positively associated with the number of ponds present. Where it was present in North Dakota, litter depth was greater, maximum vegetation height was taller, and there was more sweet clover than where it was absent. Areas where it was absent had more shrubs taller than 1 m and more coverage by aspen within 100 m and 500 m than areas where it was present. Increased woodland coverage negatively affected it as did the presence of tall shrubs. Occurrence dropped from 40% in areas with no woodland cover within 500 m to 0% at about 30% woodland coverage (Askins et al. 2007; Bedell 1996; Bent 1948; Burns 1982; Clausen 1989; Crawford 1977a; Dancey 1995a, 1995b; Dechant et al. 2002e; Erskine 1977; Fragnier and Robert in Gauthier and Aubry

1996; Grant et al. 2004; Greenlaw 1989; Hartley 1994; Herkert et al. 2020a; Jalava 1993; Johnson and Igl 2001; Leighton et al. 2002; Lingle and Bedell 1989; Meanley 1952; Meeks 1996; Mousley 1934b; Niemuth et al. 2008; Picman and Picman 1980; Walkinshaw 1935).

Panci et al. (2017) conducted point counts in coastal wetlands of all the Great Lakes to determine landscape-scale preferences of the Sedge Wren. It was 2.5 times more likely to occur west of longitude 84°W at sites with less than 11 km of roads within 1,000 m. It was negatively affected by road density within 1,000 m. Its occurrence was 4.1 times more likely at points with less than 9% woody wetland within 2,000 m. In Ontario, it occurred almost exclusively along the shoreline of Lake Superior in the Sault Ste. Marie and Thunder Bay areas. It preferred landscapes that were 0-12% forested in North Dakota (Cunningham and Johnson 2019).

Tozer et al. (2024) identified the habitat preferences of the Sedge Wren in coastal Great Lakes marshes. It was positively correlated with wetland cover, negatively affected by water levels, and negatively correlated with the amount of urban and agricultural land within the watershed. Robert et al. (2009) studied its habitat use in southern Quebec fens. Occupied areas had higher lateral visibility (or lower vertical cover) and lower shrub cover than random areas including lower density of shrubs taller than 1.5 m (61.1 compared with 357.5 per ha), fewer shrub stands along transects (0.8 compared with 3.8), and greater distance to the nearest shrub (7.0 m compared with 4.4 m). Mean lateral visibility was less than 25% below 1 m and did not differ between occupied and unoccupied sites. Visibility was consistently greater at stations occupied by wrens for higher height classes. There were no differences between occupied and unoccupied sites for water depth, plant species richness, diversity, vegetation height, evenness, and structural heterogeneity. The primary factor affecting its distribution appeared to be shrub density, with a mean density of 93 shrubs per ha at occupied sites compared with 409 at unoccupied sites. Most shrubs were alders with minimal cover by willows and meadowsweet. Lake sedge dominated the herbaceous layer, with subdominants of water sedge, purple loosestrife, marsh fern, and Canada bluegrass. These species covered 85.5% of the non-woody layer and their relative cover did not differ significantly between occupied and unoccupied sites. Cover of cattails, big bur-reed, and spotted jewelweed varied between occupied and unoccupied sites, but coverage by these species was low.

Some studies suggested that the Sedge Wren may be area sensitive; others concluded that it is not. Johnson and Igl (2001) studied relationships between its density and patch size in Montana, South and North Dakota, and Minnesota. At 1 site, patch size was significantly correlated with density; at 3 other sites there were no statistically significant correlations although trends were positive. They concluded that it was area sensitive based on increasing density with increasing patch size, but noted that Herkert (1994a) found no effect of patch size in Illinois. In Michigan Great Lakes coastal wet meadows, its presence was positively correlated with meadow size, but not significantly (Riffell et al. 2001). Another Michigan study found that its abundance was negatively correlated with wetland size (Crozier and Niemi 2003). In Iowa, it was negatively associated with the area of wetland within a 3-km radius and with the total area of wetland that was inhabited, but positively associated with the area of wet meadow within the wetland (Fairbairn and Dinsmore 2001a, 2001b). In Michigan, Walkinshaw (1935) reported as many as 40 males singing in an area of approximately 4 ha, but could only find 1 pair in smaller habitat patches. In Quebec, Mousley (1934b) reported a pair

nesting in a 0.27-ha patch. It appears as though the Sedge Wren is not particularly area sensitive because it has been documented nesting in some very small, isolated habitat patches and correlations between increasing density with increasing patch size are weak. In a review paper, Ribic et al. (2009) concluded that the Sedge Wren was area sensitive.

The population of Sedge Wrens studied by Robert et al. (2009) in southern Quebec was a long-term population in a region where there are large tracts of wetlands, including fens. Most other Sedge Wren sites in that province have been in small, wet meadows surrounded by forests or agricultural land uses. Populations in these habitats are small and site tenacity is low. This suggests that the amount of wetland in a landscape may be an important factor in determining both population size and frequency of occupation of habitat. Although it may or may not be area sensitive, larger patches are probably more likely to consistently support populations. Thogmartin et al. (2006) used Breeding Bird Survey (BBS) data in grassland-dominated landscapes to determine its broad-scale habitat preferences. It was positively associated with the amount of grassland, wetland, and mucky soils, and negatively associated with the mean January temperature, percent forest cover, and presence of the species on adjacent counts. They concluded that it was not sensitive to grassland area, but was more abundant in landscapes where the number and size of wetland patches were high.

Ontario nests were in upright clumps of both dead and living stalks of sedges, grasses, herbaceous species, and cattails. Two were at the base of a small tree, one was on the ground at the base of a clump of sedges, and one was fastened to grass stems and meadowsweet branches. Elevated nests were 0.1-0.9 m from ground, with most 0.2-0.5 m up. Dummy nests were frequently present and one was as close as 3 m to the nest that was used (Peck and James 1987).

Most nests are in dense, thick mats of sedges or grasses or occasionally herbaceous species. They may be placed near the ground or water at the base of a shrub. Although some nests are on the ground, most are a short distance above it, ranging from 0.05 to 1 m above the substrate with most 0.5 m or less in height. In addition to the nest that is ultimately used for nesting, the male builds several complete nests that may potentially be used for roosting, decoys for predators, and attracting additional females to the territory. In Minnesota, males built an average of 9 nests in their territory; 9% were incomplete. In Michigan, nests that were used averaged 30 cm from the ground. False nests tended to be higher and not as well concealed. The following year, the substrate in the same area was much drier and active nests averaged 50 cm from the ground (Bent 1948; Burns 1982; Herkert et al. 2020a; Meanley 1952; Mousley 1934b; Walkinshaw 1935).

The Sedge Wren is territorial and territories are non-overlapping. Territories are used for courtship, nesting, and most of the foraging. Twelve territories in Minnesota averaged 0.178 ha (range 0.05-0.36 ha). The maximum seasonal territory size of an individual bird was 0.226 ha (average 0.128 ha). As the season progressed, males tended to stop defending some portions of their territory and drifted to new areas (Burns 1982).

The Sedge Wren is often considered colonial because numerous pairs may be present in a small area. This is primarily a function of its small territory size and the fact that some males may be polygynous, resulting in very high local nesting densities. There appears to be no evidence that it is

a truly colonial species from a behavioural perspective. It does not concentrate nesting in a small portion of a larger patch of suitable habitat, the nesting area does not function as an information source for finding rich food resources, and communal defence of nests has not been observed.

No information is available on natal philopatry. The Sedge Wren is one of the most nomadic North American birds. Birds may suddenly appear or disappear within a breeding season. Habitat suitability may change within an area due to differences in precipitation rates and other factors such as natural succession, with wrens being quick to colonize or abandon a site. Even where there is no apparent change in habitat, birds may be abundant 1 year and absent the next. In many areas in the east, it is very erratic with few sites supporting wrens on a regular basis. Those that do are usually fens or sedge-grass meadow marshes. Of 91 sites occupied since 1959 in Quebec, only 12% were occupied more than 4 years and there was only 1 site that was consistently occupied since 1970. Breeding wrens were present at 1 site in Illinois for 14 consecutive years, although it was unknown if any of the same birds were involved. The entire population is very mobile, with breeding concentrated in widely separated portions of its range during different times within its breeding season. The first period of nesting is in late May and June and occurs primarily in the north in Ontario, Quebec, Saskatchewan, North Dakota, Wisconsin, and North Dakota. The second nesting period extends from July until September. Breeding then is much more widespread with birds expanding into southern (Nebraska, Kansas, and Missouri) and northeastern (Vermont and Massachusetts) portions of the breeding range. Although it has yet to be confirmed, there is strong circumstantial evidence that Sedge Wrens may raise multiple broods in widely separated areas of its range within the same year. The general exodus from early northern breeding sites corresponds closely to its arrival in the south where it may not appear until July or August, and breeding may continue until September or even early October. In the south, arrival dates on the breeding grounds are often unpredictable and vary with precipitation. Birds typically arrive in Nebraska in July or August, but during a very wet year arrival was in May. Birds in other areas have been observed arriving in a flooded area in May, abandoning it and returning in July to breed throughout August. It appears as though it has adapted these erratic movements over a long period of time. Each male improvises a suite of songs, and no 2 wrens have identical songs. The wide range in songs allows males to have functional songs anywhere (Bedell 1996; Burns 1982; Dancey 1995b; Fragnier and Robert in Gauthier and Aubry 1996; Herkert et al. 2020a; Kroodsma et al. 1999; Meeks 1996; Robert et al. 2009; Weir 2008).

Limiting Factors

Eggs have been found in Ontario nests from early June until the third week of July, with most present in the last half of June (Peck and James 1997). Curry (2006) reported that the Sedge Wren occasionally did not arrive at some sites near Hamilton until late July or August. It is possible that these are late-nesting birds. Throughout its range, it is inconsistent in the timing of nesting; timing at a given site may vary year to year. There may be eggs or young in nests from early May until mid-September at some sites. Nesting may be mostly in June and July at some areas and primarily July and August in others (Bedell 1996; Burns 1982; Herkert et al. 2020a; Koenig and Stahl 2007; Kroodsma et al. 1999; Lingle and Bedell 1989; Meanley 1952). Secondary females of polygynous males may not

begin laying until late in the season when primary females are initiating their second clutch (Burns 1982).

The male begins building nests about 2 weeks after arrival on the breeding ground. Approximately 7-8 days are required to build a nest exterior. The female selects a nest and adds the lining to complete it. One egg is laid per day. Incubation begins before the clutch is complete, with eggs hatching over a 2-3 day period. The incubation period at 1 Ontario nest was 12 days, but the average incubation period is approximately 14 days (range 12-16 days). In Iowa, the mean incubation period of 21 nests was 13.8 days (range 13-16 days). The average nestling period of 67 young at this site was 13.6 days (range 11-16 days). In Quebec, young left the nest when they were 13-14 days old, but could not fly (Burns 1982; Crawford 1977a; Herkert et al. 2020a; Mousley 1934b; Peck and James 1997; Walkinshaw 1935).

Some females raise 2 broods in a season; others raise a single brood. Primary females of polygynous males may raise 2 broods; secondary females raise one. Females of monogamous males typically raise a single brood. Egg dates for Ontario suggest that only 1 brood is raised in a season. Some Ontario populations become established late in summer and it is possible that these birds are nesting and raising their second brood of the year. It is unknown if birds that become established in areas in July and August are breeding for the first time or have raised another brood somewhere else (Burns 1982; Crawford 1977a; Herkert et al. 2020a; Jalava 1993; Walkinshaw 1935). Clutches of 4-8 eggs have been reported in Ontario, mostly 5-7 eggs (Peck and James 1997). Clutches of 2-8 eggs have been reported, with 7 eggs the most frequent clutch size. In Minnesota, all first clutches of primary females mated with a polygynous male and all females mated to a monogamous male contained 7 eggs. Later clutches were more variable, with 4-7 eggs, and significantly smaller (5.7 compared with 7.0 eggs). Polygynous males produced an average of 8.6 young annually compared with 5.9 by monogamous males. In Iowa, secondary females laid significantly smaller clutches (mean 5.2 eggs, range 5-6) than primary (mean 7.6 eggs, range 7-8) and monogamous females (mean 7.1 eggs, range 5-8). Secondary females raised fewer young than primary females and those mated to a monogamous male, but differences were not significant. Polygynous males produced an average of 5.6 young annually compared with 3.0 for monogamous males (Bent 1948; Burns 1982; Crawford 1977a; Herkert et al. 2020a; Walkinshaw 1935).

The age of first breeding is unknown, but is probably 1 year. It is unknown if adults breed every year (Herkert et al. 2020a). The Sedge Wren is in a guild of species that nests in wetland and grassland habitats and there is a high incidence of polygyny in this group. All females breed, but not all males hold a territory (Greenlaw 1989). Polygyny may be common, with rates of 9% and 30-50% of polygynous males being reported. There have been no reported cases of a male being mated to more than 2 females. In Iowa, some males maintained territories in June and July and remained mateless but it was unknown if they attracted females later in the breeding season. In most cases, double-brooded females mate with the same male for both clutches, but occasionally they mate with a different male for the second brood. Females appear to choose territories and hence partners based on the degree of protection that the vegetation offers from predation. Males defending territories with dense vegetation are more likely to be polygynous (Burns 1982; Crawford 1977a).

Foraging occurs mainly at ground level where the Sedge Wren searches for insects in moist soil and at bases of grasses and sedges. Young are fed moths, spiders, mosquitoes, flies, grasshoppers, and bugs, with spiders often dominating the diet. Although few data are available, it is likely that the adult diet is comprised predominantly of insects and spiders. The only diet information is from the wintering grounds. Stomachs of 34 wintering birds in Florida contained only spiders and insects, including ants, bugs, weevils, lady beetles, moths, caterpillars, locusts, crickets, and grasshoppers. In Alabama, the winter diet consisted of weevils, ants, bugs, grasshoppers, and spiders (Burns 1982; Herkert et al. 2020a; Mousley 1934b; Walkinshaw 1935).

There are no records of nests containing Brown-headed Cowbird eggs or young, but a Sedge Wren was observed feeding a large cowbird fledgling in North Dakota. The entrance diameter to the nest is usually too small (1.5-2.5 cm) to accommodate a cowbird (Herkert et al. 2020a).

Habitat loss and degradation appear to be the greatest limiting factors to the Sedge Wren. The damp to wet sedge and grass meadows that it prefers for breeding are highly vulnerable to being converted to residential areas or to being drained and farmed. These habitats are also frequently grazed. Grazing and trampling by livestock reduces vegetation structure and density and makes it less suitable for nesting. These types of meadows may be cut for hay, and it occasionally nests in hayfields. Mowing may destroy active nests and makes the habitat unsuitable for nesting. In Iowa, it nested in low density in alfalfa fields, but established territories mostly along grassed waterways. After mowing occurred, it abandoned the fields. Although disturbance of certain habitats may be detrimental, lack of disturbance may be detrimental in others. Its response to burning varies depending upon the initial density of the vegetation and the intensity of the fire. Various studies have reported positive, negative, or no response to fire. Meadows that become overgrown with shrubs and trees initially result in decreased abundance of breeding wrens and ultimate abandonment of the site if succession continues. In Minnesota, its density declined with all measures of woody vegetation: number of shrubs within 50 m, number of trees within 100 m, and the proportion of tree cover within 100 and 1,000 m. Density also declined slightly with the proportion of grass within 1,000 m. It was predicted that its density would increase 4-fold if tree-related variables were reduced from the 90th to the 10th percentile. Attempts to increase grass cover quality by increasing litter depth, grass height, and grass extent were predicted to lead to marginal increases in the Sedge Wren. Woody vegetation may attract a new guild of predators. Fine-scale habitat features are of primary importance as birds settle on territories but habitat is initially selected at a landscape scale of 1,000 m. The negative correlation with grass cover within 1,000 m was because grass and tree cover were correlated. Wrens may avoid larger grasslands when they contain trees or are close to wooded areas (Dechant et al. 2002e; Fragnier and Robert in Gauthier and Aubry 1996; Frawley and Best 1991; Herkert et al. 2020a; Jalava 1993; Lingle and Bedell 1989; Thompson et al. 2014).

In the United States, the Sedge Wren uses fields planted to switch grass for nesting and during migration. Fields planted to mixed grass–prairie forbs are also of benefit to it. Intensification of agrofuel production that maximizes biomass, homogenizes vegetation structure, and results in the cultivation of small fields is likely to reduce species richness and abundance of grassland birds (Robertson et al. 2012).

Weather may affect the Sedge Wren. Unusually dry or wet weather may make habitat unsuitable for nesting. In the core of its range, low populations appear to be associated with drought. Excessively dry weather is probably the most important weather factor, but populations fluctuate along Lake Erie with lake water levels, increasing with decreasing levels, although numbers are always low. Severe winter weather on the wintering grounds may result in mortality. Populations may have declined significantly after the severe southern winter of 1940 (Dancey 1995b; Herkert et al. 2020a; Jalava 1993).

Picman and Picman (1980) demonstrated that Sedge Wrens pecked and destroyed eggs in other nests. Intraspecific nest destruction may be an important source of loss.

Status

The Sedge Wren has probably never been common in Ontario. McIlwraith (1894) concluded that it was a western species that was irregular in its distribution. At this time, it had not been recorded near Hamilton or Ottawa, or anywhere in northern Ontario, but was common in New York and abundant in western Manitoba. He presumed that it was a probable breeder in southern Ontario despite the lack of records. Curry (2006) reported it was observed almost every year in the 1930s and 1940s in the Hamilton area and concluded that McIlwraith had simply overlooked the species. It seems more likely that the Sedge Wren arrived in the province after McIlwraith's 1894 publication. It had not been reported in Elgin County by 1891 (Lancaster et al. 2004) and the first record for the Kingston area was in 1922 (Weir 2008). Herkert et al. (2020a) stated that the Sedge Wren population appeared to have expanded eastward and northward following the arrival of European settlers and forest clearing. Baillie and Harrington (1937) considered it fairly common but irregular, breeding from the southern border north to Kenora District, southern Sudbury District, and the Ottawa area. The earliest nest record was from the Lake of the Woods area in 1920, where it was locally common. During the first atlas, the Sedge Wren bred in the Great Lakes–St. Lawrence Forest Region in scattered localities south of the Canadian Shield and sparingly in the Shield. There were also a few records in the Boreal Forest Region, primarily in the northwest (Gould in Cadman et al. 1987). James (1991) considered the Sedge Wren a rare to locally uncommon breeder north to Kenora, Sault Ste. Marie, and Sudbury; occasional and rare in the west north to Sandy Lake; and a vagrant in the James Bay area. Jalava (1993) stated that it was rare to uncommon in southern and central Ontario, but relatively abundant in the Lake of the Woods area. Except for the Lake of the Woods area, Ontario is peripheral to the main breeding range, which encompasses Minnesota, Wisconsin, northcentral Michigan, and southern and central Michigan (Bedell 1996; Jalava 1993). In most other areas, it tends to be rare, local, and erratic in occurrence; much apparently suitable breeding habitat is unused.

The second atlas revealed that there had been no overall change in the distribution of the Sedge Wren since the first atlas. It occurred predominantly in the Great Lakes–St. Lawrence Forest Region both in and south of the Shield, with minor concentrations along the Niagara Escarpment, from Kingston to Ottawa, and in the Rainy River and Kenora areas. It was scattered in distribution and generally uncommon and particularly scarce in the intensive agricultural areas of the southwest. In the Carolinian Forest Region, its probability of observation was only 4%, with concentrations in the Windsor and Hamilton areas. Scattered records occurred in the Boreal Forest Region and Hudson Bay Lowland north to Attawapiskat and the Berens River area. There was no change in its probability

of observation since the first atlas province-wide or in any region. From 2001 to 2004, it was detected on only 4 of over 2,000 point counts in the Rainy River area, but 316 point counts conducted in 2005 resulted in 43 counts with one or more wrens detected. This was an exceptionally wet year and the high numbers were probably due to immigration from areas such as Manitoba, Wisconsin, and Minnesota (Brewer in Cadman et al. 2007). In Great Lakes coastal wetlands, the Sedge Wren decreased at a nonsignificant rate of 3.2% per year 2011-21 (Tozer et al. 2024).

The overall population and range of the Sedge Wren probably increased with European settlement and removal of the forest cover in the east. Prior to that, it was probably confined to prairies, fens, and meadow marshes. Loss of these types of habitats occurred due to agriculture and urbanization with subsequent decreases in amounts of natural habitat. Long-term (1970-2021) population trends determined from BBS data included annual decreases of 0.37% in Canada and 1.42% in Ontario. The short-term (2011-21) trends were annual decreases of 0.253% in Canada and 2.63% in Ontario. The long-term trend for Canada was highly reliable; the other estimates were of low reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

After leaving the nest, young move around under dense vegetation similar to mice and they stay together with the adults until migration time (Herkert et al. 2020a).

MIGRATION

Average arrival in Ontario is mid-May, with earliest arrivals in very late April. Most spring migrants leave nonbreeding areas in the south before the end of May (Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008). There may be widespread movements of Sedge Wrens during the breeding season between the early (May and June) and late (July to September) nesting periods, mostly in southerly and easterly directions. In the northern portion of its range, there may be a gradual exodus that begins in early August with most birds gone by the end of September (Herkert et al. 2020a). Most have left the province by mid-October (James 1991), although it has been observed well into November (Curry 2006; Weir 2008).

During migration, the Sedge Wren is typically found in habitat similar to that used during the breeding season. It may also occur in mesic grasslands, saltwater marshes, and alfalfa, clover, and rye fields (Herkert et al. 2020a). In Kansas, it was usually associated with rushes or tall grasses in riparian areas. Fitch (1958) also observed it at a small pond surrounded by a 5-m-wide rim of smartweed.

The Sedge Wren is a nocturnal migrant. It frequently strikes television towers and buildings during autumn migration (Taylor et al. 1983), although there is only a single record of mortality at the Lennox generating station near Kingston (Weir 2008).

The Sedge Wren is a rare migrant in Ontario (James 1991).

Marsh Wren

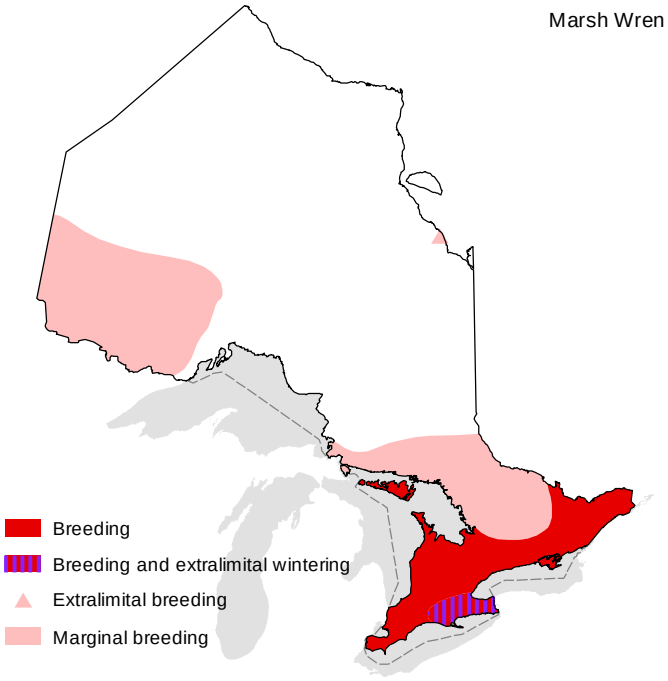
Cistothorus palustris

BREEDING SEASON

Habitat Requirements

In Ontario, the Marsh Wren nests predominantly in shallow freshwater marshes and marshy borders of lakes, rivers, and ponds. Most nests (52.2%) were in large and small cattail stands; 21.2% in unspecified marsh habitat; 9.6% in horsetail marshes; 8.8% in bulrushes, other sedges, and cattail-sedge marshes; 5.7% in grass (often reedgrass and common reed) and cattail–common reed marshes; 2.3% in bur-reed and cattail–bur-reed marshes; and 0.3% in cattail-leatherleaf. Single nests were found in a willow swale, a wet pasture, and meadowsweet bordering a marsh (Peck and James 1987).

In southern saltwater marshes, the Marsh Wren nests predominantly in cordgrass. In freshwater marshes, it nests mostly in cattail and mixed cattail-bulrush marshes, and less frequently in pure bulrushes or seldom in sedge, sweetflag, horsetail, or grass (common reed, reedgrass, wild rice) marshes. Although it tends to avoid areas of extensive shrub cover, it has nested in steeplebush, mangroves, alders, elderberries, sweet gale, buttonbush, and willows. Robust emergents such as



cattails and bulrushes are necessary to support the bulky nests. A high proportion of nests in grasses and sedges other than bulrushes fail due to collapse of the supporting vegetation. Cattails are highly preferred for nesting and, in New York and Minnesota, narrow-leaved cattail was preferred over broad-leaved cattail. Bulrush species that are used tend to be more robust species such as river bulrush, soft-stemmed bulrush, and hard-stemmed bulrush. In Wisconsin, it nested in 98% of deepwater cattail stands, 100% of shallow-water cattail stands, 72% of dry cattail stands, 88% of river bulrush stands, and 0% of sedge stands (Bent 1948; Campbell et al. 1997; Gutzwiller and Anderson 1987; Kale 1965; Kroodsma and Verner 2020; Manci and Rusch 1988; Verner 1965a; Verner and Engelsen 1970; Welter 1935; Wheeler 1931). Gutzwiller and Anderson (1987) prepared a habitat suitability index (HSI) model for the Marsh Wren. For type of emergent nesting habitat, cattails, cordgrasses, and bulrushes scored 1.0 (optimal habitat) on their model; reedgrass, reed canary grass, and sedges scored 0.5; buttonbush scored 0.1; and other emergents that are occasionally used scored 0 (unsuitable habitat). Erskine (1977) reported that it occurred only in the southern portion of the Boreal Forest Region where it nests predominantly in fens. Along the St. Lawrence River in Quebec, it prefers large marshes dominated by cattails and ponds with abundant emergent vegetation (Tanguay and Robert in Gauthier and Aubry 1996). In British Columbia, ideal habitat included a mix of cattails, shrubs, and grasses, but wet ditches with emergent vegetation also provided nesting habitat. Fifty-one percent of nests were in stands of cattails, 23% were in steeplebush, 8% were in sedges, and 6% were in willows (Campbell et al. 1997). Greenlaw (1989) considered the Marsh Wren to be 1 of only 6 North American passerines associated predominantly with marshes.

Presence of standing water is an important habitat feature. At Horicon Marsh in Wisconsin, the Marsh Wren nested in dry cattail stands, but at densities that were only 29.1% and 31.3% of those in shallow-water and deepwater cattail stands, respectively (Manci and Rusch 1988). It preferred stands of emergent vegetation from a few cm deep to 1 m in Quebec (Tanguay and Robert in Gauthier et al. 1996). Verner and Engelsen (1970) concluded that cattails were preferred only if they were in standing water. In North Dakota, water depth was more important than amount of water coverage of the marsh, and areas of dead cattails were avoided for nesting (Linz et al. 1996). Gutzwiller and Anderson (1987) ascribed a score of 0 for areas with no water on their HSI model; 0.5 for 10 cm of water; and 1.0 for 15-40 cm of water. Marshes that dry out in mid-to late summer may be used successfully but permanent water through the nesting season is required to supply a dependable

food source and provide protection from predators (Gutzwiller and Anderson 1987; Kroodsma and Verner 2020).

Density of emergent vegetation is another important habitat factor. The Marsh Wren selects the densest areas for nesting because numerous plant stems are required to support the nest. Gutzwiller and Anderson (1987) evaluated percent canopy of emergents in their HSI models. Their curve sloped from a score of 0 to 0.1 for 0-50% canopy coverage, from 0.1 to 1.0 for 50-80% canopy coverage, and remained at 1.0 for 80-100% coverage.

In coastal wetlands of the Great Lakes, the Marsh Wren occurred predominantly south of latitude 45°N where there was less than 42% developed area within 500 m. Models predicted its occurrence in areas with less than 13% emergent herbaceous wetland and less than 1% cropland, and also where there was more than 13% emergent herbaceous wetland and less than 26% woody wetlands. All these preferences were at the 500-m scale. It was predicted to be in low abundance if the percent coverage by cattails was less than 14% and in high abundance if cattail coverage exceeded 14% (Panci et al. 2017). Also in Great Lakes coastal marshes, it was positively associated with wetland cover but unaffected by water levels and amounts of urban and agricultural land within the watershed (Tozer et al. 2024). In Minnesota, the Marsh Wren was positively associated with agricultural cover at a scale of 4,000 ha. Its frequency of occupation was 10% at 10% agricultural cover and increased to 50% at 80-100% agricultural cover. It had a somewhat positive association with developed land at the same scale. Its frequency of occupation was 60% at 0% developed land, dropped to about 40% at 10-15% developed land and increased steadily to almost 100% at 35% developed land. Individual wetlands or small wetland complexes are probably sufficient to support it. Its positive association with agriculture may be explained by its common use of weedy agricultural drains. It may also nest in cattail and common reed marshes near urban and rural development (Saunders et al. 2019).

The Marsh Wren does not require large wetlands for nesting. In Connecticut, it occurred only in marshes 4 ha or larger but its density did not increase with increasing wetland area (Benoit and Askins 2002). Bent (1948) stated that isolated marshes smaller than 0.4 ha were avoided. Gutzwiller and Anderson (1987) considered 0.4 ha to be the minimum patch size that could be considered habitat, although nests were found in California in 0.04-ha patches of lakeside emergents that were at least 60 m from the nearest other patch. In Iowa, Brown and Dinsmore (1986) thought that the Marsh Wren was possibly area sensitive but acknowledged that their results were not conclusive. It was present in 25% of marshes smaller than 1 ha, 83% of marshes 1-4.9 ha, 100% of marshes 5-10.9 and 11-20 ha, and in 83% of marshes larger than 20 ha. In Iowa, it was not associated with marsh size and its density decreased with increasing marsh size. Fairbairn and Dinsmore (2001a, 2001b) concluded that this may have been because smaller marshes tended to support a higher proportion of vegetative cover than larger ones. Its presence was not associated with any landscape-level parameters. In the Prairie Pothole Region of the United States, its abundance was positively correlated with the amount of wetland habitat at the 10-km^2 and 100-km^2 scales, but not at the 1,000-km^2 scale. More important factors included the amount of precipitation and spring temperature the previous year (Forcey et al. 2014).

In Ontario, there was no difference in the abundance of Marsh Wrens at the edge (2.4 individuals) and in the interior (2.3 individuals) of marshes (Tozer et al. 2006). Birds raising a second brood tend to move into more open areas and nest in deeper water nearer the edge of emergents (Welter 1935). The portions of a marsh that are inhabited by Marsh Wrens may be influenced by the presence of blackbirds. Where Red-winged Blackbirds, Yellow-headed Blackbirds, and Marsh Wrens nest together, Red-winged Blackbirds tend to nest above shallow water or dry areas on the wetland margins, Yellow-headed Blackbirds nest in scattered emergents bordering open water, and Marsh Wrens nest in the denser vegetation between the 2 blackbird species. Where only Yellow-headed Blackbirds are present, wrens are confined to the margins of wetlands. Where only Red-winged Blackbirds are present, Marsh Wrens may nest within their territories but select areas of denser vegetation for nesting than the blackbirds (Gutzwiller and Anderson 1987; Leonard and Picman 1986; Linz et al. 1996; Picman 1980a).

During the nesting season, males usually roost nocturnally in emergent aquatic vegetation but may also roost in incomplete nests that they had built (Kroodsma and Verner 2020).

Most Ontario nests were over water, but a few were over damp ground and 14 ranged from beside open water to as far as 91 m from it. Most were in cattails, with lesser numbers in bulrushes, grasses, sedges, horsetails, bur-reeds, loosestrife, willow shrubs, and meadowsweet. The supporting vegetation was usually dead, but occasionally a mix of dead and living, or living. Water depths below nests ranged from 5 to 91 cm and heights above ground or water were 0.2-1.5 m, with most 0.5-0.9 m up. One active nest had an active Least Bittern nest on top of it (Peck and James 1987).

Elsewhere, most nests are in emergent wetland vegetation over water, but nests have been found more than 150 m from water. Cattails are highly preferred for nest attachment but bulrushes are often important later in the season as water levels decline. In Lake Erie marshes in Ohio, nests were mostly in areas where a single plant species was present. These included barnyard grass, rice cutgrass, reed canary grass, river bulrush, soft-stemmed bulrush, big bur-reed, and narrow-leaved cattail. No nests were found in common reed. Vegetation around nests averaged 89.4-98.9 cm in height. Nest height above the substrate tends to increase with the season as emergent vegetation grows taller. Early nests tend to be 15-60 cm above water; later nests may be as high as 2 m above water if in cattails, but are still low if in sedges and most other emergents. In British Columbia, nests were reported from almost at water level to 2.4 m above water, with most 0.6-0.9 m up. In Washington, nest height was directly proportional to the height of the supporting vegetation and increased with time. Nonbreeding nests tended to be higher than nests used for breeding, and mean nest height varied by study area. Mean heights of nonbreeding nests at 3 locations were 95.0 cm (range 58-196 cm), 80.0 cm (range 33-152 cm), and 90.4 cm (range 33-185 cm). Heights of breeding nests at the same locations were 92.7 cm (range 51-196 cm), 76.2 cm (range 36-178 cm), and 84.6 (range 30-140 cm). Nests are occasionally built on top of each other and in 1 case, 2 pairs of stacked nests were bound together into a 4-nest apartment. The number of dummy nests a male builds within his territory may range from 1 to 50. The functions of nonbreeding nests are uncertain but they may be used for displaying and courtship, roosting at night by adults, shelters for fledglings, winter shelters for resident birds, or as decoys to reduce predation on active nests. At Seeley's Bay, the number of dummy nests in a territory had no influence on males' success at attracting a female

or on predation rates (Bent 1948; Campbell et al. 1997; Kale 1965; Kroodsma and Verner 2020; Lazaran et al. 2013; Metz 1991; Verner 1965a; Verner and Engelsen 1970; Welter 1935; Wheeler 1931).

Male Marsh Wrens vigorously defend territories, although territories may be very small. Territorial boundaries or even entire territories may be changed once females arrive. Territorial disputes are most frequent prior to nest construction and drop off sharply thereafter but continue through nesting. Active defence of a territory ceases after the second brood is raised unless a third attempt is made. All the territory is used and almost all activities occur within the territory, although adults may occasionally forage off their territories in undefended areas. Territory boundaries are often defined by unsuitable breeding habitat or changes in vegetation such as small drainage channels, open water, or dry land so that territories are often defended only on 2 sides. Breeding females have subterritories within the male's territory and do not tolerate other females. Females mated to an individual polygynous male nest as far as possible from each other and defend their nesting area from the other. The smallest territories reported were in Georgia saltwater marshes where areas defended by males were as small as 28 m^2. Some of the smallest territories were held by males that failed to attract a mate. In this population, mean territory sizes ranged from 60 to 155.8 m^2 at different areas and in different years. The overall average used portion of territories was 82 m^2. Territories of paired males ranged from 40 to 242 m^2. Territory sizes are smallest for bachelor males and increase for monogamist and bigamist pairs. Bigamist males typically have larger territories than monogamist males. In some locations, bigamists' territories are twice as large as those of monogamists. In other areas territory size differences are not significant. In Washington, the average size of bachelor territories in 4 wetlands was 192-1,189 m^2 (range 168-2,601 m^2); territories of monogamous males averaged 472-1,826 m^2 (range 240-3,180 m^2), territories of bigamous males averaged 341-3,236 m^2 (range 240-3,600 m^2), and a single trigamous male had a territory size of 240 m^2. Territory sizes in more northern and freshwater habitats appear to be larger than those in Georgia. Overall, mated males may defend territories ranging from 60 m^2 to more than 10,000 m^2. In New York and Minnesota, male territories were 1,200-1,400 m^2 in cattails and almost 2,800 m^2 in grasses. In Washington, mean territory sizes at different locations were 418, 483, 1,254, 1,366, and 1,690 m^2 (overall range 167-3,595 m^2). In Manitoba, mean size of 4 territories was 231 m^2 when Yellow-headed Blackbirds were present and 586 m^2 10 days after the blackbirds were removed. Territories in freshwater marshes are smallest in mixed cattails and bulrushes, cattails, and bulrushes and larger in less optimal vegetation communities (Gutzwiller and Anderson 1987; Kale 1965; Kroodsma and Verner 2020; Leonard and Picman 1986; Verner 1964, 1965a; Verner and Engelsen 1970; Welter 1935).

