Some authors placed the Nashville Warbler into guilds. Based on foraging habitat preferences and techniques, Sabo (1980) placed the Nashville Warbler into a guild that included high-elevation ground foragers, deciduous tree users, lowland foragers, and those that used coniferous trees. In the northeastern United States, Niemi and Pfannmuller (1979) placed it in a guild of species that were abundant in young plantations and disturbed shrubby areas; very common in aspen regeneration and alder thickets; common in recent clear-cuts and mature coniferous lowlands; and uncommon in mature deciduous upland forests, mature coniferous upland forests, and grasslands. In Maryland, Gates and Giffen (1991) included the Nashville Warbler in the hemlock-bottomland group. In Vermont, Thompson and Capen (1988) placed the Nashville Warbler in the open-canopy association. The large number of species that the Nashville Warbler has been associated with demonstrates that it is a habitat generalist in open shrubby areas, in young forests, and in edges and openings of more mature forests.

In Ontario, the Nashville Warbler is not considered an area sensitive species (Coleman et al. 2000; James 1984b). In Wisconsin, it was not restricted to larger islands, so it did not exhibit area sensitivity (Beals 1960). Near Quebec City, territories were significantly clustered at scales of 250, 450, and 550 m. Of the species that they studied, it was most associated with forest cover, with a mean of 63.1%

forest cover near occupied areas. Bourque and Desrochers (2006) concluded that a decrease in forest size might have a negative effect on its distribution or fecundity.

Almost all Ontario nests were on the ground. One was 0.9 m from the ground in the upturned roots of a fallen hemlock, one was in a clump of sedges 0.5 m from the ground, and another was in a clump of grasses 0.3 m from the ground. Nests were in hollows in moss hummocks or in moss on the ground (66.1% of nests), in clubmosses (10.7%), in grasses (8.9%), in ferns and blueberries (8.9%), in dead leaves (3.6%), and in a small depression in a rock (1.8%). Many nests were at the base of a small tree, stump, or shrub, or were under or beside logs. Many were well concealed by overhanging bracken ferns, tree branches, grasses and forbs, shrubs, and dead leaves (Peck and James 1987). A nest near Pimisi Bay was in an open area but well hidden under a cluster of dead bracken fern fronds (Lawrence 1948).

Most publications state that the nest is always on the ground or slightly sunken into a depression, but occasionally they are on raised hummocks. The Ontario nest in upturned tree roots appears to be the only record of a truly elevated nest. Nests are frequently on hillsides, including road cuts, and they are often at the base of a tree or shrub. They are often in disturbed areas and may be adjacent to woodland trails. Nests are usually well concealed under ferns, grasses, blueberries, clubmosses, bunchberry, or wildflowers (Bent 1953; Campbell et al. 2001; Chapman 1907; Harrison 1984; Kotesovec and Zadar 1996; Lowther and Williams 2020).

The Nashville Warbler is territorial, but it has not been determined if all activities take place in the territory. Near Lake Nipigon, 7 territories averaged 1.09 ha (range 0.5-2.4 ha). Only 3-7 records per bird were obtained, so territories may have been larger (Kendeigh 1947). In Algonquin Park, the average territory size was 0.37 ha (range 0.02-2.39 ha). In most forest types, it ranged from the ground to the top of trees, but in some stands it was not observed above 9 m where it usually occupied conifers (Martin 1960). A single territory near Pimisi Bay was 0.2 ha. It stretched into a mixed forest but the nest was in the opposite corner of the territory in a more open area (Lawrence 1948). In subalpine areas of New Hampshire, the average territory size was 1.1 ha (Sabo 1980). In Maine spruce forests, territory size was 2.22 ha (Morse 1977).

No information appears to be available on natal philopatry (although it is probably low) or adult site fidelity.

Limiting Factors

Eggs have been found in Ontario nests from the last week of May until the third week of July, with most present in the first half of June (Peck and James 1987). In Algonquin Park, eggs are present from late May to mid-July, nestlings are present from early June to mid-July, and dependent fledglings have been observed from late June to late July (Tozer 2012).

Nest building begins soon after the birds arrive. The female constructs the nest over a period of 7-9 days. It is unknown if time elapses between nest completion and the initiation of egg laying. One egg is laid per day. The incubation period for 7 Ontario nests was at least 10 days at 4 nests, 11 days at 1 nest, and at least 11 days at 2 nests. Elsewhere, the incubation period has been reported as 11-12 days. Near Pimisi Bay, 2 young left the nest at age 8 days and one left when it was 7 days old. This nest contained a young cowbird; it was unknown if this affected the timing of fledging. In

other areas, young fledge at age 9-11 days (Bent 1953; Lawrence 1948; Lowther and Williams 2020; Peck and James 1987).

Only a single brood is raised. There are no records of second broods. Clutches in Ontario contained 3-7 eggs, with 88.3% of clutches containing 4 or 5 eggs (mean 4.38 eggs). Only single clutches with 6 or 7 eggs were reported. In Algonquin Park, 6 nests contained 4 young and 5 nests contained 5 young. In Illinois, the clutch size was 4-6 eggs (average 5 eggs). The mean clutch size of 14 Michigan nests was 4.71 eggs. The Nashville Warbler typically lays 4 or 5 eggs and less frequently 3 or 6 eggs. The Ontario nest containing 7 eggs is the only record of a clutch this large. Three-egg clutches may be incomplete or late clutches (Bent 1953; Graber et al. 1983; Harrison 1984; Knapton 1984c; Lowther and Williams 2020; Peck and James 1987).

No information is available on the age at first breeding, but it is probably 1 year. The Nashville Warbler is presumed to be monogamous. There are no records of polygyny (Lowther and Williams 2020).

The foraging techniques of the Nashville Warbler are very similar to those of the Tennessee, Orange-crowned, Golden-winged, and Blue-winged warblers. Consequently, only one of these species typically occupies a habitat. The Nashville Warbler is the common species of this group in young deciduous-growth forests and has minimal contact with the spruce-fir species (Morse 1989). It concentrates on foraging at the tips of branches and the western population is specialized for foraging among the needles and twigs of conifers. It often forages from unstable substrates such as leaves at the tips of twigs, in tassels of flowering trees, and on the undersides of leaves, particularly those of deciduous trees. It is in a guild with the Black-capped and Boreal chickadees for its general foraging techniques (Bock and Lynch 1970; Crawford and Jennings 1989; Lowther and Williams 2020; Morse 1989). In Quebec, LaRue et al. (1998) placed it in the shrub-foraging guild. It occasionally captures flying insects on the wing, but does not habitually flycatch. Adults capture insects on trunks, branches, and leaves of trees and shrubs, working their way up from the bottom to the top. Foraging occurs mostly in the lower storey of open woodlands and more often in low trees and shrubs around the periphery of forests (Bent 1953; Falardeau in Gauthier and Aubry 1996; Lowther and Williams 2020). In Ontario, foraging occurred 72% of the time in deciduous trees and 28% of the time in conifers on average at 72% of the tree height. Eighty-two percent of foraging occurred in foliage, and 16% of prey attacks were aerial. It captured prey in foliage by hanging upside-down 8.0% of the time and hovering 5.9% of the time. Gleaning represented the remainder of the foraging techniques (Greenberg et al. 1999). In central Ontario, it foraged mostly in white birch stands. During the breeding season, it exploited tree species more universally than during migration. Foraging heights during the breeding season were 5-15 m compared with 3-14 m during autumn migration. Unlike other species, the Nashville Warbler exhibited a greater tendency for gleaning and clinging-probing (Mills 2007). In Wisconsin, Sodhi and Paszkowski (1995) examined the habitat use and foraging strategies of the Nashville, Mourning, Chestnut-sided, and Canada warblers. The Nashville Warbler was distinctive from the other species because of its use of overstorey created by mature birch and aspen. Males foraged more frequently (54% of the time) in deciduous trees than other species. Males foraged 36% of the time in aspens, 7% in shrubs, and 4% in conifers. Females also foraged more frequently in hardwoods (57% of the time), followed by 18% in aspens, 18% in conifers,

and 6% in shrubs. Average foraging heights were 8.22 m for males (range 1.3-13.0 m) and 4.49 m for females (range 1.7-11.7 m). Both sexes foraged higher than their counterparts of other species. Substrates used by males consisted of 45% branches, 41% twigs and leaves, 4% limbs and trunks, and 7% air. Female substrate use was 67% branches, 23% twigs and leaves, 4% limbs and trunks, and 8% air. Males used twigs and leaves more than any other species. Foraging techniques used by males were 91% gleaning, 3% pouncing, 3% hovering, and 3% sallying. Females foraged by gleaning 83% of the time and pouncing 17%. Males gleaned more than males of other species. Females were more similar in their foraging habits to females of the other 3 species than they were to male Nashville Warblers. In subalpine areas of New Hampshire, foraging techniques included 57.5% leaf gleaning, 15.6% leaf hawking, 15.6% twig gleaning, 5.4% leaf hovering, 3.2% twig hawking and hovering, and 1.1% branch gleaning. Substrates used for foraging were 68.8% near the trunk and 31.2% distant from the trunk: 55% occurred on deciduous foliage and 45% on conifers. It was not observed feeding on herbaceous cover or the forest floor. Foraging heights were 43.6% at 5-8 m, 37.9% at 2-5 m, 10.0% above 8 m, and 8.5% at 0.1-2 m. The Nashville Warbler and Purple Finch used leaf gleaning the most of the species studied (Sabo 1980).

At 11 nests in Algonquin Park, the most frequent size of caterpillar delivered to nestlings was 2.5 cm long followed in decreasing frequency by larvae 2, 3, 1.5, 3.5, and 4 cm long. Prey size increased with nestling age, with 4- and 5-day olds receiving proportionately more larvae 1.5 and 2 cm long with older nestlings receiving more larvae 3-4 cm in length. Caterpillars comprised 89% of prey items delivered to nestlings. The remaining 11% of prey items consisted of adult flies, spiders, adult beetles, and unidentified insects (Knapton 1984c). Other authors observed that nestlings are fed predominantly caterpillars, especially those of geometer or owlet moths, and grubs, small beetles, flies, and other insects. Adults have been observed feeding fledglings caterpillars (Bent 1953; Harrison 1984; Lawrence 1948; Lowther and Williams 2020).

Except for spiders, adult Nashville Warblers are almost exclusively insectivorous, and caterpillars constitute a high proportion of its diet. It also consumes flies, young grasshoppers and locusts, leafhoppers, plant lice, and small wood-boring beetles (Bent 1953; Lowther and Williams 2020). The diet of 7 adults during the breeding season near Lake Nipigon consisted of 35.9% lepidopterans, 25.1% spiders, 17.2% soft-winged bugs (mostly aphids), 12.0% beetles (weevils and soldier, leaf, and click beetles), 5.9% hymenopterans, including ichneumonid wasps and sawflies, and 3.8% true bugs. It consumed more caterpillars (35.9% of the diet) than any other species. Caterpillars constituted an average of 22.3% of the overall diet for all species studied (Kendeigh 1947). Crawford and Jennings (1989) studied its response to a spruce budworm outbreak in New Hampshire spruce–balsam fir stands. They found an average of 3.5 budworms in 70 stomachs. It initially increased its budworm consumption and maximized consumption at the midpoint of availability in late June and early July and later decreased consumption of large larvae and pupae. This relationship was significant only for the Nashville Warbler and Boreal Chickadee. The Nashville Warbler exhibited no change in abundance in response to increasing budworm numbers, but it is possible that it could have increased over a period of several years. In the Manitouwadge area, Venier et al. (2009) observed no response in its numbers to spruce budworm populations. Mitchell (1952) examined the contents of 14 stomachs during a spruce budworm outbreak in Maine. In the year when budworms were

scarce, none were eaten. In the following year when budworms were abundant, 55% of the diet by volume consisted of budworm larvae and pupae.

The Nashville Warbler is an uncommon host of the Brown-headed Cowbird. Parasitized nests often fledge both warblers and cowbirds, but it is unknown what effects parasitism has on the warbler's brood size and fledging success rate. At a parasitized nest near Pimisi Bay, 1 warbler egg disappeared from the nest but the remaining warblers and cowbird all fledged. In Ontario, 10 of 93 nests (10.8%) were parasitized. In Quebec, 6 of 83 nests (7.2%) were parasitized. In British Columbia, 2 of 16 nests (12.5%) were parasitized and in 2 cases, adults were seen feeding cowbird fledglings. In New England, 1 of 14 nests (7.1%) was parasitized. Two of 8 Michigan nests (25%) were parasitized (Campbell et al. 2001; Harrison 1984; Lawrence 1948; Lowther and Williams 2020; Peck and James 1998a).

The Nashville Warbler is one of the warblers that benefitted most from European settlement, having increased significantly since pre-settlement times. Habitat loss and degradation are not significant limiting factors. It responds positively to forest fires and forest management that creates areas of deciduous second growth. Logged areas 1-30 years old in Algonquin Park have had a positive effect due to the increased shrub coverage after opening up the canopy (Tozer 2012). It colonized forest edges and regenerating second-growth forests (Falardeau in Gauthier and Aubry 1996; Lowther and Williams 2020; Morse 1989). In the Canadian Shield of Ontario, there was no difference in its abundance in early successional clear-cuts and burns, but it was significantly less abundant in mid-successional clear-cuts than in mid-successional burns. It was equally abundant in early successional, mid-successional, and mature stands (Zimmerling et al. 2017). Imbeau et al. (1999) studied black spruce stands that had been subjected to logging or fires in Quebec and concluded that the Nashville Warbler would benefit from short logging rotations. Near Quebec City, it responded positively as deciduous strips grew in areas that had been strip-cut, breeding at higher densities in old than young deciduous strips (Falardeau et al. 1999). In Idaho, Medin and Booth (1989) examined the effects of single-tree selection harvest on the Nashville Warbler. After logging, densities per km^2 increased to 21.5-40.0 compared with 12.4-30.8 in the same areas prior to logging. In Wisconsin 30-m riparian buffers adjacent to upland clear-cuts, it was more abundant in cut and partially cut buffers than in buffers that were uncut or where the upland forest and buffer were left intact. It was more common in riparian buffers adjacent to clear-cuts than in uncut forest (Hanowski et al. 2005). Its abundance did not vary significantly when full-tree or cut-to-length harvest techniques were used (Hanowski et al. 2003).

Hunter and Witham (1985) examined the effects of carbaryl spraying to reduce insect numbers in Maine. During the first year of study, only 30% of the site was sprayed. Numbers of all warblers dropped on spray day and remained low until 7 days later when a gradual recovery began. The Nashville Warbler was relatively unaffected, representing 5.9% of foraging warblers pre-spray, 10.0% post-spray, and 4.2% during the recovery period. The relative increase after spraying may have been due to many other warbler species leaving the area to forage elsewhere. In the following year, spraying covered 100% of the site and there were no differences in foraging heights, tree selection, or species composition of the warbler community. When the area was completely sprayed, birds could not fly to a nearby unsprayed area to forage.

Blake et al. (1992) studied the effects of drought on the Nashville Warbler in Wisconsin and Michigan. It exhibited significant variation in abundance among years and declined as drought progressed each year.

In Oregon, the Nashville Warbler exhibited no significant response to forest fires regardless of the severity of the burn, although it was more abundant in burned forests (Stephens et al. 2015).

In Minnesota, there were no significant differences in breeding densities under electric power transmission lines and control plots (Lowther and Williams 2020). Low-level electromagnetic fields have limited effects on the Nashville Warbler.

Price (2004) predicted that the Nashville Warbler might not breed any longer in southern Ontario if the average summer temperature increased by 2°C. In eastern Quebec and southern Labrador, it was strongly associated with stands having the warmest summer temperatures. In this area, which is near the northern extent of its breeding range, it may benefit from climate warming (DesGranges and LeBlanc 2012).

Status

The Nashville Warbler was very rare at the turn of the 19th century and was not described until 1811. In Massachusetts, it was unknown prior to 1834, irregular by 1836, very common by 1842, and less abundant by 1906. A similar pattern was observed throughout eastern North America with populations increasing starting in the 1830s and then declining around the start of the 20th century (Bent 1953; Falardeau in Gauthier and Aubry 1996; Lowther and Williams 2020).

McIlwraith (1894) reported that few Nashville Warblers remained as far south as Hamilton to breed and that most moved further north. Baillie and Harrington (1937) considered it a common summer resident north to the transcontinental railway and west to Kenora. During the first atlas, its breeding distribution included all the Boreal Forest and Great Lakes–St. Lawrence forest regions. There were scattered breeding records in the Hudson Bay Lowland and it also occurred in the Carolinian Forest Region but was absent in the intensively farmed areas of extreme southwestern Ontario. Highest densities were from the Canadian Shield north of a line from Parry Sound to Perth, through Algonquin Park to Timmins (McLaren in Cadman et al. 1987). James (1991) considered the Nashville Warbler a common summer resident across the province, north to Sandy Lake and Moosonee, and occasional and rare to Fort Severn and Winisk. It was rare south of the Shield, south to Haldimand and Norfolk counties.

The second atlas demonstrated that there had been limited change in the distribution of the Nashville Warbler since the first atlas. It was much more widespread within the Hudson Bay Lowland than previously documented. It continued to be rare in the Carolinian Forest Region, but breeding evidence was obtained from the Lake St. Clair area. Its province-wide probability of observation increased significantly since the first atlas, and also in the Great Lakes–St. Lawrence Forest Region, the Boreal Forest Region, and the Hudson Bay Lowland. A significant decrease in its probability of observation occurred in the Carolinian Forest Region. Highest density occurred in a broad band across the southern portion of the Boreal Forest Region from Sandy Lake to Moosonee. High densities also occurred in the Great Lakes–St. Lawrence Forest Region west of Lake Superior and

moderate densities occurred in the same forest region in the southern Shield (McLaren in Cadman et al. 2007).

Breeding Bird Survey data indicate that it decreased at annual rates of 0.644% in Canada and 0.32% in Ontario 1970-2021. Trends 2011-21 were annual decreases of 3.48% in Canada and 2.97% in Ontario. The short-term trend for Canada was highly reliable; the other results were of medium reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

After the parents stop feeding the young, both adult and young birds may occur singly, in pairs, or in groups of 3 in mixed-species feeding flocks while still on the breeding grounds (Lowther and Williams 2020). In Quebec, Major and Desrochers (2012) captured small numbers of Nashville Warblers in second-growth clear-cuts dominated by regenerating balsam fir, with lesser numbers of white spruce and white birch. In Minnesota, Streby et al. (2011b) considered it an early successional species during the postfledging period. During 1 breeding season, they captured 20. They captured 96 adults and 232 fledglings during the postfledging period over 4 years. In Michigan during the breeding and postfledging periods, Akresh et al. (2009) captured 16 adults and 31 juveniles. The capture rate per 100 net-hours was 0.9 in upland 100-year-old stands of trembling aspen and large-toothed aspen compared with 5.0 in riparian habitat with trembling aspen, alder, and honeysuckle. Eighty-one percent of juveniles occurred in riparian habitat.

MIGRATION

Migration occurs at night through the central United States from the Great Plains states eastward to the Appalachian Mountains and rarely through the southeastern states. Autumn migration is prompted by favourable weather conditions such as high-pressure systems, clear skies, and strong north-northwest winds (Bent 1953; Lowther and Williams 2020; Stewart 1986).

In spring, males arrive before females and older birds arrive before yearlings. At Long Point, mean capture dates were 8.5 May for after-second-year males, 11.3 May for second-year males, 10.7 May for males of unknown age, 13.3 May for after-second-year females, 14.4 May for second-year females, and 15.6 May for females of unknown age. Older males arrived significantly earlier than yearling males but there was no significant difference in arrival times of different age classes of females (Stewart et al. 2002). Also at Long Point, the spring midpoint for Nashville Warbler arrival 1975-2000 was 12 May. There was no significant change in arrival date over this period, although it did arrive slightly earlier in more recent years (Mills 2005). At Prince Edward Point, males arrived significantly earlier (13.6 May) than females (19.0 May). The difference in mean arrival dates between males and females was greatest in years when males arrived the earliest (Francis and Cooke 1986). In southern and central Ontario, migrants arrive in late April or early May and the main flight has passed through by late May, with a few persisting into the first week of June (Black and Roy 2010; Curry 2006; Keast 1980; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008). Kendeigh (1947) first observed the Nashville Warbler near Lake Nipigon on 23 May.

During autumn migration, the age classes usually migrate synchronously, but at a coastal station in Virginia, yearlings initiated migration earlier than adult birds (Lowther and Williams 2020; Stewart 1986). Wilson and McRae (1993) concluded that single Nashville Warblers seen at Longridge on 5 September and Moosonee on 21 and 24 July and 3 September were migrants. It is one of the latest

warblers to leave the southern Shield. Most leave by the end of September but a few linger into October (Mills 1981; Tozer 2012). Birds first arrive in southeastern Ontario by mid-August and approximately 40% of the flight has gone through by the first week of September, with average departure in mid-October (Keast 1980; LaForest 1993; Weir 2008). In the Hamilton area, peak autumn migration is in October. There are 6 December and 1 January records from the Hamilton area, but no evidence of successful overwintering (Curry 2006). At Long Point 1975-2000, the midpoint of autumn migration was 20 September. There were no changes in autumn arrival dates over this period (Mills 2005a).

The Nashville Warbler uses a variety of habitats during migration. In Illinois during spring migration, it showed a distinct preference for forest edges, but also occurred in mature upland forests and mature bottomland forests. A preference was also demonstrated for forest edge in autumn, but it also used forests, orchards, and residential areas (Graber et al. 1983). During migration, it frequents deciduous trees or shrubs in open mixed forests at mid-canopy level; brushy edges of woodlands along streams, roads, and paths; edges of fields, meadows, ponds, swamps, or marshes; second-growth alder-willow stands; gardens and suburban parks where there are trees and shrubs; old fields and pastures with scattered trees and shrubs; orchards; gardens; and shade trees in urban and rural areas. Habitat use during migration is similar to that used during the breeding season except for the use of suburban areas and rural residential lots (Bent 1953; Campbell et al. 2001; Chapman 1907; Leighton et al. 2002; Lowther and Williams 2020).

During spring migration in Wisconsin and Minnesota, Kirsch et al. (2013) found no significant differences in numbers of Nashville Warblers in upland and floodplain forests. During spring migration in Pennsylvania, it was most abundant in suburban forests followed by, in order of decreasing abundance, forest-agricultural edges, shrub and sapling-stage forests, forest interior, and pole-stage forests. Numbers in suburban forests were significantly higher than in forest interior and in pole-stage forests. In 1 of 3 years, suburban forests were used most frequently. Forest-agricultural edges were used the most the other 2 years. Rodewald and Brittingham (2007) considered it to be in a guild of shrub-sapling breeders whose abundance during migration was correlated with the percentage of low woody cover and canopy height. Also in Pennsylvania during spring migration, detections of this warbler per 100-m transect were 0.000 in forest and 0.100 in shrubs; captures per 1,000 mist-net hours were 0.6 in forest and 6.0 in shrubs. These differences were significant and it exhibited a strong preference for shrubby areas over forest. In 2 of 3 years, there were more flying insects in the shrub habitat, but there were no differences in populations of substrate invertebrates or caterpillars in the 2 habitat types (Smith and Hatch 2008). In Ohio during spring migration, it was significantly more abundant in mature upland forests than mature riparian forests. The 2 habitats supported similar species of shrubs but differed significantly with higher shrub coverage in upland forests (39.0% compared with 18.9%). Canopy closure was 74.4% in upland forests and 83.2% in riparian forests. It selected sites with denser shrub coverage and less canopy closure (Rodewald and Matthews 2005). Rodewald and Brittingham (2002, 2004) studied habitat usage by the Nashville Warbler during autumn migration in Pennsylvania. In the first study, it occurred in all habitats surveyed with no significant differences in numbers observed. In the later study, it was not observed in forest interior. It was most abundant in forest-agricultural edges followed by suburban forests, pole-stage forests, and shrub- and sapling-stage forests. There were no significant differences in the

numbers seen within the 4 habitats it occupied. Shrubs appear to be an important habitat component of migrating Nashville Warblers. It tends to be most abundant in shrub habitats, forest edges, and forests with open canopies.

During both spring and autumn migration, the Nashville Warbler frequently joins mixed-species foraging flocks. During spring, it tends to frequent the upper half of large trees and is more common in tall trees in woodlands than in smaller groups or rows of trees. In autumn, it tends to inhabit the middle section of large trees and also taller shrubs and saplings, especially large hawthorns. During autumn, it may also forage on herbaceous species (Bent 1953; Leighton et al. 2002; Lowther and Williams 2020). Keast (1980) described the foraging habits of the Nashville Warbler during autumn migration at Prince Edward Point. Foraging height ranged from 3 to 17 m, mostly 5-13 m with a peak at 7 m. It fed at 17 m for part of the day, then in the tops of saplings, and subsequently descended to heights of 1.0-1.5 m in tall shrubbery. Foraging substrates consisted of 33% outer leaves, 33% sapling leaves, 17% outer branches, and 17% twigs and inner leaves. It was not observed foraging in the air, on inner branches, on tree trunks, or on the ground. Feeding zones included 60% low shrubs, 25% bare twigs, and 15% branches. In Algonquin Park, Peter (2008) observed a male feeding on pin cherry nectar during a damp, cool spring day when few insects were available. Two days later under more favourable weather conditions, a male gleaned and hawked insects in the same tree with no evidence of nectar feeding. It has fed on nectar of native plum in Minnesota during adverse spring weather conditions. It may feed opportunistically on tree nectar when arthropods are scarce. In New York during autumn migration, Lebbin et al. (2007) observed Nashville Warblers sallying after moths at night in an area illuminated by football-stadium lights.

Keast (1980) examined the stomach contents of 2 Nashville Warblers killed during autumn migration at a hydro tower near Prince Edward Point. Collectively, they consumed 66 4-5-mm long beetles and caterpillars 11 mm and 13 mm long. Carlisle et al. (2012) examined its diet in relation to prey availability during autumn migration in Idaho. Prey items eaten in greater proportion than their availability included true bugs, stink bugs, spittlebugs, leafhoppers, jumping plant lice, beetles, lepidopterans, and moths. Prey consumed less than their availability included spiders, hymenopterans, ants, wasps, yellowjackets, and flies.

The Nashville Warbler is a common victim of striking tall structures during autumn migration, and it also strikes windows. A total of 172 were killed at the Lennox generating station chimneys near Kingston. Of autumn lighthouse and television tower kills, it represented 1.6-7.3% of all warbler casualties in Wisconsin, Ontario, and Michigan (Graber et al. 1983; Lowther and Williams 2020; Weir 2008). Loss et al. (2014) analyzed bird collisions with buildings in the United States. The Nashville Warbler was highly vulnerable to striking residences 1-3 stories high, being 22.2 times more likely to suffer a collision than average for birds. It was not on the lists of the 20 most vulnerable species for striking low-rises or high-rises.

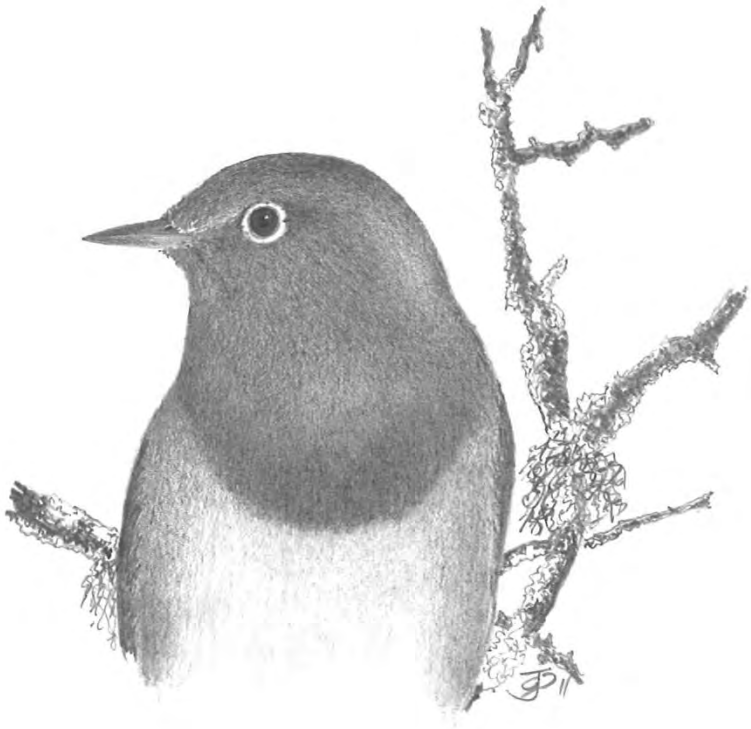
In New York, Zelt et al. (2017) compared the spring arrival dates, autumn departure dates, and length of the breeding season during 1888-1939 and 1967-2012. There was little climate change during the first period but significant warming during the second period. The Nashville Warbler arrived significantly earlier in spring during the second period, but there were no significant differences in its autumn departure dates or length of the breeding season.

McIlwraith (1894) considered the Nashville Warbler an abundant yet irregular migrant. It was common during migration some years and scarce or even absent other years. It is now a common and regular migrant (James 1991).

At Long Point Bird Observatory (LPBO) 1961-88, the Nashville Warbler experienced a significant decline of 2.9% per year. Trends by period were: 1961-70, −5.0%; 1970-79, +2.0%; and 1979-88, −6.3% (Hussell et al. 1992). More recent data from LPBO indicate a 1.2% per year increase in spring and a 1.0% per year increase in autumn 1961-2006 (Anonymous 2008).