The Marsh Wren is frequently considered colonial or semi-colonial, but there appears to be limited or no evidence for this in freshwater marshes. McIlwraith (1894) stated that the large numbers of nests gives the impression that the birds breed in colonies, but that this had not been noticed to be the case. It vigorously defends its territory against neighbours and there has been no documentation of birds cooperatively defending against predators or in finding food. In freshwater marshes, there is no evidence of birds clumping together and breeding in 1 area of suitable habitat and leaving other suitable habitat unoccupied. In wetlands in Washington and Manitoba, all marsh habitat was occupied by territorial wrens (Leonard and Picman 1987; Verner 1965a). In a marsh at

Seeley's Bay, territories were separated by more than 30 m (Metz 1991). Kale (1965) provided the only evidence for colonial nesting in saltwater cordgrass marshes in Georgia. The proximity of other wrens appeared to be an important criterion in selecting nesting territories. Birds tended to aggregate into breeding colonies with some areas of suitable habitat occupied and used intensively by groups of wrens. Adjacent suitable habitat was not occupied or was deserted early in the season. Areas that were occupied by a high density of wrens 1 year were often unoccupied in subsequent years even if no habitat changes occurred.

Natal philopatry appears to be low, especially in migratory populations. In Manitoba, 1 of 540 (0.18%) nestlings returned to breed the following year. It was a male that held 2 territories the year it returned. The first was about 140 m from his natal territory and the second was within 40 m (Leonard and Picman 1987). In Saskatchewan, 2 of 165 nestlings and fledglings (1.2%) returned the following year and nested within 100 m of their natal territory (Kroodsma and Verner 2020). In Washington, 0 of 34 young returned (Verner 1965a). In another Washington area, 10 yearling males dispersed an average of 1,951 m from their natal territory (range 180-4,090 m). None were found between 4.1 km and 160 km from their natal territory (Kroodsma and Verner 1991). This may have been a resident population.

Adult site fidelity is variable, with eastern birds being more faithful to their previous breeding areas than those on the prairie or further west. On Long Island, 12 of 28 adult males (43%) and 12 of 33 adult females (36%) returned in successive years. In Washington, 12 of 13 returning males (92%) had territories on the same lake in successive years. Five occupied the same territory and 2 moved to an adjacent territory the second year. The mean dispersal distance was 0.4 km (range 0-3.4 km). At 1 site at Delta Marsh in Manitoba, 2 of 19 males (10.5%) returned the second year and 2 of 28 (7.1%) returned the third year; at a second site, return rates of males were 2 of 22 (9.1%) and 0%. With 1 exception, all returning males settled either on or within 100 m of their previous territory. At Seattle, 2 of 3 breeding marshes were destroyed. Of 13 adult males, 10 adult females, and 61 young banded in the destroyed marsh, only 1 returned to the remaining marsh which was about 400 m distant. In the remaining marsh, 2 of 5 adult males (40%), 3 of 9 adult females (33%), and 0 of 34 young returned to breed the following year. One Saskatchewan bird moved approximately 80 km between successive breeding seasons. In most populations, males retain the same territory to raise a second brood, although the territory boundaries may be adjusted somewhat. New York and Minnesota birds may defend a new territory in a more open area to raise a second brood (Gutzwiller and Anderson 1987; Kale 1965; Kroodsma and Verner 2020; Leonard and Picman 1987; Verner 1965a; Welter 1935).

Limiting Factors

Eggs have been found in Ontario nests from the second week of May until mid-August, with most present in the first 3 weeks of June (Peck and James 1987). Males typically start nest construction the day after they arrive. Males take an average of 2 days to complete a dummy nest; some nests are built in a day, others take 3 days to complete. Females begin nest construction 6-15 days after their arrival and take 5-8 days to complete a nest. If a clutch is lost, females may complete the construction of a male nest for the second nesting attempt. In Georgia, the timing of initiation of nest building varied by as much as 2-3 weeks over several years, but the temperature was fairly consistent at 15°C

when nesting began. The female may begin egg laying the day after she completes the nest or not until a week later. One egg is laid a day; rarely females may lay 2 eggs on consecutive days and then delay laying for several days before completing the clutch. In some populations there may be 3 peaks of egg laying: first nesting attempts, which is the highest peak; the second peak consists of second brood attempts, first nesting attempts of yearlings, and renestings; and the third peak is the smallest and includes second brood attempts and replacement nests. Incubation is frequently initiated before the clutch is complete, although usually not before the third egg is laid. There is an interval of 1.5-2.5 days between hatching of the first and last eggs and in many nests young of 2 or 3 age classes are evident. The incubation period of Ontario nests was 13-15 days. Elsewhere, incubation periods of 12-16.5 days have been reported, with most eggs hatching in 13 days. Incubation periods may decrease as the season progresses. In Washington, incubation periods were about 16 days in April, 14-15 days in mid-season, and 13 days in July. The normal nestling period is 12-13 days but may be as long as 15-16 days. If a nest is disturbed, young may leave the nest at age 10-11 days before they can fly (Bent 1948; Kale 1965; Kroodsma and Verner 2020; Lazaran et al. 2013; Peck and James 1987; Verner 1965a; Welter 1935).

Most older Marsh Wrens raise 2 broods per year. Yearlings initiate breeding late in the season and probably raise only a single brood. Ontario egg dates strongly suggest that 2 broods are raised annually and perhaps even 3, although this is unlikely. The Marsh Wren breeds in more northerly areas in May to mid-July. In more southerly areas, such as Kansas and Missouri, it first appears in late July and August to breed. These birds apparently come from the north and may travel a minimum of 300 km. It appears as though it raises 2 broods in disparate geographic locations. Renesting usually occurs if a nest is lost, but not always. The tendency to renest appears to be an individual preference. In the same population, some females made 6 nesting attempts before they were successful; others did not renest at all. Renesting tends to occur 5-6 days after clutch loss, but 3 of 14 New York females (21%) started laying a replacement clutch within 36 hours. The number of second broods raised annually varies considerably. In Georgia, 35% of females raised 2 broods 1 year compared with 15% the second year and 0% the third and fourth year. Only 1 female attempted to raise a third brood during a 4-year study and it was unsuccessful. In Washington, 2 females attempted to raise 3 broods, but the breeding season was not long enough for them to be successful. A new nest is built for second broods and replacement nests, even if the same territory is used. Second clutches are initiated 1 week to 1 month after fledging of the first brood. The longer period of a month occurred in Georgia populations, but northern birds would not be able to delay this long due to the shortness of the season. Clutches of 2-9 eggs have been reported in Ontario, mostly 5 or 6 eggs. All 17 clutches at Seeley's Bay contained 6 eggs. Clutch size is larger and more variable in the north. Overall, clutches of 3-10 eggs have been documented, not including the Ontario 2-egg clutches, with 4-6 eggs the most frequent clutch sizes. Clutch size declines with the season (Bent 1948; Campbell et al. 1997; Kale 1965; Kroodsma and Verner 2020; Peck and James 1987; Metz 1991; Robbins 2015; Verner 1965a; Welter 1935; Wheeler 1931).

The age at first breeding is 1 year and adults attempt to breed every year thereafter. First-year males attempt to breed, but may be less successful in attracting a mate. In Washington, some females mated with males that already had a mate despite the presence of unmated males. Females

probably select males with superior territories, even if they are already mated. Females are monogamous, but many males are bigamous and a few are trigamous. Marsh-breeding birds tend to have a high rate of polygyny, although this tendency is not as high for the Marsh Wren as for many other species. After a male is successful in attracting a mate, he shifts to another part of his territory, usually 1-2 days before laying or shortly thereafter, and starts building a new courting centre where he advertises for additional mates. Not all birds are successful in acquiring additional mates and their success rate appears to be a function of the quality of their territory. Polygyny may be less frequent in eastern populations, with only 5% of Georgia males being bigamous. Western birds learn more songs than eastern ones and the vocal exchange between neighbours is more complex in western populations. Consequently, western birds are more apt to be polygynous. The rate of polygyny is variable and has been reported as 12.5-50% of males in Washington, 25-33% in New York and Minnesota, and 41-54% in Manitoba. In Georgia, no males remained bigamous for the second brood. In Washington, some males were bigamous throughout the season whereas others were not, suggesting that some females may have switched mates. Trigamy is rare with 1 case reported from Washington and 7 from Manitoba. In Washington, females mated to the same male nested at distant ends of the male's territory so that they did not encounter each other. In Georgia, females mated to the same male nested within 4-5 m of each other. Females defend a small territory around the nest, excluding other females and males, possibly due to their egg-pecking tendencies. Most pair bonds are retained through a single breeding season. In New York, most females stayed with the same male all season including those that had repeated nest failures. In Washington, 13 of 16 females (81%) remained with the same male for successive breeding attempts; the others switched mates (Greenlaw 1989; Kale 1965; Kroodsma and Verner 2020; Leonard and Picman 1997; Verner 1964, 1965a; Verner and Engelsen 1970; Welter 1935).

Almost all foraging occurs in marsh habitat, and this defines the diet to a large extent. In Washington, adults often foraged in dense shrub patches adjoining territories and fledglings were led into these thickets to feed. Most food is collected near or at the surface of water or occasionally slightly below the water's surface. When foraging near water or the ground, the Marsh Wren perches on adjacent emergent vegetation. It does not appear to land on the ground even when no water is present. Invertebrates are regularly gleaned from vegetation. Occasionally, it sallies into the air to capture larger flying insects such as dragonflies (Gutzwiller and Anderson 1987; Kale 1965; Kroodsma and Verner 2020; Verner 1965b; Welter 1935).

Young are initially fed small arthropods and the size of prey presented to them increases as they age. Insects and spiders are the predominant foods. Nestlings and fledglings are fed relatively large food items such as grasshoppers, dragonflies, sawflies and other hymenopterans, beetles (ground, predaceous diving, and long-horned beetles), horse flies, moth adults and larvae, and large spiders. Food items in nestling stomachs may be as long as 30 mm and as heavy as 70 mg. Adults eat much smaller food, with most items shorter than 10 mm and weighing less than 5 mg, but a few items are larger than 15 mm and 12 mg. Important adult foods include bugs (aphids, leafhoppers, treehoppers, scale insects, and assassin, damsel, and stink bugs), which may comprise as much as 29% of the diet; 17% larvae, pupae, and adult lepidopterans; 16% beetles; 8% ants and wasps; 11% flies, grasshoppers, dragonflies, and miscellaneous insects; and 5% spiders. Mites may be locally

important in the diet. Many of the insects consumed are aquatic species such as odonates and flies such as crane flies, mosquitoes, and midges. Beetles, aquatic flies, and spiders dominate the diet, and ants and parasitic wasps may be important foods. The Marsh Wren may consume snails and other molluscs. Often spiders are the most frequently consumed prey; in 1 area they were present in 78% of stomachs and constituted 15% of the volume of food. There is a single observation of a Marsh Wren drinking the contents of a Red-winged Blackbird egg. There is also 1 record of a Marsh Wren plucking a 24-28-mm-long fish from the water and swallowing it head first. It does not appear to be selective when feeding and consumes the prey that is most abundant and accessible. Although it eats spiders and insects almost exclusively, 2% of material in 53 stomachs of California birds consisted of vegetation, which was comprised of a few sedge seeds and 1 amaranth seed. In Washington during a dry year, wrens nesting in cattails ate mostly plant material but ate mostly aquatic insects when there was ample standing water (Ayers and Armacost 2010; Bent 1948; Gutzwiller and Anderson 1987; Kale 1965; Kroodsma and Verner 2020; Verner 1965a, 1965b; Verner and Engelsen 1970; Welter 1935).

The only instance of Brown-headed Cowbird parasitism of the Marsh Wren was reported in British Columbia. Of more than 1,200 nests that Picman (1986) examined, he found one that contained 2 broken wren eggs and a cold, undamaged cowbird egg.

Habitat quality is important in determining the breeding success of males. A male's pairing success is positively correlated with the percentage of the territory that is covered by cattails. The percent cattail coverage in territories was 83.2% for bachelors, 85.1% for monogamous males, and 87.8% for bigamous males. In Manitoba, pairing success was positively associated with cattail density, cattail height (28.9 cm in preferred habitat compared with 12.1 cm in unused habitat), and water depth (132.1 cm compared with 91.9 cm). In Washington, the amount of bulrushes within a territory was negatively correlated with male pairing success. The amount of dead emergent vegetation within a territory negatively affects pairing success. In some areas, pairing success appears to be correlated with the number of male nests built in the territory; in other areas it is not. Quality of vegetation appears to be the most important factor. Unmated females move among territories and assess habitat quality before selecting a mate. Territories tend to support the same number of breeding females each year even if different males are defending them. Therefore, polygyny is associated more with high-quality territories than with individual males. In territories with more cattail cover, denser vegetation, and deeper water, a higher proportion of nests were successful and the total number of young fledged per male was significantly higher (Gutzwiller and Anderson 1987; Kale 1965; Kroodsma and Verner 2020; Leonard and Picman 1987; Linz et al. 1996; Manci and Rusch 1988; Verner and Engelsen 1970).

Habitat loss and degradation may affect populations. Historical wetland destruction and drainage undoubtedly reduced the amount of habitat available for Marsh Wrens. Wetland losses are much less frequent in the province now and in some areas there may be gains in wetland habitat due to active wetland restoration projects. Low water levels in marshes due to drainage, diversion of surface runoff, or drought may make habitat less suitable or unsuitable. At Last Mountain Lake in Saskatchewan, 140 singing males were counted in 1988. The marshes were dry the following year and only 3 males were on territory (Kroodsma and Verner 2020). At Horicon Marsh in Wisconsin,

density of birds varied annually in shallow-water cattail stands and declined when water levels were lower (Manci and Rusch 1988).

Many marshes are becoming invaded by common reed which eliminates many native emergent plant species. The Marsh Wren rarely nests in common reed, so presence of this species may decrease habitat quality. In Ohio Lake Erie marshes, aerial spraying was undertaken to control common reed. Although the Marsh Wren did not nest in this species, density of males decreased 4-fold and active nest density decreased 10-fold. The most significant change in nesting behaviour was in the timing of egg laying. Females delayed egg laying an additional 36 days, waiting for regeneration of native plants from the seedbed. Lazaran et al. (2013) concluded that aerial spraying of common reed may have as much of a negative impact on the Marsh Wren as the presence of the plant itself. In Ontario, most common reed control is now done manually.

There appears to be direct interspecific competition between the Marsh Wren and the Red-winged and Yellow-headed blackbirds. In certain areas, Red-winged Blackbirds may occupy and defend all suitable nesting habitat and wrens nest within their territories. The nests of the 2 species are segregated, with the highest degree of segregation occurring where the density and height of cattails varies most. Nest segregation is less pronounced, but still occurs, in homogenous, dense stands of cattails. Blackbirds of both species frequently approach Marsh Wren nests and may land on the nest and be aggressive to the wrens. Yellow-headed Blackbirds may remove wren eggs and nestlings. Blackbirds force wrens to sing from lower perches on cattails. Wrens have smaller territories where they overlap blackbird territories. Through these activities, blackbirds may depress the mating success of wrens and reduce their nesting success. In turn, Marsh Wrens peck the eggs and nestlings of both blackbird species. Blackbird nesting success increases significantly with distance from wren nests. Both blackbirds and the Marsh Wren eat dragonflies and damselflies; damselflies are a staple of the Red-winged Blackbird's diet. There may be direct competition between the species and food may be limited in many areas (Leonard and Picman 1986; Picman 1977a, 1980a, 1980b, 1982; Verner 1975).

Marsh Wrens attack other nests of their own species. When Picman (1977b) removed incubating females in British Columbia, many Marsh Wrens attempted to break their eggs. One bigamous male pecked eggs in both his females' nests. An additional 12 males were trapped that were either trespassing neighbours or nonbreeding floaters. Ten females of unknown origin also attacked the eggs. In 1 case, the second female of a bigamous male attacked the nest of the primary female. Twenty-one juveniles of unknown origin also attacked the eggs. No nests were destroyed when incubating females were present, but there were many attacks when females were removed.

In Minnesota, mosquito control with Bti and methoprene had no negative effects on the Marsh Wren (Hanowski et al. 1997).

Cold winters and springs with above-average precipitation may affect survival, timing of nest initiation, and reproductive success. Grant and Kirby-Smith (1992) reported mortality in a North Carolina marsh as a result of a heavy December snowfall that coincided with 4 days of subfreezing temperatures. Numbers of wrens declined to 0. No birds were present the entire winter but numbers recovered the following year. In cold springs, nest initiation may be delayed 1-2 weeks or more. Late

springs result in a shortage of food and a delay in the growth of emergents. Later initiation of nesting results in smaller mean clutch sizes and a longer average time to complete 1 cycle and start a second brood (Kroodsma and Verner 2020; Manci and Rusch 1988; Verner 1965a). Although spring rains may affect reproductive success, drought may have adverse effects. In North Dakota, its abundance was significantly correlated with the number of ponds present, which was dependent upon the amount of precipitation received (Niemuth et al. 2008). In the Prairie Pothole Region of Canada, its abundance was positively correlated with spring temperature but not with amount of annual precipitation, although it was positively correlated with the amount of precipitation in the previous year (Forcey et al. 2007, 2014).

Status

The Marsh Wren has always been a common to locally common breeder in southern Ontario south of the Canadian Shield, and probably also in the Lake of the Woods area. Historically, it was probably more common in the south than at present due to loss of marsh habitat. McIlwraith (1894) considered it a common summer resident found in suitable habitat throughout the province and stated that it bred in all the inlets around Hamilton Harbour. Curry (2006) considered it an uncommon but widespread breeder in the Hamilton area and noted that the marshes that McIlwraith referred to no longer existed. Baillie and Harrington (1937) reported that it was a common breeder in cattail marshes in southern Ontario north to Simcoe, Peterborough, and Renfrew counties and also at Lake of the Woods. Where marsh habitat is common, the Marsh Wren may be one of the more abundant species. It was one of the most common marsh birds in the Kingston area (Weir 2008). Tozer et al. (2006) studied marsh birds at Long Point, Matchedash Bay, and in the Peterborough area. The Marsh Wren was the third most abundant bird behind the Red-winged Blackbird and Swamp Sparrow. Mills (1981) reported that both marshes and Marsh Wrens were rare in Muskoka and Parry Sound districts. In Elgin County, where marshes are rare, it was very unevenly distributed in 1891, with 2-3 pairs nesting near St. Thomas. In 1954, the St. Thomas reservoir was the only breeding area. It is still a rare breeder in Elgin with most records from sewage lagoons (Lancaster et al. 2004). McCracken (in Cadman et al. 1987) considered the Marsh Wren locally common in southern Ontario with estimates of more than 100 pairs per square in large marshes on Lake St. Clair, Lake Erie, in Georgian Bay, at Luther Marsh, and in the Kawartha region. The southern Ontario population and the population near Lake of the Woods appear to be discrete and occupied by 2 different subspecies. During the first atlas, a nest was found north of Moosonee 600 km north of its previously known range. James (1991) considered the Marsh Wren locally common south of the Canadian Shield, uncommon and sparsely distributed in the southern Shield, rare in the Lake of the Woods to Lac Seul area, and occasional near Thunder Bay.

The second atlas revealed that there had been no significant change in the distribution of the Marsh Wren, although it was observed in more areas in northwestern Ontario than during the first atlas. Its probability of observation did not change province-wide, but increased significantly in the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region. It was well distributed south of the Shield but with large gaps in distribution due to lack of suitable marsh habitat. Highest concentrations occurred at Lake St. Clair, in the Point Pelee and Rondeau areas, and in the Prince

Edward County to Kingston area. There was a broad band of occurrence along the southern edge of the Shield, but densities in this area were only moderate (Tozer in Cadman et al. 2007).

Tozer (2013) summarized population trends of the Marsh Wren as determined by the Great Lakes Marsh Monitoring Program from 1995 to 2012. During this period, it declined significantly at a rate of 1.1% per year. These data include monitoring routes and stations that are within the American portion of the Great Lakes basin, but exclude Ontario stations and routes that do not drain into the Great Lakes. In Great Lakes coastal wetlands, it increased at an annual rate of 11.3% 2011-21 (Tozer et al. 2024). Breeding Bird Survey data for 1970-2021 indicate that it increased at an annual rate of 1.71% in Canada and 1.69% in Ontario. The annual rates of increase 2011-21 were 3.05% in Canada and 1.99% in Ontario. The Canadian trends were of medium reliability; the long-term Ontario trend was highly reliable and the short-term trend was of low reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Young can capture some food on their own 10 days after fledging, but are cared for by the adults for at least 2 weeks after fledging. One bird was fed by an adult 27 days after fledging; another young was independent and far from the nest 23 days after fledging (Kroodsma and Verner 2020).

Fledglings initially remain in family groups that wander about and frequently leave the nesting territory. Initially, young stay in dense emergents but prefer more open areas near water later in the summer. For the first week after fledging, young remain in the vicinity of the nest but may wander a distance of 1-2 territories. As they become more independent, the young move further away and flocks of juveniles form, often comprised of 25-30 birds. Individual juveniles within flocks have been found further than 0.6 km from the nest about a month after fledging (Kale 1965; Kroodsma and Verner 2020; Verner 1965a; Welter 1935).

Fledglings tend to return to the breeding nest several nights after fledging and may later roost in courting nests or among vegetation. The brood appears to be led away from the roosting nest in the morning by the adults and back to it in the evening, travelling greater distances as the young age (Kroodsma and Verner 2020; Verner 1965a; Welter 1935). In Florida, Chicalo et al. (2019) reported that there were no fledglings or fewer fledglings than expected in some of the natal nests. On 8 occasions (17.8%) involving 6 broods, at least 1 fledgling was found in a dummy nest within the territory. Individuals from 2 of the 6 broods were found in dummy nests only after they had been disturbed in their natal nest. In 2 territories, an entire brood of 4 fledglings was located in a nearby dummy nest. Fledglings in dummy nests were 14-15 days old. Occupied dummy nests were within 5 m of the natal nest.

MIGRATION

Eastern populations are migratory and winter on the Atlantic and Gulf coasts with the extent of migration depending on the severity of winter. Older males are the most sedentary and young birds are the most migratory. Some western and southern populations may be resident. In Ontario, spring migrants arrive in numbers in mid-May, but early migrants arrive in mid- to late April. Females arrive 7-10 days after the males. In early June, there may be another wave of arriving males and more males and females arrive in mid-June. These may be young from the previous year (Black and Roy 2010;

Curry 2006; Kroodsma and Verner 2020; LaForest 1993; Leonard and Picman 1987; Weir 2008; Welter 1935).

Autumn departure starts in August but birds continue to move south from the breeding areas into October. Adults migrate as soon as they complete the post-nuptial moult. There are 2 waves of autumn migrants. The first includes adults and some young of the first brood. The second wave is predominantly juveniles from the second brood. After early September, most remaining birds are young from second broods. In southern Ontario, most birds are gone by mid-October, with rare stragglers in early November or even later (Black and Roy 2010; Curry 2006; Kroodsma and Verner 2020; LaForest 1993; Weir 2008; Welter 1935).

During migration, the Marsh Wren is typically found in wetlands with emergent vegetation and also in dense shrub cover around the perimeter of freshwater marshes. Occasionally it occurs in drier habitats distant from marshes. It has occurred in dry weed patches, damp pastures dominated by sedges, wet alfalfa fields, weedy agricultural drainage ditches, and any habitat with wet soils and dense, low vegetation. Drier habitats atypical of breeding habitat are more likely to be used during autumn migration (Bent 1948; Campbell et al. 1997; Kroodsma and Verner 2020).

Migration occurs at night. Significant numbers may be killed at tall buildings and communication towers. From 1975 to 1977, 7 were killed at the Lennox generating station chimneys near Kingston. Most kills due to strikes occur during autumn migration; high numbers of mortalities have been documented in Tennessee and Florida (Kroodsma and Verner 2020; Taylor et al. 1983; Weir 2008; Welter 1935). Taylor et al. (1983) found large number of dead House, Sedge, and Marsh wrens at a tower in mid-October and suggested that the 3 species of wrens were migrating together.

The Marsh Wren is an uncommon migrant in Ontario (James 1991).

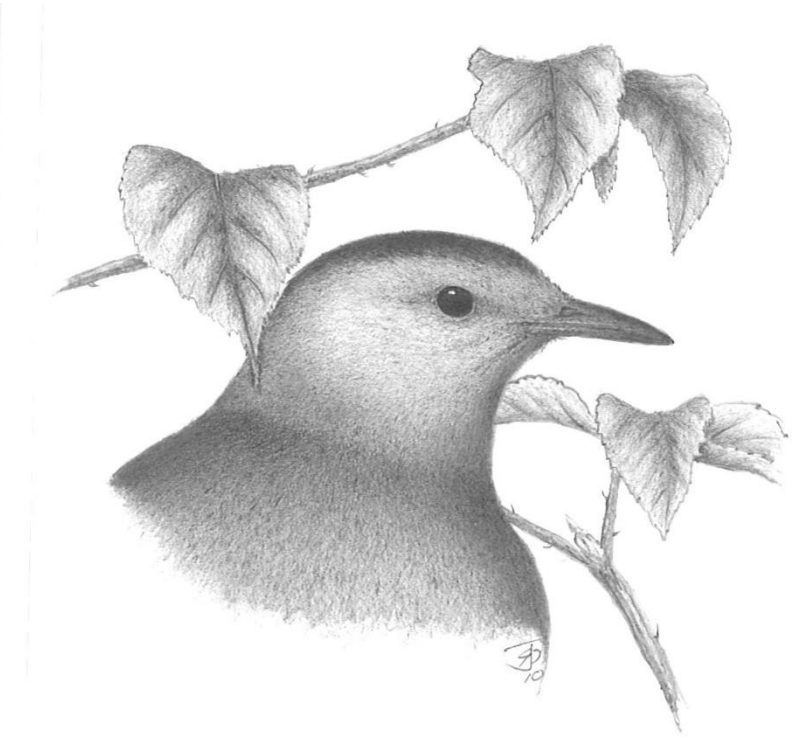
WINTER

The Marsh Wren is a rare and irregular winter resident in Ontario. Ontario is well north of the normal winter range of this species and winter records should be considered extralimital. In the south, there are numerous records from December or early January, but most of these birds probably move further south as winter progresses or perish. In the Hamilton area, there are at least 5 winter records of birds persisting until the end of February in 1 case and into April to the normal spring arrival time in the other cases (Curry 2006; James 1991; LaForest 1993).

Christmas Bird Count data indicate that the Marsh Wren population increased 0.075% annually 1970-2021 and 3.45% annually 2009-21 (National Audubon Society 2022).

Gray Catbird

Dumetella carolinensis

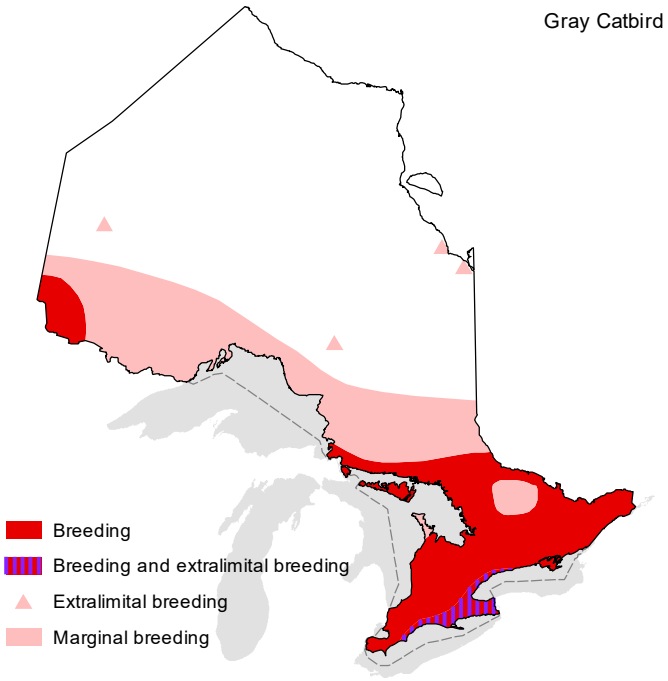


BREEDING SEASON

Habitat Requirements

In Ontario, the Gray Catbird has nested in shrubby overgrown fields and pastures (40.8% of nests); in deciduous woodlands (7.7%); in coniferous woodlands (7.3%); in mixed woodlands (5.9%); in unspecified woodlands (4.9%); in urban and rural gardens, cottage areas, fairgrounds, and farmyards (12.5%); in river floodplains (9.1%); in orchards and farm fencerows (4.5%); in wetlands, including willow swales, alder thickets, bogs, beaver meadows, and marshes (9.1%); and on road and railway rights-of-way (1.7%). Woodlands used for nesting were usually open. Many nests were at edges of woodlots or along roads, paths, and shorelines; some were in clearings. One nest was in a single tree in 0.6 m of water in a small lake (Peck and James 1987).

In the Great Lakes–St. Lawrence Forest Region in the Canadian Shield, James (1979a) did not find the catbird in any pure jack pine stands near Parry Sound, but it occurred in open pine stands mixed with deciduous species. In Muskoka and Parry Sound districts, it preferred shrubby, moist areas (Mills 1981) and in Algonquin Park, it occasionally occurred in shrubbery along streams (MacLulich 1938). In Algonquin Park, it is often associated with water, nesting in dense vegetation bordering clearings, roads, marshes, lakes, rivers, and creeks (Tozer 2012).



In Durham Region in the Great Lakes–St. Lawrence Forest Region south of the Shield, it nested in a very young pine plantation dominated by willow shrubs, in a meadow of apple trees and hawthorns, and in deciduous and mixed upland and wetland stands that were highly disturbed with open canopies and a dense shrub-sapling layer. Speirs and Orenstein (1975) considered it an early succession species that also persisted in openings and around fringes of later-succession forests.

In the Carolinian Forest Region at Rondeau, Nickell (1965) found most nests in open shrub and grassland areas, none in areas dominated by red cedar, and only 2 in white pine stands, where it nested in greenbrier.

Throughout its range, the Gray Catbird is strongly associated with shrub or sapling growth, and its abundance increases linearly with shrub abundance. It is positively associated with invasive, nonnative shrubs such as honeysuckle. Closed-canopy forests are avoided as are large, open areas. It is most abundant in shrubby areas adjacent to forests, including utility corridors cut through forests; in old fields dominated by shrubs; in fencerows; in shrubs around ponds, marshes, lakes, and streams; and in shrubby areas in urban areas. In Illinois, it reached its greatest abundance in hedgerows and urban areas. Many of the shrubby areas inhabited are in a dense tangle of grape or Virginia creeper vines. Although it often inhabits moist areas associated with bodies of water, watercourses, and thickets dominated by alder, willow, or dogwood, it also nests in dry forest edges and cultural thickets. Forests are usually not used for nesting but it is opportunistic and will nest in shrubby areas within forests created by fallen trees. Small gaps in forest cover are readily used, but large gaps tend to be avoided although it nests in 1-24-ha clear-cuts in New York. It inhabits clear-cuts about 5 years after cutting once shrub and sapling growth becomes established. It is usually much more abundant in cut-blocks than uncut forests. Other habitats that it may use include orchards, hedges, cemeteries, parks, residential yards, very young coniferous plantations that are still dominated by deciduous shrubs, marshes, abandoned farmland and home sites, edges and gaps of a wide variety of upland and lowland forest types (but rarely in coniferous forests and more mature plantations), pine and oak barrens dominated by shrubs and saplings, shrubby gullies, and thickets of wild rose, juneberries, or raspberries. It is absent in bogs unless they are fringed by other suitable habitat (Back 1979; Bielefeldt and Rosenfield 1994; Brewer 1955; Campbell et al. 1997; Capen 1979; Corbat et al. 1988; Dessecker and Yahner 1987; Faanes and Andrew 1983; Finch 1989b, 1991a; Graber and Graber 1963; Graber et al. 1970; Gross in Bent 1948; Keller et al. 2003; Leighton et al. 2002; Mossman 1989; Mossman and Hoffman 1989; Mossman et al. 1991; Nickell 1965; Niemi and

Pfannmuller 1979; Noon et al. 1979; Robbins et al. 1979; Samson 1979; R.J. Smith et al. 2020; Suthers 1988; Taylor and Taylor 1979; Temple et al. 1979; Vincent and Bombardier in Gauthier and Aubry 1996; Yahner et al. 2002). Preferred habitat in urban areas of Massachusetts included a deciduous shrub layer 1.8-4.6 m tall and a deciduous overstorey at 3.4-10.7 m. Presence of dense woody vegetation was important (Thomas et al. 1977). In a Connecticut woodlot over a 59-year period, there was a progressive shift to larger trees, a sparser shrub layer, and a less diverse tree canopy. The Gray Catbird declined in the woodlot, probably as a result of the decrease in shrub coverage (Buchanan et al. 2016).

In North Dakota in open landscapes, the catbird's probability of occurrence increased as tree cover within 100 m increased to 40% then levelled off. In wooded landscapes, its probability of observation remained stable at about 10%, similar to the more wooded areas in open landscapes (Cunningham and Johnson 2016). It preferred areas where there was 52-75% tree cover in North Dakota and 23-58% tree cover in New York (Cunningham and Johnson 2019). In North Carolina, it was negatively correlated with the amount of tree canopy at the 200-m scale. As tree canopy increases, shrub coverage declines. It was positively associated with elevation at the 200-m scale, suggesting it was capable of occupying small forest gaps in high-elevation landscapes. At the 1,000-m scale, it preferred more heterogeneous landscapes which consisted of mosaics of forest patches, lawns, and pastures with interspersed roads and other structures. It was not correlated with the amount of exurban development (Gilbert and Ferguson 2019).

The catbird is an early successional species. In Pennsylvania clear-cuts, it was absent in 1-year-old stands and occurred only in 5-year-old and mature stands. Five-year-old stands were selected and these stands had high densities of woody stems (Corbat et al. 1988). In North Dakota, it was less common in aspen stands having 15-23 cm diameter at breast height (DBH) trees (Grant and Berkey 1999). In New Jersey, it occurred in old fields that were 10, 20, and 40 years old. Suthers (1988) considered it an obligate edge species that occurred in shrubs. Densities were lowest in the 40-year-old field where a single pair was present. The edges of the field had become forested, the centre was densely covered with saplings 2-26 cm DBH, and fruit was rare. In Wisconsin, it reached its greatest abundance in pioneer stands where shrubs were most abundant (Bond 1957). In South Dakota green ash woodlands, it was most abundant in late seral stages of forest. More mature stands had a higher density of chokecherry, greater green ash DBH and basal area, and a higher percentage of canopy closure with less patchy overhead cover (Rumble and Gobeille 1989). It is likely that the catbird was keying in on the abundant chokecherry in the understorey.