Connecticut Warbler

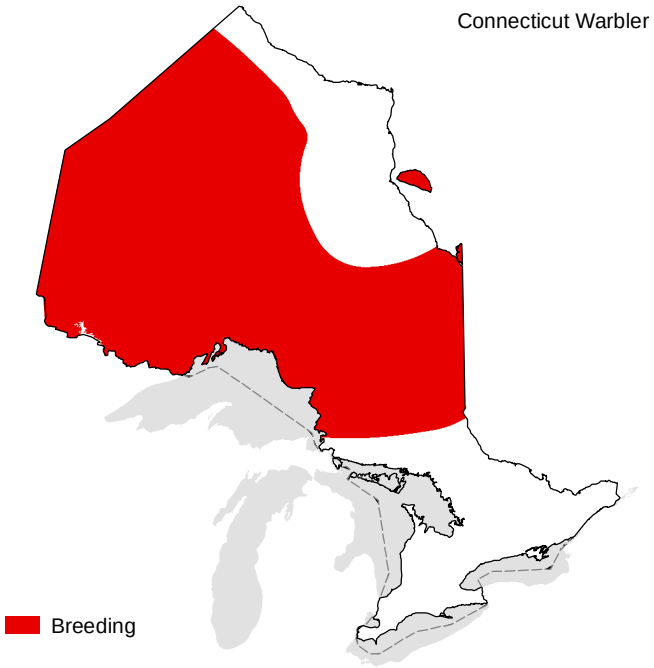
Oporornis agilis



BREEDING SEASON

Habitat Requirements

The Connecticut Warbler nests in 2 types of habitat in Ontario and Canada. In the eastern part of its range, it prefers black spruce and tamarack bogs and fens, although localized usage of immature jack pine stands occurs. In the west, it nests predominantly in open trembling aspen woods. Both habitats are used in Ontario, with the black spruce and tamarack associations used predominantly. Both types are used in Rainy River District. East of Fort Francis, the Canadian Shield is predominantly boreal in nature. Tree cover is chiefly coniferous, with jack pine in drier sites, black spruce in moist areas, trembling aspen throughout, and poorly drained areas dominated by black spruce with some tamarack. It selects these poorly drained areas for nesting. The area west of Fort Francis is flat and the landscape is mostly agricultural. Woodlands in this area are mostly trembling aspen with a few balsam fir and white and black spruce. There are some large peat bogs that may be either open or forested with mature black spruce. In this area, it avoids bogs and nests in trembling aspen forests.



The aspen woods that are occupied are fairly open with an understorey of dogwood, willow, and other shrubs. Males sing from a perch well up in aspens, often in the canopy. In the Boreal Forest Region, it demonstrates a preference for bogs with open immature or stunted stands of black spruce. The ground cover consists of sphagnum moss, Labrador tea, bog rosemary, bog laurel, and leatherleaf. In this habitat, males sing from a perch high up in a black spruce (Elder 1991). Most other information on Connecticut Warbler habitat in Ontario is from the Boreal Forest Region. An exception is the Gogama area where James and Peck (1995a) reported a single male singing in several summers in a 40-50-year-old jack pine forest where trees were 12-16 m tall. They concluded that it had not colonized this habitat type in any significant numbers anywhere within the province. From Pickle Lake north to Sachigo Lake, it occurred in coniferous forest with and without an understorey and in coniferous scrub. It was absent in deciduous or mixed forest, deciduous or mixed scrub, heath, and tundra (McLaren and McLaren 1981). Near Pickle Lake, James (1980) documented it rarely in spruce bogs. Harris (2011) provided the first documentation of an Ontario nest from north of Lake Nipigon. The habitat was an 86-ha treed fen that bordered a small lake. The fen was dominated by scattered black spruce 2-3 m tall spaced at 5-10-m intervals. The ground flora consisted of leatherleaf, bog laurel, and cottongrass within a continuous layer of sphagnum moss. Around the outer edges of the fen, the black spruces were taller and denser as they graded into coniferous swamp. The previous Ontario breeding record was from the Thunder Bay area in a cutover with dense undergrowth of raspberries (Peck and James 1987). Along the northeastern shore of Lake Superior, Baillie and Hope (1943) found the Connecticut Warbler only in spruce bogs. In the Clay Belt, Smith (1957) reported it in spruce-poplar and lowland spruce stands. In the same region, it reached its maximum abundance in black spruce stands and preferred open spruce bogs and fens. It occurred over a wide range of moisture regimes from very wet stands of black spruce to very dry stands of jack pine. It also occurred in tamarack and spruce–white birch stands (Welsh and Lougheed 1996). Welsh (1993) reported that it bred predominantly on organic soils in pure black spruce stands in the Boreal Forest Region, and that it was rare in jack pine and tamarack stands. In the Hudson Bay Lowland, it was most abundant in the Moosonee area in a tamarack fen. Wilson and McRae (1993) were of the opinion that it bred in the extensive tamarack fens inland from the Moose River and Longridge.

The Connecticut Warbler also nests in 2 main habitat types in Quebec. In the Boreal Forest Region, it nests predominantly in peatlands, in black spruce–moss forests, and in the ecotone between these 2 habitats. In more southerly areas of Quebec, a number of sightings have been

made in jack pine stands with fewer records from poplar stands, open spruce forests, and black spruce peatlands (Ibarzabal in Gauthier and Aubry 1996). At the southern extent of its range in Michigan, 1 pair nested in a mixed trembling aspen–spruce forest. The trees were widely scattered with many openings among them, creating a park-like appearance. The ground cover was extremely dense and consisted of timothy and other grasses; sedges were present in some locations (Walkinshaw and Dyer 1961). On islands in Wisconsin, it nested only in 1 aspen stand (Beals 1960). In the same state, it is a rare breeder in diverse pine and oak barrens and coniferous plantations (Mossman et al. 1991). Also in Wisconsin, it nests in oak–jack pine forests with dense underbrush and at edges of coniferous forests (Pitocchelli et al. 2023). In Minnesota, Huff (1929) reported a nest that was in an almost pure stand of black spruce, although some areas supported pure tamarack or a mix of these 2 species. Portions of the wetland were very dense, but it inhabited an area that was more open where the trees were well spaced and deep sphagnum moss covered the ground. Shrub species included Labrador tea and bog laurel and the herbaceous community was dominated by pitcher plant, sundews, bogbean, wild calla, coralroot, pink lady's slipper, and dragon's mouth. The shrubs were 38-45 cm tall and the opening was no more than 30 m from the edge of the wetland. The male sang for more than 5 hours from a tamarack 10.7-12.2 m tall standing amidst taller black spruce. Even where black spruce was the dominant tree, birds demonstrated a decided preference for singing from tamarack. Grinde et al. (2023) found nests in Minnesota in habitats dominated by tamarack or black spruce. Within 11.3-m plots around nests, the most common trees were 8-23 cm diameter at breast height (DBH) tamaracks with an average of 1,175 trees per ha, with small snags (500 per ha), small black spruce (1,075 per ha), and 23-38-cm DBH snags (125 per ha). Common understorey plants in nest plots in order of abundance were Labrador tea, leatherleaf, bog birch, and bog laurel. Other species included alder, balsam fir, blueberry, bog rosemary, gooseberry, honeysuckle, and white birch. Niemi and Hanowski (1984a) studied birds in 6 habitats (sedge fen, low shrubs, tall shrubs, open black spruce forest, closed black spruce forest, and tamarack forest) and found the Connecticut Warbler only in closed spruce forest. It was significantly more abundant in control than treatment plots. There were significant differences in tree density and heights in the 2 plots. In the preferred plots, tree height averaged 6.6 m (range 4.5-10.0 m) compared with 5.5 m (range 3.0-9.0 m) in treatment areas. Tree density was 45 per 0.01 ha (range 5-256) in control compared with 23 (range 5-100) in treatment areas. In Minnesota, breeding habitat consisted of mature lowland coniferous habitats, particularly black spruce and tamarack bogs with dense underbrush, scattered trees, and grassy openings. Of 480 observations, 90% were in black spruce, tamarack, and mixed stands of lowland conifers. Other stand types that were used included trembling aspen (4% of observations), red pine (3%), jack pine (2%), and mixed trembling aspen–balsam fir (1%). It occurred most consistently in lowland coniferous habitat within a matrix of large patches of lowland and upland coniferous habitat. Its frequency and abundance was positively correlated with the percentage of lowland black spruce and other lowland coniferous forests, positively correlated with the amount of upland coniferous cover, and negatively correlated with the percentage of upland deciduous forest, average total patch edge, and number of patches in adjacent lands. Important elements of the landscape to the Connecticut Warbler were a mosaic of coniferous forest, a combination of lowland and upland coniferous habitat, and the size of the pieces of this mosaic. Its abundance was approximately the same in buffers of 100, 500, and 1,000 m from sightings, but frequency increased with buffer size. The 1,000-m model was the best in predicting

its frequency and abundance. Important predictor variables at this scale were a high percentage of upland coniferous forest, a high percentage of lowland black spruce forest, and a low percentage of upland deciduous forest. Frequency was negatively associated with the number of patches and total patch edge. At the 500-m scale, the most important parameters were high variance of tree density, high percentage of black spruce forest, and a low density of trees. At the 100-m scale, the most important habitat variables were high density of ground cover, low percentage canopy cover, and low percentage of lowland deciduous forest (Lapin et al. 2013). Seton (1884) found the first nest for this species in Manitoba. The habitat was a large spruce forest with a tamarack bog in it. Tamarack was sparse within this area and the ground cover consisted of mosses, pitcher plants, and sundews. In Alberta and Saskatchewan, the Connecticut Warbler nests almost exclusively in trembling aspen and balsam poplar stands, usually mixed with some conifers such as jack pine, white spruce, or black spruce. Forests that it inhabits usually have a dense woody understorey that may include poplar, roses, dogwood, beaked hazel, chokecherry, juneberry, alder, and willow. In this area, it is frequently associated with clear-cuts and may be more abundant in them than in forests. Kirk et al. (1996) reported that it was associated most frequently with mixed-wood or deciduous forests in Alberta and Saskatchewan and, less frequently, with black spruce or species-poor jack pine stands. It was observed in 50% of stands 15-20 years old, but was not detected in stands 0-9 years or 40-80 years old. It occurred on average at the midpoint on the moisture and nutrient-level axes. It was associated with aspen or poplar stands rather than areas of organic soils supporting black spruce. In Alberta, it nested both in clear-cuts and forests dominated by trembling aspen and balsam poplar. It used clear-cuts by the third year after cutting when trembling aspen were 1-2 m tall. Trees were retained within these clear-cuts, and its abundance decreased with increasing basal area of trees (Tittler et al. 2001). In Alberta, it was most abundant in young aspen forests where it was a low strata species preferring deciduous forest. It was associated with high percent coverage by moss, dense small aspens, slightly above average amounts of conifers, and moderate to low canopy heterogeneity. Young aspen forests exhibited intermediate canopy heterogeneity. Mean numbers detected on point counts were 0.76 in young forests (canopy height 8-11 m, 5,000-7,000 trees per ha, 23-26 years old), 0.42 in mature stands (canopy height 15-20 m, 1,000-3,000 trees per ha, 51-63 years old), and 0.29 in old-growth (canopy height greater than 20 m, less than 1,000 trees per ha, more than 120 years old; Schieck et al. 1995)). Breeding habitat in British Columbia appears to be slightly different than what is used in the Prairie Provinces. It appears to prefer more mature stands. It breeds in old-growth and mature trembling aspen stands. There are some records from younger aspen stands, willow–trembling aspen stands, willow–balsam poplar stands, and stands of smaller trembling aspen on slightly drier ridges. Breeding habitat includes edges of old-growth and young stands of trembling aspen–spruce, mixed balsam poplar–spruce stands on islands in a river, old-growth trembling aspen with white spruce saplings in the understorey, and young to old-growth trembling aspen stands. The presence of spruce in the understorey of trembling aspen stands may be characteristic of good habitat. In all inhabited areas, there was a noticeable gap of open space between the canopy and shrub layer (Campbell et al. 2001). Another British Columbia study characterized habitat as a wide range of age of aspen stands (average 68 years), canopy containing gaps, low densities of spruce, average of less than 20% shrub coverage, less than 5% coverage by shrubs shorter than 2 m tall, more than 75% herbaceous cover, 40% coverage by grasses, and terrain with an average slope of 8.1%. Tall cover by herbaceous plants combined with low shrub coverage

was the best predictor of breeding habitat (Pitocchelli et al. 2023). In Minnesota, it was positively correlated with the amount of both productive and non-productive stands of black spruce and tamarack within 200 m, basal area, and stand age. It was negatively correlated with the amount of white cedar within 1 km, the amount of sedge meadow within 1 km, and the amount of upland forest within 200 m. It would benefit from forest management that avoids harvesting black spruce–tamarack forests with intermediate basal area, especially in landscapes surrounded by additional black spruce–tamarack forests (Zlonis et al. 2017).

The Connecticut Warbler may be area sensitive. In the United States Great Lakes region, bogs inhabited by this species are typically larger than 40 ha (Pitocchelli et al. 2023). In Minnesota, Lapin et al. (2013) concluded that it may be area sensitive, even in forested landscapes. It was often absent in areas of suitable habitat that were in small patches of lowland and upland conifers. One stand was in both a mature black spruce plantation and an area that was logged shortly after the survey was initiated. Even though the landscape still consisted of potentially suitable breeding habitat with a high proportion of black spruce forest (37.7% of the area within 1,000 m), the alteration of a portion of the stand rendered it unsuitable. The authors concluded that larger patches of lowland and upland coniferous forest within a forested mosaic were important. Lowland coniferous forests in northern Minnesota have not been extensively altered, but surrounding forests have been frequently harvested and this has the potential to have an effect on it. In Saskatchewan, its abundance was positively correlated with forest size. It was more common in large fragments or in areas with a high local percentage of forest cover within 5 km. It was randomly distributed in landscapes, occurring in both forest fragments and contiguous forest (Hobson and Bayne 2000). Also in Saskatchewan, Johns (1993) examined aspen groves ranging in size from 0.2 to 36.7 ha. Smaller groves tended to be highly isolated from their nearest neighbour; large groves were less isolated. The Connecticut Warbler exhibited a significant negative trend with increasing isolation. Despite this relationship, it was found in groves as small as 3.2 ha as well as in larger stands. In British Columbia, birds were observed in stands as small as 4 ha (Campbell et al. 2001). These studies suggest that the Connecticut Warbler may be area sensitive, particularly in coniferous wetland habitats in the east. Although it may exhibit some area sensitivity in western aspen forests, it inhabits some small patches that are only 3.2-4 ha.

The first Ontario nest of the Connecticut Warbler was found in 1971 when 3 young were observed leaving a nest in Sleeping Giant Provincial Park at Thunder Bay. The nest was on the ground in a raspberry thicket in a logged area with dense undergrowth (Peck and James 1987). Nests are notoriously difficult to find because the male typically sings 100 m or further from the nest and the female walks the last 10-15 m when approaching the nest. Harris (2011) provided the first complete account of an Ontario nest, which he found north of Lake Nipigon. The nest was in a fen sparsely treed with short black spruce. It was 50 cm from the base of a 2.5-m tall black spruce and in a hummock of sphagnum moss under a tussock of cottongrass and leatherleaf. It was sunken approximately 12 cm below the surface of the hummock. The nest was about 100 m from the edge of the surrounding poplar-dominated forest. Kells (1889) attributed several nests that he found near Listowel to the Connecticut Warbler. It appears as though this was a case of mistaken identity. The habitat described was atypical of that used by the Connecticut Warbler and the sightings were considerably south of its known range. These records were not accepted or mentioned by

McIlwraith (1894), Baillie and Harrington (1937), or Peck and James (1987). A subsequent paper by Kells (1904) on the Connecticut Warbler in Ontario did not mention nesting.

Few nests of the Connecticut Warbler have been found. Seton (1884) found the first nest in Manitoba 51 years after the species was originally described. It was sunken in moss level with the surface. A nest in Minnesota was in the open except that it was overtopped by 30-cm tall Labrador tea and bog laurel that offered it some protection (Huff 1929). A Michigan nest was on dry ground. Vegetation within 5 m consisted of bracken ferns, small basswoods, strawberries, violets, morning-glories, goldenrods, fireweed, and large-leaved aster. A Minnesota nest was among tall grasses in an abandoned field at the edge of a spruce forest. Alberta nests are frequently in open poplar woods on a ridge above a small slough. They are typically on the ground, well concealed by grasses or other vegetation. An Alberta nest was in an open growth of fire-killed aspen, small shrubs, and herbaceous species and 15 cm from the ground in a rose bush. Minnesota nests were in moss, except for one in grass. They were concealed by grass, Labrador tea, bog birch, tamarack, and moss. The dominant cover type was tamarack at 10 nests and black spruce at 1 nest. Throughout its range, the Connecticut Warbler places its nest on or near the ground in dense undergrowth of saplings, among thickets, at the base of a shrub, in a mound of moss, or in dry grasses, and it is often covered by overhanging vegetation (Bent 1953; Grinde et al. 2023; Huff 1929; Pitocchelli et al. 1997; Walkinshaw and Dyer 1961).

In many areas, populations are too sparse for territorial behaviour to be required. Where isolated pairs nest, they may occupy a large territory or home range, with males frequently singing as far as 145 m from the nest (Walkinshaw and Dyer 1961). Pitocchelli et al. (2023) reported that the Connecticut Warbler was highly territorial when conspecifics were present. In Minnesota, territory sizes averaged 0.24 ha in open spruce forest and 0.48 ha in closed spruce forest. Isolated pairs may occupy larger areas than those that have neighbours.

No information is available on natal philopatry or adult site fidelity. Lapin et al. (2013) monitored Connecticut Warbler populations at a site in Minnesota over an 18-year period. During this study, its frequency per stand ranged from 0-72%. This suggested that site fidelity was low. The authors concluded that short-term studies would unlikely be able to detect the consistency in which an individual stand was used by the Connecticut Warbler.

Limiting Factors

Peck and James (1987) concluded that eggs would likely be present in Ontario nests during the month of June. Harris (2011) reported an Ontario nest with eggs on 15 June, but young were seen leaving a nest on 24 July (Peck and James 1987) suggesting that eggs may be present at least to the first or second week of July. In Michigan at the southern limit of this warbler's breeding range, Walkinshaw and Dyer (1961) estimated that egg laying began by 5 June with nest building occurring in late May or early June. No information is available on how soon nest building begins after spring arrival, how long nest building takes, or if there is a delay between nest completion and initiation of egg laying. It is likely that 1 egg is laid daily, but this has not been confirmed. It is unknown when incubation is initiated and how long it takes. The nestling period is 7-10 days (Pitocchelli et al. 2023).

The Connecticut Warbler raises a single brood. A brood observed leaving a nest in Sleeping Giant Provincial Park consisted of 3 young, but it is possible that the clutch size was larger. The single

nest described for the province had a clutch of 5 eggs. Clutches of 3-5 eggs have been reported throughout its range, with 4-egg clutches most common (Bent 1953; Harris 2011; Huff 1929; Leighton et al. 2002; Peck and James 1987; Pitocchelli et al. 2023; Seton 1884; Walkinshaw and Dyer 1961).

No information is available on the age of first breeding, but it is probably 1 year. The mating system is monogamous (Pitocchelli et al. 2023).

During the breeding season, the Connecticut Warbler gleans invertebrates from vegetation near the ground. Two were observed hunting a spider running over water, which they captured by gliding in the same manner as a swallow does when drinking. The stomach contents of these 2 birds consisted of 50 of these spiders and nothing else. Both adults feed the young raspberries, caterpillars, moths, and small insect larvae. Adults consume mostly spiders and insect adults, larvae, and pupae. They have been reported feeding on beetles, snails, and occasionally small seeds and berries (Bent 1953; Pitocchelli et al. 2023). A male in black spruce forest near Lake Nipigon had eaten 30 spiders, 5 true bugs, 5 beetles, 30 flies, and 2 hymenopterans (Kendeigh 1947).

The Connecticut Warbler has been parasitized by the Brown-headed Cowbird, but the extent of parasitism is unknown (Pitocchelli et al. 2023). The likelihood of parasitism in Ontario is low because there is limited overlap in the breeding distributions of these 2 species. In addition, the Connecticut Warbler nests in coniferous forests, bogs, and fens in the Boreal Forest Region, habitat that is generally avoided by the cowbird. The highest potential for parasitism in the province is in Rainy River District where the Connecticut Warbler nests in aspen stands.

The effects of forest harvesting in Ontario are uncertain. In the Canadian Shield of Ontario, there were no significant differences in its abundance in early successional and mid-successional clear-cuts and burns of the same seral stage and there were no differences in its abundance in early, mid-successional, or mature stands (Zimmerling et al. 2017). In Alberta, Tittler et al. (2001) concluded that it may benefit from logging and by retention of low densities of residual trees. To retain it in this area, it was considered desirable to leave fewer rather than more residual trees in clear-cuts or to allow some natural fires to occur. Retention of high densities of residual trees may be detrimental. In other areas, higher warbler densities occurred in post-fire than post-logging stands; burned areas had fewer trees and living shrubs (Pitocchelli et al. 2023). In Minnesota, it was vulnerable to loss and fragmentation of coniferous forest. Even when the wetland coniferous stands that it inhabited were left undisturbed, harvesting adjacent upland coniferous stands made some otherwise suitable habitats unsuitable (Lapin et al. 2013). In Saskatchewan, it may demonstrate a differential response to forest fragmentation depending upon distance from contiguous forest (Hobson and Bayne 2000). In British Columbia, logging of aspen stands combined with herbicides that reduce understorey vegetation is the most important threat. Much habitat is being lost there because harvested areas tend to be converted to agricultural land or to pure white spruce or trembling aspen stands with short rotation periods (Campbell et al. 2001). Threats that have been identified in Wisconsin include loss of jack pine forest due to spruce budworm outbreaks, forest fragmentation which may cause increased predation and parasitism, fire suppression, and loss of pine barrens (Pitocchelli et al. 2023).

Niemi and Hanowski (1984b) studied the effects of a 55-m-wide hydro transmission line right-of-way through forested habitat. Breeding Connecticut Warblers were at a greater mean distance

from the transect line in treatment areas (144 m) than in control areas (108 m). The authors found little basis for suggesting any positive or negative effects of the transmission line and attributed the results to differences in habitat between the control and treatment areas.

In Alberta, Bayne et al. (2008) determined that there was no difference in abundance of the Connecticut Warbler near noisy compressor stations and quiet well pads. It did not appear to be affected by chronic noise.

In Alberta, the Connecticut Warbler was significantly more abundant at pipelines than in adjacent forest interior. There was no difference in its abundance at seismic lines and well pads than in forest interior adjacent to these features (Bayne et al. 2016).

Venier et al. (1999) used results from the first atlas to compare the distribution of the Connecticut Warbler to those derived from climate models. The only parameter used in the model for this species was the range of precipitation. The model resulted in very high rates (95.3%) of false positives. The authors concluded that this type of large-scale model is not very useful for predicting the range of rare species such as the Connecticut Warbler. It is considered highly vulnerable to climate change because bogs and lowland coniferous forests are expected to disappear in their southern range limits (Grinde et al. 2023).

Status

Based on observations of juveniles accompanied by adults during early autumn migration, McIlwraith (1894) concluded that the Connecticut Warbler nested in the province. Baillie and Harrington (1937) reported it as a rare summer resident of Cochrane, Algoma, and Thunder Bay districts. The first evidence of breeding was obtained on 17 August 1918 in Algoma District where a pair was observed feeding young. The first nest was found in Sleeping Giant Provincial Park near Thunder Bay on 24 July 1971, but details of this nesting were not documented (Peck and James 1987). The first documented nest was found north of Lake Nipigon on 15 June 2010 (Harris 2011). The first atlas extended the known breeding range of the Connecticut Warbler. It occurred sparingly from Sault Ste. Marie to Moosonee in the east, west to the Manitoba border north to the lower Sachigo River, about 300 km northeast of Sandy Lake, the previously known northern limit. There were many gaps in its distribution within this range, but it was concluded that it was potentially present throughout and that it was actually quite common in some locations (Helleiner in Cadman et al. 1987). James (1991) considered it a locally uncommon summer resident across central Ontario, north to Big Trout Lake and Fort Albany and south to Wawa and Cochrane. He considered it occasional and rare south to Sault Ste. Marie and Sudbury. At Moosonee, it was locally common in a tamarack fen (Wilson and McRae 1993).

The second atlas demonstrated that there had been little change in the overall breeding distribution of the Connecticut Warbler, and numerous gaps within that range persisted. Its probability of observation increased significantly province-wide and in the Boreal Forest Region and Hudson Bay Lowland. The most substantial increase was in the Hudson Bay Lowland where the probability of observation increased several fold. It was difficult to determine if the increase was real, a result of enhanced atlassing effort, or an artifact of a small data set. It was most abundant in the western portion of the Boreal Forest Region and in the Great Lakes–St. Lawrence Forest Region west

of Thunder Bay. Overall, it was uncommon, but high densities may occur in isolated areas (McLaren in Cadman et al. 2007).

Breeding population trends for the Connecticut Warbler are uncertain. From 1966 to 2019, Breeding Bird Survey (BBS) results indicated an annual decrease of 0.8%, or an overall decrease of 60% (Pitocchelli et al. 2023). BBS data to 2008 indicate a 1.6% annual decline in Bird Conservation Region 12, with declines in Ontario, Manitoba, Saskatchewan, Minnesota, Wisconsin, and the entire United States. Reasons for the apparent decline are uncertain, but may include nest predation, changes in landscape, loss of nesting habitat as a result of fragmentation and climate change, loss of winter habitat, and collisions with human-made structures (Lapin et al. 2013).

In Ontario, results from the BBS and atlases are contradictory. The BBS is probably not very reliable for the Connecticut Warbler in the province because much of its breeding range and habitat is inaccessible by road. Conversely, the apparent increase reported by the second atlas may have been a result of better coverage. BBS results indicate that it decreased at annual rates of 1.6% in Canada and 2.39% in Ontario 1970-2021. Trends 2011-21 were annual decreases of 3.53% in Canada and 3.32% in Ontario. All results were of medium reliability except for the Ontario short-term trend, which was of low reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Fledglings stay close to the ground in dense thickets and come out in the open only when being fed by the adults. They are unable to fly when they first leave the nest. Young disperse from the nest by walking on moss or through thick vegetation. In Wisconsin, a family appeared among tamaracks at the edge of a bog on 20 July. At first, the young remained near the ground in a small tamarack, other conifers, and shrubs on the bog. Later, they spent most of their time in piles of treetops and coniferous slash lying on the ground and appeared to prefer this microhabitat. On 2 August, they were found approximately 73 m away. They moved further away every day but remained in a narrow belt of conifers until 20 August. After that, they began to flock with other Connecticut Warblers and a flock of 20-25 was seen several times (Bent 1953; Grinde et al. 2023; Pitocchelli et al. 2023). In Minnesota over the entire postfledging period, the average daily distance moved from nests was 88.5 m (range 7.6-203.0 m). The average daily distance moved from nests 0-7 days postfledging was 35.5 m (range 7.6-104.0 m). Young did not move more than 100 m from the nest until 7 days postfledging. The average distance from the previous day's location was 53.5 m (range 7.6-272.4 m). Average habitat characteristics at fledgling locations were 38% canopy cover (range 0-86.3%), 16.4 m tree height (range 7.5-27.5 m), and 7.9 cm moss depth (range 2.3-24.8 cm). Habitat was similar at random plots. Tamarack was the dominant cover at all fledgling locations. Microhabitats where fledglings were located had significantly higher stem counts than random sites, but there were no differences in other vegetation characteristics. Both parents continued to feed the fledglings until 17 days after they left the nest (Grinde et al. 2023). McIlwraith (1894) reported adults accompanied by young in August in the Hamilton area. It is possible that families remain together for the first stages of autumn migration, or it is possible that the adults and juveniles were unrelated.

MIGRATION

Migration appears to be nocturnal based on kills at tall structures. In southern and central Ontario, most spring records are from mid- to late May with the earliest migrants arriving in the first week of

May. A few remain into the first or second week of June (Black and Roy 2010; Curry 2006; Fleming 1907; LaForest 1993; Lancaster et al. 2004; Tozer 2012; Weir 2008).

One observed at Longridge by Wilson and McRae (1993) on 9 September was an autumn migrant. Further south, migration is from late August to late September with some remaining into the second week of October (Black and Roy 2010; Curry 2006; Fleming 1907; LaForest 1993; Lancaster et al. 2004; Tozer 2012; Weir 2008).

During spring migration, the Connecticut Warbler occurs predominantly on the ground in tangles of dense undergrowth, in wet thickets, in woodlands and undergrowth in rural areas, on or near the ground in mature floodplain forests, and in moist forests and fallow fields. It is uncommon but regular in city parks and residential areas with shrubs and other low, dense vegetation. It prefers dense undergrowth during migration (Pitocchelli et al. 2023). During spring migration, Saunders (1885) reported it feeding on the ground in dry places at Point Pelee and in swamps near London. In Illinois, Graber et al. (1983) often found it during spring migration in weedy patches and gooseberries, in shrubby swamps, and occasionally in bottomland swamps. It was more numerous in forest edges and shrubs than in forests. Walkinshaw and Dyer (1961) often found it along shrubby roadsides in Michigan during spring, where it remained near the ground. In Ohio during spring migration, it occurred almost entirely in bushy tangles of remnants of swamp forests and was only seen in upland woodlands twice (Bent 1953). Within Illinois woodlands, it occurred more often in forest gaps created by treefalls with a dense understorey than in undisturbed forests (Pitocchelli et al. 2023).

During autumn migration, the Connecticut Warbler may occur in wet brushy areas, damp woodlands with dense undergrowth, weed and raspberry patches, maple swamps, shrub thickets, on the ground under or among rank vegetation, and in dense growths of willows. In British Columbia, it has been observed in autumn in tamarack-spruce bogs with dense shrub growth and in shrub willows along creeks. In autumn in Ohio, it is not confined to swamp remnants, but also inhabits shrubby, weedy, and fallow fields. It may occur in weedy growths bordering hedgerows some distance from woodlands. During autumn in Massachusetts, it was often seen in beds of jewelweed in swamps and along ditches where nightshade overhung the water. Elsewhere, it has occurred in autumn in dense undergrowths of ragweed, sunflowers, asters, greenbrier, poison ivy, and barberry (Bent 1953; Campbell et al. 2001; Chapman 1907; Pitocchelli et al. 2023).

During migration, the Connecticut Warbler may occur at all levels, but is most commonly found on or near the ground. In autumn, it may forage within mixed-species flocks. During cloudy weather in autumn, it may forage at the tops of trees 15-18 m from the ground in the company of other warbler species. It often feeds on owlet moth caterpillars during autumn migration (Chapman 1907; Pitocchelli et al. 2023).