Some studies determined that the Gray Catbird prefers wet habitats; others found the opposite. In the mid-Atlantic states, abundance of the catbird was correlated with increasing moisture but it was most common in xeric stands in Wisconsin (Bond 1957; Graber et al. 1970; Robbins et al. 1989). In Wyoming, it was a habitat specialist associated with high foliage density at mid-canopy or shrub height. The structure of the lower woody vegetation strata appeared to be more important than the moisture regime (Finch 1991a). In Rhode Island, it was one of the most frequently detected species at small seasonal pools. It was more abundant at urban seasonal pools suggesting that it may be exploiting these resources in the absence of competition from species intolerant of urban habitat. Pools provide high densities of flying insects and the higher density of shrubs around pools may

provide food and shelter (McKinney and Paton 2009). Nickell (1965) found that the catbird frequently nested on the periphery of wetlands occupied by Red-winged Blackbirds. The blackbirds kept catbirds out of their territories, but catbirds were able to use the shrubby outer fringe. Dominant shrubs in these areas were Carolina rose, buttonbush, sandbar willow, swamp birch, highbush blueberry, winterberry, nannyberry, and meadowsweet.

Some studies identified microhabitat requirements of the catbird. In the mid-Atlantic states, its abundance was positively correlated with the number of trees larger than 38 cm DBH and negatively correlated with the number of trees within a 0.04-ha circle, percent canopy cover, and canopy height (Robbins et al. 1979). In Maryland, its abundance was negatively correlated with shrub species diversity and abundance of pines (Lynch 1987). In Iowa, it was positively correlated with sapling richness, sapling and tree size, vertical patchiness of vegetation, vertical stratification of vegetation, and snag size. It was negatively correlated with sapling and tree density, slope, and the number of deciduous trees and vines (Stauffer and Best 1980).

The catbird is associated with fragmented patches and small forested areas. All but 1 study determined that it is not area sensitive and that it decreases in abundance as forest size increases. In southern Ontario, its probability of detection was negatively correlated with the amount of forest 100 m or further from edge, woodlot size, the amount of forest cover within 2 km, and the amount of regional forest cover. The latter 2 relationships were significant (Austen et al. 2001). In Pennsylvania, it occurred most frequently in fragmented landscapes during the breeding season (Keller and Yahner 2007). Keller et al. (1993) reported that its abundance declined significantly as the width of riparian forests increased. Probability of occurrence was 39% in 50-m wide forests and declined to 1% in 800-m wide forests. In the mid-Atlantic states, its abundance was negatively correlated with the percentage of forest within 2 km and forest area. Its probability of observation was 72% in 0.3-ha woodlots, 50% in 10-ha woodlands, 35% in 100-ha woodlands, and 20% in 1,000-ha woodlands (Robbins et al. 1989). In Maryland, its abundance was negatively associated with forest size. Probabilities of observation were 80% in 0.1-ha woodlots, 50% in 10-ha woodlands, 35% in 100-ha woodlands, and 18% in 3,200-ha woodlands (Lynch 1987). In North Dakota aspen stands, probability of occurrence was 65% in 1-ha stands, 45% in 10-ha woodlands, 20% in 100-ha woodlands, and 10% in 1,000-ha woodlands (Grant and Berkey 1999). In Rhode Island red maple swamps, there was no relationship between forest size and catbird abundance (Golet et al. 2001). The catbird was considered area sensitive in Missouri. The smallest forest it was observed in was 5.6 ha. Hayden et al. (1985) estimated that forests would have to be larger than 340 ha to reach 100% occurrence. Because the catbird is associated more with shrubby habitats and avoids nesting within forests except where there are openings, it is not surprising that its abundance declines with increasing forest size. It is more relevant if the catbird requires large shrubby patches. This does not appear to be the case, although it has not been well documented. Corbat et al. (1988) concluded that the catbird was not area dependent in Pennsylvania where it was common in regenerating 1-ha clear-cuts. The catbird occasionally nests in solitary hawthorns in pastures (Nickell 1965) and frequently in small patches of shrubs around dwellings indicating that it is not area sensitive.

Most Ontario nests were in living shrubs, trees, and vines. Nine were in dead woody vegetation, 2 were supported by cattails, 1 was in a brush pile, 1 was on a vine-covered trellis, and 4 were in

fallen trees. One nest was on or very near the ground in a tangle of vines near the base of a beech tree. Nest trees were typically small or saplings. Deciduous shrubs, trees, and vines (37 species, 81.9% of nests) were preferred to coniferous trees and shrubs (8 species, 18.1% of nests). Species most frequently selected for nesting were hawthorn (57 nests), grape vines (23), raspberries (23), willow (21), apple (20), white cedar (19), spruce (18), and dogwood (17). Nests were positioned at all heights within trees and shrubs and there was a tendency to locate nests centrally near the trunk rather than distant from it. Nests were usually well concealed in upright crotches, on horizontal branches, or occasionally between 2 adjacent upright tree trunks. Nests were 0.3-4.9 m from ground, with most 1.1-1.8 m up (Peck and James 1987). Nickell (1965) found 200 nests in Rondeau Park; 65.3% were in grape canopies exposed to full sunlight and growing over thickets of small beech, sugar maple, basswood, tulip tree, elm, ash, and birch to a maximum height of approximately 4.6 m. Nearly all other nests were in forks between thinner coverings of grape. Of the Rondeau nests, 66.0% were in wild grape an average of 2.3 m above ground, 7.0% were in beech an average of 1.6 m up, 4.5% were in sugar maple an average of 2.2 m up, 3.5% were in hawthorn an average of 1.6 m up, 3.5% were in gray dogwood an average of 1.9 m up, 3.0% were in hophornbeam an average of 2.2 m up, and 12.5% were in miscellaneous species. The average height of 175 nests was 2.2 m (range 0.8-5.2 m). One nest in Parry Sound District was 4.9 m from the ground in a jack pine (Mills 1981).

A new nest is usually built for each brood but rarely a nest from the previous year may be reused. The catbird has been known to usurp Brown Thrasher nests and use old Northern Cardinal nests (Horn et al. 2007; Marshall et al. 2001; Nickell 1965; Potter 1988). Nests are typically in deciduous shrubs and trees that are mostly living but occasionally dead, and seldom in coniferous species. Dominant species used for nesting are grape, hawthorn, gray dogwood, tartarian honeysuckle, and elderberry. Nests in marshes or thicket swamps are often in shrub willows, buttonbush, Carolina rose, highbush blueberry, meadowsweet, and winterberry holly. At the margins of water, nests are often in dogwoods and elderberries. Several Michigan nests were in shrubbery overhanging water including swamps, lagoons, streams, and lakes. Distance of nests from shore averaged 54.9 m for swamps, 2.1 m for lagoons, 0.9 m for streams, and 3.4 m for lakes. Any deciduous shrub or tree species may be used for nesting, but those that have several vertical stems or branches, such as gray dogwood and honeysuckle, are greatly preferred. More linear and open species, such as staghorn sumac and prickly-ash, tend to be used only when an adjacent plant provides cover. Of almost 4,000 Michigan nests, 14.8% were in gray dogwood, 13.8% in tartarian honeysuckle, 11.3% in hawthorn, 8.2% in grapes, 5.8% in common elderberry, 3.5% in Japanese barberry, 3.4% in privet, 2.5% in shrub willows, 2.2% in American hazel, 2.0% in mock orange, 1.8% in ninebark, 1.6% in lilac, 1.6% in highbush blueberry, 1.4% in forsythia, 1.2% in prickly-ash, 1.2% in Carolina rose, 1.2% in cultivated roses, 1.2% in white spruce, and 1.0% in American plum. Other nest species supporting 0.3-1.0% of nests (in descending order of importance) were blackberry, bittersweet, buttonbush, elm, cultivated spirea, nannyberry, meadowsweet, red raspberry, black spruce, crabapple, winterberry holly, apple, white cedar, winter honeysuckle, Virginia creeper, silky dogwood, beech, nightshade, hophornbeam, sugar maple, Norway spruce, and American yew; an additional 73 woody species each supported less than 0.3% of nests. Only 1 nest was found in a herbaceous species: meadow-rue. At Delta Marsh, Manitoba, over 50% of nests were in Manitoba maple although it constituted only 25% of the available trees. Sandbar and peach-leaved willow represented 55% of the available

trees but were seldom used for nesting. In Iowa, 72% of nests were in deciduous shrubs, 11% in deciduous saplings, 14% in deciduous trees, and 2% in coniferous trees; none were in forbs or grass. Two Ohio nests were built on the ground despite other suitable nest substrates being present: 1 nest was in a cavity in a tree and 2 were in marsh vegetation. In British Columbia, 91 of 93 nests (98%) were in deciduous shrubs or small trees, usually in dense tangles of vegetation. Forty-seven percent of nests were in wild roses, 25% in lilacs, 7% in grape, 4% in red-osier dogwood, and 4% in willows; 20 other species of shrubs and small trees supported nests. In Iowa, most nests were in gooseberry, multiflora rose, and prickly-ash, but also in elm, red mulberry, and honey locust. Rose was used more than its availability and was most commonly used later in the season; elm and mulberry were used only later in the season. Gooseberry was used most commonly for nesting, especially early in the season and was used in proportion to its availability. Prickly-ash was used less than its availability. All nests in this species were concealed by other woody species. A moderate amount of vegetation density in the immediate vicinity of the nest and edge habitat are apparent requirements. In Pennsylvania, nest sites had higher woody stem density than randomly selected sites. In Michigan, 45% of nests were at an edge. Most nests are hidden from above but many are easily visible from below and at least 1 side. The nest is situated where it offers good visibility for the sitting female and the male anywhere in the immediate vicinity of the nest. Nests have been reported on the ground (rarely) to more than 15 m from the ground, but most are 1-2 m up. The mean height of 4,572 nests was 1.5 m (Brackbill 1950a; Campbell et al. 1997; Gabrielson 1913; Graber et al. 1970; Gross in Bent 1948; Johnson and Best 1980; MacKenzie et al. 1982; Nickell 1965; Schill and Yahner 2009; R.J. Smith et al. 2020; Stauffer and Best 1980).

The male guards the nest and expels other birds and small mammals from this area. Territory size in London averaged 0.32 ha. Two territories in Illinois were 0.06 and 0.45 ha; territories in Georgia and Bermuda were 0.20-0.41 ha. Home range sizes have not been quantified, but are much larger. Birds have been documented traveling 73 m to obtain nest material and 1 pair was seen regularly 183 m from the nest. Catbirds may fly several hundred metres to feed in undefended areas where there are no territorial disputes among birds. Active nests may be close to each other. Two Illinois nests were 14.6 m apart; 2 Ontario nests were within 18 m of another nest (Brewer 1955; Graber et al. 1970; Nickell 1965; Peck and James 1987; Slack 1976; R.J. Smith et al. 2020).

Natal philopatry is low. Nickell (1965) banded more than 1,000 nestlings in Michigan over 16 years and only 2 returned for a return rate of approximately 0.2%. In Ohio shrublands, 3 of 304 juveniles (1%) returned to the natal area (Lehnen and Rodewald 2009b). In New Jersey old-field habitat, 11 of 765 young (1.4%) returned to nest (Suthers 1988). In Iowa, 0 of 32 nestlings returned (Johnson and Best 1980). In New York, 7% of nestlings returned to breed in the natal area. The mean distance from natal nests to the first nests of returning juveniles was 358 m (R.J. Smith et al. 2020). Schlossberg (2009) estimated natal philopatry at 2% based on a sample of 389 from 3 studies.

Adult site fidelity is higher. Schlossberg (2009) calculated that the return rate of adults averaged 23% based on a sample of 576 from 4 studies. In London, 17 of 51 males (33.3%) returned; 7 returned twice and 1 returned 3 times. Eighteen of 58 females (31.0%) returned and 6 returned twice. Combining the sexes, the return rate was 32%. The return rate was strongly influenced by sex and slightly by reproductive success, but not by age of birds, which were all after-hatch-year birds (Darley

et al. 1977). In Ohio shrublands, 8 of 189 adults (4.2%) returned to the same site. There was some evidence that shrubland birds dispersed to younger patches, but they did not seem to move to larger patches (Lehnen and Rodewald 2009b). R.J. Smith et al. (2020) stated that 12% of adults returned to breeding sites in New York and Johnson and Best (1980) reported a return rate of 40% in Iowa. There are several reports of individuals or pairs returning to the same area to nest, often in the same territory or very close. Birds have been known to nest in the same area for as long as 5 years (Brackbill 1950a; Gill 1935, 1936; Graber et al. 1970; Gross in Bent 1948). In London, the rate of return ranged from a high of 64% for males that had nested successfully the previous year to a low of 35% for unsuccessful males and females. No bird that deserted its first territory of a season returned to it in subsequent years. For successful males, there were no differences in return rates to first and second territories held in a single year. No unsuccessful females returned to the last territory but 4 of 7 unsuccessful males did. Only 6 females returned to their previous territory and 4 of these retained the same mate (Darley et al. 1977). In New York, birds tended to return to the territory that they held last (Gill 1935). In Iowa, 3 returning males occupied territories 0 m, 180 m, and 280 m from their previous territories; distances for 3 females were 110 m, 350 m, and 420 m (Johnson and Best 1980).

Some birds retain the same territory for all nests within a season; others desert the first territory (Darley et al. 1971; Gill 1935). Successive nests in London were usually within 50 m of each other if the territory was retained. When a territory was abandoned, the birds often disappeared completely or re-established a territory more than 100 m distant from the first. In all cases, the second territory was not within the home range of the birds while they were on their first territory. Deserting pairs moved distances of 150-450 m. A single male moved 600 m and a pair moved to an adjacent territory 50 m away. Both members of a pair typically deserted together. Causes of territory desertion were failure of a female to appear on the territory, death of a mate, and nest destruction. Most desertions occurred after laying had begun and always after at least partial loss of the eggs. Birds exhibited an inconsistent response to nest loss: some deserted the territory, some remained, and some individuals deserted 1 year and remained another after similar losses. Approximately 38% of birds shifted territories within a season and some of the shifts were by pairs. There was a tendency for seasonal faithfulness to territories and partners (Darley et al. 1971).

Limiting Factors

Eggs have been reported in Ontario nests from early May to mid-August, with most present in June and the first 3 weeks of July (Peck and James 1987). London birds initiated egg laying between 13 and 24 May over 4 years. Initiation of egg laying was related to air temperature. In a year when the mean average temperature in the first 2 weeks of May was 14.5ºC, egg laying was initiated on 13 May. When the average temperature during this period was 4.5ºC, egg laying began on 24 May. The last eggs in the latest nests at London were laid between 7 and 14 July (Scott et al. 1987, 1988). In Algonquin Park, nests are under construction from late May to early June, eggs are present from late May to late June, nestlings are present from mid-June to late July, and dependent fledglings have been observed from early July to late August (Tozer 2012).

Nest building begins 7-10 days after arrival and usually takes 5-6 days; later nests are built quicker. Laying normally begins 1-3 days after the nest is complete, but may begin as soon as the

lining is complete or be delayed for as long as 6 days after completion. In 1 case, an egg was laid the day after the nest was completed and egg laying was delayed until the 6th day in another nest. At London, the time between pair formation to laying of the first egg averaged 10 days. One egg is laid per day. Some incubation occurs with the laying of the second egg, but full incubation is reached when the last or penultimate egg is laid. The incubation period of 24 Ontario nests was 11-15 days, mostly 12-13 days. Elsewhere, incubation periods of 12-15 days have been reported (average 12.9 days). Hatching periods between successive eggs may vary considerably among broods suggesting irregular incubation. The nestling period is 9-15 days, but mostly 11-13 days (average 11.3 days in Michigan). At London, the time elapsed between initiation of egg laying to fledging was 24-25 days for 3-egg clutches, 26-28 days for 4-egg clutches, and 29 days for a single 5-egg clutch. It typically took 15 days between fledging and initiation of a second brood, so it was an average of 42 days to fledge a 4-egg clutch and prepare for a second. The average interval between fledging and laying of the first egg of the second brood was 7.6 days in Iowa and 10.8 days in Michigan for an average of 36 days to produce 1 brood and prepare for another. Overall, intervals of 2-19 days have been reported between fledging and laying the first egg of the second brood. The average time between loss of a nest and laying of the first egg in 41 replacement clutches in London was 5.05 days. Intervals were 5-8 days for losses during laying, 3-7 days during incubation, and 3-6 days during brooding (Balogh et al. 2011; Campbell et al. 1997; Darley et al. 1971; Gabrielson 1913; Graber et al. 1970; Gross in Bent 1948; Johnson and Best 1980, 1982; Nickell 1965; Peck and James 1987; Scott et al. 1987, 1988; R.J. Smith et al. 2020; Whittle 1923).

In most of its range, the catbird raises 2 broods and 3 broods may be attempted in the southeastern states. Double-brooding has been confirmed in Ontario, Quebec, and British Columbia. At the University of Western Ontario campus, only 3 pairs attempted second broods and these were among the 4 earliest to produce a brood. If the first nest is unsuccessful, it is unlikely that birds would have sufficient time to raise a second brood. Renesting is common if a nest is lost. Replacement nests are more likely to occur if the loss occurs early in the season. At London, 8 of 11 birds (72.7%) that lost nests in the last week of June renested, 2 of 3 (66.7%) that lost nests in the first week of July renested, and 0 of 10 that lost nests in the second week of July renested. Clutches of 1-6 eggs have been reported in Ontario, with 4 eggs most frequent. In London, clutches of 2-5 eggs occurred, but 2-egg clutches may have been due to partial loss of the clutch. Mean clutch size was 3.9 eggs 13 May to 2 June, 3.5 eggs 3-22 June, and 3.1 eggs 23 June to 12 July. During the early period, most nests (67.9%) contained 4 eggs, 17.0% had 3 eggs, 13.2% had 5 eggs, and 1.9% had 2 eggs. In the middle period, clutch sizes were 47.3% 3 eggs, 43.6% 4 eggs, 5.5% 5 eggs, and 3.6% 2 eggs. In the last period, 77.8% of clutches had 3 eggs, 11.1% had 2 or 4 eggs, and there were no 5-egg clutches. Clutch sizes decreased by about 1 egg between May and July, but the change was not abrupt because some females had second clutches of the same size as the first. Annual production depends on the success of the first nest because a successful nest may provide sufficient time to raise a second brood, and earlier nests are likely to produce more young than later nests. In Illinois, clutches averaged 3.7 eggs in May and June and 3.1 in July and August. Similar declines in clutch size with season were reported in Michigan and Iowa. Late nests in Iowa were smaller during a drought year than in a year with normal precipitation. In New York, clutch size averaged 3.24 eggs in years with a high density of catbirds compared with 3.60 in a year with low density. Mean clutch

sizes in the east have been reported as 3.2-3.8 eggs. Differences in reported clutch sizes may be due in part to the proportion of early versus late nests in the sample. Western clutches tend to be larger with means of 3.9 in Manitoba and 4.1 in British Columbia (Campbell et al. 1997; Gill 1935; Graber et al. 1970; Gross in Bent 1948; Johnson and Best 1980; Lent 1992; Nickell 1965; Peck and James 1987; R.J. Smith et al. 2020; Vincent and Bombardier in Gauthier and Aubry 1996; Weir 2008).

The age at first breeding is 1 year and the catbird breeds annually thereafter (R.J. Smith et al. 2020). It is typically monogamous, but 2 cases of bigamy have been documented. A male in Iowa defended 2 nests 160 m apart separated by an active territory (Johnson and Best 1980). Another male in Pennsylvania defended 2 nests 69.5 m apart and there did not appear to be any intervening territories. The nests were in an area that appeared to have the highest densities of shrubs, thorny vegetation, and fruiting species within the study area (Hanley et al. 2007; Johnson and Best 1980). The pair bond is usually retained for both broods and replacement clutches within a year. If 1 member of a pair is lost, remating typically occurs. Occasionally birds divorce after the first brood and select different mates. Usually a new mate is chosen each year, but pairs may occasionally remate in subsequent years. In London, both members of 12 of 56 pairs (21.4%) returned and 4 of the returning pairs (33.3%) remated. In each case, the pair had nested successfully the previous year and retained the same territory throughout the year. Remating requires that both birds return at about the same time or the male is likely to mate with another female (Brackbill 1950a; Darley et al. 1971, 1977; Gill 1935; R.J. Smith et al. 2020).

The catbird forages from the ground to treetops. In Georgia and Bermuda, 50% of foraging occurred on the ground, 42% on foliage, 7% on bark, and 1% by flycatching. Foraging techniques included 96% gleaning, 3% hovering, and 1% flycatching. It has been observed flicking leaves from the eavestrough of a house to obtain food and it also turns over leaves on the forest floor to feed. It is an opportunistic feeder that may regularly visit electric lights at dawn to eat attached insects. It foraged at night under a stadium light where one made a 10-m sally to hawk an insect. It may also feed regularly at night on moths under artificial lighting. It has been observed searching marsh vegetation for emerging dragonflies and may feed heavily on moths during migration using a flush-chase technique. The catbird has been known to peck the eggs of other bird species and ate the contents of a Chipping Sparrow egg. In an experiment near Ottawa, catbirds broke eggs throughout their nesting cycle and were more likely to break eggs of other species than their own. They were more likely to peck cowbird eggs than those of conspecifics and pecked eggs rather than young when both were present in a nest. Unpalatable eggs were not pecked. Catbirds appeared to break eggs to eat their contents and to prevent parasitism of their nests (Gross in Bent 1948; Lebbin et al. 2007; Nickell 1965; Rodewald and Kearns 2011; R.J. Smith et al. 2020; Spooner et al. 1996).

Nestlings in first nests are initially fed mostly insects although they may be offered some fruit later, but young in later nests are fed much more fruit. Young in first nests are fed about 95% insects. At 1 nest young were fed June beetle adults and larvae, cutworms, flies, crickets, grasshoppers, geometer and sphinx moth caterpillars, and small amounts of cherries and blackberries. At another nest, food provided to young included 16.6% flies; 6.7% grasshoppers; 23.8% adult and larval moths and beetles (weevils and June, click, and tiger beetles); and 1.5% fruit (raspberries and gooseberries). At 1 nest, young were fed small geometer caterpillars and flies within 1 hour of hatching, and one

was fed a mayfly. Almost half the food provided to young consisted of flies, grasshoppers, beetles, and moths. Young may be fed large adult moths such as cecropia, prometheus, and sphinx moths. A small frog was fed to young. Fruit consumed by young includes those of dewberry, red and black raspberries, mulberries, black cherry, chokecherry, and tartarian honeysuckle. Where feeders are provided, adults may feed nestlings raisins and small suet chunks (Gabrielson 1913; Graber et al. 1970; Nickell 1965; R.J. Smith et al. 2020).

In spring, the diet of the catbird is predominantly insects and spiders, with increasing amounts of fruit eaten as the season progresses. The percentage of fruit in the diet is 20% in spring, 60% in summer, 81% in autumn, and 76% in winter. In May, Illinois birds consumed animal matter almost exclusively, predominantly ants, caterpillars, crane flies, ground beetles, and spiders. Beginning in June, fruit became increasingly important, and it fed on newly emerged dragonflies which appeared to be an important food. Other insects it eats regularly included beetles, grasshoppers, midges, moths, and cicadas. An analysis of 645 stomachs found that 44% of the diet consisted of animal matter. About 75% of this was ants, beetles, grasshoppers, and caterpillars. Of the vegetation consumed, about a third was cultivated strawberries, raspberries, and blackberries. Wild fruits included those of cherries, dogwoods, black gum, elderberries, greenbrier, spicebush, black alder, and sumac. Another analysis of 192 stomachs found that the diet was comprised of 55% vegetation: 18% cultivated fruits, 35% wild fruits, and 2% miscellaneous vegetation. Of the animal food, beetles comprised 24% of the entire diet, ants were 10%, caterpillars and miscellaneous animals were each 5%, grasshoppers were 4%, millipedes and spiders combined were 4%, and bugs were 2%. In May, about 66% of the diet consisted of ants, millipedes, June and ground beetles, and caterpillars. At the end of June, grasshoppers and crickets were important at 10% of the diet, but were rarely eaten earlier; consumption of them dwindled to almost nothing after June. By August, the amount of insects in the diet was only 1%, but an increase occurred again in September. Miscellaneous animal foods that the catbird has eaten include slugs, honey bees, aphids, gypsy moth caterpillars, skin beetles, trout fry from a hatchery, carpenter ants, ash borers, leaf beetles, leafhoppers, treehoppers, jumping plant lice, and sawflies. Several anthropogenic foods may be consumed such as suet, raisins, apple slices, walnut kernels, cheese, bread, milk, corn flakes, puffed wheat soaked in milk, mushrooms, garbage, boiled potato, fried fish, beef stew and soup, and peanuts. Other fruits it consumes are those of holly, honeysuckle, autumn olive, nightshade, guelder-rose, nannyberry, Virginia creeper, common elderberry, southern arrowwood, sweet gale, pokeweed, sassafras, poison ivy, buckthorn, mountain-ash, bittersweet, mulberries, grapes, and hawthorns. In Michigan, spicebush berries were the preferred fruit of autumn migrants. In southern Manitoba, it eats willow flowers early in the spring and rarely grain (Beal 1897a; Graber et al. 1970; Gross in Bent 1948; Holt 1918; Oguchi et al. 2018; R.J. Smith et al. 2020; Whittle 1923). In Illinois, all birds ate fruit. In the first year, the fruit diet consisted of 82% elderberries and 18% spicebush; in the second year it was 74% grapes, 24% poison ivy, and 2% Virginia creeper; and in the third year it was 100% grapes. Ninety-three percent of frugivory occurred in forest gaps and it fed more on solitary fruit-bearing shrubs (62%) than clumps of shrubs. It concentrated on 1 or 2 fruit species each year, and the species selected were not usually the same in different years (Malmborg and Willson 1988). Stutchbury et al. (2005a) studied frugivory on red elderberry by the catbird and found that it foraged at only 5.9%

of sites and on 5.7% of visits. They concluded that the low level of frugivory was probably due to its low abundance in the forest.

Cowbird parasitism is seldom documented because the catbird is an ejector of parasitic eggs. Egg ejection is often almost immediate, but some eggs are tolerated for 2-3 days before they are removed. Birds in the west appear to be more tolerant of parasitism; a lower percentage of eggs are ejected and the reported incidence of parasitism is higher. Rarely, the catbird may bury a cowbird egg in the nest lining. Reported parasitism rates are 20 of 1,241 Ontario nests (1.6%), only 1 record in Illinois, 8 of more than 3,000 Michigan nests (0.3%), 1 in 60 (1.7%) in another Michigan study, 5 of 183 British Columbia nests (2.7%), 4 of 35 nests (11.4%) in an Illinois arboretum, and 5.2% of 58 Kansas nests. There are fewer than 10 documented records of catbirds successfully fledging a cowbird, including 1 nest in Windsor, so parasitism of catbird nests is not very profitable for cowbirds. Cowbirds may remove a catbird egg prior to laying their own egg, so this may affect productivity of the catbird. In Ohio, it was estimated that 1.2% of catbird eggs were lost from the population as a result of parasitism (Campbell et al. 1997; Graber et al. 1970; Gross in Bent 1948; Johnson and Best 1980; Lowther 1997; McGeen and McGeen 1962; Nickell 1958; Peck and James 1998a; Rasmussen et al. 2009; Rivers et al. 2010; Rothstein 1974, 1975; R.J. Smith et al. 2020; Woodward 1976). In London, 7 of 16 nests (44%) were parasitized including 3 of 8 first nests and 4 of 8 replacement clutches. Three of the 7 parasitized nests had lost a catbird egg. This is the highest rate of parasitism reported for the catbird, but is probably more indicative of the actual rate. Despite being the highest rate of parasitism documented for the species, catbird nests were parasitized significantly less than other species in the study area. The nest-guarding behaviour of males may reduce parasitism (Scott 1977).

Certain human habitat alterations have been beneficial for the catbird but others have been detrimental. Initial forest clearing created much new habitat. Clear-cutting and other forest management may be beneficial by converting unsuitable forested habitat into early successional areas. Holmes et al. (2004) did not document the catbird in woodlots with no recent history of timber harvesting in the Carolinian Forest Region of Ontario. It was present in woodlots where diameter-limit cuts and selective thinning had occurred. In 1 of the 2 years of study, its abundance was negatively correlated with the amount of residual basal area. In New York, it colonized clear-cuts within 2 years of harvest and increased annually until the sixth year after cutting, when the study was terminated. Urbanization may have been beneficial earlier when lots were much larger and trees and shrubs were retained to a large degree. Modern urbanization results in habitat loss because lots are very small with minimal woody cover. There is also a tendency to clean up urban areas by removing shrubs and mowing. Typically no forest management is undertaken in urban woodlots so that these eventually become mature with limited shrub and sapling growth and become unsuitable for catbirds. Intensification of agriculture has resulted in the loss of many hedgerows. Road widening and improvements also frequently result in the loss of shrubby vegetation on roadsides. Rights-of-way cut through forests for electric transmission lines and pipelines and the regular maintenance to halt succession is beneficial. Considerable habitat has been lost due to maturation of abandoned agricultural fields and planting of coniferous plantations. Habitat for the catbird probably started to decline in Ontario in the mid-1950s due to agricultural intensification, and losses have continued more rapidly due to additional agricultural intensification,

urbanization, road improvements, maturation of old fields, and establishment of plantations (Corbat et al. 1998; Keller et al. 2003; Nickell 1965; R.J. Smith et al. 2020; Vincent and Bombardier in Gauthier and Aubry 1996).

In North Carolina, the catbird increased significantly as the number of houses and buildings within 200 m of the centre of a woodlot increased. It was 1 of only 5 species that increased with housing density (Lumpkin and Pearson 2013). In Washington, DC, 61% of fledglings died before reaching independence. Predation accounted for 79% of mortality. Lower survival at 2 of the 3 sites was probably due to higher densities of gray squirrels and domestic cats, and potentially rats. Forty-seven percent of known predation events were attributable to cats. One site appeared to provide good nesting habitat whereas the other 2 sites were sinks. Urban habitats present significant variation in habitat suitability for breeding catbirds (Balogh et al. 2011).

In urban woodlots in Chicago, abundance of the catbird was positively correlated with abundance of exotic honeysuckle species. It appeared to be attracted by the arching structure and tall cover provided by honeysuckles (Schneider and Miller 2014).

In Pennsylvania and New Jersey over a 15-year period, hemlock declined from 56% of the total basal area to 46% due to the hemlock woolly adelgid, resulting in an increased understorey of deciduous shrubs. The catbird increased, probably in response to the openings in the canopy and increased shrub coverage (Toenies et al. 2018).

Farwell et al. (2019) studied the effect of shale gas infrastructure (well pads, access roads, and pipelines) on the Gray Catbird in contiguous forest in West Virginia. It demonstrated no significant response to any of these features.

The catbird may be affected by environmental contaminants. In Illinois, it disappeared from an area treated with heptachlor and the population appeared to be depressed the following year, possibly due to a shortage of food. It has been suggested that pesticides used in orchards and gardens may have contributed to its decline (Graber et al. 1970; Vincent and Bombardier in Gauthier and Aubry 1996).

Cold and wet weather in spring may delay the onset of nesting (Darley et al. 1971). This may reduce the average clutch size for the season and fewer birds may have time to raise a second brood. High winds cause a significant proportion of nest failures. Nests are not attached to stems or limbs so they are vulnerable to being dislodged by wind (MacKenzie et al. 1982; R.J. Smith et al. 2020).

The catbird is vulnerable to being struck by vehicles because it typically flies low and often nests on roadsides (Gross in Bent 1948; R.J. Smith et al. 2020).

Price (2004) predicted that the breeding range of the Gray Catbird might contract in southern Ontario if the average summer temperature increased by 2°C.

Status

The catbird undoubtedly increased significantly with forest clearing associated with European settlement. Prior to this, it was probably confined to shrub growth at forest edges along streams and marshes, clumps of shrubs in open marshlands, and the understorey of more open woodlands (Nickell 1965). McIlwraith (1894) considered it a common summer resident and Baillie and

Harrington (1937) concluded that it was a common summer resident north to Sudbury and southern Kenora District. In Elgin County, it was a very common breeder in 1891 and 1954 and common in 2000 (Lancaster et al. 2004). During the first atlas, the range of the catbird was confirmed to cover most of the Great Lakes–St. Lawrence and Carolinian forest regions and there were scattered records from the Boreal Forest Region and southern Hudson Bay Lowland (Curry in Cadman et al. 2007; Wilson and McRae 1993). Greatest abundance occurred south of the Canadian Shield. Curry (in Cadman et al. 1987) concluded that numerous squares containing abandoned farmland near the southern edge of the Shield probably supported in excess of 1,000 pairs. James (1991) considered the catbird a common summer resident in the south, locally rare north to Kenora and Timmins, and a vagrant to southern James Bay and Big Trout Lake.

The second atlas demonstrated that there had been no change in the breeding distribution of the catbird except for a range extension in a band north of Lake Superior and Sudbury. Once again, breeding evidence was obtained in the Moosonee area. Its probability of observation did not change province-wide between atlases, but a significant decrease occurred in the Great Lakes–St. Lawrence Forest Region. The greatest decrease occurred in the Shield and may have been due to succession of shrubby areas into forest. It was most abundant south of the Shield and occurred in almost every square. Two areas of high density occurred in a wide band north of Lake Erie from Rondeau to Niagara Region (much of the Carolinian Forest Region), and in southeastern Ontario from the Peterborough area along Lake Ontario and the St. Lawrence River to the Brockville area (Curry in Cadman et al. 2007).

Breeding Bird Survey data for 1970-2021 indicate that the catbird decreased at annual rates of 0.000539% in Canada and 0.588% in Ontario. For 2009-21, it increased at annual rates of 1.66% in Canada and 0.395% in Ontario. All results were highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

The young are dependent upon the adults for 12-14 days after fledging. In Washington, DC, fledglings were attended for an average of 18.9 days. Adults attended female fledglings for a significantly shorter period (18.3 days) than the 21.0 days spent attending male fledglings (R.J. Smith et al. 2020).

Fledglings and postbreeding adults leave the territory a few hours to 5-8 days after the young leave the nest. They often congregate in shrubby riparian areas or other thickets near water (Akresh et al. 2009; Nickell 1965; R.J. Smith et al. 2020). During the postbreeding period, the capture rate of the Gray Catbird in West Virginia clear-cuts was negatively correlated with the amount of ripe fruit. Important habitat parameters were basal area, stem density, and vertical complexity (McDermott and Wood 2010). In Minnesota, Streby et al. (2011b) captured only 1 catbird in regenerating clear-cuts during the breeding season, but caught 36 adults and 36 fledglings during the postbreeding period. In Ohio, Vitz and Rodewald (2006) captured 37 adults and 186 juveniles in regenerating clear-cuts during the postfledging period. In Pennsylvania during the postfledging period, Stoleson (2013) captured 38 adults and 67 juveniles in clear-cuts and 1 adult and 0 juvenile in mature forest with a dense understory. In Missouri, Porneluzi et al. (2014) netted birds during the postfledging period in an oak-pine-hickory forest 2-15 years after it was clear-cut. Only a single catbird was captured during this period.

MIGRATION

Migration appears to be strictly nocturnal. Adult males arrive first in spring followed shortly by adult females, and older birds typically pair with each other. Yearling males are the next to arrive and yearling females are the last arrivals. In Pennsylvania, males did not arrive before females but adults arrived before yearlings. In southern Ontario, the catbird arrives in late April or early May with peak numbers occurring in mid-May. In the southern Shield, average arrival is mid-May but it does not occur until late May at Moosonee. Autumn migration is well underway in September, with most birds leaving the province by late September or early October. Stragglers may persist until mid- to late November (Black and Roy 2010; Curry 2006; Darley et al. 1971, 1977; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008).