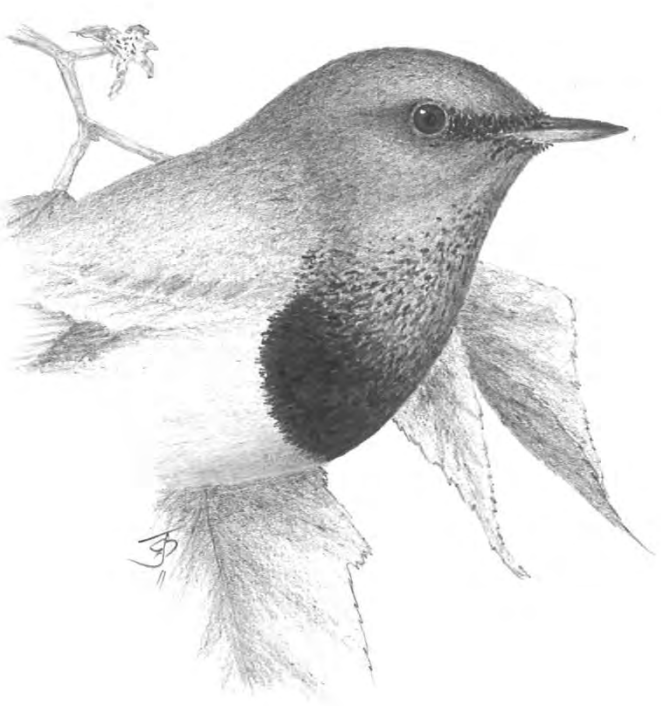
The Connecticut Warbler commonly strikes tall buildings, communication towers, and other structures during migration. During the autumn of 1981, only 2 were observed in the Kingston area but 15 were killed at the Lennox generating station chimneys: 7 each on 5 and 7 September and 1 on 4 September. A total of 19 kills occurred there 1972-82. Some tower kills were reported in Illinois, also in greater numbers than observers see. In Wisconsin, 330 were killed at towers in 1 location during autumn migration in 1 year; 140 were killed in a single night. At 2 sites, it represented 1% and

2% of all warblers killed. Both kills at structures and banding efforts reveal much larger numbers passing through than are reported by observers (Graber et al. 1983; Pitocchelli et al. 2023; Weir 2008). Loss et al. (2014) determined that it was at high risk of colliding with buildings in the United States. It was 22.9 times more likely than average to strike buildings. It was not on the list of the top 20 vulnerable species for striking residences 1-3 stories tall. At low-rises, it was 35.7 times more likely to suffer a collision than average and 52.0 times more likely at high-rises.

James (1991) considered the Connecticut Warbler a rare migrant in Ontario. All regional books on Ontario birds rank it as very uncommon, rare, or very rare, and it is also irregular in occurrence in most areas. It is rarely observed, but it is likely more common than observer records indicate. It is also likely to be more common in autumn due to the presence of juveniles in the population and the eastward migration pattern whereby birds that bred in western Canada pass through Ontario. Early accounts of migrants suggest that it may have previously been more common. The first official Canadian specimen was a bird that flew into a store in London on 15 September 1883, but McIlwraith apparently had several specimens in his possession many years prior to that. Saunders (1885) considered it tolerably common in swamps near London in May and quite common at Point Pelee for a few days in early June. In Toronto, it was considered one of the rarest warblers until 1896 when it was found to be fairly common in May. Thereafter, Fleming (1907) considered it a regular but not common migrant.

Mourning Warbler

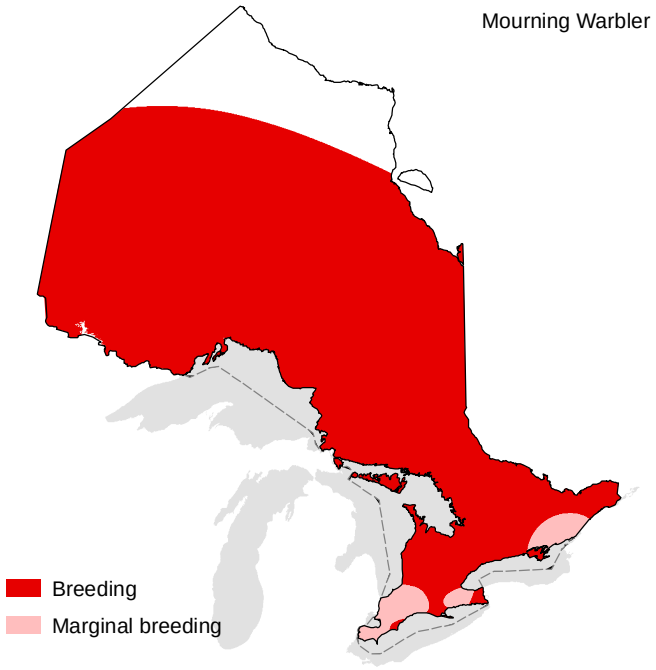
Geothlypis philadelphia



BREEDING SEASON

Habitat Requirements

In Ontario, 76.9% of Mourning Warbler nests were in forests, with 26.9% in mixed woods, 7.7% in deciduous woods, and 3.8% in coniferous woods; the other forest types were not specified. All forested areas that it used had a dense understorey and either had an open canopy or the nest was at the woodland edge, in a clearing, or near roadsides. Single nests (3.8% each) were in a brushy thicket; an alder swale; a deciduous thicket of alder, willow, and dogwood; and in a burn. Two nests (7.7%) were in residential gardens. Most nests were in upland habitat, but 7 were in damp or swampy areas (Peck and James 1987). James (1984b) reported that the Mourning Warbler nested in mixed and deciduous forests in Ontario and rarely in coniferous forests. It requires a dense deciduous layer under trees, particularly aspen, in open woods, edges, or clearings. Nesting may occur in dry or moist areas.



In the Hudson Bay Lowland, the Mourning Warbler was fairly common in aspen groves near Moosonee, especially further inland along the banks of the Moose River (Wilson and McRae 1993).

In the Boreal Forest Region near Pickle Lake, the Mourning Warbler occurred in coniferous forest with and without an understorey layer, in mixed scrub, and in deciduous forest. It was absent in mixed forest, deciduous or coniferous scrub, heath, and tundra (McLaren and McLaren 1981). In the same area, James (1980) encountered it irregularly in edge situations. North of Lake Nipigon, it nested in openings in the forest and in clear-cuts (Kendeigh 1947). Near White River in jack pine stands, it was significantly associated with the youngest forest age class, 3-5 years after clear-cutting. The Mourning Warbler had the second-highest indicator value of all species studied, indicating that it was highly specialized for inhabiting early successional habitat. Its abundance was strongly associated with the volume of coarse woody debris in decay stage 1 that had most of the bark still intact and more than 75% of the wood still hard (Venier and Pearce 2005). Near Quetico Park, it was most abundant in stands 1-23 years old where it was fourth in importance values of the species present. It was not detected in intermediate-aged stands (67-73 years) and was of low importance in mature (112-176 years) and old-growth (367-370 years) stands (Apfelbaum and Haney 1999). Near Hearst, Welsh and Fillman (1980) found it in uncut upland deciduous stands but not in uncut lowland coniferous stands. It occurred in upland clear-cuts 3-19 years old, lower-slope mixed clear-cuts 17 years old, and lowland coniferous cuts 3-9 years old. Welsh (1993) considered it an early successional species in the Boreal Forest Region. It occurred in clear-cuts 1 year after cutting, was most abundant in 3-8-year-old cuts, but occurred regularly in cuts as old as 16 years and irregularly in older stands to 33 years of age. It was not detected in stands 57-220 years old. Northeast of Lake Superior, it frequented new growth in burns, clear-cuts, and forest clearings (Baillie and Hope 1943). In the Clay Belt, it was most common in nutrient-rich stands and those that were wetter than average. It was most abundant in stands dominated by trembling aspen and trembling aspen with mixed conifers. Although it was most abundant in these stand types, it occurred in all stand types investigated, including those dominated by black spruce, balsam fir, jack pine–trembling aspen, and balsam poplar–trembling aspen (Welsh and Lougheed 1996).

In the Great Lakes–St. Lawrence Forest Region in the Canadian Shield, James and Peck (1995a) surveyed jack pine stands near Gogama. They found the Mourning Warbler where tall deciduous shrub coverage was at least 50% and often nearly 100%. It usually occurred in areas cut or burned 5-10 years previously, but also at edges of tall pine forests where shrubs and raspberries were

common. In Algonquin Park, MacLulich (1938), Martin (1960), and Tozer (2012) concurred that it inhabits open, brushy habitats such as forest edges and open cuts. It was common in cuts in white pine stands 2-9 years old, uncommon in 10-18-year-old cuts, and absent in areas with no history of cutting. Kingsley and Nol (1999) considered it a shrub-nesting species that responded positively to most silvicultural treatments. It was most abundant in stands with a greater extent of herbaceous cover and deciduous and coniferous subcanopy. In Muskoka and Parry Sound districts, it thrived in dense, moist thickets. It nests there in disturbed areas such as margins of cottage and secondary roads, along hydro-line corridors, and in forest and river edges (Mills 1981).

South of the Shield in the Great Lakes–St. Lawrence Forest Region, Speirs and Orenstein (1975) considered it a mid-successional species in Durham Region, where it was not associated with any coniferous species. They observed it in stands with an open canopy and dense growth of shrubs such as raspberries, winterberry holly, mountain holly, and highbush blueberry. Within this forest region, it also nests in meadows dominated by large hawthorns, in grassy and herbaceous cultural meadows with residual tree cover and scattered clumps of shrubs, shrubby edges and openings in coniferous plantations, and on shrubby hydro transmission line rights-of-way passing through deciduous forest (personal observation).

In the Carolinian Forest Region, the Mourning Warbler was frequently the most common warbler in Elgin County in thickets, woodland edges, regenerating second-growth scrub, damp wooded areas, raspberry tangles, and anywhere that dense underbrush was present (Lancaster et al. 2004). In Waterloo Region, it inhabited a mature sugar maple forest for approximately 5 years after it was heavily logged (personal observation). In southern Ontario, its abundance was positively correlated with the amount of forest cover 100 m from edge, woodlot size, the amount of forest cover within 2 km, and the amount of regional forest cover. Only the relationship with the amount of forest within 2 km was significant (Austen et al. 2001).

Throughout its range, the Mourning Warbler nests in shrubby meadows, forest edges, and small openings in forests created by treefalls, wind, fire, and disease. Clear-cuts and burns in forested areas create good habitat 1-3 years after disturbance, with highest densities occurring in the east when forests are 10-15 years old and declining in older stands. It is associated mostly with deciduous and mixed stands but may occur in coniferous forests and plantations provided that an understorey of deciduous shrubs and saplings is present. It is often strongly associated with aspen stands and, in the west, prefers mature aspen stands over younger forests. Nesting may occur in both upland and wetland sites and it tends to prefer nutrient-rich habitats over nutrient-poor areas. In many areas, it is slightly more frequent in damp areas such as alder, willow, or dogwood thickets and margins of bogs and fens. It occurs at edges and in openings of lowland forests, including those dominated by spruce and balsam fir as well as deciduous riparian forests. Presence of dense deciduous shrubs is essential and it may be found in areas with a variety of shrub or sapling species such as red-osier dogwood, willow, alder, bur oak, trembling aspen, rose, highbush cranberry, raspberries, hawthorn, white birch, maple, chokecherry, winterberry holly, blue beech, and gooseberries. It may also nest in dense patches of tall herbaceous plants such as nettles, fireweed, goldenrods, thistles, and jewelweed. In most areas where it nests, there may be little to no canopy closure. The Mourning Warbler is often one of the dominant species in recent clear-cuts and burns. In Minnesota, it

occurred on all clear-cuts studied and was one of the 4 most abundant species. It was positively correlated with snag density and basal area (BA), shrub density and BA, and shrub height. It was negatively correlated with tree density, tree BA, and shrub patchiness. None of these relationships were significant. It is frequently common on roadsides, ski-hill cuts, cuts for seismic lines, and utility rights-of-way passing through forested habitat (Back 1979; Beals 1960; Bent 1953; Bielefeldt and Rosenfield 1994; Brooks 1940, 1947b; Brooks and Bonter 2010; Campbell et al. 2001; Capen 1979; Chapman 1907; Collins 1983a; Collins et al. 1982; Cox 1960; Dessecker and Yahner 1987; Faanes and Andrew 1983; Freedman and Johnson 1999; Freemark and Collins 1992; Graber et al. 1983; Gromme 1934; Haney 1999; Harrison 1984; Hoffman 1989; Hofslund 1954; Imbeau et al. 1999; Kirk et al. 1996; Lent and Capen 1995; Morgan and Freedman 1986; Mossman 1988; Mossman and Hoffman 1989; Mossman et al. 1991; Nadeau and Gauthier in Gauthier and Aubry 1996; Niemi and Hanowski 1984a; Niemi and Pfannmueller 1979; Noon et al. 1979; Pitocchelli 2020; Samson 1979; Schieck et al. 1995; Sinclair et al. 2003; Taylor and Taylor 1979; Thompson et al. 1999; Titterington et al. 1979; Whitaker and Montevecchi 1997, 1999).

Freemark and Collins (1992) considered the Mourning Warbler an area-sensitive species and Mossman and Hoffman (1989) concluded that it preferred larger forests in Wisconsin. These studies did not provide any supporting documentation for these conclusions. There is no indication that the Mourning Warbler is area sensitive in Ontario. Austen et al. (2001) found no significant relationship between forest size and its abundance or presence in southern Ontario. James (1984b) and Coleman et al. (2000) did not consider it an area-sensitive species. It is a common breeder in ravines and urban parks within the city of Toronto, which is highly suggestive of it not being an area-sensitive species (Zimmerling in Cadman et al. 2007). It was common in 30-m-wide buffers between water bodies and clear-cuts in Newfoundland (Whitaker and Montevecchi 1999). In Saskatchewan, there was no relationship between forest size and its abundance (Hobson and Bayne 2000).

Essentially all studies concluded that the Mourning Warbler is a forest edge species (when it inhabits forested habitat) or that it nests in small forest gaps. It is possible for it to prefer both forest edge and local landscapes with high forest coverage. In Saskatchewan, it was randomly distributed in contiguous and fragmented forested landscapes, but was more common in areas with a high percentage of forest cover within 5 km. It was an edge species. Its presence and abundance were not significantly correlated with forest size (Hobson and Bayne 2000).

Ontario nests were in or among plant stalks, raspberry canes, fern fronds, hazel stems, grasses, and garden flowers. One was in a brush pile and another was on a clump of sedges. Most were 0-15 cm from the ground, but 2 were 0.3 m up, 2 were 0.6 m up, and 1 was 0.9 m from the ground (Peck and James 1987). Mills (1981) reported a Muskoka nest that was just off the ground in a patch of raspberries and jewelweed.

Throughout its range, the Mourning Warbler places its nest on or near the ground. Raised nests are typically 15-50 cm from the ground, rarely as high as 1 m. Nests are usually well concealed in dense herbaceous vegetation or shrubs, but rarely may be completely exposed. One was on top of a vine on the ground with no cover. Most nests are in tangles of dense vegetation such as raspberries, blueberries, chokecherry, horsetails, elderberries, jewelweed, roses, goldenrods, ferns, or coppice growth around stumps. Nests are frequently on top of hummocks or clumps of grasses and

sedges and occasionally on tops of logs. One nest was 14 cm from the ground and supported by fallen tree branches. The nest site is often in a grassy area among treetops left by loggers, near paths through forests, or at forest edges and roadsides. Some nests were in very wet areas, including within clumps of skunk cabbage and marsh marigolds, but most are in drier areas (Bent 1953; Campbell et al. 2001; Chapman 1907; Cox 1958, 1960; Gromme 1934; Harrison 1984; Hofslund 1954; Pitocchelli 2020).

The Mourning Warbler is territorial and the territory appears to contain both the nest site and foraging areas. In Minnesota, interspecific aggression was directed at the Common Yellowthroat and Chestnut-sided Warbler, but there was no mutual exclusion of territories. North of Lake Nipigon, 2 territories were 0.36 and 0.61 ha, but few observations were made and they may have been larger. Ten Minnesota territories averaged 0.77 ha (range 0.49-0.97 ha). One New Hampshire pair foraged within an area of 0.5 ha. Vermont territories were smaller than 0.5 ha (Cox 1960; Kendeigh 1947; Lent and Capen 1995).

No information is available on natal philopatry or adult site fidelity (Pitocchelli 2020). It is probable that natal philopatry is very low. Site fidelity may be low because the early successional habitat that the Mourning Warbler prefers does not persist long. Lent and Capen (1995) termed it a fugitive species that was constantly shifting its distribution to find ephemeral canopy openings embedded within a forested matrix.

Limiting Factors

Eggs have been reported in Ontario nests from late May until the third week of July, with most present in the last half of June (Peck and James 1987). In Algonquin Park, eggs are present from mid-June to mid-July, nestlings are present from late June to mid-July, and dependent fledglings have been observed from mid- to late July (Tozer 2012).

Courtship begins shortly after birds arrive and nesting occurs soon thereafter. No information is available on the time it takes to build a nest and whether there is a delay between nest completion and egg laying. One egg is laid per day. Incubation may begin with laying of the penultimate or even the first egg. The incubation period was at least 11 days at 1 Ontario nest and 12 days at 3 Minnesota nests. Young leave the nest when they are 7-9 days old (Cox 1960; Hofslund 1954; Peck and James 1987; Pitocchelli 2020).

No double broods have been recorded for the Mourning Warbler. It probably raises a single brood per season throughout its range. Clutches of 2-5 eggs were reported in Ontario (mode 4 eggs, average 3.71 eggs). In the remainder of its range, clutches of 2-5 eggs have been recorded, with 4 eggs most frequent and an average of 3.7 eggs (Bent 1953; Chapman 1907; Cox 1960; Harrison 1984; Peck and James 1998a; Pitocchelli 2020).

No information is available on the age of first breeding (Pitocchelli 2020), but it is probably 1 year. The mating system is probably monogamous, but this has not been confirmed.

The Mourning Warbler forages in dense undergrowth on but usually above the ground. Males forage at higher heights than females so they can alternate between singing and foraging. Females remain lower in the underbrush near the nest. North of Lake Nipigon, males sang at heights of 0.3-18 m (average 7.9 m). In Minnesota, males sang from near the ground level to a height of 12 m. Most

singing (37%) occurred in low underbrush less than 1.5 m tall. The second-most frequently used stratum was 6.1-7.6 m (22% of the time) where males often perched and sang for long periods of time. The primary foraging technique consists of gleaning branches of shrubs and turning over leaves to find prey (Cox 1960; Kendeigh 1947; Morse 1989; Pitocchelli 2020; Sodhi and Paskowski 1995). In Wisconsin, Sodhi and Paskowski (1995) compared the foraging strategies of the Mourning, Nashville, Chestnut-sided and Canada warblers. The woody plant species used most frequently for foraging by all species were trembling aspen, large-toothed aspen, sugar maple, red maple, white birch, hazel, and white pine. The Mourning Warbler and Canada Warbler foraged more frequently in aspens than the other species. Female Mourning Warblers foraged most frequently in shrubs. Male Mourning Warblers foraged lower than males of other species. Male Mourning Warblers foraged in shrubs 19% of the time, hardwoods 25%, aspens 39%, and conifers 17%. Females foraged in shrubs 42% of the time, hardwoods 30%, aspens 18%, and conifers 10%. Substrate usage by males was 15% twigs and leaves, 68% branches, 5% limbs and trunks, and 12% air. Female substrate usage was 15% twigs and leaves, 70% branches, 5% limbs and trunks, and 10% air. Foraging techniques for males consisted of 58% gleaning, 18% pouncing, 5% hovering, and 17% sallying compared with 34% gleaning, 34% pouncing, 16% hovering, and 16% sallying for females. The differences in gleaning by sexes were significant. Male and female Mourning Warblers were more similar in their foraging behaviours to birds of the same sex of other species than they were to each other. Average foraging height was 3.07 m for males and 2.68 m for females. The high use of hazel indicated use of young disturbed forest with high light penetration and a well-developed herbaceous and shrub layer.

The Mourning Warbler is largely insectivorous during the breeding season. The male feeds the female during the incubation period, typically with large green caterpillars. Both sexes feed the young, mostly caterpillars and other small insects (Bent 1953; Cox 1960; Pitocchelli 2020). Kendeigh (1947) analyzed the stomach contents of 8 adults north of Lake Nipigon. By frequency, the diet consisted of 24.2% lepidopterans, 15.8% spiders, 13.4% beetles (including click and soldier beetles), 11.6% true bugs (including stink bugs), 5.9% sawflies and other hymenopterans, 5.6% flies (including snipe, deer, and crane flies), and 1.5% soft-winged bugs. It demonstrates no numerical response to spruce budworm abundance. Near Manitouwadge, it decreased over time as budworm numbers increased, but not significantly (Venier et al. 2009). In Maine, a severe spruce budworm outbreak opened up the forest canopy allowing a dense understorey of raspberries, deciduous saplings, and regenerating conifers to develop. The forest was colonized by the Mourning Warbler shortly after this occurred (Pitocchelli 2020).

In Ontario, 3 of 35 Mourning Warbler (8.6%) nests were parasitized by the Brown-headed Cowbird. The cowbird has parasitized the Mourning Warbler in much of its range, including Illinois, Minnesota, and British Columbia. Outside Ontario, the number of nests reported in studies is 5 or fewer, so it is not possible to make meaningful estimates of the rate of parasitism, and it is likely to vary geographically. The effects of parasitism on its reproductive success are unknown (Campbell et al. 2001; Cox 1960; Graber et al. 1983; Harrison 1984; Manolis et al. 2002; Peck and James 1998a).

Habitat loss and degradation are not significant limiting factors for the Mourning Warbler in Ontario and throughout its range. It benefitted from the deforestation that occurred due to European settlement. Practices such as road building, mining, and clear-cut logging that open vast

expanses of boreal forest may be contributing to its range expansion. Large-scale habitat alterations may have allowed it to colonize northeastern British Columbia as late as the 1970s (Campbell et al. 2001; Nadeau and Gauthier in Gauthier and Aubry 1996; Pitocchelli 2020). Large-scale conversion of forested habitat to agricultural or urban uses may be detrimental. It appears to prefer areas where there is considerable forest cover locally, even if it is not area sensitive.

The Mourning Warbler responds well to forest management and is resilient, capable of adjusting to a variety of silvicultural practices (James 1984b; Pitocchelli 2020). Vanderwel et al. (2007) reviewed 42 studies on the effects of partial forest harvesting in the Boreal Forest Region with special reference to Ontario, and concluded that there were no significant effects on it at any level of harvest. Near Sault Ste. Marie, it was essentially absent in uncut northern hardwoods stands and increased significantly after stands were selectively cut (Holmes and Pitt 2007). Jobes et al. (2004) reported similar results in Algonquin Park. It was significantly more abundant in recent cuts (1-5 years old) than in cuts 15-20 years old. In the Carolinian Forest Region of Ontario, Holmes et al. (2004) found no significant differences in its abundance in uncut forests and those that had been harvested using selection or diameter-limit thinning. In the Canadian Shield of Ontario, there was no difference in its abundance in early successional clear-cuts and burns, but it was significantly more abundant in mid-successional clear-cuts than in mid-successional burns. It was significantly more abundant in early successional than mature stands, but significantly less abundant in mid-successional than mature stands (Zimmerling et al. 2017). In New York, Webb et al. (1977) completed bird surveys in uncut forests and forests where 25%, 50%, 75%, or 100% of the merchantable timber was removed. The Mourning Warbler was 1 of 6 species that occurred in all 4 logged areas at approximately the same density but was absent in the natural forest. Haché et al. (2013) studied the effects of selection harvesting in New Brunswick sugar maple–beech–yellow birch forests. Canopy closure was reduced by 20%. The first 2 years postharvest, shrub density was 13.7% lower than preharvest, but increased steadily thereafter until it was 29.5% higher 5 years postharvest. The selection harvest method was favourable to the Mourning Warbler. It was associated with a dense shrub layer and increased in density following harvest. It was first observed 3 years postharvest and increased thereafter with shrub density. It was absent in unharvested forests. In Nova Scotia and New Brunswick, it was absent in uncut stands but present in clear-cuts, plots thinned to 45% of their previous BA in shelterwood cuts, and in strip-cuts (Freedman and Johnson 1999; Freedman et al. 1981). In strip-cuts in Quebec, it was abundant in final cuts and found adequate breeding habitat in newly created strips, but was much less abundant in older strips where regeneration formed a closed canopy (Falardeau et al. 1999). In Alberta, it increased significantly when 90% of trees were removed from mixed stands, but there were no significant changes related to tree harvesting in deciduous and coniferous stands (Harrison et al. 2005). In the same province, it had a neutral response to clear-cut edges, with no difference in the mean distance that it occurred from edge in contiguous forest and adjacent clear-cuts; Villard et al. (2007) considered it a generalist species. Tittler et al. (2001) considered the Mourning Warbler a habitat generalist in Alberta. In the first year after clear-cutting, its abundance increased significantly with increasing BA retained within the cut. Three years postharvest, its abundance was unaffected by the amount of retained timber. Titterington et al. (1979) recorded its abundance in different seral stages of clear-cuts in Maine spruce–balsam fir stands. Abundance was low in the first stage, which consisted of dense slash and abundant open ground that dominated

for 2 years after cutting; highest in stage 2, which consisted of dense raspberries and regenerating hardwoods less than 2 m tall, typically 3-5 years after cutting; and intermediate in stage 3, which consisted of hardwood regeneration taller than 2 m with a well-developed but slower growing layer of coniferous regeneration. It was absent in the last 2 stages, which consisted of hardwood regeneration 4.5 m and taller with 10-15-cm diameter-at-breast-height trees, and a dense conifer overstorey with an open forest floor. In Minnesota, it was absent in uncut forests and responded positively to all levels of timber harvesting (Hanowski et al. 2003, 2005).

In Alberta, the Mourning Warbler was equally abundant at noisy compressor stations and quiet well pads, exhibiting no response to chronic noise (Bayne et al. 2008).

In Alberta, Bayne et al. (2016) studied the effects of energy sector disturbances on the Mourning Warbler. It exhibited no response, with no difference in its abundance at seismic lines, pipelines, or well pads and forest interior adjacent to these features.

Price (2004) predicted that the Mourning Warbler might disappear as a breeding species in southern Ontario if the average summer temperature increased by 2°C.

Status

Fleming (1907) stated that the Mourning Warbler was a rare summer resident and breeder in the Toronto area, and that it had been rare even as a migrant a few years previously. Baillie and Harrington (1937) considered it fairly common, breeding north to the transcontinental railway line and west to Lake of the Woods. Breeding was not documented in Middlesex County until 1962 (Scott 1988). In Elgin County, it was unknown even as a migrant in 1891, was a regular migrant but not a breeder in 1954, and was a locally common breeder by 2000. By then, it was the most common breeding warbler at some sites. Throughout the county, it was tied for third in abundance with the Ovenbird (Lancaster et al. 2004). The first atlas determined that it bred north approximately to a line from Sandy Lake to Attawapiskat. It was sparsely distributed in the Carolinian Forest Region and essentially absent in Essex and Haldimand counties. In the Great Lakes–St. Lawrence Forest Region, it was absent in much of Prince Edward and Frontenac counties. It was a common breeder, particularly in the Great Lakes–St. Lawrence and Boreal Forest regions (Fraser in Cadman et al. 1987). James (1991) considered the Mourning Warbler a common summer resident across the province north to Sandy Lake and Fort Albany.

The second atlas indicated that there had been no substantial change in the distribution of the Mourning Warbler. It was observed in a few locations north of the previously known northward limit. There were scattered new records for Essex, Haldimand, Prince Edward, and Northumberland counties, but it still remained largely absent from these areas. There was no change in its overall probability of observation, but there was a significant decline in the Great Lakes–St. Lawrence Forest Region in the Canadian Shield, and a significant increase in the Boreal Forest Region. The decline in the southern portion of the Shield may be due to forest maturation and succession. The increase in the Boreal Forest Region is likely because of increased forest management which provides suitable early successional forest cover. It was most abundant in a band across the province between latitudes 48°N and 50°N. This corresponds roughly to the area from Thunder Bay and Rainy River north of Kenora in the west, east to Lake Nipigon and the Clay Belt area (Zimmerling in Cadman et al. 2007).

The Mourning Warbler appears to have increased considerably since the late 19th and early 20th centuries. Chapman (1907) concluded that it was more or less rare throughout its range, and it also appeared to be rare in Ontario and Quebec at about the same period. Bent (1953) concluded that it still was not common in the eastern United States. The Breeding Bird Survey indicated annual decreases of 1.31% in Canada and 1.46% in Ontario 1970-2021. The trends 2011-21 were annual decreases of 0.55% in Canada and 0.388% in Ontario. All results were highly reliable except for the short-term Ontario trend which was of medium reliability (A.C. Smith 2023).

POSTFLEDGING PERIOD

At 1 Minnesota nest, fledglings remained in thick underbrush within the general area of the territory for 3 weeks after fledging. The young were unable to fly when they left the nest but could fly about 9 m with a fluttering, uneven flight 6 days after fledging. The young were last seen 20 days after fledging. They were feeding independently but were still accompanied by the adults (Cox 1960).

The Mourning Warbler continues to be an early successional species during the postfledging period. It is most common in regenerating clear-cuts and other areas with dense growths of deciduous shrubs and saplings, but it also occurs in forests. In Pennsylvania, Stoleson (2013) mist netted Mourning Warblers in 3-6-year-old clear-cuts and 90-110-year-old deciduous forests. They captured 4 adults and 17 juveniles in clear-cuts and 0 adult and 2 juveniles in forests. Streby et al. (2011b) caught 141 in regenerating clear-cuts 2-10 years old in Michigan, including 92 adults and 49 fledglings. In Michigan, Akresh et al. (2009) reported captures of Mourning Warblers per 1,000 hours of 0.1 in upland forest and 2.5 in riparian forest, with 80% of juveniles captured in riparian forest. Upland habitat was dominated by trembling and large-toothed aspen 100 years old. The riparian habitat was dominated by trembling aspen with an open canopy and a dense understorey of alder and honeysuckle.