In Pennsylvania over an 18-year period, there was no change in spring temperature, but the amount of rain received in May increased. Spring arrival of the catbird advanced by 6.6 days per decade (R.J. Smith et al. 2023).

Similar habitat is used during migration as during the breeding season, except that greater use may be made of forested habitat (Campbell et al. 1997; R.J. Smith et al. 2020). During spring migration in Pennsylvania, Smith and Hatch (2008) netted significantly more catbirds in shrub than forested habitat. Also in Pennsylvania, it was associated with more fragmented landscapes during both spring and autumn migration. Its abundance was negatively correlated with forest patch size during spring migration (Keller and Yahner 2007). During spring migration in Wisconsin and Minnesota, there was no difference in its abundance in floodplain and upland forests (Kirsch et al. 2013). During autumn migration in New York, detections of the Gray Catbird increased with increasing numbers of species of fruiting shrubs (Mudrzynski and Norment 2013). Oguchi et al. (2018) studied its usage of exotic and native shrublands in Michigan during autumn migration. Exotic shrublands were dominated by autumn olive, nonnative honeysuckles, and multiflora rose; native shrublands were dominated by gray dogwood, winterberry holly, and spicebush. Capture rates of catbirds were significantly higher in native shrublands and were 3.74 and 4.32 times higher in 2 years. Native shrublands were actively selected as habitat and were used 32% more frequently than expected. The minimum stay duration averaged 18.3 days (range 1.0-50.0 days). Time spent by habitat included 2.5 days in exotic shrublands, 4.7 days in native shrublands, 0.6 day in open habitat, 0 day in marshland, and 1.1 day in woodland. It consumed spicebush berries significantly more in native than in exotic shrublands; spicebush was highly preferred in the diet. The 50% kernel home range of 9 individuals averaged 6.5 ha (range 1.1-15.8 ha); the 99% kernel range averaged 39.3 ha (range 8.6-89.7 ha).

In Florida, 21 of 1,779 catbirds (1.2%) banded during migration were site faithful. A higher percentage (23.3%) of birds was faithful to their wintering areas in subsequent years (Somershoe et al. 2009).

One late autumn migrant in Algonquin Park fed on suet, bacon grease, and cereal. Natural foods consumed in autumn included fruits of winterberry holly and wild raisin (Tozer 2012). During autumn migration in New York, 20% of fecal samples contained Bella honeysuckle fruits, 20% contained fruits of red-osier and gray dogwood, and 55% contained common buckthorn fruits (Mudrzynski and Norment 2013).

In Michigan, Oguchi et al. (2017) studied the effects of stopping over in autumn in exotic shrublands compared with native shrublands. Fruits of nonnative shrubs such as autumn olive, common buckthorn, and honeysuckle have higher sugar and water content but lower fat and energy content compared with native species such as spicebush, gray dogwood, and Virginia creeper. Catbirds stopping over in exotic shrublands did not maintain their mass in 1 of 2 years. They had poorer immune status and lower plasma total carotenoids (which are immunostimulatory antioxidants) in that year compared with those stopping over in native shrublands. Antioxidant capacity was lower in both years for birds foraging in nonnative shrubs. Habitat quality may affect the health status of migrating catbirds.

During migration, the catbird is commonly killed by striking tall structures such as electric transmission towers, television towers, office buildings, and lighthouses. In Manhattan, it was among the top 20 species involved with collisions with buildings (Graber et al. 1970; Gross in Bent 1948; Leighton et al. 2002; R.J. Smith et al. 2020). In the United States, the catbird was more vulnerable to striking buildings than average. For all building types combined, it was 12.8 times more likely to strike a building than the average for birds. It was 20.7 times more likely than average to strike a 1-3 storey residence, 23.2 times more likely than average to strike a low-rise, and 23.9 times more likely than average to strike a high-rise (Loss et al. 2014).

In Pennsylvania, an outbreak of the viburnum leaf beetle resulted in almost complete mortality of the southern arrowwood, which was formerly the third most abundant shrub. Prior to the infestation, spring migrating catbirds gained significant mass after sunrise, but no weight gains occurred after the infestation (Smith and Hatch 2017).

The catbird is common during migration in Ontario. Daily numbers tend to be lower in autumn, probably due to the more protracted migration period (James 1991).

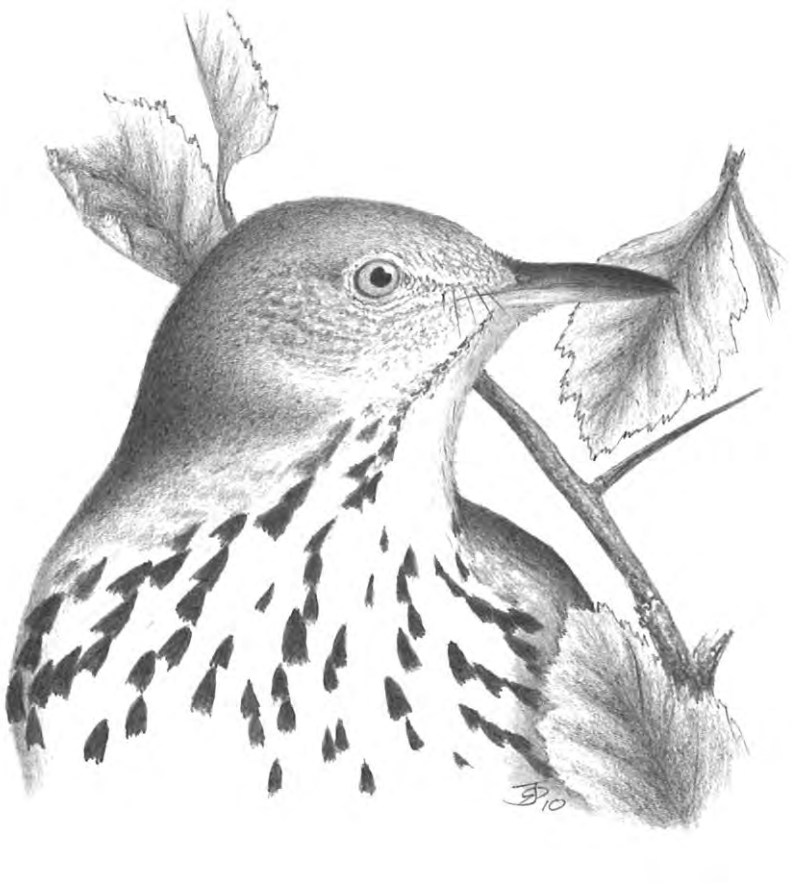
WINTER

The catbird is rare in winter north to the Toronto area, although there are a few winter records from the Kingston and Presqu'ile areas. One spent the entire winter south of Cambridge only to expire just prior to the normal spring migration period (Neil Sandilands, personal communication). Prior to the 1990s, catbirds were seen in only 33% of winters in the Hamilton area, but now one and sometimes several are seen each winter. This was attributed to a combination of milder winters and more observers. In Niagara Region, there are 2 December records and 5 January records and it has been seen on 19 Christmas Bird Counts (CBC) collectively from St. Catharines and Niagara Falls (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008).

CBC data indicate that the catbird increased in Ontario 2.73% annually 1970-2021 and 5.96% 2009-21 (National Audubon Society 2022).

Brown Thrasher

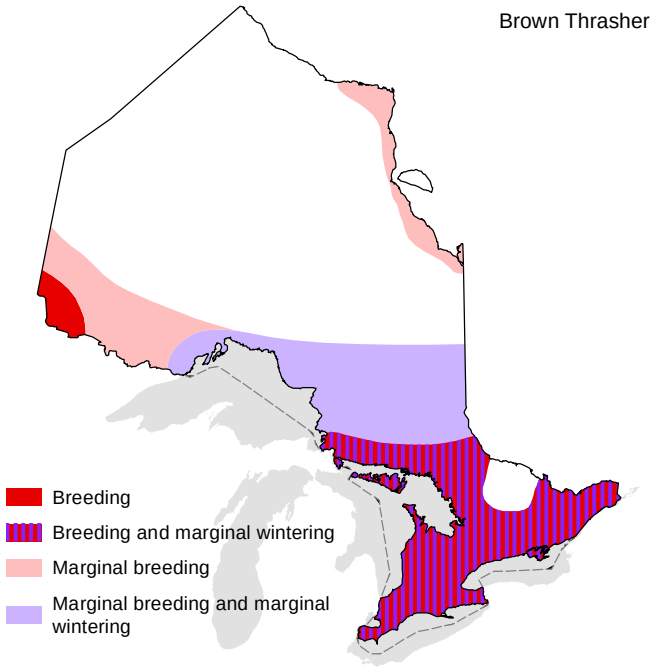
Toxostoma rufum



BREEDING SEASON

Habitat Requirements

In Ontario, the Brown Thrasher breeds in a variety of open and early successional habitats. Most nests (54.0%) were in open rural habitats, including hawthorn meadows (25.9% of nests), in overgrown farm fields and pastures (24.5%), in orchards and vineyards (1.6%), in willow swales (0.8%), in gravel pits (0.8%), and in river floodplains (0.4%). A total of 18.2% of nests were in woodlands, including 6.7% in mixed woods, 4.7% in deciduous woods, 3.4% in coniferous woods, and 3.4% in unspecified woods. An additional 27.7% of nests were in miscellaneous habitats including along fencerows and road and railway rights-of-way (16.6%); in residential gardens (6.3%); in other manicured areas such as cemeteries, parkway medians, golf courses, fairgrounds, and parks (2.0%); on sand dunes (2.0%); at edges of marshes (0.4%); and on limestone savannahs (0.4%). Woodlands selected for nesting were open in character. Many woodland nests were at edges, clearings, and hydro cuts, or near shorelines. Dry areas were much preferred to wet sites (Peck and James 1987).



In jack pine stands near Gogama, where the Brown Thrasher is near the northern extent of its range, James and Peck (1995a) detected it at 1 site where it was associated with open shrubby areas in pine and mixed forests. Near Parry Sound, it was absent in pure jack pine stands and occurred in low densities in open, mixed pine-hardwood stands. All had 25% or less canopy cover and some deciduous cover with openings associated with bedrock outcrops or logging (James 1979a). In Algonquin Park, it was rare in open woods and thickets (MacLulich 1938). Mills (1981) concluded that it preferred drier brushy areas in Muskoka and Parry Sound districts; McIlwraith (1894) reported the same from the Hamilton area. In Durham Region, it nested in a young pine plantation that was still dominated by shrub willows, in an old field dominated by apple trees and hawthorns with an understorey of grass, and in a sugar maple forest sloping down to a white cedar–balsam fir–spruce swamp. This stand was open with a dense undergrowth of raspberries and bittersweet nightshade (Speirs and Orenstein 1975). In eastern Ontario, nesting habitat includes early successional areas such as overgrown fields, deciduous thickets, woodland edges, and young second growth. It avoids nesting close to human habitation but a few pairs nested within a Kingston cemetery and on conservation lands within the city (LaForest 1993; Weir 2008). In Ontario, it has nested in a tamarack swamp (Rodrique and Tardif in Gauthier and Aubry 1996).

In southern Ontario, the Brown Thrasher was more abundant on conventional than organic farms, but not significantly. The only statistically significant relationship was with the presence of hedgerows. It also tended to be associated with pasture, riparian and upland woods, and habitat heterogeneity. It was negatively associated with large isolated trees, field size, use of herbicides, grassy strips between fields that often contained fences, and road, railway, and hydro rights-of-way (Kirk et al. 2011).

In the east, the Brown Thrasher inhabits thickets, hedgerows, small openings in forest clearings, and forest edge. In the Midwest, it commonly breeds in fencerows, shelterbelts, and woody draws. In the east, it favours underbrush and hedgerows in dry, well-drained habitat. It has a marked preference for young second growth with a well-developed shrub layer. It also occurs in agricultural habitat such as old fields, berry plantations, and orchards; in woodland edges; in suburban and rural habitat; and occasionally near human habitation. It is scarce in suburban and urban habitat where it may occur in cemeteries, parklands with shrubby or young second growth, and on university campuses. In many areas, it avoids suburban and urban areas and is more likely to occur in these

habitats in the Midwest. In Illinois, it showed a marked preference for hedgerows and other roadside or field-edge vegetation, thickets, and shrub-grown areas. It nested in woodlands, but only at edges and not in the interior. Edges of large forest blocks were seldom used, with smaller woodlots preferred. It was as closely tied to edges such as hedgerows as any Illinois bird species, and the habitats that it favoured were those that were least available. In 2000 in Illinois, it was most abundant in shrub and savannah habitats, occurring in lower densities in upland forest, grazed grass, low-density developed, and developed open space habitats. It was rarely documented in corn and idle grass habitats. The forests it used were small and linear. The most apparent habitat requirement is shrubby cover where thorny or dense plants are particularly favoured for nesting. In addition to these key nesting habitats, the Brown Thrasher may nest in gardens, orchards, swamps, moderately grazed pastures, open woods, pine and oak barrens, shelterbelts and wooded draws, riparian woodlands, tallgrass prairies with isolated patches of trees, small openings in forest cover, blueberry plantations, oak savannahs, and young conifer plantations. In Wisconsin, it is a characteristic species of pine and oak barrens, nesting there equally or more commonly than in any other native community. The thrasher may nest in a variety of forest types including northern hardwoods, deciduous swamps and lowland stands, aspen-birch, pines, mixed woods, and green ash stands. In Quebec, it is common in open deciduous woods but rare in mixed forests. It occurs in low density in these stands where it is associated with seedling-sapling stages, young burns or cuts, or older stands that have open canopies with considerable woody undergrowth (Back 1979; Beal et al. 1916; Bent 1948; Campbell et al. 1997; Capen 1979; Cavitt and Haas 2020; Erwin 1935; Gentry et al. 2006; Graber and Graber 1963; Graber et al. 1970; Haas 1998; Heagy and Best 1983; Leighton et al. 2002; Mossman and Hoffman 1989; Mossman et al. 1991; Murphy and Fleischer 1986; Noon et al. 1979; Raynor 1976; Rodique and Tardif in Gauthier and Aubry 1996; Rumble and Gobeille 1998; Samson 1979; Taylor and Taylor 1979; Temple et al. 1979; Vickery et al. 1994; Walk et al. 2011).

In North Carolina, the Brown Thrasher was negatively correlated with tree canopy coverage at the 200-m scale. As canopy cover increases, shrub cover decreases. It was not correlated with the amount of exurban development within the landscape (Gilbert and Ferguson 2019). In North Dakota, it preferred areas with 9-40% tree cover (Cunningham and Johnson 2019).

Due to its predilection for shrubby habitat, the Brown Thrasher is usually associated with early successional habitats. Speirs and Orenstein (1975) considered it an early successional species in Ontario. In New York, it declined over a 35-year period on a successional plot that transitioned from an open agricultural field to second-growth forest. It was absent throughout the study in a forested plot but numbers remained constant in a Christmas tree plantation that was maintained in an early succession stage (Brooks and Bonter 2010). In New Jersey, it was present in fields that were 20 years old, but absent in 10- and 40-year-old fields (Suthers 1988). Temple et al. (1979) stated that it was associated with mid-seral mixed woods in the northeast, but reported it in only 1 of 16 woodlands. It occurred in higher densities in late than early seral stages of green ash woodlands in South Dakota. Late seral stages contained high densities of chokecherries that may have provided food and a suitable nesting substrate (Rumble and Gobeille 1998).

Cade (1986) prepared a habitat suitability index (HSI) model for the Brown Thrasher. It occupied a wide range of cover types but densities were highest in dense woody vegetation associated with

shrub thickets, hedgerows, forest edges, or mid-successional forests. The most consistent habitat characteristic around song perches in Missouri was a litter depth of 1-2 cm. Habitat characteristics associated with forest edges, overgrown grasslands, or old fields that were used were 350-2,450 stems smaller than 2.5 cm per ha, 24-1,000 stems larger than 2.5 cm per ha, 55-95% litter coverage, and a canopy height of 4-18 m. In Louisiana bottomland forests, it occurred mainly at heights of 0.6-7.6 m, but was commonly observed at all other heights. Early successional woody fields in Arkansas supported highest densities where there was 25% tree cover, 519 trees larger than 7.6 cm diameter at breast height (DBH) per ha, and 11,243 understorey stems 7.6 cm DBH or smaller and 1.4 m or more tall per ha. In North Dakota, territories had fewer trees (245 compared with 445 per ha) and lower percent canopy cover (19.5% compared with 32.7%) than unoccupied areas. At 115 Brown Thrasher locations in Iowa, the density of stems 5 cm DBH or larger averaged 391 per ha (range 14-2,700) and the density of stems smaller than 5 cm DBH averaged 1,370 per ha (range 16-20,400). Presence of deep, non-acidic humus on the ground is associated with an abundance of invertebrates. This is best provided by early successional deciduous trees and shrubs with low carbon to nitrogen ratios in their leaves. The model assumed that shrub and forest stands with 10,000-30,000 woody stems 1.0 m or taller per ha, 10-30% canopy cover by trees 5 m or taller, and 80% or more litter cover at least 1 cm deep provided optimal habitat. Suitability decreases when the woody stem density is less than 10,000 or greater than 30,000 stems per ha, when the tree canopy cover is less than 10% or greater than 30%, or when the litter coverage is less than 80%.

Thomas et al. (1977) summarized habitat usage by the Brown Thrasher in Massachusetts suburban areas. They considered this habitat marginal for it. Its abundance was correlated with deciduous tree volume at heights of 1.8-3.0 m and 3.3-4.6 m, and deciduous shrub volume at heights 4.9-6.1 m, but none of these associations approached significance. The most important layer was 0-6.1 m. It was negatively correlated with deciduous tree volume at heights 6.4-7.6 m indicating that canopies taller than 6.1 m decreased habitat suitability.

The Brown Thrasher does not appear to be an area-sensitive species and frequently nests in narrow, linear habitats such as hedgerows. In Mississippi, it nested in 10-m wide borders around fields but was absent when borders were 30 m or more wide or lacking (Conover et al. 2009). The minimum mean width of wooded riparian habitat that it used in Iowa was 40 m (Stauffer and Best 1980). In South Dakota, the area of the smallest shelterbelt that was occupied was 0.3 ha (Cavitt and Haas 2020). In New Jersey, it was absent in woodlots smaller than 0.8 ha and rare in those smaller than 4 ha (Cavitt and Haas 2020). In Maine, it was negatively associated with grassland patch size but positively associated with the presence of trees. Larger areas were more intensively managed for blueberry production; the relative proportion of shrubby habitat declined with increasing patch size (Vickery et al. 1994). There do not appear to have been any studies done on the response of Brown Thrashers to different sizes of shrubby fields.

Ontario nests were both elevated (75.2% of nests) and on the ground. Most elevated nests were in shrubs, trees, and vines, with a few on fallen trees, branches, and brush. One nest was on a fence among vines and another was in a limestone crevice 1.7 m from the ground. Deciduous trees and shrubs (27 species, 89.3% of nests) were selected for nest sites more frequently than coniferous trees and shrubs (5 species, 11.7% of nests). Species chosen most frequently for nesting were hawthorns

(70.1% of nests), grape and other vines (9.6%), white cedar (5.0%), apple (4.3%), rose (4.0%), lilac (3.7%), and pines (3.3%). Nests in trees and shrubs were mostly in crotches but some were on horizontal branches. They were randomly situated from near the trunk to away from it and at various levels. A few were supported between vertical main stems and 1 tree nest was under a fallen piece of bark. Elevated nests were 0.2-6.7 m from the ground, with most 0.9-1.5 m up. Ground nests were under or near the bases of shrubs, trees, and vines (63.5% of nests); under branches, brush, and fallen trees (10.4%); under plants, dead weeds, and long grass (12.2%); under ends of logs (7.0%); and under boards and picnic tables (2.6%). Single nests were found under a rail fence, inside a wire guard on a young apple tree, between 2 blades of a disc-harrow, and beside a rock. Some ground nests were in depressions; some were concealed in grasses but a few were exposed. One nest was built on top of what appeared to be an old robin's nest (Peck and James 1987). Sheppard et al. (1936) observed that clumps of hawthorns appeared to be favourite nesting sites in Niagara Region.

In eastern North America, 25-50% of nests are on the ground. Ground-nesting is rare further west, probably due to the presence of several species of large snakes that are potential nest predators. Ground nests are usually near shrubby cover, often at the base of a shrub, or among tufts of grass. In prairie habitat, many ground nests are under fences. Dense shrubs are preferred for above-ground nesting, particularly thorny species. The Brown Thrasher has been reported nesting in hawthorn, gooseberry, greenbrier, rose, honey locust, lilac, grapevine tangles, forsythia, honeysuckle, red cedar, sumac, American plum, rough-leaved dogwood, small elms, euonymus, and privet. In Kentucky, 50% of nests were in small sumacs entangled with honeysuckle vines and 21% were in rose bushes. In Kansas, 27% of nests were in American plum, 27% in rough-leaved dogwood, 20% in small elms, 9% in honey locust, 5% in winter honeysuckle, and 3% in gooseberry. In Iowa, 77% of nests were in shrubs, 3% in deciduous saplings, 16% in deciduous trees, and 3% in coniferous trees. Most nests are in thickets or clearings but they may rarely be near buildings. Nests are occasionally placed in brush piles. One Tennessee nest was in a crack at the top of a post at the edge of a thicket. A bird house with the roof raised was used for nesting in 2 consecutive years. Nests tend to be near the ground, with an overall height range of 0-10.5 m, mostly within 2 m of the ground. Nests may be placed higher up as the season progresses. Thrashers frequently reuse old nests from previous years but rarely reuse nests that were used in the same season (Bent 1948; Cavitt and Haas 2020; Cavitt et al. 1999; Erwin 1935; Graber et al. 1970; Potter 1988; Rodrique and Tardif in Gauthier and Aubry 1996; Snow 1994; Stauffer and Best 1980; Tyler 1994).

Limited information is available on territory size. In Illinois forest-edge habitat, territories averaged 0.6, 1.1, and 1.1 ha over 3 years. Territories were larger when the population was low and smaller when the population was high. In Kentucky, territories were 0.5 ha to less than 1.0 ha. Urban-nesting thrashers in Tennessee tended to adopt buildings, driveways, sidewalks, and hedges as territorial boundaries. Once boundaries were established, the activities of a pair were almost entirely confined to the territory. The Brown Thrasher may compete with the Gray Catbird and has been documented ejecting its eggs and usurping the nest (Bent 1948; Cavitt and Haas 2020; Erwin 1935; Graber et al. 1970).

Limited information is available on natal philopatry and adult site fidelity. Graber et al. (1970) noted that at least some juveniles and adults returned in Illinois, but had no quantitative data. South

Carolina thrashers tended to build repeatedly in the same vine, shrub, or sapling, either for successive nests in a single season or for single nests in successive seasons. The birds were not banded, so it was unknown if the same individuals were involved (Potter 1988). In North Dakota, 8 of 392 young (2%) returned to nest, but no returning birds nested in their natal shelterbelt. The average natal dispersal distance to the first breeding site was 4.9 km (range 3.8-8.9 km; Haas 1995, 1998).

In North Dakota, return rates of adults were related to nesting success the previous year. For successful birds, 36% of males and 24% of females returned for an overall return rate of 30%. For birds whose nests failed naturally the previous year, return rates were 17% for males, 9% for females, and 13% overall. Return rates for birds whose nests had been experimentally failed were 12% for males, females, and overall. The return rate of birds that nested successfully was significantly greater than for those whose nests had failed when results for the sexes were combined. The return rates for females did not vary significantly for successful and unsuccessful birds. Of successful birds returning between years, 3 moved 50 m, 1 moved 150 m, 1 moved 500 m, and 1 moved more than 750 m; for unsuccessful birds, 7 moved 50 m, 1 moved 150 m, 1 moved 550 m, 2 moved 650 m, and 3 moved more than 750 m. Differences between nesting outcome and dispersal distance were not significant (Haas 1998). Among years, 66% of males and 71% of females remained in the same shelterbelt in North Dakota; 97% of males and 95% of females were at the same site, 3% of males and 5% of females moved to a wooded draw, and no birds moved to another site. Distance moved between nests in subsequent years averaged 259 m (range 0-1,200 m; Haas 1995). Of birds that renested after either a successful or unsuccessful nest, 81% did so in the same shelterbelt, 98% remained in the same site, and only 1 left its original site to breed in a wooded draw. Thrashers moved a mean distance of 86 m within a breeding season (range 7-464 m; Haas 1995, 1998).

Limiting Factors

Eggs have been found in Ontario nests from the last week of April until the third week of July, with most reported from the last week of May until mid-June (Peck and James 1987). A nest in York Region contained 2 young on 7 August suggesting a later egg date (Peck and James 1998a). In Algonquin Park, eggs are present from late May to mid-June; nestlings are present from early June to mid-July (Tozer 2012).

Nest building takes 4-14 days, but averages 3.8-4.2 days with a typical range of 2-8 days; most Tennessee nests took 3-4 days to build. Nests built early in the season take longer to construct. In Kansas 3-4% of nests were old. Nest reuse saved 3-8 days in nest construction time; clutches in old nests were initiated an average of 17.4 days earlier than those in new nests. Eggs are laid an average of 2 days (range 1-5 days) after nest completion. The female may start building the nest for the second brood 2-5 days after the first brood fledges. One egg is laid a day and incubation begins with the laying of the last egg or possibly earlier because asynchronous hatching may occur. The incubation period is 10-14 days with averages of 11.5 days in Kentucky, 12.5-13 days in Illinois, and 13.6 days in Kansas. Twenty-two Ontario clutches took 10-14 days to hatch, with 19 hatching in 11-13 days. Eggs in first clutches tend to hatch synchronously, but late-season nests usually hatch asynchronously over more than a day. Young fledge when they are 9-14 days old, but most leave after 10-11 days (average 10.5 days in Kentucky and Kansas). Young may be fully feathered and able

to leave the nest at age 9 days, an adaptation that may help reduce rates of nest predation (Bent 1948; Cavitt and Haas 2020; Cavitt et al. 1999; Erwin 1935; Gabrielson 1912; Graber et al. 1970; Heagy and Best 1983; Murphy and Fleischer 1986; Peck and James 1998a).

The Brown Thrasher may raise 1 or 2 broods annually. Double broods have been confirmed in Ontario, but there is no evidence of double brooding in Quebec. The egg-laying curve for Illinois suggests that most birds raise a single brood. In Kansas, birds at 1 study area raised 2 broods; those at another site were single brooded. In North Dakota, 2 broods were raised only occasionally. Renesting typically occurs if a clutch is lost. Second clutches may be laid in either the same or a new nest, but replacement clutches are usually in the same nest. Clutches of 2-7 eggs have been reported in Ontario, with most containing 4 eggs. Only 1 clutch each of 6 and 7 eggs was reported; it is possible that more than 1 female contributed to these nests. Elsewhere, clutches of 2-7 eggs have been reported. Nearly all clutches contain 3-5 eggs and mostly 4. Two-egg clutches are rare and may represent nests where some egg loss has occurred. One Kentucky clutch of 6 eggs and 1 Illinois clutch with 7 eggs were known to have been laid by 2 females. Clutches of 5 eggs are more common during the peak laying period or early in the season, and at more northerly latitudes. Two Kansas studies reported slightly larger clutches in late May than in early or late-season nests; another study found no seasonal variation. In Illinois, most April and May clutches have 4 eggs; June and July clutches have 3 eggs. Clutches of 5 eggs are more common in the northern portion of that state. In some years, large clutches are particularly prevalent in Illinois, but the reason for this is unknown (Bent 1948; Cavitt and Haas 2020; Erwin 1935; Graber et al. 1970; Murphy and Fleischer 1986; Peck and James 1987; Rodrique and Tardif in Gauthier and Aubry 1996).

The age at first breeding is 1 year and presumably breeding occurs annually thereafter. Birds are typically monogamous, although 1 male apparently attended 2 females. Pairs usually remain together for the entire breeding season. At least 1 case of divorce has been documented and this occurred after successfully rearing a brood (Bent 1948; Cavitt and Haas 2020).

The Brown Thrasher usually forages on the ground or a short distance above it. Foraging is usually undertaken by searching through leaf litter for insects and fallen seeds and berries. Occasionally, it obtains insects from below the surface of the soil by pecking or hammering its bill into the ground. It also picks fruit off trees, seeds off herbaceous plants, and occasionally flycatches from an elevated perch. It may carry nuts away in the beak to open elsewhere. Even during summer, it may visit bird feeders and bring its young along. Because it is wary of humans, it visits only those feeders where there is considerable shrubbery nearby (Cavitt and Haas 2020; Dunn and Tessaglia-Hymes 1999; Graber et al. 1970). One bird waded in water as deep as its breast feathers to feed on water striders (Hodges 1948). A female ran twice at a robin and drove it away from an earthworm that it had begun to pull up (Van Tyne 1948). Royall (1995) observed thrashers pursuing and capturing fireflies on a lawn.

The dominant foods given to nestlings at an Iowa nest, in decreasing order of abundance, were mayflies, grasshoppers, moths, and cutworms. Other food items included crickets, June beetles, dragonflies, butterflies, centipedes, other beetles, spiders, caterpillars, flies, earthworms, bugs, ants, and wireworms. Cherries, nuts, and raisins placed near the nest were fed to the young. In Kentucky, 25.2% of items fed to nestlings consisted of flies, 24.0% were beetle or fly larvae, 19.6% were

grasshoppers, and 12.0% were adult beetles. In Kansas, adults fed nestlings sumac berries and blackberries (Cavitt and Haas 2020; Gabrielson 1912; Heagy and Best 1983).

Beal et al. (1916) examined the contents of 266 stomachs from the southeastern United States. The diet consisted of 62.6% animal matter and 37.4% vegetable matter. No single item appeared to be favoured. Beetles were most frequently consumed and comprised 18.1% of the diet. They were eaten throughout the year but were a little more prevalent in the diet from March to June. Ants comprised 1.4% of the diet, surprisingly low given that the Brown Thrasher feeds predominantly on the ground; bees and wasps were 0.9% of the diet. Bugs comprised 1.5% of food items; most were stink bugs. Caterpillars were eaten in every month except November and constituted 6.0% of food items. Almost all flies were eaten in November and they comprised 1.8% of the diet. Grasshoppers comprised 2.4% of the annual diet with a maximum of 8.5% in September. The diet also included 0.6% spiders, 2.2% millipedes, and 1.3% miscellaneous invertebrates such as crayfish, isopods, snails, and earthworms. Eleven stomachs contained bones of lizards, salamanders, or treefrogs. Wild fruit was eaten every month with an annual average of 19.9% of the diet with a peak of 46.0% in September; January and February were next in abundance for wild fruit. Thirty species of wild fruits were eaten with the most abundant being blueberries, huckleberries, holly berries, elderberries, pokeweed, hackberries, Virginia creeper, and black gum. The Brown Thrasher also ate fruits of bayberry, sumacs (including poison sumac), pine, and sweetgum. Fruit was eaten from April to December with an annual average of 12.4% and most (53.2%) consumed in July. These included raspberries or blackberries, currants, grapes, cherries, and strawberries. It is likely that most were taken from uncultivated plants. Mast comprised 23.7% of the diet and was chiefly acorns. Mast was eaten every month except August, but mostly in autumn and winter with the peak of 57.4% in November. Grain comprised 2.6% of the diet and was almost all corn with a little wheat and oats; most was evidently waste grain. In Illinois, beetles were important in the diet in spring but the thrasher also ate earthworms, seeds, and grain; corn was especially important in April. From June on, fruit was more important in the diet; it was documented feeding on pokeweed and barberries. At feeders, nut meats were a favourite, including cracked black walnuts; it also ate sunflowers (Graber et al. 1970). It has eaten the fruits of mulberries and Canada moonseed (Breiding 1946; Holt 1918). It occasionally eats small frogs, snakes, and crabs (Cavitt and Haas 2020).

The Brown Thrasher is the largest regular host of the Brown-headed Cowbird. Parasitism rates vary considerably geographically and may vary annually in a given location. It is an egg rejecter, or at least an intermediate egg rejecter, ejecting some eggs from nests. Eggs were rejected from 25 of 26 experimentally parasitized nests in 1 study. In North Dakota, 33% of cowbird eggs in naturally parasitized nests were removed by thrashers; 58% of experimentally parasitic eggs were removed. Because of egg rejection, reported rates of parasitism are probably lower than actual rates. There is 1 report of a thrasher building the nest up over a cowbird egg and 2 reports of 3-4-day-old cowbirds disappearing from nests in which young thrashers remained. In Ontario, 18 of 768 nests (2.3%) were parasitized. Parasitism rates reported elsewhere range from 0% to 37.5%, but most are 12% or less. In North Dakota, the rate of parasitism was 12-36% when cowbird eggs lost to rejection were considered. In North Dakota, parasitized nests fledged a mean of 0.7 and a median of 2 fewer fledglings than unparasitized nests. Many parasitized nests do not successfully fledge any cowbirds

(Cavitt and Haas 2020; Graber et al. 1970; Haas and Haas 1998; Lowther 1985, 1991, 1997; Moore 1956; Nickell 1955; Peck and James 1998a; Rivers et al. 2010; Rothstein 1975).

Habitat loss is the most significant limiting factor for the Brown Thrasher. The initial clearing of forest cover and early farming practices were beneficial. Now the shrubby habitats that it requires are scarce and declining due to a number of factors. These include enlargement of farm fields and removal of hedgerows, road improvements and removal of roadside vegetation, reduced areas of orchards and more manicuring in them, natural succession, planting coniferous plantations, and urbanization (Cavitt and Haas 2020; Curry 2006; Graber and Graber 1963).

The Brown Thrasher is vulnerable to environmental contaminants. Adults have been found dead in fields treated with dieldrin or heptachlor. Nestlings in pecan groves treated with organophosphate or carbamate pesticides showed reduced rates of mass increase and decreased survival rates (Cavitt and Haas 2020; Graber et al. 1970).

Raynor (1976) partially attributed the decline of the Brown Thrasher on Long Island, New York, to the increase in the Northern Mockingbird. During the period of decline, there was little change in habitat except for some natural succession. When the mockingbird first colonized the area, it occupied residential areas that were little used by thrashers. It then spread into all habitats except forest interior. Mockingbirds continued to increase and replace thrashers at feeders, berry-bearing plants, and other food resources. The aggressive nature of the mockingbird probably allowed it to dominate and displace the thrasher, although direct conflicts between the species were not observed.

The Brown Thrasher does not appear to adapt well to human activities. In Illinois, thrasher populations were high in residential areas early in the 20th century, but are now low (Graber et al. 1970). It now seldom occurs in residential areas and is not common near rural residences even when suitable habitat is present. In suburban areas of Massachusetts, however, Thomas et al. (1977) found no indication that human density, dogs, or cats had any significant effects on thrashers but the habitat was marginal for the thrasher. Because it often nests close to the ground along roads, it is vulnerable to being struck by vehicles. It was 1 of the 8 most common birds struck by cars around Peoria, Illinois, and the 5th most frequent roadkill near Urbana, Illinois (Cavitt and Haas 2020; Graber et al. 1970). Nests may be abandoned if they are disturbed by humans during the laying stage. Flagging of nests by researchers increased predation by the American Crow (Cavitt and Haas 2020).

In Georgia, the Brown Thrasher benefitted slightly from burns that opened up the canopy in hardwood stands. It was absent on control plots and forests subjected to low-intensity burns, with less than 5% canopy loss. In medium-density burns causing 5-20% canopy mortality, it was absent 1-2 years after fire and present at a density of 1 per km^2 3-6 years after the burn. It occurred at the same density 1-6 years after fire in high-intensity burns that killed 20-50% of the canopy (Klaus et al. 2010).

DesGranges and Morneau (2010) concluded that the Brown Thrasher was sensitive to climate change in Quebec.

Status

The breeding range of the Brown Thrasher probably expanded considerably after forest clearing by European settlers. McIlwraith (1894) noted that it was not as abundant as the Gray Catbird and was somewhat local in distribution. There were considerable areas of suitable habitat where it was absent but it was a common summer resident in the Hamilton area. Baillie and Harrington (1937) concluded that it bred almost entirely south of Lake Nipissing and Ottawa and considered it a fairly common breeder. They reported earlier records from Manitoulin Island and Thunder Bay, but had no confirmed breeding records from these areas. Sheppard et al. (1936) reported that it was not particularly common in the Niagara region and was local in occurrence. In 1891 in Elgin County, it was an uncommon summer resident that appeared to have decreased greatly in the past 5 years. By 1954, it was considered a breeder that was less abundant than the catbird. In 2000, it was a local and uncommon breeder (Lancaster et al. 2004). In the Hamilton area, it occurred in every square during the second atlas, but there were fewer than there were 50 years ago (Curry 2006). It was common in the Kingston area during the 19th and 20th centuries (Weir 2008). At Presqu'ile, the general consensus was that it had declined in the park due to natural succession (LaForest 1993). Mills (1981) reported that it was decidedly scarce in some regions of Muskoka and Parry Sound districts. Breeding occasionally occurred in the Hudson Bay Lowland (Wilson and McRae 1993). The first atlas showed a wider breeding distribution than that reported by Baillie and Harrington (1937). It bred north to Sault Ste. Marie, north of Sudbury, near Thunder Bay, in the western portion of Rainy River District and southern portion of Kenora District, and there was 1 record from North Point north of Moosonee. The apparent range expansion may have been due to abandonment of marginal agricultural land, but continuing natural succession may have been inducing declines even by the time the first atlas was conducted. Its range was discontinuous in the Canadian Shield, and it was notably absent from the heavily treed Algonquin Highlands and other uncleared areas of the Great Lakes–St. Lawrence Forest Region (Curry in Cadman et al. 1987). James (1991) considered the Brown Thrasher a common summer resident in the south, rare and local in the north to Kenora and Timmins, and a vagrant north to the Moosonee area.

The second atlas revealed that very little change in the distribution of the Brown Thrasher had occurred since the first atlas. It occurred regularly north to the Sudbury and Sault Ste. Marie areas and in Rainy River District, with scattered records north to Winisk. It continued to be virtually absent in heavily forested regions of the Great Lakes–St. Lawrence Forest Region in the Shield, particularly in the Algonquin Highlands. Its probability of observation declined significantly province-wide and in all regions except the Hudson Bay Lowland. Although there was a nonsignificant increase in this region, it continued to be rare and sporadic there. Declines were probably attributable to natural succession, hedgerow removal, forest growth, and establishment of coniferous plantations. It was most abundant south of the Shield. Highest densities occurred in a band from Elgin County northwest to Lake Huron, in a broad band south of the Shield from Lake Simcoe south to Lake Ontario and eastward beyond Ottawa, along the Ottawa River east of the Algonquin Highlands, and south of the base of the Bruce Peninsula. These areas still support extensive areas of shrubby growth. Low densities were found in agricultural areas such as the extreme southwest, the Niagara Peninsula, and the urban areas of Hamilton east through Toronto (Curry in Cadman et al. 2007).

Breeding Bird Survey data for 1970-2021 indicate that the Brown Thrasher decreased at annual rates of 1.12% in Canada and 1.25% in Ontario. It decreased at an annual rate of 0.187% in Canada and increased at an annual rate of 1.029% in Ontario 2011-21. All results were highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Young remain in shrubbery near the nest for several days. The adults and fledglings remain together for about 19 days, but the young may remain in the territory for as long as 45 days. During the postbreeding season, fledglings moved an average of 0.2 km (range 0-5.4 km; Haas 1995, 1998). When a second brood is attempted, the female assists in raising the first young for only a few days and they are the responsibility of the male thereafter. When the female does not attempt a second brood, brood division occurs with each adult caring for half the brood. In these cases, the territory may be divided (Cavitt and Haas 2020).

In regenerating clear-cuts in Ohio, Vitz and Rodewald (2006) captured 8 adults and 37 juveniles during the postfledging period. It is possible that the thrasher bred within these clear-cuts, but birds may also have moved from other nesting locations once the young fledged. In Missouri, Porneluzi et al. (2014) netted birds during the postfledging period in an oak-pine-hickory forest 2-15 years after it was clear-cut. Only a single Brown Thrasher was captured.

MIGRATION

The Brown Thrasher is a short-distance, partial migrant that migrates nocturnally. It is usually solitary during migration, although 2-4 may occasionally be found together in suitable habitat patches. It may migrate with Gray Catbirds and various species of sparrows. A bird banded in Ontario was recovered in Maine the following winter and another Ontario-banded bird was encountered in New England 4 years later (Brewer et al. 2018; Cavitt and Haas 2020; Graber et al. 1970).

Males arrive 7-10 days earlier in spring than females. Arrival in Ontario is in mid- to late April, with migration extending into mid-May. In the Hudson Bay Lowland, the thrasher occurs annually, usually as a spring overshoot, between early May and 6 June. Autumn migration may begin in late August in the Hudson Bay Lowland, with a record of a migrant at Shagamu on 28 August. It is typically gone from the province by the end of September with stragglers persisting until late October (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008; Wilson and McRae 1993).

During migration, the Brown Thrasher may occur in hedgerows, along railway rights-of-way, in mature deciduous forests, and in urban parks and gardens, particularly those with fruit-bearing plants and feeders (Cavitt and Haas 2020).

The Brown Thrasher may strike television towers and other tall structures during migration. It tends to be less vulnerable to this than many other species and represented only 0.1% of mortalities at Illinois towers during autumn migration (Cavitt and Haas 2020; Graber et al. 1970).

At Long Point Bird Observatory, the Brown Thrasher experienced a significant decline of 3.3% per year 1961-88. It was 1 of 7 species that showed a weak, nonsignificant increase in 1 decade (the

1960s) combined with highly significant declines in other decades (12.0% in the 1970s and 3.1% in the 1980s; Hussell et al. 1992).

James (1991) considered the Brown Thrasher a common migrant.

WINTER

Root (1988) concluded that temperature and vegetation were the primary factors associated with the winter distribution of the Brown Thrasher. In autumn, most move to areas where the average January temperature is above –4°C. All areas of high winter concentrations are where the temperature rarely drops below freezing. It is a snow avoider associated with areas where there are frequent changes between presence and absence of snow (Keyser et al. 2022).

Habitats selected in winter are similar to those used during the breeding season. The Brown Thrasher may occur in dense riparian thickets, brushy woodland edges, fencerows, gardens, yards, cultivated areas, vine-covered thickets, brier patches, hedgerows, urban areas near feeders, and in sheltered areas with heavy woody growth. It may prefer thickets near water. In Texas, it preferred dense riparian thickets and woodlands. Foraging occurred at sites with well-developed overstoreys and rarely in open areas with no canopy cover. In Alabama, it occurred mostly in successional shrub and sapling areas in openings (Bent 1948; Cavitt and Haas 2020; Fischer 1981a, 1981b; McClure et al. 2013a).

Wintering birds establish territories soon after their arrival in September and October. Birds are very sedentary in these territories and highly aggressive toward any intruders. In Texas, 27% of banded thrashers returned the following year. All were found in the vicinity of their initial point of capture, suggesting that returning birds use the same winter territories each year (Fischer 1981a, 1981b).

During winter in the Hamilton area, the thrasher ate seeds and fruits and sometimes frequented bird feeders (Curry 2006). Bent (1948) reported that acorns are an essential part of the winter food and that it favoured sumac berries in December. In Texas, it foraged by tossing aside the leaf litter with its bill and occasionally pecking and probing into the ground. Ninety-five percent of all foraging activity was on the ground with some foraging occurring in clusters of dead leaves in trees or on berries of trees (Fischer 1981a, 1981b). When snow covers the ground, it may visit feeders. Early in the 1900s, it was a rare visitor to feeders but it is now a regular visitor to feeders and birdbaths, especially in the south. Favourite foods at feeders are mixed seeds, bird puddings, and millet and it infrequently eats black-oil sunflowers and cracked corn and drinks water. It may occasionally eat hulled sunflowers, milo, wheat, suet, peanut butter mixes, baked goods, and whole corn (Dunn and Tessaglia-Hymes 1999).

Severe winter weather may cause mortality of the Brown Thrasher. One was found dead in Alberta when January temperatures dropped to –35°C. After a severe winter storm in Illinois, 1 dead thrasher was found. Prior to the storm, the density of thrashers was 9.4 per km² in bottomland forest; density declined to 1.5 km² after the storm, a decline of 84.2%. It was absent in upland forest and urban residential areas before and after the storm. The decline was probably due to high mortality. It may be vulnerable there because it is a ground forager at the northern extent of its range (Cavitt and Haas 2020; Graber and Graber 1979).

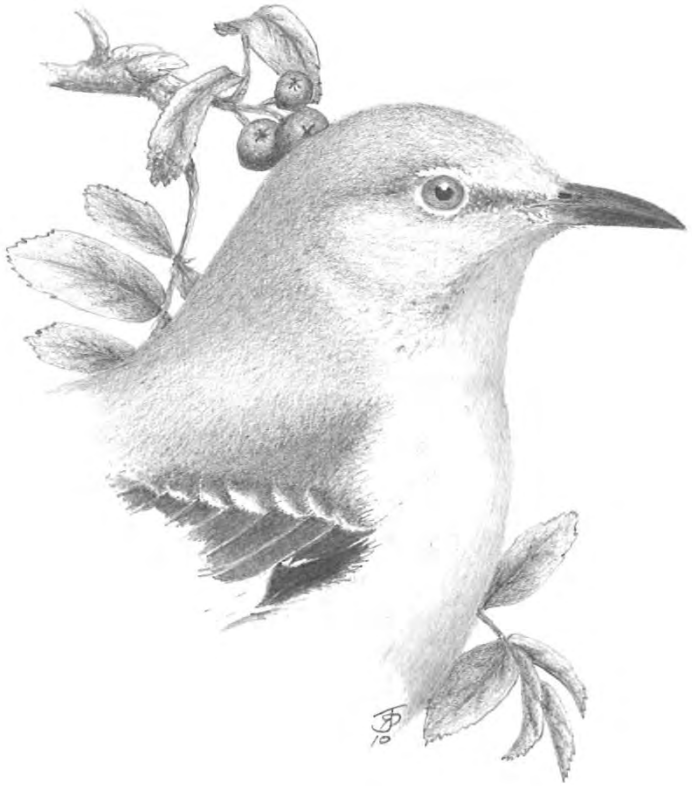
The Brown Thrasher appears to be extending its winter range northward, possibly in response to warmer weather or provision of bird feeders. It is now very local in winter north to the Great Lakes area where it is mostly reported from urban areas with feeders or thickets with abundant berries (Cavitt and Haas 2020). Graber et al. (1970) concluded that it was possibly wintering in Illinois in greater numbers than previously.

James (1991) considered the Brown Thrasher a rare winter resident in Ontario, occurring mainly in the south but occasionally north to Thunder Bay and Kirkland Lake. Since the 1950s in the Hamilton area, 1 or 2, or rarely several, have spent the winter (Curry 2006). From 1964-2007, it was found near Kingston during December in 15 years and remained throughout 8 winters (Weir 2008). In Elgin County, it is rare in winter and usually remains there only until early winter; it has been observed on 20% of Christmas Bird Counts (CBC) conducted since the late 1940s (Lancaster et al. 2004). In Niagara Region, there are 9 January records and 5 February records (Black and Roy 2010). One survived the winter at Huntsville (Mills 1981).

CBC data for Ontario indicate that the Brown Thrasher decreased at annual rates of 4.24% 1970-2021 and 4.04% 2009-21 (National Audubon Society 2022).

Northern Mockingbird

Mimus polyglottos

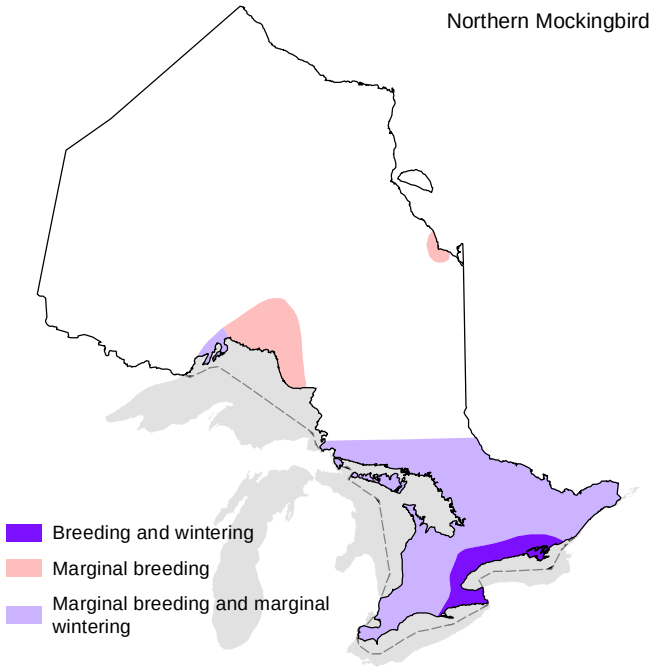


BREEDING SEASON

Habitat Requirements

In Ontario, the Northern Mockingbird has nested in rural fields, pastures, orchards, and floodplains (43.4%); residential gardens and cemeteries (28.3%); shrub- and tree-covered sand dunes (10.0%); coniferous woods and plantations (8.3%); deciduous woods (6.7%); and 1 nest each in a shrubby border of a marsh and a park campground. Wooded areas used for nesting tend to be more open than closed (Peck and James 1987). In the Greater Toronto Area (GTA) in the 1930s, breeding tended to occur in rural areas beyond the urban fringe. The current GTA range largely coincides with the urbanized area with only a handful of territories on or north of the Oak Ridges Moraine. Fifty-three percent of territories were in industrial areas. It showed a strong preference for linear features such as railways and, to a lesser extent, hydro corridors. Density was greatest in large industrial areas west of the airport and in Mississauga and Etobicoke. Many urban parks, cemeteries, and suburban areas that would be suitable habitat elsewhere are unused or rarely occupied (Smith and Poon 2006).

Throughout its range, the mockingbird is associated with human-altered areas. It reaches its greatest abundance in suburban and urban areas where it prefers lawns with scattered trees and



shrubs, particularly those that bear fruit. Hedges may be particularly attractive to it. It occurs in small towns, old suburbs, landscaped cemeteries, golf courses, vacant lots, school yards, and university campuses. In rural areas, it is associated with farmsteads, hedgerows, edges of thickets bordered by pastures and cultivated fields, orchards, woodlot edges, and prairie-like areas. In Illinois, it was much more tolerant of open-field conditions than the Gray Catbird. It was found in sandy prairie areas more than the Brown Thrasher and may have an affinity for sandy areas, but occurs in a wide range of soil types. In Illinois, it was much more common in hedgerows than any other habitat; densities were higher in rural than urban habitats. Forest interior is avoided but forest edge may be used, although it is not particularly favoured. It occurs in willow thickets, clearings and edges in forested areas, logging slash, coastal beaches, and garbage dumps in British Columbia. In the Kingston area, it occurs in more open and built-up areas in a 20-km band along the St. Lawrence River and Lake Ontario (Campbell et al. 1997; Crowell et al. 1982; David in Gauthier and Aubry 1996; David et al. 1990; Doughty 1988; Farnsworth et al. 2020; Graber and Graber 1963; Graber et al. 1970; Joern and Jackson 1983; Laskey 1962; Leighton et al. 2002; Sprunt in Bent 1948; Weir 2008).

The mockingbird prefers narrows strips of vegetation to wide strips or no vegetation. In Mississippi, it was absent in field margins with no vegetated borders or with borders 30 m or more wide, but was common in 10-m wide borders (Conover et al. 2009). Its overall probability of occurrence in Maryland and Delaware riparian forests was 48% and was significantly greater in narrow than wide forests: 65% in 50-m wide forests, 56% in 100 m, 37% in 200 m, 21% in 300 m, and 1% in 800 m (Keller et al. 1993).

Areas with short grass are preferred to those with tall grass. Tall-grass habitats support a significantly lower density of mockingbirds (Roth 1979).

Mockingbirds roost predominantly in deciduous shrubs, trees, and vines. These may be very close to human habitation. One roosted in a shrub near a window and 1 pair roosted in a garage over winter but moved to a rose vine when the weather became warmer (Laskey 1935, 1936).

Nests reported to the Ontario Nest Records Scheme were in living trees, shrubs, and vines, with deciduous species (62.1% of nests) preferred to conifers. Tree species used most frequently were hawthorn (20 nests), cedar (11 nests), spruce (4 nests), maple (4 nests), and pine (4 nests). Nests were well concealed and randomly positioned in crotches and on branches near or at the trunk, or at the end of horizontal or drooping branches. They were usually supported by upright branches. Nest

heights ranged from 0.3 to 4 m, with most 1.1-2.0 m up (Peck and James 1987, 1998a). Of 663 nests in the GTA, 59% were in small conifers with 44% in small spruce. Small spruce in landscaped areas initially provide good nesting habitat but are abandoned once they mature. Nests early in the season were often in honeysuckle. They were highly conspicuous because nesting was initiated prior to leaf-out (Poon and Smith 2005; Smith and Poon 2006). Two nests were on artificial structures in the Toronto area. One was 1.1 m from the ground on a pipeline valve within a chain-link fence enclosure. The other was on wire mesh hanging below the eavestrough of a shed (Smith 2024).

In addition to the plants that supported Ontario nests, nests have been found in rose vines and shrubs, hackberry, sycamore, privet, sassafras, grape, catalpa, greenbrier, trumpet creeper, mulberry, snowberry, plum, pear, Virginia creeper, ash, elm, basswood, locust, and rough-leaved dogwood. In Tennessee, 53.8% of nests were in conifers, including white cedar, spruce, pine, and red cedar. Red cedar was favoured and supported 33% of nests. Nest building started before leaf-out with almost all early nests in coniferous vines and saplings. Later nests may be in deciduous trees and shrubs and be higher off the ground. The percentage of higher nests began to increase in May with leaf-out and progressively increased into June and July. Nest height changed seasonally in Illinois also, with average nest height just under 1.5 m in April and May and almost 2.1 m June through August. A seasonal increase in nest height has been reported from many areas, but there is no change in nest heights in other areas. Most nests are 1-3 m from the ground, with extremes of 0.3-19 m. In Tennessee, 76% of nests were 1-2 m from the ground, 18% were 2-5 m up, and 5% were lower than 1 m. One nest was in a gourd designed for Purple Martin nesting. It was nailed under the eaves at the peak of a small shed. Others were under the eaves of a well house, in a leafless grape vine, in a leafless shrub at a wire fence, on the ledge of a grape arbour, on a protruding tree root in a creek bank, in a section of a 2-compartment nest box on a fence post, in a pile of fence rails, in a cavity in a tree, in a bluebird box, and in the top of a hollowed-out fence post covered with vines (Campbell et al. 1997; Crowell et al. 1982; Farnsworth et al. 2020; Graber et al. 1970; Joern and Jackson 1983; Laskey 1935, 1962; Murray 1958; Sprunt in Bent 1948; Turcotte 1995).

Both sexes defend a territory against other mockingbirds of the same sex. Territoriality declines in July or early August, depending upon when young fledge from the last nest and the moult begins. In Tennessee, where birds held territories year round, the boundaries shifted slightly each nesting season in response to food supplies and presence of suitable roosting and nesting sites. In California, exactly the same boundaries were retained. In California, 5 breeding territories were 0.25-0.55 ha. Food was provided by humans in these territories so they may have been smaller than normal. Florida breeding territories averaged 1.27 ha (range 0.41-2.00 ha). Texas territories ranged from 0.66 to 2.53 ha. Territories of 2 Tennessee birds were about 2 ha, but the space occupied in any given time never exceeded half that size. Even in areas of dense population along railways in the GTA, pairs tended to be 200-300 m apart. The closest nests were 73 m apart and this was considered exceptional, possibly due to a lack of suitable nest sites. Spacing between pairs along Illinois roadsides was about 85 m. Mockingbirds rarely leave their territories except during the transitional period between winter and breeding seasons (Farnsworth et al. 2020; Graber et al. 1970; Laskey 1935, 1962; Michener and Michener 1935; Smith and Poon 2006).

No mockingbird is known to have nested on its natal territory, but at least 2 females have done so on adjacent territories. Young appear to disperse at least several territories away, but no detailed studies have been done on this. After dispersal from the natal territory, juveniles attempt to establish autumn territories. Those that are successful may nest near their natal area; others may disperse as far as 320 km. In California where it is a permanent resident, only 11% of birds banded as juveniles were recovered after 1 year. In Tennessee, 2 juveniles were captured 1.6 km from where they had been banded, 1 was recovered at its nest 5.2 km away, and 2 were retrapped where they had been banded. Of over 900 nestlings banded near Nashville, 5 (approximately 0.6%) were recovered 32-320 km away; the total range of distance for recoveries was 0.5-320 km (Doughty 1988; Farnsworth et al. 2020; Laskey 1936, 1962; Michener 1951; Michener and Michener 1935).

Mockingbirds in the southeast and west tend to be permanent residents and remain on the same territory for life. No adults banded in Nashville were ever recovered outside that city. Site fidelity of northern migratory populations is unknown. In Ontario and Quebec, individual territories may only be occupied in 1 or 2 years. In Ontario, there is considerable turnover in territories year to year because of changing habitat, such as young spruce becoming too large to be attractive for nesting. Some territories persist for several years in the GTA, but it is unknown if they are occupied by the same individuals. In Quebec, individual territories are rarely occupied for more than 2 years so occurrence at most sites is highly irregular. These birds probably winter in the northern United States where they would have to compete with resident birds defending food supplies. Many may not survive which may explain why few return to breed at the same locations (David in Gauthier and Aubry 1996; David et al. 1990; Farnsworth et al. 2020; Laskey 1962; Smith and Poon 2006; Whittle 1922).

Limiting Factors

Eggs have been found in Ontario nests from the last week of May until mid-August, with most present from mid-June to mid-July (Peck and James 1987). In the GTA, some mockingbirds began nesting in mid-April; 14 April was the earliest egg-date (Poon and Smith 2005). Nest building may take as long as 14 days or as little as 2 or 3 days. Nests started early in the season tend to take longer to finish. Nests for subsequent broods are usually completed in 2 or, most often, 3 days. Some birds start laying as soon as the nest is complete; others may wait 3 or 4 days. Eggs are laid at the rate of 1 a day, although a day may rarely be skipped. Incubation is sporadic until the clutch is complete. Females may delay incubating the second clutch to feed larger broods from first nests. The incubation period of 8 Ontario clutches was 11-13 days. Overall, incubation periods range from 9 to 15 days, but are mostly 12-13 days. Eggs may hatch synchronously or asynchronously but typically all hatch within a 24-hour period. The nestling period is 10-15 days but usually 12-13 days. Nest building for the subsequent brood may start as soon as 2 days after the first young fledge. In Illinois, an entire nesting cycle from nest building to fledging took 33-36 days (Breitwisch and Gottleib 1992; Breitwisch et al. 1986a; Doughty 1998; Farnsworth et al. 2020; Graber et al. 1970; Laskey 1935, 1962; Michener and Michener 1935; Peck and James 1987; Sprunt in Bent 1948; Zaias and Breitwisch 1989).

In Ontario, the mockingbird typically raises 2 or 3 broods (Peck and James 1987; Poon and Smith 2005). This is normal throughout its range, although 1 Tennessee bird was confirmed raising 4 broods. Renesting is common if a clutch is lost. Usually a new nest is built for each brood but

occasionally nest materials may be taken from an old nest. One pair used the same nest for its second and fourth broods. Due to high predation rates and the number of broods raised, the mockingbird builds a minimum of 3 nests a year and often as many as 5 or 6. Clutches of 2-5 eggs have been reported in Ontario, with most containing 4 eggs. Overall, clutches of 2-7 eggs have been reported, with clutches larger than 5 eggs rare. Mean clutch sizes range from 3.5 to 3.9. In Tennessee, 63% of nests contained 4 eggs, 23% contained 3 eggs, and 14% contained 5 eggs. The peak for 3- and 4-egg clutches was in April; most 5-egg clutches occurred in May. Usually only a single 5-egg clutch was found per season in this population, but there were 11 in a year when May and June temperatures were 4ºC above normal. Clutch size does not appear to decline as the nesting season progresses (Farnsworth et al. 2020; Graber et al. 1970; Laskey 1935, 1962; Sprunt in Bent 1948; Zaias and Breitwisch 1989).

It is likely that all yearling females breed. Males are physiologically capable of breeding at age 1 year, but many are not successful in attracting a mate. Even yearling males that successfully defend a territory may not become mated. The sex ratio is male biased, so populations may contain significant numbers of nonbreeding males. The mockingbird is typically monogamous, but there are several reported cases of bigamy. Bigamy often occurs in response to the loss of a neighbouring male leaving the female without a mate, but it may also occur when adjacent territories are occupied by a pair or an unmated male. Bigamy is suppressed by the aggressiveness of females toward each other. Bigamous males tend to have larger than average territories so that females can keep further apart, and they tend to be more aggressive in defending their territories than monogamous males. Because males build the base of the nest, a bigamous male can influence the timing of nesting of his females so that there is minimal overlap in the feeding of the broods. When the broods do not overlap, the male helps to feed both of them, but if 2 broods are present at the same time, the male feeds only one. Bigamy appears to be opportunistic, with some males being bigamous in consecutive years; others alternate between monogamy and bigamy. A case of polyandry was reported from North Carolina. A female ranged over the territories of 2 males and nested in both territories and exhibited this behaviour over 4 years. The female often took food from 1 territory to feed nestlings in the other territory. Some pairs have been together 6-8 years, but it is uncertain if there is any persistence of pair bonds in subsequent years in northern migratory populations. Most pairs remain together during a breeding season, but divorce and mate switching occasionally occur. Although mate switching often occurs as a result of nest failure, females may assess mates by evaluating adjacent territories before electing to mate with one of the males. This may occur even if she has been mated to one of the males for a long time. In North Carolina, 12% of females copulated with a male and then renested with another. In 1 year, 22% of females switched territories after active courtship with 1 male (Breitwisch et al. 1986b; Derrickson 1989; Doughty 1988; Farnsworth et al. 2020; Fulk et al. 1987; Laskey 1962; Logan 1991, 1997; Logan and Rulli 1981; Zaias and Breitwisch 1989). Extra-pair copulations have been documented in Florida. Many broods had more than 1 father and a few had more than 1 mother (Farnsworth et al. 2020).

Both adults and juveniles capture arthropods on or near the ground, take fallen fruit from the ground, and pick fruit from trees and shrubs. Medium- to large-bodied (3 cm) ground-inhabiting vermiform larvae were commonly taken by adults but rarely caught by juveniles. Both adults and

juveniles captured prey by spotting it from perches and flying to make the capture. Juveniles frequently picked fruit from trees and met a significant proportion of their daily nutritional requirements from fruit, a food easier to obtain than arthropods (Breitwisch et al. 1987). In Texas, mockingbirds used 3 main foraging techniques: aerial hawking, ground hawking (watching for prey from an elevated perch and flying to the ground to capture it), and gleaning. Birds in areas of tall grass fed significantly more in shrubs and in the air than those in more typical foraging habitat of short grass. Foraging substrates were 64% on the ground and herbaceous species, 23% in shrubs, and 13% in air in tall-grass areas and 93% on the ground and herbaceous species, 4% in shrubs, and 3% in air in short grass. Foraging techniques in the ground-herb layer were 18% gleaning and 82% ground hawking in tall grass and 87% gleaning and 13% ground hawking in short grass. Hawking techniques were 23% aerial and 54% ground in tall grass and 9% aerial and 12% ground in short grass. Tall, dense grasses and forbs caused mockingbirds to use aerial perches and above-ground substrates instead of gleaning from the ground-herb layer (Roth 1979). There are cases of the mockingbird successfully capturing prey after wing-flashing (quickly opening and closing the wings while simultaneously spreading the tail). It may pick fruit while perched in a tree or shrub, but occasionally hovers while picking fruit. It may occasionally cling to tree trunks in woodpecker fashion when preying upon arthropods on trunks and has been observed drinking sap from recently pruned deciduous trees. It may knock cicadas to the ground by hitting them with the wings and chest before grabbing them in the bill (Fairfield and Fairfield 1997; Farnsworth et al. 2020).

Eighty-five food items collected from nestlings in Texas consisted of 64.3% orthopterans (25.6% nymphs and 38.7% adults), 11.5% lepidopterans (9.3% larvae, 2.2% adults), 13.2% other insects, 9.8% spiders, and 1.2% snails. In British Columbia, adults fed young juneberries, cabbage white butterflies, and crickets. The amount of fruit delivered increases with time. Overall, nestlings are fed a mixture of arthropods (82%) and fruit (19%). Initially, they are fed arthropods almost exclusively, including spiders, dragonflies, grasshoppers, crickets, beetles, moths, butterflies, and ants. Twenty-five to 30% of food fed to older nestlings is fruit. In Florida, young may also be fed small lizards. A similar diet is provided to fledglings (Breitwisch et al. 1986a; Farnsworth et al. 2020; Fischer 1983; Laskey 1962; MacKenzie et al. 1995).

Beal et al. (1916) summarized the contents of 417 mockingbird stomachs from the southeastern United States. They contained 47.8% animal matter and 52.2% vegetable matter. Most animal food was consumed in May (85.4% of food eaten that month); the most vegetation consumed was in December and January (86.6% both months). The food items indicated that most food was obtained from the ground. Grasshoppers appeared to be the preferred animal food (average of 14.9% of food items, increasing to 43.3% in July but with only a trace in February). It also ate locusts and crickets. Caterpillars comprised 9.5% of the diet and were eaten every month with peaks in August (23.9%) and to a lesser extent in May, with the fewest eaten in October. Hymenopterans comprised 7.5% of the diet (4.5% ants and 3.0% bees and wasps). Bugs and flies were seldom eaten. Spiders comprised less than 2% of the diet every month except October. Mockingbirds also ate a few millipedes, crayfish, isopods, and snails, plus lizards and a small snake. Fruits most commonly consumed were those of hollies, greenbriers, blackberries, pokeweed, elderberries, mulberries, and black gum. Fruit comprised 3.4% of the diet, and was either raspberries or blackberries that were consumed from

May through August. It is most likely that these were taken in the wild rather than in gardens. It occasionally ate grapes. The remainder of the vegetation consumed was of no great importance in the diet and included various weed seeds; sumac berries of various species, including poison sumac; flower petals; and vegetative rubbish. In Ontario, fruit may be more important in the diet given that invertebrates are not very available in winter. Breitwisch et al. (1987) stated that the overall diet of the mockingbird was 35% fruit June through August and 67% in September and October. During the breeding season, the proportion of invertebrates in the diet is almost 85% compared with 13% in winter. Other fruits that may be consumed are those of privet, bittersweet, hackberry, hawthorn, apple, yew, crabapple, hophornbeam, barberry, guelder-rose, poison ivy, Virginia creeper, red cedar, black alder, and nightshade (Doughty 1988; Farnsworth et al. 2020; Graber et al. 1970; Laskey 1936; Sprunt in Bent 1948; Whittle 1922).

The Northern Mockingbird is a fairly rare host of the Brown-headed Cowbird. Peck and James (1998a) reported that 0 of 107 Ontario nests were parasitized, but Poon and Smith (2005) found 9 cases of parasitism in 483 GTA nests (1.9%). It appeared as though all cowbird eggs were laid in May and 8 of 9 cases of parasitism occurred before 22 May. The parasitism rate in May was 4.5%, considerably lower than other species nesting in the area. During April and May, cowbirds have a limited range of hosts in the GTA, predominantly the American Robin and House Finch. The robin is a known egg rejecter and no cowbirds ever fledge from House Finch nests because of the unsuitable diet of seeds fed to nestlings. By late May, more host species become available and the cowbird can select more suitable hosts than the mockingbird. Abandonment occurred at 6 of the 9 parasitized nests; eggs were initially accepted at 2 nests before they were abandoned. No cowbird young fledged from any of the nests. The mockingbird is an intermediate rejecter, ejecting 60-68% of foreign eggs. Most birds are either acceptors, ejecting 0% of eggs, or rejecters, ejecting them all. It is one of very few species that shows an intermediate reaction. Rejection rates vary seasonally and were 50% in March and April in Louisiana and 82% in May to July. Parasitism rates were 0% in Louisiana (607 nests) and Texas (222 nests), and 4.0% and 8.7% in Oklahoma (50 and 23 nests, respectively), but the mockingbird is 1 of the 24 most parasitized species in Kansas. In Oklahoma, it appeared as though both mockingbirds and cowbirds fledged from parasitized nests (Peer et al. 2002; Quinn and Tolson 2009; Wolfe 1995).

Because most Ontario mockingbirds nest in urban areas, habitat loss is not a significant issue. Removal of hedgerows along roads and between fields has the potential to remove suitable habitat for rural mockingbirds. This has been identified as an issue in Illinois (Graber and Graber 1963).

Several habitat features may affect nesting success of the mockingbird. These include height of grasses and forbs, degree of isolation of the nest shrub or tree, amount of cover over the nest, and nest location within shrubs. In Texas, nesting success in ground vegetation with dense cover (99% at ground level and 37% at 0.6 m) was significantly less than in short and sparse cover (81% at ground level and 14% at 0.6 m). Density of mockingbirds was significantly lower in areas of tall vegetation; no young were produced from first nests, and no attempts were made to renest. Approximately 13-22% of birds nesting in short vegetation successfully reared first broods, and birds continued to nest throughout the summer (Roth 1979).

In Louisiana, nests in isolated patches of vegetation suffered significantly less predation than those in continuous strips of vegetation. Linear corridors provided cover for the large snakes that were the primary predators, and probably other predators. A high density of vegetation around the nest may have marginal antipredator value if it includes a combination of very dense patches interspersed with open corridors. The percent reduction in light transmission above the nest was the best predictor of the number of days that young survived in the nest. Dense canopy over a nest increases the likelihood of young fledging (Joern and Johnson 1983).

In Florida, nests in low shrubs or placed low in shrubs were more successful than nests higher up. Nests at the juncture of a branch and the trunk were more successful than those along a branch or among twigs or leaves (Farnsworth et al. 2020).

In Florida, urban mockingbirds started nesting earlier and produced significantly more fledglings than rural birds. Survival rates of young were greater in urban areas. Residential birds tended to remain on their territories year round. Urban birds were more likely to return to the same territory the following year if they were successful at nesting. Successful and unsuccessful females nesting in pastures and wildlife preserves showed little difference in their probability of returning. Their return rate was similar to that of unsuccessful urban females. Rural populations were sinks, parking-lot populations were sources, and residential populations were sources in 2 of 3 years. It was considerably more abundant in urban than rural habitats (Stracey and Robinson 2012).

In Florida, Stracey et al. (2014) studied the effects of light pollution on the mockingbird. As light levels increased, there was a significant increase in feeding time past sunset. Although light pollution created conditions bright enough to allow it to feed young later into the night, this did not increase brood size. Birds at brightly lit parking lots fed nestlings later than those in sites with no artificial lighting, but those in residential areas did not. This suggests that there may be a threshold of light required to elicit later feeding.

In Florida, Walters et al. (2019) studied the response of the mockingbird to urban noise. As background noise increased, there were significant declines in its song of syllables in the 1-3 kHz range and significant increases in those 3-5 kHz in frequency. There was no difference in use of syllables greater than 5 kHz in noisy environments. It altered its song in response to noise and was adapted to inhabiting noisy environments.