MIGRATION

Judging by kills at television towers and other tall structures, migration appears to be nocturnal. Males arrive a few days earlier in spring than females. Males precede females by 5.0 days in upstate New York and 3.8 days in Massachusetts (Pitocchelli 2020). At Prince Edward Point, the mean date of spring arrival for males was 26.1 May and 30.4 May for females. It was the second-last warbler to arrive. There were few recaptures, suggesting that it stayed over for only 1 or 2 days. The difference in mean arrival dates between the sexes was greatest in years when males arrived the earliest (Francis and Cooke 1986). In Massachusetts, neither sex arrived significantly earlier over time 1970-2002; the difference in arrival times between the sexes did not change. Arrival time was not significantly related to any climate variables. The sex ratio did not change over time, but more females were captured in years with higher temperatures (Bauböck et al. 2012). In southern Ontario, most pass through in the last half of May, with some arriving in the first week of May (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008). In the southern Shield, average arrival is in the third week of May with the earliest birds arriving in mid-May (Mills 1981; Tozer 2012). North of Lake Nipigon, the Mourning Warbler was first seen on 7 June (Kendeigh 1947). A bird observed at Shagamu on 5 June was considered a spring overshoot, as this is north of its known breeding range (Wilson and McRae 1993).

Autumn migration usually begins in August in Ontario. In the southern Shield, autumn migration begins in mid-August and continues into September, with some remaining into early October (Mills 1981; Tozer 2012). In the south, migration is underway by early August and most have passed through by mid-September, with a few remaining until late October (Black and Roy 2010; Curry 2006; Keast 1980; LaForest 1993; Lancaster et al. 2004; Weir 2008).

During migration, the Mourning Warbler seeks out low, dense vegetation. It tends to remain in dense vegetation less than 1.5 m tall and may occur in a variety of habitats provided they have a dense deciduous understorey. During migration in Illinois, it has been observed in brushy edges, thickets, understorey vegetation in open woods, mature bottomland forests, mature upland forests, and forest edges. It may occur in wetland margins and riparian areas with dense growths of willows, alders, and other shrubs. Birds in upland forests often seek wetter areas such as lower portions of ravines, which probably afford denser shrub coverage. Autumn migrants in South Dakota used both an extensive wooded riparian corridor and a 3.5-ha farm woodlot. Birds were able to gain weight while they remained within the woodlot, suggesting that it was good habitat (Bent 1953; Campbell et al. 2001; Chapman 1907; Cox 1960; Dean et al. 2004; Graber et al. 1983; Pitocchelli 2020).

Male Mourning Warblers may exhibit territorial behaviour during spring migration. Cox (1960) noted territoriality in some migrants. One male defended about 0.4 ha in a brushy area adjacent to a small stream.

During autumn migration, the Mourning Warbler is usually solitary, but it infrequently forages in mixed-species flocks. In Rhode Island, 5 fecal samples contained fruit, 4 contained insects, and 3 contained both fruit and insects (Pitocchelli 2020).

The Mourning Warbler is frequently killed during migration by colliding with communication towers and other tall human-made structures. More than 360 were killed at television towers in Wisconsin 1960-69. At the Lennox generating station chimneys, 202 were killed 1972-82. Highest kills occurred in 1981 when 82 were killed on 6 September and 74 were killed the following night (Graber et al. 1983; Pitocchelli 2020; Weir 2008). In the United States, the Mourning Warbler was highly vulnerable to striking low-rises and was 19.3 times more likely to suffer a collision with this type of building than average. It was not on the lists of the 20 most vulnerable species for striking residences 1-3 stories high or for high-rises (Loss et al. 2014). In Toronto, it was more likely to collide with buildings surrounded by hard surfaces such as parking lots, other buildings, and roads than buildings with vegetation and more canopy cover (Pitocchelli 2020).

The Mourning Warbler may suffer mass mortality during severe weather while migrating. A large kill occurred in spring over Lake Michigan following 2 storm systems with high winds, heavy rain, and hail. It is probably affected by storms while crossing the Gulf of Mexico and in the North Atlantic. Declines in eastern populations 1967-96 were correlated with storm frequency (Pitocchelli 2020).

James (1991) considered the Mourning Warbler an uncommon migrant in Ontario. Netting and banding results in the Kingston area indicate that it is more common than sight records suggest. In other areas, it has been noted that it appears rarer than it actually is, particularly in autumn when it does not sing, because it is very secretive, skulking in dense thickets and rank herbage (Bent 1953; Pitocchelli 2020; Weir 2008).

Common Yellowthroat

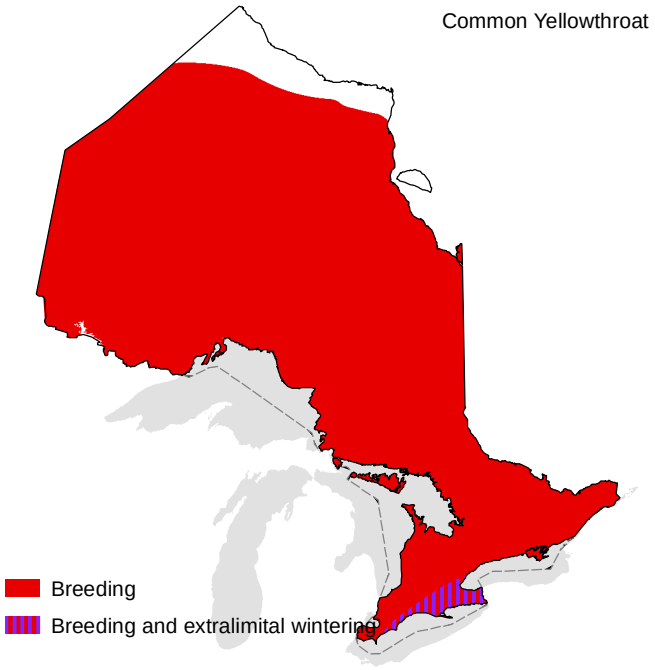
Geothlypis trichas

BREEDING SEASON

Habitat Requirements

In Ontario, the Common Yellowthroat breeds mostly in wet areas (83.1% of nests) and less frequently in dry habitats. Wet areas used for nesting included sedge, grass, and rush meadows and other types of meadow marshes (30.5% of nests); cattail and bulrush marshes (23.7%); bogs (13.6%); margins of lakes, rivers, and ponds (10.2%); and open, wooded swamps (5.1%). Dry nesting areas included brushy sites (10.2% of nests), grassy fields (5.9%), and a woodland edge at a road (0.8%). Nest sites had tall dense growths of rushes, grasses, sedges, and shrubs occurring either singly or in combination (Peck and James 1987).

In the Boreal Forest Region of Ontario, the yellowthroat occurs predominantly in wet habitats but occasionally in dry areas, and is strongly associated with the presence of deciduous shrubs and saplings. It occurs in open shrubby bogs and fens; shrub thickets along margins of lakes, rivers, and wetlands; in young clear-cuts regenerating with deciduous shrubs and saplings; and in open-



canopied forests. In the Pickle Lake area, it inhabited mostly shrub thickets, including deciduous and mixed shrubby areas. It was absent in forests, coniferous scrub, heath, and tundra (James 1980; McLaren and McLaren 1981). Near White River and Manitouwadge, it nested in regenerating stands 21 years old and younger, but not in stands 24-223 years old. It was significantly more abundant in clear-cuts 8-10 years old than those 3-5 or 13-25 years old (Venier and Pearce 2005; Venier et al. 2009). Near Hearst, Welsh and Fillman (1980) reported it in a 19-year-old clear-cut in a lower-slope mixed forest and in lowland coniferous clear-cuts 3-17 years old as well as in uncut lowland coniferous forest. It was most abundant in stands 5-13 years old, with numbers dropping off significantly in 17-year-old stands. It was the dominant species in 5- and 6-year-old clear-cuts. In the Clay Belt, it was most common in jack pine, black spruce, and balsam poplar stands. It occurred mostly in wetter, nutrient-poor stands (Welsh and Lougheed 1996). In the Boreal Forest Region of Ontario, it was associated with young, open-canopied, deciduous and mixed forests with high levels of disturbance and high interspersion of habitats, particularly between young and old forests. Stand size was the most important factor in determining its abundance, explaining 62% of variation (Rempel 2007; Rempel et al. 2007).

The yellowthroat breeds in similar habitat in the Great Lakes–St. Lawrence Forest Region in the Canadian Shield. Near Gogama, it was common in regenerating jack pine stands where grasses and sedges covered most of the ground and deciduous shrub coverage was 25-75%. It gradually disappeared as the trees grew and shaded the ground. Maximum densities occurred when stands were 6-9 years old and few, if any, remained when trees were 20 years old (James and Peck 1995a). It was moderately common in jack pine stands near Parry Sound. These were open immature stands mixed with a variety of deciduous tree species with numerous openings due to the presence of rock outcrops and wetlands (James 1979a). In Muskoka and Parry Sound districts, Mills (1981) reported it along road and hydro line rights-of-way, in wet open areas, in bogs and alder thickets, and in shrubby fields. Three different studies examined its habitat use in Algonquin Park. MacLulich (1938) reported that it was abundant in beaver meadows, alder and willow thicket swamps, and other thickets. Martin (1960) reported it in wet and dry bogs, with lesser numbers in black spruce–white cedar stands. It was a characteristic species of bogs along with the Swamp Sparrow and these 2 species occurred in higher densities in bogs than reported for any other species in any habitat. In bogs, the yellowthroat ranged from the ground to 6 m, which represented the top of the canopy, but did not occur at the top of dead snags that extended 9 m from the ground. In black spruce–

white cedar stands, it ranged from the ground to 3 m, which corresponded to the top of the shrub layer and the bottom of the canopy. It occurred in low densities in balsam fir–spruce and balsam fir–spruce-hardwood stands and at edges of forest stands. In white pine shelterwood cuts in Algonquin Park, it was absent in 2-9-year-old cuts, present in 10% and 27.3% of plots over 2 years in 10-16-year-old cuts, and present in stands with no recent history of harvesting in 7.1% and 0% of plots (Kingsley and Nol 1999).

South of the Shield, the yellowthroat is associated mostly with marshes and thicket swamps, although it also occurs in treed swamps with open canopies and undergrowth of aquatic emergent plants. It is much less likely to use upland areas dominated by deciduous shrubs and saplings south of the Shield than further north. Cattail marshes are preferred habitat. One Ontario study found that there was no difference in its abundance in the interior and at the edge of marshes (Timmermans and McCracken 2001; Tozer et al. 2006). It usually prefers the outer portions of marshes where the water is shallow or the soil is only moist, particularly where there are scattered clumps of shrubs such as willows and dogwoods and occasional short trees. Where open-water marshes have an outer fringe of shrubs or meadow marsh communities, these are more likely to be inhabited. At Point Pelee, low numbers nested in forests with nearly complete canopy closure containing a high proportion of ash trees (Dodds and Otis 2009). In Durham Region, it nested in a very young pine plantation that was still dominated by willow shrubs and meadowsweet; in an old orchard overgrown with apples, hawthorns, and grasses; in open-canopied forests containing standing water and supporting dense shrub growth; and in a black spruce bog (Speirs and Orenstein 1975).

In Great Lakes coastal wetlands, the yellowthroat was positively correlated with wetland cover and negatively correlated with the amount of urban and agricultural land in the watershed. It was mostly unaffected by water levels but tended to decrease with higher water levels (Tozer et al. 2024).

In southern Ontario, the Common Yellowthroat was negatively correlated with organic farms and use of herbicides, but positively associated with corridors such as roads, railways, and utility rights-of-way. The negative association with organic farms may have been because conventional farms had significantly more riparian woodland, which is preferred habitat (Kirk et al. 2011).

Throughout its range, the Common Yellowthroat nests in a variety of habitats. These include all types of wetlands (bogs, fens, marshes, and thicket and treed swamps); thickets along margins of water bodies and watercourses and on dry hillsides and mountain slopes; in clear-cuts, burns, and other regenerating areas; in open-canopied forests, forest edges and forest clearings; in prairies and grasslands; in pine and oak barrens; and in agricultural lands. Despite its usage of numerous vegetation types, many authors consider the yellowthroat a habitat specialist. It occurs almost exclusively in open, early successional habitats. Presence of shrubs appears to be more significant than the moisture regime of sites. In some areas it chooses habitat based on shrub density and height.

The yellowthroat is commonly thought to be a wetland species, but it may be more abundant in wetlands because shrubs are more prevalent in these habitats. It may be one of the more abundant species in open bogs and fens and in thicket swamps. It is characteristic of marshes, but tends to inhabit edges of shallow-water marshes and meadow marshes where there is at least some woody growth. In treed swamps, it is most common in stands with an open canopy, standing water,

and patches of emergent vegetation or shrubs in the understorey. In New York, it was the most abundant species in clear-cuts 2-6 years old (Keller et al. 2003). In Wisconsin, it was abundant in cattail and bulrush marshes but nested in patches of medium-height willows (Hutto 1981). In Michigan, it nested in sites with damp or wet soils. Occupied habitat was characterized by a mixture of dense, lush herbaceous vegetation and woody plants, mainly shrubs and small trees. This habitat usually occurred along margins of streams, ponds, and lakes; in bogs; and in seepage areas below springs. Habitats ranged from savannah-like areas with scattered groups of shrubs and trees 0.9-4.6 m tall, to dense thickets of small woody plants that were usually less than 1 m tall. Habitats included marshes, sedge meadow marshes, shrub thicket swamps, and forest edges. Stewart (1953) concluded that the key habitat feature may be the dense growth of low vegetation, which is more prevalent in wet areas, rather than moisture itself. In Minnesota, Niemi and Hanowski (1984a) reported higher densities in tall than low shrub communities. It was uncommon in open spruce forests and absent in closed spruce forests and fens. In riparian willow habitat in Wyoming, the yellowthroat was significantly more abundant where willows were taller and less dense, although it used areas where willows were 0.27-2.12 m tall. It was most abundant where the willow habitat was more structurally complex (Olechnoswki and Debinski 2008). In North Dakota, highest densities were in juneberry thickets and willow shrub communities. Lowest densities were in lowland forests. It was associated predominantly with early stage deciduous habitats (Faanes and Andrew 1983). Grant et al. (2004) studied the effects of shrub invasion in mixed-grass prairies in North Dakota. Maximum vegetation height and coverage by shrubs 1 m tall or less and taller shrubs were significantly higher where the yellowthroat was present, and coverage by smooth brome was higher where it was absent. It increased as abundance of shrubs increased. Also in North Dakota, it was present in shrubby plots and absent in grassy and herbaceous plots without shrubs (Arnold and Higgins 1986). This was also the case in Georgia where it was one of the most common species in mixed grass and shrub habitats (Johnston and Odum 1956). In Great Lakes coastal marshes along Lake Michigan, increased woody vegetation improved habitat for the Common Yellowthroat. It was most abundant in wet meadows supporting more shrubs, deciduous trees, and deciduous snags and had a particular preference for wet meadows with willow shrubs. Its abundance was positively correlated with increasing shrub density; increasing abundance of alder, moss, trees, and snags; increasing shrub foliage diversity; and increasing frequency of willow. It was negatively correlated with graminoid cover, coniferous snags, and deep water. In these meadow marshes, it was one of the most abundant species (Riffell et al. 2001). In Utah, it was restricted in habitat use and preferred areas with high shrub density, moderate ground coverage, and little canopy coverage (Whitmore 1977). In Iowa, Delphey and Dinsmore (1993) studied yellowthroat usage of natural and restored prairie potholes. It was present in significantly more natural than restored potholes. All natural wetlands had zones ranging from open water in the interior to outer zones of aquatic emergents and low prairie or meadow marsh zones. The outer zone was often lacking in restored wetlands and the abrupt transition from pothole to upland habitat was less attractive to it. Also in Iowa, Fairbairn and Dinsmore (2001a) considered it associated with wet meadows and concluded that it may select wetlands based upon their vegetative structure. In Iowa, it also nests in managed grasslands planted to switch grass. In this habitat, it selected areas with higher forb abundance for nesting but this parameter was associated with lower nesting success. It selected sites with denser and more senescent vegetation for nest sites. The number of young fledged was positively correlated with the