In South Carolina, mockingbirds declined and almost disappeared in agricultural lands dominated by cotton, but there was no decline in areas of corn, tobacco, and soybeans, or in urban or suburban areas. This may have been due to the aerial spraying of pesticides on cotton plantations (Stewart 1974).

Cold, wet weather in spring or early summer may result in nest abandonment; even half-grown nestlings may perish (Farnsworth et al. 2020; Graber et al. 1970; Poon and Smith 2005). Although the mockingbird is fairly tame and will allow humans to approach closely, nests may be abandoned if they are disturbed during incubation. Once the eggs hatch, mockingbirds are tolerant of disturbance (Farnsworth et al. 2020).

In some areas, the mockingbird may be affected by the 13- and 17-year cycle of cicadas. It may experience a population dip the year before local emergence of cicadas, suggesting that it increases after emergence of adult cicadas and then gradually declines (Farnsworth et al. 2020).

Price (2004) predicted that the range of the mockingbird could increase in southern Ontario if the average summer temperature increased by 2ºC.

Status

The Northern Mockingbird is a recent arrival in Ontario. The first record was from Chatham in 1860 and a pair was observed in Hamilton in 1883. As late as 1937, only 4 nests had been found, 3 in Essex County and 1 in Haldimand; the first nest was at Amherstburg in 1906. It spread gradually into Ontario during the 20th century as part of a continent-wide expansion of the northern limits of its range. Most early records were from the extreme southwestern portion of the province, with 12 occurrences in Ontario between 1900 and 1920. The pattern shifted during the 1920s with scattered, isolated records across a broad front of southern Ontario. The first records for the GTA were in the 1930s, with one spending the winter of 1935-36. The first nest was documented in 1936. Early colonization was slow with several years between successive sightings. There was a slow and erratic increase in sightings through the 1940s with a more pronounced increase after about 1954. It was still rare in the province in the 1950s, but some birds were pioneering and nesting further north, including on Manitoulin Island and at Ottawa, Moosonee, and Sioux Lookout. In the 1960s, it was still rare in the GTA and in Niagara, with the first breeding for Niagara documented in 1961. The area from Vineland to Niagara Falls was populated in the 1960s. During the late 1970s, there were increasing numbers in central and northern Ontario including on Manitoulin Island and in Algoma District. Breeding was confirmed at Moosonee in 1979. It began to occur more regularly in the Hamilton area beginning in 1953, with a gradual expansion both by pioneering males in spring and postbreeding dispersal in autumn. The first record for Elgin County was in 1948, with 3-10 reports annually since 1990, except for 2 years when none were seen. The first record in the Kingston area was prior to 1915, with the next records in 1936 and 1955. Starting in 1962, it was found there every year and numbers rose steadily annually; the first nest was reported in 1966. The first record from Muskoka District was in 1959 and breeding was confirmed in 1975. During the first atlas, the mockingbird was well established in the Niagara Peninsula, although its contiguous range ended at Hamilton. There were only 10 squares with breeding evidence for the GTA. It was found in 29 contiguous squares in Niagara and occurred in scattered areas south of the Canadian Shield, with some records in the southern Shield and northern records from Cochrane, Moosonee, Thunder Bay, and Kenora. In the south, there were minor concentrations in the region from Prince Edward County to Kingston and near Ottawa (Baillie 1967; Baillie and Harrington 1937; Curry 2006; Curry in Cadman et al. 1987; de Vos 1964; Lancaster et al. 2004; McIlwraith 1894; Mills 1981; Poon and Smith 2005; Smith and Poon 2006; Weir 2008; Wright 1921). James (1991) considered the mockingbird an uncommon permanent resident in the Niagara Peninsula, rare and irregular elsewhere in the south, and occasional north to Thunder Bay and Moosonee.

The second atlas demonstrated that the mockingbird had increased in abundance and expanded its range since the first atlas. Its probability of observation increased significantly province-wide and in and south of the Canadian Shield. It extended its contiguous range in Niagara to include

the entire region and the urbanized area south of the Oak Ridges Moraine as far east as Bowmanville. There was a consolidation of range in the Prince Edward County to Kingston area. It also bred in Chatham-Kent and in Haldimand County along the shoreline of Lake Erie. Elsewhere, its distribution was scattered. There were additional records from the north from Sudbury, east of Lake Nipigon, and at Moosonee. Its greatest abundance occurred in Niagara Region and, to a lesser extent, the GTA (Smith and Poon in Cadman et al. 2007).

The main expansion into the GTA did not begin until the early to mid-1990s. The estimated number of breeding territories in the GTA during different periods was 1921-30, 0; 1931-40, 4: 1941-50, 3; 1951-60, 9; 1961-70, 15; 1971-80, 23; 1981-90, 51; 1991-2000, 247; 2001-05, 1,591. Of the total of 1,943 territories recorded in the GTA, only 352 (18.1%) were documented prior to 2001. During the early 2000s, numbers more than doubled over those of the 1990s, especially for Peel, Toronto, and York. During the second atlas, breeding was confirmed in every urbanized square in the southern half of the GTA. The population was estimated at 640 adults comprised of 200 confirmed pairs, about 40 additional pairs, and approximately 160 single birds (Smith and Poon 2006).

The increase in population of the mockingbird in Ontario is consistent with increases throughout its range. It was rare in New England between 1900 and 1920 but increased markedly there. It first occurred in Illinois in the 1880s with a major surge in population in the last half of the 20th century. Some range expansions and population increases may have been due to repopulation of areas where numbers had been decimated by selling mockingbirds for caged song birds. Populations continue to expand northward and are predicted to continue to do so (Doughty 1988; Farnsworth et al. 2020; Wright 1921).

Breeding Bird Survey data indicate that the mockingbird is decreasing. Population trends 1970-2021 were annual decreases of 1.27% in Canada and 1.7% in Ontario. The 2011-21 trends were annual decreases of 4.97% in Canada and 6.61% in Ontario. The long-term results were highly reliable for Canada and of medium reliability for Ontario; the short-term results were of low reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Young may not be able to fly until about 8 days after leaving the nest. In Florida, about half of fledglings could fly 5 days after leaving the nest. In 1 year, all could fly 8 days after fledging, but all did not fly until 13 days after fledging another year. For as long as 2 weeks, the young remain close to each other, often within a metre. The parents provide food to the young for 3 weeks after they leave the nest, at which time the young leave the natal territory. Care of fledglings from the first brood ends abruptly when the next clutch hatches. No brood division occurs in early broods but it may occur in the last brood. In some cases, the final brood may be cared for entirely by one of the parents. Young from the last brood of the year remain on the natal territory an additional 2-4 weeks (Farnsworth et al. 2020; Zaias and Breitwisch 1989, 1990).

Most fledglings jump to the ground upon fledging and remain low in shrubs or small trees for 1-2 days before climbing to greater heights. In Florida, the mean height of 4-day-old fledglings above ground was 5.2 m. Later, fledglings descend to the ground and initiate the foraging techniques used by adults. Fledglings spent 89% of their time perched in vegetation. They were not

more concealed by vegetation when they were young. They spent 31% of their time in vegetation partially or completely hidden from view (Breitwisch and Gottleib 1992; Zaias and Breitwisch 1989).

Fledglings are driven from their natal territory 1-2 days after the next clutch hatches. After dispersal, some juveniles attempt to establish territories. Others form flocks and forage in areas between territories held by adults (Breitwisch and Gottleib 1992; Farnsworth et al. 2020; Laskey 1962).

MIGRATION/AUTUMN

It appears as though most, but not all, northern birds are migratory, but even some southern residents may move considerable distances in autumn or winter, returning to their territories after a brief absence. In the GTA, about 25% of birds remained on a territory year-round; the remainder either migrated or dispersed. Dispersal within the GTA appears to be mainly along railway and hydro corridors. Of 881 territories in the GTA, 559 (63.5%) were breeding season only, 120 (13.6%) were winter only, and 202 (22.9%) had records in both seasons. This suggests that many birds withdrew from their breeding territory to initiate a territory elsewhere, making local movements of a few kilometers rather than undertaking full-scale migration. The Toronto Islands and Leslie Street Spit have yielded numerous May records and there are no breeding season records for these areas. These birds are presumably spring migrants. Prior to 2000, there was a pronounced spring peak in Toronto and Durham Region with a less defined peak in Halton and Peel. The peak is even more pronounced in Northumberland County. These peaks are highly suggestive of regular spring migration. Long Point Bird Observatory data do not provide strong support for autumn migration. In Elgin County, where there are only 2 nest records, there are several spring records between 10 April and 9 May; autumn records are from 28 August to 29 November. Some birds arrive there in early October and remain over winter, staying until late April. In Hamilton, there were numerous May and November observations in the 1950s and 1960s. In Algonquin Park, where there has been no evidence of nesting, the mockingbird is a regular but rare visitor that occurs predominantly in spring from mid-April to early May. Birds may travel as far as 800 km between breeding and autumn or winter territories. It appears as though all Quebec mockingbirds are migratory. It is absent from February to April, with a sudden increase in May and peak numbers in June and July. In interior British Columbia, spring migration is suggested by a peak in May and many birds apparently leave in August and September. Even in Tennessee and Illinois, there are peaks of observation in late April and May and again in autumn from August through November. In Maryland and Delaware, it is considered a short-distance migrant rather than a resident. It appeared in northern Illinois from September to November where there were few breeding pairs suggesting that postbreeding dispersal may include northward movements. Rare collisions with television towers suggest that it is a nocturnal migrant (Campbell et al. 1997; Curry 2006; David in Gauthier and Aubry 1996; David et al. 1990; Doughty 1988; Farnsworth et al. 2020; Graber and Graber 1963; Graber et al. 1970; Keller et al. 1993; Lancaster et al. 2004; Laskey 1935; Smith and Poon 2006; Sprunt in Bent 1948; Tozer 2012).

Habitat used in autumn and winter is similar to that used during the breeding season: suburban and urban areas, industrial areas, and edge habitat or linear corridors in rural areas. Most birds are associated with human habitation or development. Habitats with an abundance of fruit are essential in autumn and winter (Graber et al. 1970; Hailman 1960a; Laskey 1936).

In autumn, there may be major shifts in the areas inhabited. Adults may begin their moult a short time after the young of the last brood fledge, often in late July (Zaias and Breitwisch 1990). At this time, defence of the breeding territory ceases and there may be large influxes of birds to areas with feeders or large amounts of food that were previously defended by 1 or 2 pairs. Territorial behaviour is reasserted in late September and is intense because birds attempt to establish a territory that will be used throughout autumn and winter. In southern resident populations, the pair may remain intact and stay year-round on the breeding territory. In the northern portion of its range, birds tend to have separate breeding and autumn-winter territories. Of 23 North Carolina birds holding autumn territories, 15 had resided on the same territory at least 1 year, 7 were new to the area and acquired a territory, and 1 shifted its territory within the same general area. Autumn-winter territories may be held by juveniles, females, and males. Many juveniles are successful in establishing territories between areas defended by adults; these are often used for breeding. Other juveniles either are unsuccessful in establishing a territory or do not attempt to do so, and congregate in flocks. Females may establish territories distant from those of their previous mate or may defend a small territory adjacent to their mate, often within a small portion of the breeding territory. Both mated and unmated males may defend autumn-winter territories. Either sex may abandon a territory at any time due to insufficient food resources, or annex adjacent unoccupied territory. Territorial birds may band together to eject intruding birds attempting to take food resources (Farnsworth et al. 2020; Hailman 1960a; Laskey 1935, 1962; Logan and Wingfield 1990; Michener and Michener 1935).

Autumn territories are required to protect food resources and may be smaller than those defended during the breeding season. In Tennessee, males' territories were about 0.6 ha in area compared with 0.3 ha for females. A single territory in Virginia was 0.45 ha. In North Carolina, sizes of territories in September were an average of 0.53 ha 1 year (range 0.37-0.72 ha) and 0.39 ha (0.26-0.57 ha) in October another year (Hailman 1960a; Laskey 1936; Logan 1987; Michener and Michener 1935).

In autumn and winter, other frugivorous species may be attacked and driven from the territory. Specific resources, such as a fruit-laden tree, may be vigorously defended. Mockingbirds in South Carolina defended holly trees against other species, with aggression directed most to those that were potential competitors for food. The mockingbird has been known to kill Cedar Waxwings while defending a fruit tree (Hedrick and Woody 1983; Laskey 1935; Moore 1978).

Mockingbirds may forage in groups in fruit-bearing trees in late autumn. Birds tend to arrive simultaneously from all directions, usually shortly after a series of calls that may act as a signal. Foraging in groups may overwhelm birds defending the tree and reduces the chances of any individual bird being chased away by the defender (Merritt 1980).

The mockingbird is rare in Ontario during migration and rare to locally uncommon in autumn where birds are still on territory. Fifty-one were seen on the 1991 autumn count in Hamilton (Curry 2006).

WINTER

The mockingbird tends to avoid areas with snow in winter. Frozen ground without snow is an important predictor of its presence (Keyser et al. 2022). Winter habitat is similar to that used at other times of the year. Birds typically remain on the territories they established in autumn throughout the winter. In Tennessee, there was considerable wandering by wintering birds during January and February. Three birds moved 4.8 km away during winter and one returned. In Florida, winter birds may wander from the territory, presumably as pairs, and return in 1-4 weeks, but this behaviour was not documented in Pennsylvania or Maryland (Farnsworth et al. 2020; Graber et al. 1970; Laskey 1935).

The winter territory is established around food resources, particularly fruit. Although food resources decline through the winter, birds are usually able to remain at the same site all winter. Three territories in New York were 0.35, 0.89, and 1.65 ha. Despite the disparities in size, the territories had similar numbers of rose bushes (68-80), area covered by fruit bushes (460-495 m^2), and fruit bush surface area (1,100-1,600 m^2). Birds appeared to assess the amount of food resources to determine the required territory size, with most territories containing a similar amount of food resources regardless of the territory size. The size of territories changed over winter, but there was no consistent pattern of increase or decrease in size. Territory size fluctuations appeared to be unrelated to food supply. The initial size of 5 territories was 0.35-1.65 ha (Safina and Utter 1989). Logan (1987) noted changes in winter territory sizes in North Carolina. Over 2 years, December territory sizes averaged 0.24 ha both years (range 0.09-0.56 ha). December territories were 49.1% the size of September territories and 64.3% the size of October territories. Territory size increased in January to the size they were in early autumn. Changes in territory size were highly irregular. In 1 year, all territories shrunk in December. In another year, some decreased, some did not change, and others increased. The consistent decrease in territory size occurred only in the colder year. Smaller territories may minimize energy expenditure because less activity is necessary to patrol the territory. Michener and Michener (1935) also noted that winter territories were smaller and fluctuated in size. The smaller size might be due to withdrawal to areas with the greatest food supply or due to giving up some of the territory to the female. Winter territories of 4 females were 0.25 ha, later reduced to 0.19 ha; 0.03 ha, later increased to 0.10 ha; 0.06 ha, later increased to 0.25 ha; and 0.03 ha. Territories may have been smaller because the authors provided abundant food to the mockingbirds. In Florida, winter territories averaged 0.31 ha November to January (range 0.08-0.59 ha). Territory sizes increased slowly to 0.37 ha (range 0.14-0.55 ha) by mid-March and 0.74 ha (range 0.15-2.61 ha) by the end of March (Farnsworth et al. 2020). In Tennessee, 1 male had a feeding range about 300 m long (Laskey 1936).

Fruit of the multiflora rose is one of the most favoured winter foods of the mockingbird. In the GTA, presence of multiflora rose was one of the best predictors for finding mockingbirds, but only 12% of territories contained this plant. In Nova Scotia, 1 in about every 25 multiflora rose clumps contained a mockingbird in winter. The northward range expansion of the Northern Mockingbird has largely been attributed to planting of multiflora rose. It maintains a slight positive energy balance when feeding on multiflora rose. Without this fruit in winter, it is unlikely that it could maintain a positive energy balance. There is evidence that it moves away from residential areas

without roses in mid-winter (Castrale and Donaldson 1986; David et al. 1990; Farnsworth et al. 2020; Graber et al. 1970; Smith and Poon 2006; Stiles 1982).

In Ontario, the mockingbird rarely visits winter feeders and relies mostly on natural foods, but many of these are nonnative species. It has fed on multiflora rose hips, sumac seeds, frozen apples still on the tree, fallen pears, and Boston ivy berries. It may also take scraps from dumpsters (Sheppard et al. 1936; Smith and Poon 2006). One near Branchton spent many mornings over a 3-week period in a small roadside common buckthorn eating the berries until they were depleted (personal observation). In Boston, Whittle (1922) observed a female feeding on the ground under a hickory tree and presumed that it was eating the nuts. Important fruits were those of pokeweed, juneberry, hophornbeam, barberry, holly, guelder-rose, and crabapple. Other fruits reported in the diet are hawthorns, figs, plums, elderberries, red cedar, mountain-ash, hackberry, Japanese honeysuckle, and viburnums. Of 1,845 food items eaten by a single bird, all were fruit: 31.5% multiflora rose, 65.6% sumac, 2.4% Japanese honeysuckle, 0.4% viburnums, and 0.1% red cedar. By dry weight, it ate 72.9% rose and 19.8% sumac with 66.6% of calories obtained from rose and 26.3% from sumac. A second bird ate 76.4% rose, 86.7% of the calories consumed. Fecal pellets from a third bird contained 547 rose seeds, 65 Japanese honeysuckle seeds, and 2 red cedar seeds, with rose representing 89.1% of the diet (Laskey 1962; Leighton et al. 2002; Stiles 1982; Wright 1921).

The mockingbird visits about half the feeders within its range. Nearly twice as many feeders are visited in urban and suburban areas as in rural areas. Most feeders are visited in the coldest months. Favourite feeder foods are peanut butter mixes, fresh and dried fruit, bird puddings, and water. Infrequent choices are mixed seeds, all kinds of sunflowers, hulled peanuts, pet food, suet, baked goods, and sugar water (Dunn and Tessaglia-Hymes 1999). In the GTA, it has eaten suet, raisins, chopped grapes, chopped apples, and rarely seeds. Other items consumed at feeders are apples, holly berries from a wreath, asparagus berries, bittersweet berries, and cherries. Usually only 1 bird visits a feeder at once, although there may occasionally be 2 or 3. Adults are dominant over juveniles, so fewer of them attend feeders (Doughty 1988; Dunn and Tessaglia-Hymes 1999; Graber et al. 1970; Laskey 1936; Michener 1951; Michener and Michener 1935; Smith and Poon 2006).

The mockingbird is restricted in winter to areas that have an average minimum January temperature of at least −7°C. All areas of higher concentration have average minimum January temperatures of at least −1°C (Root 1988). In Ontario and British Columbia, it withstands colder temperatures than these (Campbell et al. 1997; Smith and Poon 2006).

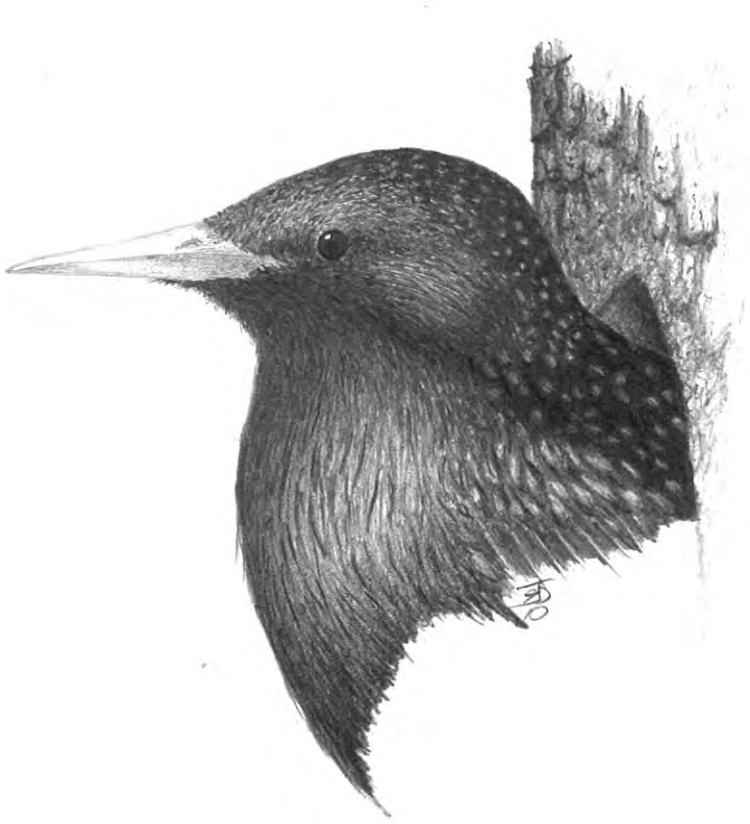
Severe winter weather may cause significant mortality of the mockingbird, particularly of juveniles that are unable to secure a winter territory. This may also be true of northern migratory birds that have to compete for food resources with southern resident birds in winter. Some birds that wintered in Niagara Region in the 1960s disappeared after a severe ice storm in mid-January. On the Ozarks Plateau, severe winter weather was a factor affecting its winter occurrence; it was adversely affected by severe storms in the mid- to late 1970s. After severe winter weather in Illinois, birds shifted to residential habitat where they survived because of feeders and shrub plantings. The density of birds per km² in urban residential areas was 3.25 before the storm and 27.75 afterwards (Farnsworth et al. 2020; Graber and Graber 1979; Smith 1986b; Smith and Poon 2006).

Wintering birds first appeared in the province much later than breeding birds. The first record of wintering was in London during the winter of 1922-23, 2 overwintered in Hamilton 1927-28, and the first Niagara record of overwintering was in 1931-32. The first record on the Hamilton Christmas Bird Count (CBC) was in 1941, but the mockingbird was not recorded consistently on this count until 1965. On the Peel-Halton CBC, there was an initial increase starting around 1990 and more substantial increases around 1995 and around 1997-98 for the Toronto count. An increase was not noticed in Richmond Hill, Kleinburg, and Oshawa until the 2000s (Curry 2006; Sheppard et al. 1936; Smith and Poon 2006). The mockingbird is still a rare winter resident in Ontario. Smith and Poon (2006) estimated the winter population in the GTA at 120 birds, 25% of the breeding population.

CBC data for Ontario for 1970-2021 indicate that the Northern Mockingbird increased at an annual rate of more than 3.15%. The trend 2009-21 was an annual decrease of 8.18% (National Audubon Society 2022).

European Starling

Sturnus vulgaris

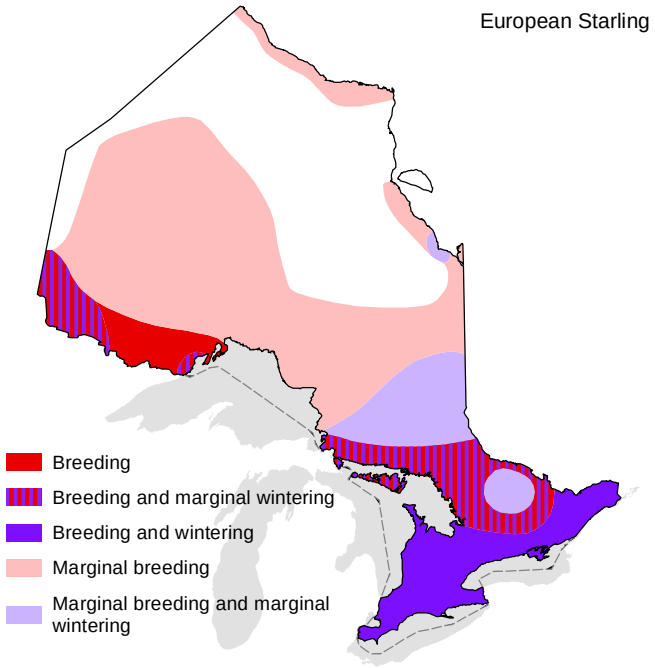


BREEDING SEASON

Habitat Requirements

In Ontario, the European Starling has nested in deciduous, mixed, and coniferous woods and swamps (30.1% of nests); in farmlands, including fields, pastures, orchards, and gravel pits (27.8%); in urban and rural populated areas, including gardens, streets, cottage areas, campgrounds, cemeteries, and golf courses (22.0%); along roadsides, floodplains, shorelines, and edges of canals (10.7%); in beaver ponds, marshes, wet meadows, and muskeg and bog areas (6.5%); on sand dunes and banks (1.9%); and on cliffs (0.9%). One nest was in a building in dry tundra. Dry areas were used more frequently than wet areas. The number of sites in wet areas was indicative of the presence of dead trees for nesting (Peck and James 1987).

The pattern of colonization in Ontario and other areas gives an indication of the starling's habitat preferences. Urban areas and towns were settled first. In many areas, its distribution is still strongly linked to areas of human concentrations. In the Hudson Bay Lowland and Boreal Forest Region, it is primarily restricted to human settlements and structures. In extensively forested areas, it may occur along highways but avoids forests (Baillie and Hope 1943; Campbell et al. 1997; Cotter et al. in



Gauthier and Aubry 1996; Graber and Graber 1963; James 1980; Kalinowski and Johnson 2010; Kalmbach and Gabrielson 1921; Lumsden 1980; Smith 1957; Wilson and McRae 1993). The second area inhabited was rural villages and farms where it nested primarily in cavities in houses, barns, and other structures. In rural areas, larger river valleys and lowland areas were populated first. Next it moved into smaller woodlots where it nested in trees with natural cavities or woodpecker holes. The last areas inhabited were isolated towns and human-made structures in extensively forested and tundra habitats, major highway corridors through extensive forests, and clear-cuts and burns with residual snags. A key habitat component is presence of extensive areas of short grass for foraging such as lawns, hayfields, old fields and meadows, and pastures. For grasslands to be suitable there must be nearby cavities for nesting. It avoids large expanses of non-grassland habitat such as extensively forested areas, muskegs, and areas north of the treeline. Highest densities occur in urban and agricultural areas (Baillie and Hope 1943; Cabe 2020; Campbell et al. 1997; Cramner-Byng 1990; Erskine 1977; Kalinowski and Johnson 2010; Kalmbach and Gabrielson 1921; Peck 1972; Schueler et al. 1974).

In Timiskaming District, Lumsden (1980) studied the distance from mowed or agricultural land that starlings nested in boxes designed for Common Goldeneyes. The furthest it nested from a cleared area was 503 m. This may be the maximum distance that it is able to carry enough food to nourish a brood. The percentages of available nest boxes used at different distances from suitable open habitat were: 0-100m, 84.6%; 100-200 m, 91.7%; 200-300 m, 69.2%; 300-400 m, 53.3%; 400-500 m, 53.8%; 500-600 m, 10.0%; 600-700 m and 700-2,000 m, 0%. In Muskoka and Parry Sound districts, it occasionally nests in trees in beaver ponds (Mills 1981). In wooded tracts in Durham Region, it was associated mostly with stands with open canopies. Highest densities occurred in woodlots that contained old beech trees, which were favoured nest sites (Speirs and Orenstein 1975).

In southern Ontario, there was no difference in the starling's abundance on organic and conventional farms. Its presence was significantly associated with farmsteads. It was negatively correlated with spring grain, pasture, and hay, although only the latter relationship was significant (Kirk et al. 2011).

In Quebec, the starling nests in cliffs exposed to sea spray along the Gaspé coast (Cotter et al. in Gauthier and Aubry 1996). In Wisconsin, it is a rare breeder in pine and oak barrens (Hoffman et al. 1991). In Iowa riparian areas, it was most abundant in floodplain woodlands followed by savannah, scrub, upland woodland, and wooded edge (Stauffer and Best 1980). In British Columbia, the most

frequently selected nesting habitats were associated with human settlement (50%), forest (38%), and grassland. Within broad habitat types, 54% of nests were in rural, suburban, or urban settings; 18% were in woodlands; and in grasslands (Campbell et al. 1997). In most areas, it reaches higher densities in urban than agricultural areas. Near Saskatoon, it has become a rural species with few, if any, occurring within the city (Leighton et al. 2002). In California, it was most abundant in oak savannahs with grass cover, intermediate in abundance in oak woodlands, and least abundant in oak savannahs with shrub cover and montane hardwoods (Wood et al. 2013).

At the landscape level, the European Starling preferred areas that were 10-29% forested in North Dakota (Cunningham and Johnson 2019).

Although the starling may occur in shrubby openings and disturbed areas in the interior of large forests, it occurs predominantly at edges of small woodlots when it uses forested habitat. Small, open-canopied tracts and edges are preferred for nesting and most nests are within 15 m of edge. In many areas, even edges of extensive forests are avoided. In South Dakota, densities were 2.7-7.0 times greater in small, isolated woodlots than in large, contiguous, riparian forests. In the mid-Atlantic states, its abundance was significantly negatively correlated with woodland size. Its probability of detection was 62% in 0.3-ha woodlots, 50% in 1-ha woodlots, 35% in 3.2-ha woodlots, 25% in 10-ha woodlots, 15% in 32.0-ha woodlots, and 10% in 100-ha woodlands with a gradual decline to 1-2% in 3,200-ha woodlands. In Maryland and Delaware, its probability of detection declined significantly with width of riparian forests. Probability of detection was 50% in 50-m wide forests, 49% in 100-m wide, 37% in 200-m wide, 26% in 300-m wide, and 2% in 800-m wide forests. In the mid-Atlantic states, its abundance was positively associated with moisture gradient, foliage density between 2 and 3 m, the number of trees larger than 3 cm diameter at breast height (DBH), and the number of tree species at the counting point. In Colorado floodplain forests, it was associated with areas with a high density of trees with a large DBH. In Durham Region, it was considered a late-successional species; in northern hardwoods in the northeast, it occurred most frequently in mature stands. Its association with large trees and older stands is due to its requirement for cavities for nesting (Aitken et al. 2002; Gentry et al. 2006; Keller et al. 1993; Mossman and Hoffman 1989; Noon et al. 1979; Robbins et al. 1979; Sedgwick and Knopf 1990; Speirs and Orenstein 1975).

All but 2 Ontario nests were in elevated holes or recesses. One nest was in a broken limb on the ground and another was in a wooden cable spool on the ground. Of 1,546 nests, 62.9% were in trees, stubs, and stumps; 36.0% were in bird boxes; 27.3% were in buildings; 18.8% were in fence posts; 8.7% were in mail boxes; 6.3% were in utility and flag poles and pipes; 1.4% were in miscellaneous human-made objects; 1.0% were in cliffs and banks; 0.5% were in bridges and dams; and 0.2% were in raptor nests. Both living (58.3% of nests) and dead (41.7%) trees were used for nesting. Deciduous trees (21 species, 91.8% of nests) were preferred to conifers (5 species, 8.2% of nests). Tree species used most often were elm (26.3% of nests), maple (25.4%), apple (16.7%), birch (12.3%), willow (10.0%), and poplar (9.3%). Most tree nests were in natural cavities or new or old woodpecker cavities. Nests were both inside and outside buildings. They were in human-made structures such as signs, radiators, gas tanks, pumps, air vents, air conditioners, and an aircraft. One nest was in a boiler tank that was half submerged in a lake. Three nests were in Bank Swallow tunnels. Single nests were reported in each of the sides of Red-tailed Hawk, Osprey, and Bald Eagle nests.

Nest sites were often reused; 1 tree cavity site was used in 17 of 20 years. Nests in trees were 0.3-23 m from the ground, with most 2.4-6 m up. Nests in buildings were 1.2-18 m from the ground, with most 2.7-6 m up. A nest in a sandbank tunnel was 30 m from the ground (Peck and James 1987).

Nest cavities tend to be in trees that are larger than average in the habitat that is being used. In New Jersey, the starling nested almost exclusively in 50-100-year-old silver maples that lined city streets. Only once the number of trees declined did birds start nesting in buildings. Tree cavities are preferred to those in buildings when they are available. Cavities used by starlings are similar to those used by the Northern Flicker, Red-headed Woodpecker, Red-bellied Woodpecker, and Great Crested Flycatcher, probably due in part because many nest cavities are usurped from the 3 woodpecker species (Campbell et al. 1997; Hutto and Gallo 2006; Sedgwick and Knopf 1990; Stauffer and Best 1980, 1982; Suthers 1978). Near Kingston, it exhibited no preference for orientation of cavity entrances (Rendell and Robertson 1994a). It shows a decided preference for nesting in deciduous trees and prefers cavities in branches to those in tree trunks. In some areas, it nested mostly in living trees and in other areas mostly in dead trees. When using woodpecker cavities, it has a strong preference for cavities that still have bark around the entrance and that face downward, thereby minimizing water flow into the cavity and giving the nesting bird an advantage when facing potential competitors or predators. Nest cavities in trees are usually 3-7.6 m from the ground. In British Columbia, height of nests not in nest boxes ranged from the ground to 75 m, with most 2.1-6.0 m up. Cavities in open areas are required. Along the British Columbia coast, it nests in natural cavities and woodpecker holes in pilings, often over water. It also nests in cavities in telephone poles, concrete power poles, and fence posts (Aitken et al. 2002; Bent 1950; Cabe 2020; Campbell et al. 1997; Erskine and McLaren 1976; Hutto and Gallo 2006; Ingold 1989; Kalmbach and Gabrielson 1921; Sedgwick and Knopf 1990; Stouffer and Best 1980).

The starling readily uses nest boxes and appropriates boxes designed for bluebirds, Tree Swallows, Purple Martins, American Kestrels, and waterfowl (Wood Duck, Bufflehead, Common Goldeneye, and Hooded Merganser). Gibo et al. (1976) provided nest boxes for starlings in 7 different habitats in Mississauga: in an arboretum, old field, orchard, pine stand, oak-maple stand, and on poles in the centre of an old field. The pine and oak-maple stands did not contain any grassy areas suitable for foraging but there were lawns and fields within 100 m. The seventh habitat was a suburban area. Boxes in the centre of an old field were preferred and the arboretum had fewer nests than expected. Boxes in the centre of the old field had the highest survival rate, so starlings may have been selecting nest sites that were less likely to suffer predation. In Kentucky, it preferred boxes affixed to isolated trees or poles or located on edges of isolated, small, wooded areas within pastures. It tended to avoid boxes on edges of larger wooded areas and dense overgrown hedgerows. It was also less likely to use nest boxes associated with cropland such as corn or wheat (Twedt and Oddo 1984). It cannot access boxes designed for bluebirds or Tree Swallows that have a circular diameter smaller than 3.8 cm (Bent 1950; Davis et al. 1986; McComb et al. 1987). The starling preferred wooden Purple Martin houses (1.8% occupancy rate) over aluminum houses (0.3%; Jackson and Tate 1974). In boxes designed for kestrels and goldeneyes, it showed a strong preference for boxes measuring 33 cm from the bottom of the entrance hole to the floor of the box over those measuring 24.5 cm or 18 cm. Goldeneye boxes with 6.3 cm entrances were used; those with 12.5 cm entrances were

avoided. In another study, 3 entrance-hole sizes were available in goldeneye boxes: 13 by 10 cm, 10.5 by 8 cm, and 7.5 by 6 cm. Of 42 pairs of starlings, 35 chose the smaller entrance hole, 7 the medium-sized hole, and 0 the large entrance. Starlings showed a strong preference for boxes painted black inside. The cavity entrances in kestrel and duck boxes are much larger than what the starling prefers, which may partially explain its preference for deep boxes with black interiors (Erskine and McLaren 1976; Lumsden 1976, 1986).

The starling nests on or in a variety of human-made structures, especially buildings. Savard and Falls (1981) studied its nesting preferences in several Toronto neighbourhoods. Although it occasionally nested in trees, most nests were in crevices and holes in buildings. Openings around eaves and eavestroughs accounted for 79% of nest sites. In Don Mills, vent holes between bricks of the attic provided 75% of nest sites and the remainder were around eaves and eavestroughs. Two pairs nested in dryer vent holes and had to lift up the small door closing the vent to access their nests. Nests averaged 6.83 m above ground in areas with 2-storey homes and 4.15 m in plots with 1-storey houses. The overall average nest height was 6.92 m. Nesting occurred more often in areas with 2-storey houses which may have been a reflection of more nest sites. It may prefer higher nest sites and preferred to nest at greater heights than the House Sparrow. The starling preferred to nest in buildings in Vancouver. Two nests were in tree cavities, 1 was in a nest box, and 62 were in buildings. The mean height of nests was 6.2 m with most nests in 2-storey buildings and apartment buildings rather than 1-storey buildings (Weber 1975). Nests have been found in chimneys, church steeples, silos, grain elevators, oil drums, posts, poles, holes in haystacks, cavities among rocks or piles of stones, and cliffs and earthen banks (Bent 1950; Campbell et al. 1997; Feare 1984). Several starlings nested in a Bank Swallow colony in a Maryland gravel pit (Robbins 1985).

Unusual nest sites include in old magpie nests, on fire escapes, hay tracks, barn doors, and in open boxes erected for pigeons. The starling occasionally nests on the ground when no elevated sites are available in sites such as old rabbit holes, under loose stones along shores, in cracks in the ground, in heaps of stones, in an indentation in an area of sloping ground, and in old tins and boxes in rubbish heaps. It rarely nests in the open outside a cavity in conifers, dense clumps of bushes, or in ivy (Kalmbach and Gabrielson 1921; Kessel 1957).

The starling defends only a small area around the nesting cavity. The territory may be limited to the nesting hole itself, but usually includes a 25-50 cm radius about the hole. Very early in the nesting season, a radius of 10 m around the nest site may be defended. Prior to egg laying, defence of the nesting cavity is intense, with many battles occurring. These may be severe, even resulting in the death of a combatant. Early in the breeding season, it may oust Northern Flickers and Eastern Bluebirds from their nesting cavities and even kill them. Once territorial boundaries are settled, aggression declines. Nest boxes with 10 compartments were never occupied by more than 1 pair, suggesting territoriality. Nonetheless, starlings may nest close to each other, with 30 pairs reported nesting in a church steeple, as many as 9 nests in a single silver maple tree, and 5 in a willow tree. Away from the nest cavity, starlings are very gregarious. Males may share singing perches distant from the nest, feeding areas are undefended, and it spends most of its time within flocks or at communal roosts (Bent 1950; Chapman 1925; Feare 1984; Gutzwiller and Anderson 1986b; Kessel 1957; Peck and James 1987; Suthers 1978).

The starling maintains a small home range immediately prior to nesting through incubation, but expands it during the nestling period. Early in the nesting period, the male remains within 100 m of the nest, decreasing to less than 60 m during laying and only 30 m during incubation. The female usually starts with a home-range radius of more than 100 m. Although the female's range contracts somewhat, it continues to remain larger than that of the male (Dunnet 1955; Fischl and Caccamise 1985; Kessel 1957).

Of 1,111 nestlings at Ithaca, New York, 33 (3.0%) returned: 21 at Ithaca (1.9% of the number banded) and 10 more than 32 km away. A few returned to the natal area to breed, but most did not. Birds have been found breeding 320-400 km from their natal site. In New Jersey, 10 of 78 young (12.8%) returned to the natal area. An analysis of banding recoveries in the Great Lakes region revealed that 30% of hatching-year birds were recovered in subsequent breeding seasons more than 50 km from their natal site and about 12% dispersed more than 200 km. Most remained within 130 km of the nest site until November when migration began. The mean recovery distance for hatching-year birds was 80 km, significantly more than for adult birds (Cabe 2020; Dolbeer 1982; Dunnet 1955; Kessel 1953a; Suthers 1978).

Once an adult breeds, it tends to remain in the same general area to breed for the remainder of its life. In New York, 22 of 68 females (32.4%) nested in the same nest box in consecutive years. Sixty-three (92.6%) moved less than 0.8 km from their previous nest site; only 5 (7.4%) moved more than 0.8 km (range 1.6-4.0 km). One female used the same box in 4 consecutive years and another did so for 3 years. Another female shifted her nesting site about 0.5 km between each of 4 consecutive nesting seasons. Approximately half the breeding females of 1 season returned the next year. The annual mortality rate is approximately 50%, so it is likely that all living females returned. In New Jersey, 0 of 558 adult birds banded outside a town moved into the town to breed. In a breeding colony isolated 3 km from the nearest breeding starlings, 60-70% of the breeding adults in any given year were immigrants. Banding recoveries of adults in the Great Lakes area demonstrated that the mean distance between banding and recovery sites was 15 km for males and 10 km for females. This indicated that adults usually return to near their previous nesting site (Cabe 2020; Dolbeer 1982; Kessel 1953a, 1957; Suthers 1978).

Limiting Factors

Eggs have been found in Ontario nests from the second week of March until mid-July, with most present in the last 3 weeks of May (Peck and James 1987). In Algonquin Park, eggs occur from mid- to late May, nestlings are present from late May to late June, and dependent fledglings have been observed from mid-June to late July (Tozer 2012). Lougheed and Graham (1985) found a nest at Long Point that contained young on 10 March and estimated an egg date of 24 February.

Resident males begin prospecting for nest cavities in August of the previous breeding season and may roost in them over winter to defend the cavity. In February, both sexes, but particularly males, start visiting cavities to inspect them (Kessel 1957; Stewart 1976). The male identifies a number of suitable nesting sites, but the female ultimately selects the one that is used for nesting. The first nest of the season is built very leisurely. In New York, nest building begins during the third week of March but egg laying does not begin until mid-April. Nest building begins in earnest about a week before egg laying commences. Many nests are built within 2-3 days of egg laying and a nest

can be built in a day. One female built a nest in a mail box and laid an egg in it every day, the previous day's nest and egg having been removed (Cabe 2020; Clark and Mason 1985; Kessel 1957; Soulliere and Rusch 1996; Twedt and Oddo 1984). Egg laying may not be initiated for a few weeks after the nest is complete, but mostly soon after nest completion. Within a given area, egg laying for the first brood is highly synchronized, with all females initiating egg laying within a 3-4 day period. Temperature appears to be the primary factor determining when egg laying starts. In Guelph, egg laying started with a minimum of 11 days (range 11-16 days) of mean temperatures of 4.4ºC or higher. In New York, laying did not begin until mean temperatures had been above 4.4ºC for at least 17 days and remained above this temperature consistently for at least 12 days. In Kentucky, egg laying started after 12-20 consecutive days with a mean daily temperature higher than 4.5ºC. In British Columbia, the onset of egg laying was positively correlated with long-term temperatures between January and March. Photoperiod affects gonadal development and egg laying does not start in the north until there are 13 or more hours of daylight. Because temperature is a key factor in determining timing of egg laying, there is considerable annual variation. At Ithaca, dates of first eggs differed by as much as 19 days over 7 years (Collins and de Vos 1966; Dunnet 1955; Erskine and McLaren 1976; Feare 1984; Källander and Karlson 1993; Kessel 1957; Twedt and Oddo 1984). One egg is laid a day; rarely a day is missed. Females laying 5-egg clutches incubated 11.2% of the time on day 1 and began continuous incubation on day 3; those laying 4-egg clutches incubated 27.6% of the time on the first day and continuously on the third day (Kessel 1957; Meijer 1990, 1993; Romagnano et al. 1990; Stouffer and Power 1990; Wright and Cuthill 1992). The incubation period is typically 12-13 days. More variable incubation periods of 10-15 days have been reported in Ontario, with most eggs hatching in 11-13 days. Incubation periods of 10-13 days have been reported in British Columbia. Because of the variable onset of incubation, hatching may be asynchronous, especially in larger clutches, and may take place over 2 days. Often the last-born nestling dies of starvation; the brood size frequently averages 1 less than clutch size. Nestlings typically leave the nest when they are 21 days old, but some remain in the nest another day or 2 after the first young fledge. The range of ages when young may leave the nest is 19-25 days (Brown 1951; Cabe 2020; Campbell et al. 1997; Dunnet 1955; Kalmbach and Gabrielson 1921; Kessel 1957; Meijer 1990; Peck and James 1987; Ricklefs and Smeraski 1983; Stouffer and Power 1990). In British Columbia, a complete nesting cycle from lining of the nest to fledging took 41 days (Erskine and McLaren 1976). Adults that attempt to raise a second brood may start bringing new nesting material to the old nest as soon as a day after the first brood has fledged. First eggs of the second brood have been laid 1-2 days after the first young leave the nest, but 6-10 days is more typical. Egg laying for the second brood is not as synchronized as that for the first brood; 37-50 days may elapse between the laying of the first egg in the first and second clutches. Over 3 years, the intervals between the first egg in the first and second clutches were 46, 44, and 42 days at Guelph (Brown 1951; Collins and de Vos 1966; Dunnet 1955; Kessel 1953b, 1957; Stouffer 1991; Twedt and Oddo 1984; Yom-tov et al. 1974).

Double broods have not been reported north of latitude 48ºN, but are typical further south. To successfully rear 2 broods, a female must initiate nesting early during the first synchronized egg-laying period. The incidence of double clutches ranges from 0% to 70% of females in a given population, but 60-93% of females that successfully raise a first brood attempt a second; a rate of 92% was reported from Guelph. The percentage of females raising second broods varies annually in

a given area depending upon how soon suitable temperatures for initiation of egg laying occurs, weather (with few or no double broods during droughts), and food availability. In British Columbia, 38% of females attempted a second brood; 20% successfully reared a second brood. It has been suggested that 3 broods may occasionally occur, but the breeding season is generally too short to raise a third brood and females appear to be physically incapable of doing so. Renesting is common if a clutch is lost, usually within 2 weeks. The occurrence of second broods produces a bimodal egg-date curve. The late peak is a combination of birds that are raising their second brood and those nesting for the first time in the season. A small proportion of clutches are laid between the 2 main peaks, termed intermediate clutches. These are a combination of replacement clutches, clutches of additional broods of polygynous males, and late first clutches (Brackbill 1949; Cabe 2020; Campbell et al. 1997; Collins and de Vos 1966; Cornell and Williams 2016; Dunnet 1955; Erskine and McLaren 1976; Kalmbach and Gabrielson 1921; Kessel 1953b, 1957; Peck and James 1987; Pinxten et al. 1990, 1991a; Stouffer 1991; Twedt and Oddo 1984). Clutches of 2-10 eggs have been reported in Ontario with most containing 4 or 5 eggs; 1 nest contained 9 young (Peck and James 1987). At Guelph, first clutches averaged 5.6 eggs and second clutches averaged 5.0 eggs. Sixty-five percent of females laid smaller second clutches, 22% laid clutches of the same size, and 13% laid larger second clutches. Intermediate clutches averaged 5.2 eggs. The modal clutch size was 6 for first clutches and 5 for second clutches. First clutches of adults were larger (5.6 eggs) than those of yearlings (5.1 eggs), but there was no difference in size of second clutches (5.0 for adults and 5.1 for yearlings). The mean clutch size in Ontario is 5.10 compared with 5.15 eggs in eastern North America (Collins and deVos 1966). Overall, the typical clutch size is 3-6 eggs but clutches of 7 and 8 occur regularly, with overall clutch sizes of 1-11 eggs reported. In New York, 6 was the modal clutch size for first clutches with 5 eggs the second-most frequent; 4 eggs was the modal size for second clutches with 3 eggs a close second. Average clutch size of yearlings was 5.1 eggs compared with 5.6 eggs for adults. Clutch size typically declines with the season, but second clutches that are larger than first clutches occasionally occur. Six appears to be the optimum clutch size, with clutches of this size producing the most fledglings. Larger clutches produce fewer young due to problems incubating larger clutches or feeding more young. Increased brood size reduces the probability that the youngest chick will survive, with brood mortality higher in broods of 6 or 7 than in broods of 5. In New Jersey, mortality of nestlings from last-laid eggs accounted for 55% of all brood reduction. Mortality of these nestlings increased from less than 27% in broods of 3 and 4 to more than 75% in broods of 5 and 6 (Bent 1950; Cabe 2020; Dunnet 1955; Erskine and McLaren 1976; Kalmbach and Gabrielson 1921; Kessel 1957; Meijer 1990; Power et al. 1989; Stouffer 1991; Stouffer and Power 1990, 1991a; Twedt and Oddo 1984; Wright and Cuthill 1992; Yom-tov et al. 1974).

At least some birds breed in their first year, but more females than males breed as yearlings. Some first-year males are not physiologically capable of breeding. At Guelph, 13% of 295 breeding females were yearlings. The sex ratio is male biased, which may make it difficult for yearling males to defend a nest cavity and attract a mate. The proportion of yearling females breeding varies annually with the highest reported rate of 66% occurring in colonies that were newly created by installing nest boxes. Competition with older birds may be an important determinant of the number of yearlings that breed. At Guelph, 8 of 20 yearling females (40%) attempted second broods and 5 were successful. Populations typically contain large numbers of nonbreeding yearling males, but

also nonbreeding yearling females and adults of both sexes. This is due to a scarcity of suitable nest cavities (Cabe 2020; Clobert et al. 1987; Collins and de Vos 1996; Dunnet 1955; Kessel 1953b, 1957; Pinxten et al. 1990; Sandell and Smith 1997; Stewart 1976).

The mating system is predominantly monogamous, with the male assisting in incubation and care of the young. Polygyny occurs either irregularly or regularly. Most cases of polygyny were in populations nesting in boxes where nest sites were common. Males may defend as many as 10 nest boxes, usually within 50 m of the nest of the primary female. Males attempt to attract additional females while the primary female is in the nest-building or egg-laying phases. Some males have as many as 5 female mates. They may continue to attract new mates through the incubation and nestling phases. Although most polygyny occurs sequentially, it occasionally occurs simultaneously. Cases of 2 females mated to the same male nesting in the same box and sharing incubation and rearing duties have occurred even though there were adjacent unoccupied boxes. Males assist the primary female the most in raising young and may not help subsequent mates. In an attempt to avoid males becoming polygynous, females are aggressive toward other females and solicit copulations more frequently while the male is singing at other cavities. Mates may or may not be retained throughout the breeding season. Pairs rarely remain mated for more than 1 season. If a female loses her mate, she is capable of raising the brood on her own. If she is successful in remating, the new male may remove the existing eggs and start his own clutch with the female. Males that lose their mates usually abandon the nest. Because males do not incubate or brood at night, they are incapable of successfully hatching eggs and unlikely to fledge young, although some males successfully raised broods during periods of warm nights. If the male attracts a new female to the same nesting cavity, existing eggs are destroyed or buried by new nest material (Eens and Pinxten 1995a, 1995b; Feare 1984; Kessel 1950, 1957; Pinxten and Eens 1994; Pinxten et al. 1989a, 1989b, 1994; Sandell and Smith 1997; Smith et al. 1996; Stouffer et al. 1988; Wright and Cuthill 1992). Extra-pair copulations are rare, with 2.1-8.7% of young in New Jersey and Sweden populations not being related to their behavioural father. All occurred in second clutches, which are not as closely attended by males as first clutches. Males attempt to avoid cuckoldry by closely guarding their female during their fertile period, from 4 days prior to laying until the second day of the laying period (Hoffenberg et al. 1988; Pinxten and Eens 1997; Pinxten et al. 1987; Power et al. 1981; Smith and von Schantz 1993).

Intraspecific nest parasitism occurs. Males guard their females away from the nest, leaving the nest vulnerable to intraspecific brood parasitism. Most parasitic females are those that have lost a nest or did not originally have a nest. Many parasitic females subsequently lay and care for a clutch of their own. Parasitic eggs laid before the host has started laying are ejected, but those laid during the host's laying period are accepted. Some parasitic females may remove one of the host's eggs. Most parasitism occurs in first clutches although a few intermediate clutches may be parasitized; parasitism of late clutches is rare. Starting incubation with the laying of the third egg reduces the effectiveness of parasitism. Parasitic eggs laid once incubation starts may hatch late with the young having no chance of fledging. Parasitism increases clutch size but does not increase the number of fledglings produced. The number of young fledged may be lower than that of unparasitized nests. This occurs when parasitism results in the creation of a superclutch that the adults are unable to

care for adequately. Some females lay smaller clutches than the optimum size to account for parasitic eggs. In New Jersey, parasitism caused a 16% reduction in the number of host fledglings but did not reduce the number of nests that produced at least 1 host fledgling, suggesting that parasitism costs were minor. The rate of nest parasitism ranges from 0 to 46% in different populations. The rate does not appear to be related to the proportion of nest sites that are occupied unless they are all occupied (Cabe 2020; Hoffenberg et al. 1988; Kessel 1957; Lombardo et al. 1989a; Pinxten et al. 1991a, 1991b; Power et al. 1989; Romagnano et al. 1990; Stouffer and Power 1991b; Stouffer et al. 1987; Yom-tov et al. 1974).

When feeding nestlings, the adults of a pair may fly to different feeding areas. Feeding areas may be adjacent to the nesting areas or as far as 1.6 km away. Usually the same flight paths are used daily. Areas of apparently suitable habitat may be flown over to reach the preferred feeding area. During the breeding season, birds occasionally forage singly, but mostly in small flocks. In autumn and winter, flocks forage in lines as a unit across fields by leap-frogging or in circles or arcs that move outward radially. Preferred feeding sites are areas with short grass, particularly lawns, grazed pastures, feedlots, and mown hayfields. It usually avoids tall grass. In Maryland, 60% of foraging was in vegetation 2.5 cm tall, 20% at 5 cm, 10% at 7.5 cm, and 7% in vegetation taller than 7.5 cm. In Oregon, numbers of foraging starlings decreased significantly once cattle-grazing was terminated. The increased shrub coverage degraded foraging habitat. In New Jersey, 95% of starlings foraged in 5 habitat types: urban-suburban, soybeans, corn, feedlots, and old fields. Highest numbers occurred in urban-suburban habitats. It obtains most of its food from the ground, typically by probing in the soil to a depth of 2.5 cm for invertebrates. During the breeding season, about 95% of food is obtained in this manner or by picking food from the ground. On rare occasions, it may open and close its wings very rapidly to startle insects. In the postbreeding season, the starling commonly hawks insects in the manner of a flycatcher. Less frequently, it may soar aerially at heights of 20-60 m to forage on flying insects. Some engaged in this activity were feeding on box elder bugs but most feed on flying ants. It associates with cattle, picking maggots from their dung. It may peck insects from the legs of cattle and ride on the backs and heads of cattle and deer, presumably feeding on insects. It may kleptoparasitize the American Robin by driving it away from earthworms that it has captured. In summer, it may feed on corn by puncturing the kernels, removing the milky contents and leaving the pericarps. In North Carolina and Virginia, it fed on larvae of corn earworms and fall armyworm moths without damaging the corn. It missed no ears containing larvae and opened no ears that were without larvae. It has captured monarch butterflies on the wing and eaten them. In Niagara vineyards, damage to grapes by starlings is greatest at the edges where they fly from adjacent overhead wires and trees a short distance to the top of the vines, remove a single grape, and return to the perch to eat it. In vineyards, 22-30% of grapes at the edge were damaged compared with 5-20% 30 m from edge and 0.5-2.5% at 70 m. In the first 30 m, bunches of grapes near the top of vines sustained 3-4.5 times more damage than those at the bottom. In California, it regularly feeds on nectar of the coral tree (Bernhardt et al. 1987; Brackbill 1952b; Brooks 1952; Cayouette 1947; Dunnet 1955; Earnst et al. 2012; Feare 1984, 1993; Hailman 1959; Hodges 1950; Kalmbach and Gabrielson 1921; Murphy 1981; Somers 2010; P.A. Stewart 1973; Suthers 1978; Tucker 1950; Van Tyne 1946; Williamson and Gray 1975; Ziraldo 2010).

During the first few days, the adults bring the nestlings small caterpillars, grubs, and other insects, with larger insects brought as the young increase in size (Brown 1951; Kessel 1957). Kalmbach and Gabrielson (1921) examined the diet of 325 nestlings. The diet of young 1-5 days old consisted of 2.4% ground beetles, 3.9% June beetles, 5.6% weevils, 14.0% orthopterans, 45.3% caterpillars, 1.5% millipedes, 23.4% spiders, and 0.2% cherries and miscellaneous material. From 6 to 10 days of age, nestlings ate 11.6% ground beetles, 18.3% June beetles, 4.5% weevils, 11.2% orthopterans, 34.9% caterpillars, 5.3% millipedes, 3.6% spiders, and 3.4% cherries. Nestlings older than 10 days ate 7.7% ground beetles, 18.3% June beetles, 1.0% weevils, 9.0% orthopterans, 37.8% caterpillars, 6.4% millipedes, 3.3% spiders, and 4.8% cherries. As the young grow older, there is a decline in consumption of soft and easily digested foods. Most spiders (8.6% of the diet) are consumed in the first few days. The overall diet of nestlings consisted of 95.1% animal food, with the most prevalent food being caterpillars, along with a few moths and cocoons. These formed 38.2% of the diet, with a large proportion being cutworms. Beetles comprised 30.0% of the diet (almost half of which were June beetle larvae), and 11.3% was orthopterans (mostly crickets). No other insect orders comprised as much as 1% of the diet, with ants and stink bugs being most prevalent among these. Millipedes totalled 4.4% of the nestling diet compared with 33.0% for adults. Cultivated cherries (3.2% of food) were the only vegetable matter of importance. Lindsey (1939) reported that the diet of 139 nestlings in New York consisted of 95% animal matter and 5% vegetation. Beetles and their larvae formed 46.9% of nestlings' food with adult and larval June beetles comprising 27.0% of the food. Caterpillars comprised about 25% of the food of nestlings and these were dominated by cutworms. Orthopterans were important in the diet of nestlings, with a single species of cricket comprising 2.6% of the food. The predominant bugs eaten by both adults and nestlings were stink bugs and these occurred in the diet year-round.

Chapman (1925) considered the starling beneficial based on its diet. It is an effective destroyer of insect pests such as cutworms, grasshoppers, and weevils. Kalmbach and Gabrielson (1921) concurred and noted that its greatest damage was to cherries. Damage to peaches and pears was rare and they considered damage to grapes and corn trivial. In Ontario, Fleming (1927) concluded that the starling was economically beneficial but cautioned that it had the potential to do serious harm to fruit crops if it became abundant. Of 12 bird species that visit vineyards in Niagara Region, only the robin and starling are abundant enough to pose economic threats, and most damage to grapes is done by starlings (Somers 2010). The starling also has the potential to damage corn crops.

Three studies (Fleming 1927; Kalmbach and Gabrielson 1921; Lindsey 1939) collectively analyzed the contents of 3,214 adult stomachs. The diet consisted of 47.9-58.6% animal matter and 41.4-52.1% vegetable matter. Animal food was most important in April and May, constituting more than 90% of the diet. From spring through early autumn, animal food comprised a minimum of 50% of the diet, with lowest consumption from late autumn through winter. Beetles were the most important animal food (19.6-22.4% of food items), especially the clover leaf weevil which was the most abundant insect consumed. It also ate scarab, rove, click, ground, darkling, Colorado potato, lady, pill, clown, and leaf beetles. Short-horned grasshoppers and crickets were important and comprised 5.7-12.4% of the diet. They were particularly prevalent in the diet in August and September. Millipedes constituted 3.3-14.2% of the diet and were about half the items consumed

in April and May. Lepidopterans represented 3.2-6.0% of the annual diet. These were mostly caterpillars but some adults were eaten. Other insects eaten included hymenopterans (mostly ants), bugs (mostly stink bugs), and green bottle flies. Spiders represented 0.5-1.5% of the diet; snails represented 0.9% of the diet in 1 study. Miscellaneous animal foods included isopods and salamanders. The starling commonly eats seeds of ragweed and yellow foxtail. Mast and various grass and weed seeds are eaten in insignificant amounts. The predominant vegetable foods are fruits and items taken from human garbage. Garbage is important in winter and may constitute 35-50% of the diet. It includes coffee grounds, orange seeds, beans, and parings of various vegetables and fruits. Wild fruits confirmed in the diet include mulberries, juneberries, blackberries, elderberries, chokecherry, black cherry, black gum, Virginia creeper, bayberry, staghorn sumac, poison ivy, roses, dogwoods, apples, viburnums, and buckthorns. Corn and other grains were unimportant in the diet and were considered to be waste. In Quebec, vegetation comprised less than 0.1% of the volume of the diet 10-19 May (all barley), 10.6% 14-29 July (4.8% cherries, 2.4% vetch, 1.9% grasses, 0.8% water parsnip, 0.7% field bindweed, 0.1% barley), and 9.3% 12 August to 16 September (3.1% cherries, 4.1% barley, 1.3% oats, 0.8% bindweed, and less than 0.1% grasses). Animal food constituted 100% of the diet 10-19 May, 79% 14-29 July, and 89.3% 12 August to 16 September. From 10 to 19 May, the diet consisted of 17.2% millipedes, 75.9% beetles, and 6.9% ants; from 14 to 29 July, 43.3% beetles, 10.2% ants, 10.2% millipedes, 7.5% snails, 2.6% bristle flies, 2.6% owlet moths, and 2.6% plant bugs; and from 12 August to 16 September, 41.4% beetles, 15.9% orthopterans, 12.8% flies, 9.8% ants and wasps, 3.2% aphids, and 3.2% other bugs (Potvin et al. 1976). Other plant species in the diet in New Jersey included pokeweed, clover, and wheat. During development of roosts, the starling focused on a few insect groups. During the decline of roosts from mid-July onwards, the contribution of insects to the diet decreased and remained low through the decline. As roosting populations approached their maximum, it fed increasingly on plant material, including both natural and agricultural foods (Fischl and Caccamise 1987). It favoured hackberry fruits in autumn (Cabe 2020). In an Illinois woodlot, the fruit eaten 1 year was 20% grapes and 80% Virginia creeper and 77% grapes and 23% Virginia creeper the next year. All frugivory occurred in forest gaps rather than forest interior (Malmborg and Willson 1988). Captive birds strongly and consistently preferred the fruit of invasive species to those of native species. Autumn olive was preferred over winterberry holly and multiflora rose was preferred over Carolina rose. Only when choosing between glossy buckthorn and highbush blueberry did it select the native species and eat some of both choices. Of the nonnative fruits, the starling preferred autumn olive over multiflora rose or Asiatic bittersweet. The starling may be a factor in the spread of these and other nonnative plant species (La Fleur et al. 2007). In Algonquin Park, the autumn diet includes berries of mountain holly and winterberry holly (Tozer 2012).

The starling is a rare host of the Brown-headed Cowbird, with no cases of parasitism reported from Ontario. The cowbird egg was accepted in both cases in 2 nests that were experimentally parasitized. A 1973 observation of starlings feeding cowbird fledglings was only the third known incident of parasitism at that time. The rarity of parasitism may be because the starling is a cavity nester that aggressively defends its nest (Cabe 2020; Kessel 1957; Peck and James 1987; Thomas 1973).

Considerable competition takes place for nesting cavities. The starling is usually successful in ousting Tree Swallows, Carolina and Northern House wrens, bluebirds, and chickadees. House Sparrows may successfully defend their nest sites against the starling but often the starling is victorious. The starling may occasionally usurp nests of the Rock Pigeon, Purple Martin, and Great Crested Flycatcher. The most intense competition is between starlings and woodpeckers. The Northern Flicker is most affected by starlings who take over many of its cavities and may remove eggs or even kill adults. The Red-bellied Woodpecker nests at the same time and the starling is usually successful in usurping their nest cavities, although there are records of Red-bellied Woodpeckers killing and removing starling nestlings and taking over the cavity. The Red-headed Woodpecker nests later than the starling, so there are fewer conflicts between these species. Starlings may commit infanticide at other starlings' nests, presumably in an attempt to take over the nesting cavity (Baker and Payne 1993; Bent 1950; Erskine and McLaren 1976; Ingold 1989, 1994; Kalmbach and Gabrielson 1921; Romagnano et al. 1986; Stauffer and Best 1982; Stewart 1976).

The starling is experiencing habitat loss, with fewer available nesting cavities and a decline in the amount of suitable habitat. Nest boxes erected for bluebirds, wrens, and swallows are now designed so that the cavity entrance is too small to allow access to starlings. The number of farm buildings and silos is declining and wooden structures are being replaced with steel buildings that preclude entry and offer no external cavities. Old buildings in cities that had ornate cornices and ledges are either being refurbished or replaced with modern buildings. Most modern buildings have aluminum soffit and fascia with no cavities. Orchards are now well maintained with no decadent trees with cavities. Although urban sprawl creates more lawns for foraging, new subdivisions have no trees with cavities in them and the houses also are cavity-free. Most agricultural land is in row-crop production with considerably less area in pasture and hay. Most hay crops are dominated by alfalfa which grows quickly after cutting and therefore is suitable for foraging for only short periods.

Starling nestlings exposed to an organophosphate representative of a direct cholinesterase inhibitor had a significantly lower probability of survival than control birds. A total of 18.5% of treated nestlings died within 48 hours. The response was reversible in those that survived and did not extend into the fledgling stage (Stromborg et al. 1988). In an area with high selenium levels in California, there was no significant effect on hatching success or the embryos, with no abnormalities or defects detected (Santolo 2007). Parathion initially causes intoxication and death at higher doses (Rattner and Grue 1990).

The starling is much maligned because it roosts and flocks in large numbers. It and several species of blackbirds are treated at roosts in the United States in efforts to reduce numbers. A product called Tergitol was used 1974-92 but is no longer registered for use. It was an industrial detergent that made the birds' feathers pervious to water, robbing them of their insulating qualities. Treated birds subsequently died of hypothermia. Now, a nonpersistent organochlorine pesticide is used that shuts down birds' liver and kidney functions. Several million blackbirds and starlings are killed annually in the south and Midwest (McCracken 2003b).

Weather conditions can greatly affect productivity during the breeding season. Cold and wet weather may contribute to mortality of nestlings as may high temperatures in the nest cavity. Precipitation is an important reproductive variable because starlings feed by probing their beaks

into the soil. Dry years result in lower productivity because dry soil is harder to probe (Cabe 2020). In Texas, a thunderstorm with a downfall of large hail resulted in an estimated mortality rate of 26% (Hall and Harvey 2007). In Illinois, approximately 4% of birds died following a heavy rainfall with high wind and temperatures dropping suddenly below freezing (Bent 1950).

In the Midwest, the starling occurred in very low density when fire frequency was low, but increased substantially when the frequency of fires every 15 years rose from 4 to 7.3, the maximum recorded. Fires create snags and inhibit woody growth, enhancing conditions for foraging (Grundel and Pavlovic 2007b).

In Georgia, there was no difference in the number of fledglings produced by starlings nesting in rural and urban habitats (Guindre-Parker et al. 2025).

Status

The starling was introduced to North America from Europe. The current North American population originated from a release of 100 birds in New York's Central Park in 1890 and 1891. Its range spread north, east, and south from New York City and within 20 years it was known from Maine to Virginia. By the 1920s, millions were present. By 1952, it was found throughout southern Canada, the entire United States except southern Florida, and northeastern Mexico. It may still be slowly expanding and increasing along the southern edges of its range. Typical of a species expanding into new territory, it initially increased its population exponentially and then experienced a decline in numbers. Populations started to level off in New York, Ohio, and Massachusetts as early as the 1930s. In the east, the population declined by an estimated 75% from 1932 to 1942 (Bent 1950; Cabe 2020; Chapman 1925; Cotter et al. in Gauthier and Aubry 1996; Davis 1960b; Kalmbach and Gabrielson 1921; Kessel 1953a).

The first Ontario starling record was a flock of 4 or 5 seen in Niagara Falls in autumn 1914. In 1919, several were seen near Brockville, including some recently fledged young, but it was uncertain if the birds had nested in Ontario or across the St. Lawrence River in New York. The next record was in the winter of 1919-20 when a small flock was observed in St. Catharines. The first breeding record was in 1920 near Beamsville and nests were confirmed in Burlington in 1922 and Guelph in 1924. By 1922, it had reached Kingston, Toronto, Hamilton, and Chatham and the following year it appeared in Kitchener, London, and on the outskirts of Toronto. Nesting was confirmed in Toronto in 1926 and the population burgeoned there after birds started to remain year-round during the winter of 1929-30. It was first seen in Kingston in 1921 with confirmed breeding in 1926. The range of the starling was continuous across southern Ontario by 1925; by 1926, there were records from 75 locations and 32 counties. It reached Orillia in 1925, Muskoka in 1926, North Bay in 1927, and Port Sydney in 1926 and was well established in Muskoka and Parry Sound districts by the mid-1930s. Even shortly after its appearance, the starling was abundant. In autumn 1929, a flock of 5,000 was seen in Toronto and 3,000 were seen in London; 10,000 were seen in Brantford in the spring of 1930 (Baillie and Harrington 1937; Cramner-Byng 1990; Curry 2006; Fleming 1927; Mills 1981; Putman 1947; Saunders 1930b; Sheppard et al. 1936; Snyder and Baillie 1930; Weir 2008). Baillie and Harrington (1937) stated that it had become one of the most common birds in Ontario. At that time, it nested in suitable locations everywhere throughout southern Ontario north to at least Thunder Bay and Sudbury districts. It had been found as far north as Kapuskasing, Moose Factory, and York

Factory on Hudson Bay. In 1964, starlings were observed at radar site 415 near Cape Henrietta Maria and breeding appeared to have taken place (Peck 1972). Birds were first reported at Winisk in 1965 and the first nest was found there in 1967 (Lumsden 1980).

During the first atlas, the range of the starling covered the entire province, but with large gaps in distribution in the heavily forested Boreal Forest Region, the Hudson Bay Lowland, and the Algonquin Highlands. Presence in these areas was associated with towns or areas where there were buildings or other structures (Bowman in Cadman et al. 1987). James (1991) considered the starling an abundant permanent resident in the south, becoming a rare and local summer resident north to Winisk and Cape Henrietta Maria. Wilson and McRae (1993) noted that the starling was a common breeder in Moosonee.

The second atlas revealed that there had been no change in the breeding distribution of the starling, where it remained associated with human settlement and agricultural land. There was no change in its probability of observation province-wide, but there was a significant decline in the southern Canadian Shield, probably due to natural succession. Highest densities occurred in southwestern agricultural areas and in larger urban areas such as the Greater Toronto Area, Kingston, and Ottawa. Breeding Bird Survey (BBS) data demonstrated that Ontario south of the Shield and much of the United States Midwest, Pennsylvania, and New York have the highest starling densities on the continent (Cadman in Cadman et al. 2007).

Human alteration of natural habitats benefitted the starling and it quickly settled into agricultural and urban areas. It had a history of reaching its peak abundance in the third or fourth decade after its appearance, followed by a decline. Declines are continuing in much of its range due to modernization of buildings, less agricultural land in pasture and hay, and natural succession. Despite these declines, the starling continues to be an abundant breeding species in Ontario (Cabe 2020; Campbell et al. 1997; Cotter et al. in Gauthier and Aubry 1996; McCracken 2003b). BBS data indicate that the starling decreased at an annual rate of 2.28% in Canada and 2.31% in Ontario from 1970 to 2021. The trends 2011-21 were annual decreases of 0.947% in Canada and 3.36% in Ontario. All results were highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Fledglings are capable of strong flight as soon as they leave the nest. After leaving the nest, they usually go to a perch 20-30 m from the nest and remain together, with the adults tending them for 3-4 days or even less if they are starting a second brood. Fledglings are capable of foraging by themselves at this time and become independent, joining postbreeding flocks. Many Ithaca fledglings remained within 32 km of their natal site but others wandered considerably. Fledglings were documented wandering 247 km and 320-547 km. Some remained as residents in the area that they wandered to; others migrated south (Cabe 2020).

Flocks form shortly after breeding and flocking is an important behaviour year-round. Fledglings may form flocks as soon as 4 days after leaving the nest. Flocks of juveniles tend to remain discrete from those of adults during the postbreeding period, although juveniles may occasionally return to the natal area to forage or visit the feeding areas of adults feeding late broods. Flocks of juveniles tend to occur in different habitats than those of adults. Juveniles move out of urban-suburban areas

into rural areas to sites where they are more proficient at capturing prey. They occur mostly in unmanaged grassland where vegetation is taller, such as pastures and meadows, and in soybean and wheat fields. The use of soybean fields and grasslands by juveniles in New Jersey was significantly correlated with insect density. Foraging areas used by juveniles were relatively poor compared with those used by adults, but usage of these areas may reduce competition with adults and juveniles may be more adept at capturing insects in longer grass and obtaining waste grain than probing for insects in short grass. Flocks of adults were most common on lawns and at feeders and sources of garbage. The aggressiveness of adults prevented juveniles from accessing the latter 2 food sources. Adults continued to feed on soil invertebrates throughout the summer in managed grasslands. Starlings exhibit fidelity to the same daily foraging areas, which may be 2-4 km². Individuals return to the same area each day over periods of weeks or even months or the entire year for resident birds. Although birds may change their roosting areas, most remain faithful to their feeding area. A few birds change daily foraging areas, and changes may be associated with a change in roosts. In New Jersey, only 5 of 63 adults (7.9%) switched foraging areas over a 5-month period. In 2 areas in New Jersey, home ranges around individuals' feeding sites averaged 33 and 49 km². Home ranges around all sites (including roosts) in these same areas were 30 and 525 km² from June to November. Of 15 adults, 13 commuted to the same foraging areas from 1-5 different roosts over 3-4 months. The distance to the roost increases in late summer and autumn to 4-12 km from about 2 km most of the remainder of the year; commutes as far as 38-50 km have been documented (Caccamise 1991; Dunnet 1955; Fischl and Caccamise 1985, 1987; Henty 1989; Kalmbach and Gabrielson 1921; Kessel 1975; Maccarone 1987a; Morrison and Caccamise 1985, 1990; Suthers 1978; Yapp 1989).

Roosts are important to the starling year-round. During the nesting period, males and females may roost alone in nest cavities or pairs may roost together. Of 50 pairs of birds found roosting together in New York, 49 were of a male and a female and one was of 2 males. Unmated males may roost in nest cavities and defend them from other species. Almost immediately after fledging, young form communal postbreeding roosts and these may be used by adults as well. Early roosts are small and numerous, but as the season progresses, roosts coalesce into fewer but larger roosts. Mid-June roosts tend to be near the daily foraging areas and consist of 500 or fewer birds. By mid- to late August, birds travel further to larger roosts that may support more than 100,000 birds. These roosts are occupied until mid-November when birds either migrate or switch to winter roosts. Large premigratory roosts are usually near a rich food supply, such as a large grain field. Birds feed as they make the commute to and from their daily foraging areas. The starling may roost in a variety of habitats during the postbreeding season and may do damage when roosts are in warehouses, airplane hangars, electrical substations, on bridges, on ledges of buildings, or in coniferous trees. Most roosts are in deciduous trees along highways, in parks, and particularly in residential areas. It prefers densely leaved trees such as Norway maples and sycamores. In summer, it selects areas where trees grow close together, are heavily leaved, and form a dense canopy. Where trees in such areas have been trimmed or topped, roosting starlings have been eliminated entirely. From August to December, 50,000 roosted in Niagara Region in an area of open water and common reed. The Hamilton Skyway Bridge is another traditional roost, with a high count of 70,000 on 3 November. In Presqu'ile, the maximum summer roost was 3,600 on 21 July. This was likely one of the smaller early

season roosts before roosts become scarcer and larger. The primary function of large roosts appears to be their proximity to a rich feeding area along with sources of food between them and the daily feeding areas. Communal roosting may also decrease the incidence of predation. Starlings follow the same established route each morning and evening. Routes are not in a straight line, avoiding crossing even the smallest of hills and often following a watercourse or valley. In Pennsylvania, there were 3 periods of communal roosts prior to winter: an early summer roost in cattails mixed with shrubby growth from mid-May to mid-June; summer roosts in residential areas from mid-June to September; and the autumn roost from late September through October. Individuals may switch roosts 1-5 times during the postbreeding period while maintaining the same feeding area. In New Jersey, all 36 birds that switched roosts moved more than 2 km from the previous night's roost. Although individual roosts may be used for only 2-4 months of the year, the same sites seem to be selected each year, especially for the larger premigratory roosts. Long-term roosts tend to be in sites that the birds cannot destroy, such as cliffs, or that will regenerate each year. Starling roosts are frequently occupied by other bird species. The most common species sharing starling roosts are the Common Grackle, Red-winged Blackbird, and Brown-headed Cowbird although the American Robin may also be common at times. Other species that occur less frequently are House Sparrow, Rusty Blackbird, and swallows (Bent 1950; Black and Roy 2010; Caccamise 1991; Campbell et al. 1997; Curry 2006; Feare 1984; Fischl and Caccamise 1987; Jumber 1956; Kalmbach and Gabrielson 1921; Kessel 1957; LaForest 1993; Morrison and Caccamise 1985, 1990; Suthers 1978; Weatherhead et al. 1980).

MIGRATION

Some members of each sex and age class may migrate, but most starlings south of latitude 40ºN are permanent residents. Many juveniles wander great distances south of their natal area during the summer and winter. Those that do not breed until their second year may behave much like first-year birds in their wanderings and migration. Migration strategies are irregular, with some individuals migrating some years and not in others. Some nestlings from a nest may migrate; others from the same nest may not migrate. Siblings that migrate may winter far apart. Two Michigan nest mates wintered in Wisconsin and Missouri. As of the early 1950s, 22% of recoveries of birds banded in Ontario were out of the province. Birds banded in Tennessee, Arkansas, and Louisiana migrate northeast and enter southern Ontario from southeastern Michigan. Some birds banded in New York and Washington DC enter Ontario east of Lake Ontario; some Missouri birds have been found in Leeds County. Many follow the southern shores of Lake Erie and Lake Ontario to the St. Lawrence River to Ottawa and Montreal. Birds travel along the northern shores of these lakes in autumn. The extension of the breeding range of the starling was largely due to the migrations and wanderings of yearlings and nonbreeding birds. The more migratory populations of starlings occur in the central and south Midwestern states rather than the Great Lakes region, the northeast, and the Atlantic seaboard. The starling also may be more migratory at the edge of its range (Kessel 1953a). Burtt and Giltz (1977) prepared a vector diagram for all North American recoveries of the starling. Birds from southwestern and central Ontario travelled in a south-southwest to north-northeast direction. Those from north of Lake Superior travelled southwest to west-southwest. Sixty-five percent of birds moved southward in autumn. Dolbeer (1982) summarized banding results from the Great Lakes area. Maximum distances from the nesting area occurred in January (534 km) and February (375 km). Hatch-year birds migrated an average of 249 km further than adults. The mean dispersal distance

from southwestern Ontario was 289 km with recoveries in Ohio, Illinois, Kentucky, and Arkansas. Ontario birds winter primarily in the province and Great Lakes states, but others move to the mid-Atlantic states and as far south as the Gulf Coast (Brewer et al. 2018).

Most migration occurs during the day. Starlings are highly social during migration and migrate in flocks that may number from several birds to 100,000. Flocks routinely fly at heights in excess of 1,000 m, but may fly much lower in high winds or head winds. When flying lower, the starling frequently uses river valleys, lake plains, and coastal plains as flyways. Adults tend to migrate to a specific area; juveniles apparently migrate in a specific direction without reference to any particular area. Juveniles appear to migrate for some specified time after which they depend on external cues to locate suitable winter habitat and cease migration (Cabe 2020; Kessel 1953a).

Spring migration is from mid-February to early April. At Guelph, some starlings arrived in late February but the major influx was in mid-March. In the St. Lawrence valley of eastern Ontario, some arrived in March but most did not appear until April. The peak of arrival at North Bay is in early April. Males may migrate earlier in spring than females (Collins and de Vos 1966; Curry 2006; Kessel 1953a, 1957; Mills 1981; Weatherhead et al. 1980). Autumn migration may extend from late September throughout October and into November; the peak is in August in North Bay. In Parry Sound and Muskoka districts, most birds congregate in flocks in August, and these remain intact into October. The autumn peak at Presqu'ile is in October. At Hawk Cliff in Elgin County, thousands fly westward daily along the Lake Erie shore in October and early November (Kessel 1953a; LaForest 1993; Lancaster et al. 2004; Mills 1981).

During spring migration in New Jersey, feedlots and agricultural crops were the habitats most preferred by the starling, but it also showed some preference for pastures and urban-suburban areas. Near Saskatoon, spring migrants congregate in stubble fields and pastures to feed on waste grain and insects. It begins to organize roosts early in March when spring migrants arrive and maximum numbers occur in late March when migration is almost complete. Spring roosts break up in early May with a shift to several smaller roosts coincident with the start of the breeding season (Fischl and Caccamise 1985; Jumber 1956; Leighton et al. 2002). During autumn migration, birds move to fields of swathed grain or stubble and large flocks may occur in corn fields (Fischl and Caccamise 1985; Leighton et al. 2002).

The starling is an abundant migrant in Ontario with higher numbers in autumn than in spring. In the Kingston area, spring flocks typically contain a maximum of 1,000 birds but 5,000-10,000 may occur in autumn. At Presqu'ile, the highest spring count was 1,000; high autumn counts were 1,000 and 2,300 (LaForest 1993; Weir 2008).

WINTER

During winter in Ontario, the starling is found almost exclusively in towns and urban areas. In rural areas, it is restricted to areas with abundant sources of food such as feedlots and landfill sites; it occasionally occurs at feeders. When the ground is snow-free, it may still inhabit agricultural fields. Smith (2003) summarized its winter habitat in southern Ontario based upon results from Winter Bird-Population Studies. Densities per km^2 were 81.9 in cities, 63.8 in urban natural areas smaller than 10 ha, 38.7 in larger urban natural areas, 1.0 in mixed rural (forest, old field, and agriculture), and 0 in

farmland and forest. Densities in cities were significantly higher than in other habitats. In Muskoka and Parry Sound districts, only the largest towns support starlings year-round (Mills 1981). In British Columbia, wintering birds forage in cultivated areas, parks, gardens, vegetated playgrounds, fallow fields, airports, cattle yards, orchards, berry plantations, landfills, sewage lagoons, poultry runs, and natural areas (Campbell et al. 1997). In Illinois, it was most consistently observed in small grain stubble but high densities also occurred in fallow fields and all types of shrubbery (Graber and Graber 1963). In New Jersey rural areas, it preferred feedlots and agricultural crops in winter, especially corn and soybeans (Fischl and Caccamise 1985).

Roosts continue to be important in winter. The starling may roost in large aggregations or individually or in small numbers in cavities that may be potential nest sites. In Ontario, communal roosts have been documented in a pine plantation in Kingsville, in a cedar swamp in Guelph, and at a St. Catharines apartment complex (Bent 1950; Black and Roy 2010; Curry 2006). In October or November, it abandons deciduous tree roosts and moves to church towers, barns, or other buildings and remains in these areas until the breeding season. Other areas that may be used for communal winter roosts include ledges of city buildings, metal cross-members of bridges, airplane hangars, warehouses, electrical substations, groves of coniferous trees, common reed growths, and thick matted grasses on the ground. In cities where good roost sites are lacking or overcrowded, it may roost in bare deciduous trees well protected by buildings (Campbell et al. 1997; Jumber 1956; Kalmbach and Gabrielson 1921; Whitehead et al. 1995; Yom-tov et al. 1977). Communal roost sites are selected for their warmer microclimate. In Ohio, roosts were established throughout a pine forest in early December. By mid-December, areas along the periphery of the woods had been abandoned in favour of centrally located roosts. Within areas that were used for roosting throughout the winter, the wind velocity was almost always zero. Birds rarely roosted at heights above 3.7 m. Temperatures from the ground to 3.7 m were fairly uniform and consistently higher than at heights of 4.9 and 6.1 m (Kelty and Lustick 1977; Yom-tov et al. 1977). Dominant males occupy the centre of communal roosts where they are most protected from the weather and predators (Dunn and Tessaglia-Hymes 1989). In New Jersey, as many as 25 starlings roosted in an old silver maple along an urban street, with as many as 4 birds per cavity. Individuals tended to nest in the same cavities, with most retaining possession of the cavity until they died, the tree fell, or they were driven out by another starling (Suthers 1978). It may roost overnight in boxes designed specifically for them, and has been known to roost in Purple Martin houses (Stewart 1977) and American Kestrel nesting boxes (Davis et al. 2017). In December, some birds begin roosting in boxes instead of returning to the communal roosts. By mid-December, small numbers of both sexes may be found roosting in boxes. Many flock-roosting birds do not visit nest cavities in winter; others alternate between roosting in boxes and at a communal roost. During the 3 months of winter that roosting in boxes occurs, a bird may change its roosting site and switch partners several times. Birds may move their roosting sites 800 m or more, but are usually faithful to a localized area that decreases in size as spring approaches. Sometimes a bird will roost in the same box all winter but 1 bird was recovered 4.0 km away from the box it had roosted in 2 days previously. Use of cavities for winter roosting is part of the nest-site selection process for resident birds. A high proportion of birds that use nest boxes for winter roosting have previously nested in the general area (Kessel 1953a, 1957; Lombardo et al. 1989b).

In winter, the starling may select warm perches on cold days. It frequently uses chimneys as perches where it sits on the lee side to obtain maximum warmth. Chimneys may be abandoned if high wind or rain result in a greater heat loss than in more sheltered areas. It may also perch on light fixtures, incinerators, and manure piles (Brewer 1963b; Campbell et al. 1997; Leighton et al. 2002; Suthers 1978).

The winter diet of the starling varies depending upon whether there is snow on the ground. In New Jersey, grasses, soybean fields, and corn fields accounted for 35% of the study area and were used by 55% of foraging starlings when the ground was clear. Only 17% used these fields after snow coverage. The few flocks that fed in grassy areas during snow days were on the leeward side of buildings and hedgerows. It had a difficult time finding food once the ground was covered with snow. The most apparent change was a 2-fold increase in the proportion of flocks using human-generated foods from feedlots, dumpsters, and landfills. These areas may be defended by birds in winter (Maccarone 1987b). Hamilton (1949) compared the winter diet of the starling in New York when the ground was bare and snow-covered. The percent occurrence of food items when the ground was bare was 45% fruits and berries, 42% sumac, 7% garbage, 19% grains, 20% green vegetation, 18% insects, 4% millipedes, and 3% snails. Percent occurrences when the ground was snow-covered were 49% fruits and berries, 27% sumac, 19% garbage, 4% grains, 6% green vegetation, 1% insects, and 0% millipedes and snails. Fruits and berries that were consumed included sumac, viburnum, grape, Virginia creeper, poison ivy, hawthorn, and frozen apples; these were available regardless of snow depth. Garbage was also available during periods of deep snow. Most insects, grains, and green vegetation were less available when the ground was snow-covered. When snow was present, it was more dependent on fruits, especially those of staghorn sumac, bittersweet, grapes, and several viburnums, particularly nannyberry. In Saskatoon, it feeds on waste grain, garbage, crabapples, and mountain-ash berries in winter (Leighton et al. 2002). It may feed on waste grain in winter but cannot subsist on this diet and loses weight, even in captivity. It requires invertebrates in the diet to sustain itself (Feare and McGinnity 1986).

The starling is a widespread visitor to winter bird feeders. The number of feeders visited more than doubles from autumn to mid-winter and remains high. The number of birds present at a given time declines as winter progresses. Favourite foods are suet and bird puddings, but it readily eats mixed seeds, cracked corn, hulled peanuts and peanut hearts, pet food, peanut butter mixes, baked goods, and water. Infrequent choices include millet, canary seed, sunflowers, whole corn, milo, wheat, peanuts in the shell, fresh or dried fruit, meat scraps, sugar water, popped corn, and oats (Dunn and Tessaglia-Hymes 1999).

Cold weather may commonly kill roosting birds. Approximately 4.0% of birds at an Illinois roost died after an overnight storm. In 1927, about 500 dead starlings were found at a Massachusetts roost after a storm. At a Kentucky roost, 84% of starlings died after 2 nights when the temperature dropped to −17.2°C and −24.4°C. These birds were roosting in trees, but only 0.4% of those roosting in a nearby barn died. Densities of starlings per km² before and after a severe storm in Illinois were 5.2 and 0 in bottomland forest, 24.0 and 0 in upland forest, and 1,249.4 and 1,605.2 in urban residential, respectively. No dead starlings were observed. They appeared to shift from forested to urban habitat in response to the storm (Graber and Graber 1963; Kalmbach and Gabrielson 1921;

Odum and Pitelka 1939; Stewart 1978). Starlings bathing in a Minnesota bird bath died when the ambient temperature was –30ºC with a windchill of about –45ºC (Longley 1944).

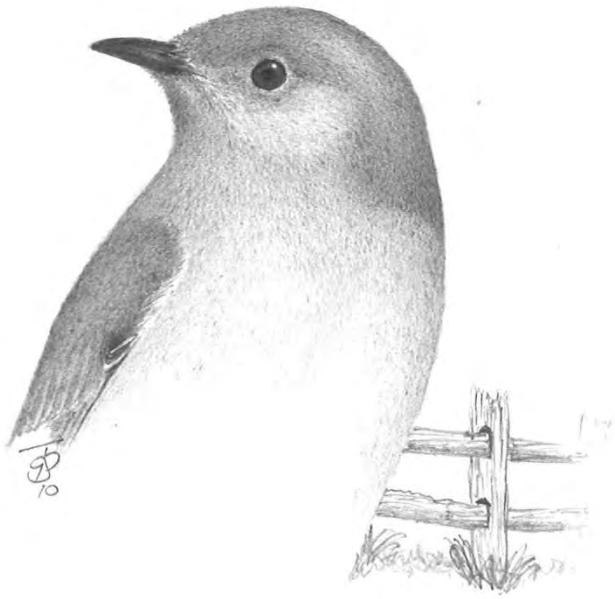
The starling is locally abundant in winter in southern Ontario where it occurs mainly in towns and larger urban centres. It winters north to Kenora and Cochrane and occasionally to Moosonee (James 1991), but it is much less common and more local in the north. The starling was the most abundant bird observed on the Niagara Christmas Bird Count (CBC) and tens of thousands roosted at a St. Catharines apartment during January and February (Black and Roy 2010). The roost at Guelph supported an estimated 100,000 birds. The highest count on the Hamilton CBC was 73,000 in 1980 (Curry 2006).

Numbers of starlings recorded on Ontario CBCs originally increased, but appear to have been declining since the early 1980s. Numbers were relatively stable from 1929 to 1966, after which they averaged about 3 times higher. That was largely because of expanded numbers on the Hamilton count due to birds using the Burlington Skyway bridge as a roost. In 1924, a single bird was observed on the Hamilton CBC; 1,714 were seen in 1928. The average number surveyed there was 3,400 1956-66 compared with 27,000 1967-77. After the high of 73,000 in 1980, numbers dropped steadily. The average for the 10 years ending in 2005 was 18,344 (Curry 2006; Freedman and Riley 1980). CBC data for Ontario indicate that the starling increased at an annual rate of 1.61% 1970-2021 but decreased at an annual rate of 3.91% 2009-21 (National Audubon Society 2022).

Project FeederWatch counts indicate declines, although the starling is still very common at feeders. The percentage of feeders in Canada that it was observed at was 68% in 1988; 60% in 1993, 1998, and 2003; and 58% in 2008 (Wilcox 2008).

Eastern Bluebird

Sialia sialis

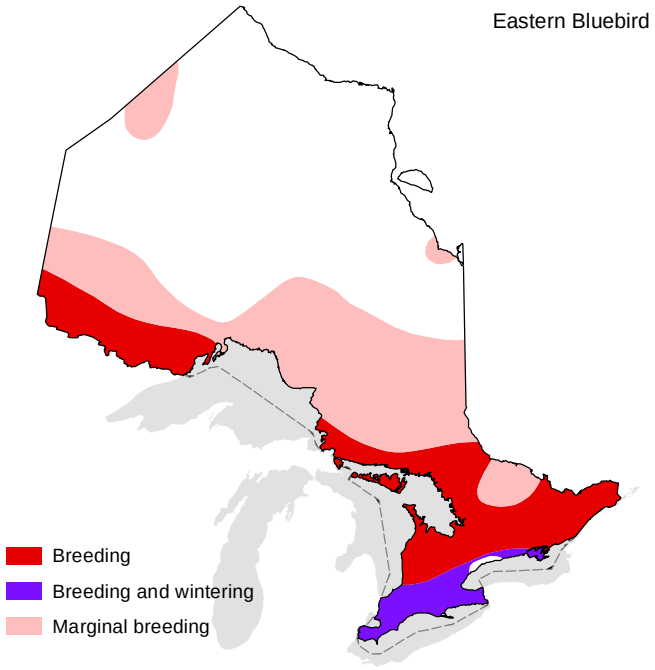


BREEDING SEASON

Habitat Requirements

The Eastern Bluebird is an open-country bird that requires scattered trees or shrubs for foraging. It avoids areas of extensive forest, grasslands with no woody vegetation, and urban areas. It readily nests in boxes constructed for it, so placement of boxes has influenced habitat selection. In Ontario, it has nested in farmland, including orchards, quarries, fencerows, pastures, fields, and willow swales (71.3% of nests); woodlands, including swamps, burns, clear-cuts, and slashes (11.8%); and beaver ponds and marsh edges (1.5%). Single nests were in a sand dune area and in a Cliff Swallow nest attached to a rural school (Peck and James 1987).

The 3 most important habitat characteristics for the bluebird in Ontario are a proper physical setting, a suitable nesting cavity, and foraging perches. It shows a strong preference for old-field habitat with patches of bare soil and standing trees. It shifted from presettlement habitats of natural burns, forest clearings, and stream openings to pastures, fields, orchards, roadsides, and gardens. The most favoured habitat is overgrown upland pasture, although it may inhabit second-growth brushy fields. The physical setting must include nearby foraging areas and shelter. It rarely uses habitats with few or no perches (Risley 1981). James and Peck (1995a) rarely observed it in jack pine stands near Gogama and only in recent clear-cuts or burns where it nested in old woodpecker holes



in snags. Where snags were left after cutting, it remained for several years as long as there was open ground where it could forage.

Ideal habitat is open with scattered trees and sparse ground cover. Natural savannahs or other habitats with savannah-like structure may provide excellent habitat provided that the grass-herbaceous layer is not too tall or dense (Askins et al. 2007; Fitch 1958; Gowaty and Plissner 2020; Pogue and Carter 1995). Large areas of Illinois were devoid of bluebirds, especially in intensively farmed areas. Flat, treeless areas were unsuitable even if nest boxes were provided. Large blocks of forest were poor habitat, although forest edges supported low populations. The earliest successional stages of forest were unsuitable. Nesting habitat usually included woody vegetation in and adjacent to open fields, especially grasslands. Ideal habitat was edge shrubs, forests, pastures, fallow fields, and roadsides (Graber and Graber 1963; Graber et al. 1971). Also in Illinois, all nest boxes placed short distances from woodlots and wooded ravines were occupied but those in open prairie were not (Musselman 1935). The Eastern Bluebird frequently nested in apple orchards and in towns and villages prior to the arrival of the House Sparrow. This species and the European Starling drove bluebirds further from dwellings. Usage of orchards declined due to pruning of dead limbs, filling cavities, and replacing old apple trees with younger ones. The bluebird still nested in rural orchards, along country roads, and in open groves or burned or cut-over woodlands where there were numerous dead trees and stumps to provide suitable nesting cavities (Bent 1949). In Virginia, 7 of 10 clear-cuts supported nesting bluebirds. The cuts were 1-5 years old and sparsely to moderately stocked with regenerating hardwoods 1-2 m tall. One nest was in a 12-year-old cut densely stocked with 4-5-m tall oak and hickory. The 3 clear-cuts that were devoid of nesting bluebirds were 10-15 years old and densely stocked with 3-6-m tall hardwoods (Conner and Adkisson 1974). In Quebec, it inhabits clear-cuts (especially those with retained stumps and snags), burns, and open peatlands near James Bay. Abandoned orchards provide suitable habitat in the south (Banville and Robert in Gauthier and Aubry 1999). Golf courses may be used by bluebirds, and golf course habitat has been reported to be both poor (Stanback and Seifert 2005) and good habitat (Cornell et al. 2011; LeClerc et al. 2005). On Wisconsin golf courses, short-grass areas supported significantly lower biomasses of insects and spiders than tallgrass areas, but bluebirds were more successful at capturing prey in short-grass areas. There were no significant differences in fledging success rates between the 2 habitats. Short mowed areas on golf courses could provide valuable habitat (Ambardar et al. 2018). It has been reported nesting in several types of forest. It was the only cavity-nesting bird species to not nest in bottomland forests in Missouri (Brawn et al. 1984), but Samson (1979) reported it nesting

in lowland hardwoods in northeastern North America. It has nested in or at edges of northern hardwoods, pitch pine stands following fire, oak stands, and aspen-birch (Capen 1979; Evans and Conner 1979). Taylor and Taylor (1979) characterized the Eastern Bluebird as a species of upland openings and edges. Zeleny (1976) stated that it prefers open areas with scattered trees, especially if the trees have a few low dead branches that can be used as perches. These include open fields with fences or wires for perching, pastures, open wastelands, large lawns, country cemeteries, golf courses, and abandoned orchards. It selects areas where the ground is not heavily covered with vegetation or where grass or other vegetation is kept short by mowing or grazing. Gowaty and Plissner (2020) summarized its preferred habitat as open areas with little to no understorey and with sparse ground cover. Modern breeding habitats included orchards, clear-cuts, burned areas, railway lines, and both upland and swampy habitat, including those close to major urban centres.

In 400-m landscapes with less than 30% tree cover in North Dakota, bluebird populations remained stable as tree cover within 100 m increased, but decreased in response to increasing tree cover in wooded landscapes. It preferred areas with 20-46% forest cover (Cunningham and Johnson 2016, 2019). In North Carolina, it was negatively correlated with the amount of tree canopy within 200 m, with greater tree canopy associated with less shrubby cover. It was negatively associated with elevation at the 200-m scale, indicating that it requires some disturbance, which is less frequent at higher elevations. It was negatively correlated with the amount of development within 1,000 m. Exurban development did not create habitat for it (Gilbert and Ferguson 2019).

Some studies used nest boxes to determine microhabitat preferences of Eastern Bluebirds. Near Kingston, 69% of bluebirds nested less than 30 m from forest edge (range 10-53 m). Mean distance from forest edge was not significantly different between the bluebird (25.8 m) and the Northern House Wren (13.9 m), but it was for the bluebird and Tree Swallow (41.3 m; Rendell and Robertson 1990). In Manitoba, bluebirds used sites with the greatest availability of grass and wooded pasture, with a large component of shrub pasture, but devoid of long grass and fallow lands. Occupied sites differed significantly in the percentage of wooded pasture, long grass, and fallow lands. Habitat at used sites was 14.3% forest, 29.4% wooded pasture, 8.2% shrub pasture, 34.5% grass pasture, 12.3% long grass, and 1.3% fallow fields. Habitat at unused sites was 12.8% forest, 11.9% wooded pasture, 5.1% shrub pasture, 26.5% grass pasture, 32.2% long grass, and 11.4% fallow fields. Parameters of used and unused boxes were: trail age, 11.8 and 9.9 years; distance to the nearest tree or shrub taller than 2 m, 27.0 and 59.1 m; distance to the nearest road, 61.4 and 25.3 m; and distance to nearest building, 1,269.2 and 979.4 m, respectively. Distance from the nearest building best separated habitat selection by the Eastern Bluebird and House Sparrow. Distance to the nearest tree, fallow fields, and entrance-hole diameter best separated the bluebird and Northern House Wren. Nest sites were associated with livestock more than expected. Areas where utility lines were present were used less often than expected. Most utility lines were 6 m from the ground and probably too high for effective foraging. Entrance holes to nests were oriented randomly (Munro and Rounds 1985). In Ohio, there was a significant relationship between nest-box usage and distance to the nearest tree. Used boxes were a mean of 4.80 m from the nearest tree compared with 3.04 m for unused boxes. The mean distance to a large tree from boxes that fledged at least 1 young was 6.55 m compared with 2.67 m for unsuccessful nests (Horn et al. 1996). In Maryland, preferred boxes were close (about

6 m) to small shrubs with surrounding low grass and nearby perches. Boxes facing northeast to south were preferred (Gowaty and Plissner 2020). In Wisconsin, selected boxes were in open areas with less than 5% tree cover within 11 m, less than 10% cover within 30 m, and were more than 35 m from the nearest forest edge and more than 200 m from the nearest permanent water (Gowaty and Plissner 2020). In Vermont, used nest boxes had fewer small woody stems under and around the box and were further from high perches. Bluebird nesting sites were in larger openings than those of Tree Swallows and were further from high perches and provided a longer view from the box entrance than those of the Northern House Wren. More bluebirds nested 10 m or more from a tall perch than expected by chance. Only 1 nest box further than 10 m from a tall perch was used by a wren. Sites with 25 or fewer small stems were used by bluebirds nearly twice as often as sites having more stems. Bluebird and swallow nest sites were not sufficiently different to provide useful habitat guidelines (Parren 1991). In Manitoba, tall, weedy growth at the base of the nest site discouraged nesting by the bluebird (Miller 1970).

Roosts are an important habitat component for the Eastern Bluebird. During the breeding season, adults sleep in nesting cavities or on protected limbs of trees, occasionally communally. During inclement weather, 20 or more birds have roosted together in cavities or nest boxes, or on branches in sheltered areas (Bent 1949; Gowaty and Plissner 2020).

Ontario nests were in nest boxes (81.1% of nests); in cavities in fence posts (7.6%); in natural and woodpecker cavities in stumps, in dead and occasionally living trees, and in trunk and branch stubs (7.4%); in cavities in utility poles (1.1%); and in unspecified cavities (0.3%). One nest was in an old Cliff Swallow nest and another was in a hollow of a well pump with a missing cap. Heights of 97 nests in natural cavities were 0.6-18 m, with most 1.4-3.7 m up (Peck and James 1987).

Throughout its range, the Eastern Bluebird changed its nest-site selection. Prior to 1900, it nested mostly in natural cavities and woodpecker holes in trees. After the extensive forests were cleared for agriculture, it adapted to nesting in cavities in wooden fence posts and occasionally in utility poles, and these were the dominant nest sites from 1900 to 1950. Its decline in the mid-1990s was attributed in part to replacement of wooden posts with steel posts. Removal of dead limbs and decadent trees in orchards contributed to loss of natural cavities during this period. Starting circa 1950, most bluebirds nested in boxes especially designed for them. Although it still nests occasionally in woodpecker and natural cavities, it appears to prefer nest boxes if given a choice (Bent 1949; Graber et al. 1971; Hersey 1933; Pinkowski 1976a; Risley 1994; Zeleny 1976). Nests outside of cavities are rare, but Bent (1949) reported South Carolina nests that were saddled on a 3-cm oak limb 3.7-4.6 m from the ground and 4.6 m from the trunk of the tree. Other unusual nest sites were in a drain pipe where the pipes were stacked on top of each other; in empty tin cans or jars; in Cliff Swallow nests, even within active colonies; in a railway signal ball that was raised and lowered about 50 times a day; in the hollow iron coupling of a railway car sitting on a siding; in a cavity in a steep earthen bank similar to that used by the Northern Rough-winged Swallow; in a cannon barrel; in a pile of concrete blocks at a construction site; in mailboxes; in tin newspaper cylinders; in a cavity of a limestone rock; and in a house under construction (Bent 1949; Laskey 1971; Matthey 1987).

Some studies described Eastern Bluebird nests in natural cavities and fence posts after nest boxes became preferred for nesting. Pinkowski (1976a) described 98 nests in trees in Michigan. Most

(88.8%) were in dead trees and 9.2% were in dead limbs of live trees. The other 2 nests were in a Hairy Woodpecker cavity in a white birch and in a decayed portion of an oak that was alive although the heartwood had deteriorated. All 9 nests in dead limbs of live trees were at 1 site and constituted 27.3% of nests found there; 0 of 65 nests at another site were in similar situations. Significantly more nests (86.2%) were in the main trunk of trees at 1 site compared with 63.6% at the other. The differences between sites may have been due to different tree growth (open- versus forest-grown) or to presence of different species of trees. Nest-tree species were used proportional to their availability except for elms which were used more than expected. Abandoned woodpecker nests accounted for 77.6% of the cavities that were used; 17.3% were in cavities produced by natural decay; 5% were in cavities created by fire. Significantly more cavities faced southeastward than any other direction, providing protection from the prevailing wind and exposure to the morning sun. Mean cavity height was 3.6 m. Bluebirds used old nest cavities of the Red-headed Woodpecker, Downy Woodpecker, Hairy Woodpecker, and Northern Flicker. Significantly more flicker nests were unused than those of the Downy Woodpecker and significantly more natural cavities than woodpecker cavities were not used. In Virginia clear-cuts, all nests were in dead snags averaging 23.6 cm diameter at breast height (DBH) and 133.9 m from mature woodlands. Nest cavities averaged 3.3 m from the ground. Many nests were in old flicker nests (Conner and Adkisson 1974). In Illinois, nests in natural cavities were 0.45-3.4 m from the ground; most recent records were less than 2.1 m up (Graber et al. 1971). In Missouri, Brawn et al. (1984) described 4 natural bluebird nests. The average DBH of nest trees was 38.9 cm, tree diameter at the nest was 18.3 cm, the cavity entrance averaged 4.7 m from the ground, average tree height was 8.7 m, basal area averaged 6.3 m^3 per ha, there were 62 stems per ha, the distance to the nearest opening in the canopy was 0 m, canopy height was 0 m, and the average tree decay class was 2.9 where 1 is the least decayed and 5 the most decayed. It nested in the youngest stands of all primary and secondary cavity nesters and in the smallest trees with the exception of the Downy Woodpecker.

Pierson and Scanlon (1986) examined 35 Eastern Bluebird nests in fence-post cavities in Virginia. Ninety-one percent of nest cavities were excavated by woodpeckers. The remainder were created by decay and had entrances at the top of posts. Mean nest cavity height from ground was 133.6 cm (range 78.9-181.3 cm). Hsu and Humpert (1988) checked for use of cavities in fence posts along interstate highways in Ohio by nesting bluebirds. In the first year, 6 of 296 cavities (2%) were used compared with 14 of 374 (3.7%) in the second year. Highest use of cavities occurred when mouse nests were removed prior to the breeding season.

In Ontario, bluebirds preferred boxes with a 4.4-cm diameter entrance hole over those with a 3.5-cm entrance. They preferred box floors measuring 10 x 10 cm over those measuring 15.3 x 15.3 cm, although differences were not significant (Lumsden 1986). Preferences for cavity features vary geographically and are influenced by competition. The cavity entrance size used by bluebirds was large enough to admit starlings, but no starlings used the boxes. This was probably because the interior of the boxes was painted white and the starling prefers black interiors (Lumsden 1989). Pitts (1977) demonstrated that bluebirds preferred boxes with white interiors over those with black interiors, although some boxes with black interiors were used. In Mississippi, bluebirds regularly used 3.5-L wooden boxes but avoided large wooden boxes with a volume of 16.5 L and a 7.6-cm entrance