proportion of senescent vegetation. In Wyoming, Finch (1989b, 1991a) studied its habitat use in different elevational zones and concluded that it was a habitat specialist because its use of habitat differed from habitat availability. Although it nested in both moist and dry areas, it selected areas with dense shrub coverage (more than 70% willow coverage), dense foliage cover through the shrub layer, and few trees. In Wisconsin, it was 1 of 12 species that commonly nested in tall thickets dominated by red-osier dogwood, meadowsweet, and a variety of willow species, and 1 of 13 that regularly nested in alder thickets (Hoffman 1989b). In the Boreal Forest Region, Erskine (1977) considered the yellowthroat characteristic of low shrubbery in tamarack and bog forests and one of the more numerous species in open, wet bogs dominated by sedges and low shrubs. In shrubby bogs, it is often a dominant species; it is also common in spruce bogs. In riparian habitat in Iowa, Stauffer and Best (1980) considered it a habitat specialist. It did not nest in forb, deciduous sapling, or deciduous or coniferous tree cover. Its abundance was significantly correlated with sapling richness and vertical stratification of vegetation less than 3 m tall, but negatively correlated with sapling size and shrubs. In Minnesota and Maine, it nested in open areas, marshes, bogs, and tall grasses. It was associated chiefly with high ground coverage in open marshland with few or no trees where it was codominant with the Yellow Warbler. The yellowthroat was also associated with shrub coverage (Collins 1983a; Collins et al. 1982). In New Hampshire and Maine, it was most abundant in white pine stands with numerous small deciduous trees in the understorey and in aspen stands. It was considerably less abundant in hemlock, northern hardwood, and spruce-fir stands and even less abundant in swamp hardwoods. It was absent in white birch stands. It was significantly more abundant in sapling-sized stands than in those dominated by pole-sized, sawtimber-sized, or large-sawtimber-sized trees. It was positively correlated with the number of deciduous trees larger than 10 cm diameter at breast height (DBH), the number of coniferous trees 2-10 cm DBH, and the total foliage volume of coniferous trees 2-10 cm DBH. It was negatively correlated with percent ground cover and the total foliage volume of deciduous and coniferous trees larger than 10 cm DBH (DeGraaf et al. 1998). In British Columbia, it often preferred willows but also occurred in drier habitats along edges of agricultural fields, airport runways, or damp meadows; in tall grass meadows bordered by shrubs; young cottonwood stands; and undergrowth of trembling aspen–conifer forests. More characteristic habitat included densely vegetated wetlands such as shallow lakes or ponds and similar habitat dominated by emergent vegetation such as tall sedges, reeds, cattails, or low shrub coverage of steeplebush, sweet gale, and willows; meadow marshes of sedges, grasses, and bulrushes; estuarine salt marshes, borders of rivers, beaver ponds, and sewage lagoons; ditches; permanent ponds in fields; wooded swamps; regenerating trembling aspen clear-cuts; and abandoned quarries (Campbell et al. 2001). In the Yukon, it always breeds in moist areas with shrubs, most frequently in shrubby wetlands dominated by willows and birches. Old beaver dams overgrown with shrubs provide good habitat. In forested communities, it is limited to riparian areas along back channels and sloughs rather than occurring along main rivers (Sinclair et al. 2003).

The yellowthroat may use a variety of open upland habitats. Most frequently, these are dry shrub thickets that may include shrubby fields, including those on hillsides; edges of drainage ditches in agricultural lands; hedgerows; overgrown orchards; pastures and abandoned fields; and road rights-of-way, particularly those through forests. It has also nested in Christmas tree plantations. In New Jersey regenerating fields, it occurred in fields 10-40 years old, the entire range of ages that was

studied. Along an interstate highway through forested habitat in Maine, it was significantly more abundant near the road than in forest interior. It was presumably attracted to the edge and open habitat created by the right-of-way (Brooks and Bonter 2010; Ferris 1979; Graber and Graber 1963; Gross in Bent 1953; Guzy and Ritichison 2020; Harrison 1984; Kendeigh 1947; Létourneau and Lafontaine in Gauthier and Aubry 1996; Parnell 1969; Suthers 1988). In North Carolina, it showed a preference for thickets, although it occasionally occurred in forests. Relative numbers seen were 2.89 in wet thickets, 2.59 in dry thickets, 0.55 in floodplain forests, 0.43 in pine-hardwoods forests, 0.20 in oak-hickory forests, 0.10 in pine forests, and 0 in beech forests. It was most common where the greatest proportion of vegetation was between 0 and 60 cm (Parnell 1969).

The Common Yellowthroat is characteristic of large open habitats created by clear-cuts or burns, and is often a dominant species in these habitats. It may also be common to abundant on utility rights-of-way where the vegetation is managed to keep it in an early successional stage. It usually inhabits clear-cuts about 3 years after cutting once a dense growth of raspberries and deciduous saplings becomes established. Populations tend to peak 5-10 years after cutting, and then decline rapidly with few remaining once trees reach pole size. How long a cut remains suitable depends upon how fast the regeneration grows and how much of the cover is coniferous, with conifers being less suitable. Clear-cuts where patches of trees are retained support lower densities because the retained areas are not used. Young burns are less suitable than similarly aged cuts. Burns tend to have lower densities of shrubs and saplings and very hot burns may affect productivity of the soils. Although regeneration may take longer on burns, they are valuable habitat and may remain suitable longer than cuts. Historically, fires would have been the principal means of establishing yellowthroat habitat in the Canadian Shield (Dessecker and Yahner 1987; Erskine 1977; Falardeau et al. 1999; Freedman and Johnson 1999; Hanski et al. 1996; Harrison and Kilgo 2004; Hoffman 1989a; Imbeau et al. 1999; Keller et al. 2003; Kirk et al. 1996; Lent and Capen 1995; Morgan and Freedman 1986; Thompson and Capen 1988; Titterington et al. 1979; Tittler et al. 2001; Yahner 1993, 2003). Yahner et al. (2002) examined avian assemblages on power-line rights-of-way through deciduous forests in Pennsylvania. The yellowthroat did not occur within the adjacent forest habitat, but was sixth in abundance on the right-of-way. It was ubiquitous and common in all treatment areas, which included areas where vegetation was hand cut, sprayed, mowed, or a combination of these techniques. It was most common in areas bordering the forest which were a combination of shrub cover types mixed with forb, grass, or tree cover. It was also common under the hydro wires where vegetation was mostly forbs and ferns.

The yellowthroat has nested in a variety of forest types, but is not a forest-dependent species. In almost all cases, it is associated either with very early successional stages of forest, shrubs at edges of forests, or openings within forests. In most cases, it is not attracted by the forest cover, but by open, shrubby areas associated with them. In Illinois woodlots, it had a strong negative association with distance to edge and the percentage of urban coverage within 1 km. An exception may be red maple swamps, where it is one of the most abundant breeding species in southern New England. It has the potential to occur in most swamps and lowland forests where there are openings in the canopy and deciduous shrubs and saplings in the understorey. In upland forests, it is associated with stands dominated by early successional species such as poplar and birch. It is absent from climax upland forests dominated by sugar maple and beech. In riparian forests in Michigan, it was much

more abundant in the outer upland band of forest, where it was presumably associated with edge shrubs, than in the contiguous floodplain forest. In Pennsylvania, it demonstrated a negative affinity for old-growth forests and was significantly more abundant in younger stands. Virtually all studies demonstrated that it is more abundant in stands with an open canopy (Back 1979; Beals 1960; Capen 1979; Dawson 1979; Fitch 1958; Golet et al. 2001; Graber and Graber 1963; Grant and Berkey 1999; Haney 1999; Inman et al. 2002; Mossman 1988; Niemi and Pfannmuller 1979; Noon et al. 1979; Robbins et al. 1979; Rumble and Gobeille 1998; Samson 1979; Schneider and Miller 2014; Taylor and Taylor 1979; Temple et al. 1979). In very open forest habitat in Indiana, its density was highest where coverage by low ground vegetation was 80+-100%. High densities were also associated with high shrub and low tree density. Fire in these communities was beneficial and it reached peak abundance when fire frequency was 7.3 fires every 15 years, the maximum frequency of fires (Grundel and Pavlovic 2007a).

Askins et al. (2007) stated that the yellowthroat was not an obligate grassland bird but that it was commonly found in tallgrass prairies where it was associated with low to moderate amounts of woody vegetation. In Illinois, it exhibits a preference for prairie-marsh ecotones and reaches its highest density in prairie, marsh–wet prairie, and meadow habitats. Its occurrence was positively correlated with mean grass height and shrub density and negatively correlated with density of live vegetation and grasses (Graber et al. 1983; Herkert 1994a). In Iowa, it was one of the most abundant species in Conservation Reserve Program fields. It was most abundant in fields with high coverage by forbs such as alfalfa, Canada thistle, dandelions, and prickly lettuce. It rarely occurred in fields with homogeneous grass cover, but was abundant in plots with patches of weedy forbs. Reed canary grass planted in waterways provided attractive habitat, and it was most abundant in grassed waterways in fields dominated by other grasses such as smooth brome, orchard grass, and red fescue. Its abundance was positively correlated with horizontal patchiness and percent coverage by forbs. It was negatively correlated with percent coverage by grasses (Patterson and Best 1996). In grasslands managed for waterfowl in Saskatchewan, it was more abundant in dense nesting cover plots than in native grasslands, and was absent in wheat fields. Dense nesting cover consisted of a mix of native and introduced wheat grasses, brome grass, alfalfa, and sweet clover (Hartley 1994).

In many areas, the Common Yellowthroat is a common inhabitant of pine and oak barrens. In Massachusetts, it is 1 of the 3 most common species in pine barrens. These areas are characterized by well-drained sandy soils supporting stands of open-canopied pitch pine with a dense shrub layer. Deciduous trees are uncommon in this habitat and consist primarily of black and white oaks. The ground cover is dominated by wintergreen and bearberry (Morimoto and Wasserman 1991a, 1991b). In New Jersey pitch pine barrens, it was the most common species in pine swamps. It was also common in upland forests with a dense, low shrub layer and uncommon on unburned plains (Brush 1987). In Wisconsin, it was one of the most common and regular species in pine and oak barrens. It occurred in every barren type except oak savannah. It was abundant in brush prairie; common in diverse barrens and clear-cuts; fairly common in open aspect barrens, almost forest, and coniferous plantations; and uncommon in open aspect and river terrace barrens (Mossman et al. 1991).

The yellowthroat rarely nests in low densities in agricultural crops. It is most likely to occur in fields of red clover, alfalfa, and mixed hay and is rare and infrequent in grain fields (Fitch 1958; Graber and Graber 1963; Graber et al. 1983).

Some studies examined the habitat requirements of the Common Yellowthroat at the landscape level. In Iowa, Fairbairn and Dinsmore (2001b) concluded that habitat features outside a wetland could be important in determining its presence. Its presence was positively correlated with the amount of semi-permanent wetland within 3 km, but negatively correlated with the amount of seasonal wetlands. In Connecticut, its probability of occurrence was negatively correlated with the amount of forest cover within 2 km (Askins et al. 1987). Austen et al. (2001) observed a similar relationship in southern Ontario, but it was not significant. In Illinois at the 400-m scale, it was positively associated with agricultural land (Glass and Eichholz 2023).

Other studies examined the yellowthroat's microhabitat requirements. In open habitat in Minnesota, its average habitat characteristics were 98.2% ground cover, 39% shrub cover, 12.4% canopy cover, 5.2 m tall canopy, 6.8% conifers, and 0.9 tree per 0.04 ha (Collins et al. 1982). In Vermont clear-cuts, habitat characteristics were 86.4% ground coverage by green vegetation, 7.9% ground coverage by slash, 30.9% canopy closure, 8.5 m tall canopy, 5.7 m canopy depth, 30 m^2 basal area (BA) deciduous trees, 0.4 m^2 BA conifers, and average DBH of 5.1 cm for deciduous species and 4.4 cm for conifers (Thompson and Capen 1988). In forests in the mid-Atlantic states, its abundance was positively correlated with moisture, percent ground cover, percent coverage by conifers, and number of trees smaller than 3 cm DBH. It was negatively correlated with canopy closure and the number of trees within a 0.04-ha circle (Robbins et al. 1989). In Illinois, its density was negatively associated with shrub density, which was an indicator of the abundance of nonnative shrubs, particularly common buckthorn (Schneider and Miller 2014). In Arizona, it nested in low dense shrubs. It tended to nest close to water and distant from trees. It occurred mostly in marshy habitat with dense foliage from the ground to 2 m. Brown and Trosset (1989) considered it a habitat specialist.

In Illinois, Rodewald and Vitz (2005) examined edge effects on the yellowthroat by netting in 3-7-year-old clear-cuts at differing distances from a mature forest edge. More were captured 50 and 80 m from edge than at 20 m from edge, but the difference was not significant. It exhibited no avoidance of edge. In Illinois, nests closer to edge had lower survival rates. It did not avoid edges or roads and nest density was higher in grasslands with a greater proportion of roads around the perimeter (Glass and Eichholz 2023).

The Common Yellowthroat is not an area-sensitive species in any of the habitats it uses. It was not area sensitive in Great Lakes coastal marshes (Riffell et al 2001) and Golet et al. (2001) reached the same conclusion for red maple swamps in Rhode Island. In Illinois, Lehnen and Rodewald (2009a) found no evidence of area sensitivity of it in shrub patches. Capture rates did increase with patch size, but not significantly. In the same area, Rodewald and Vitz (2005) captured more yellowthroats in large (13-16 ha) than small (4-8 ha) clear-cuts, but the difference was not significant. Two studies in Michigan and Iowa determined that its occurrence was positively correlated with wetland size. Both studies examined very small wetlands that were below its minimum territory size. The authors of the Michigan study concluded that analyzing their data from a finer or coarser scale could yield

different results (Crozier and Niemi 2003; Fairbairn and Dinsmore 2001a). The maximum sizes of wetlands investigated in these 2 studies were 9.42 and 20.5 ha, with means only slightly above 2 ha. It is unlikely that the yellowthroat was truly area sensitive in these areas. Studies conducted in grassland habitat concluded that it is not area sensitive. In Illinois, Walk and Werner (1999) and Herbert (1994a) observed no evidence of area sensitivity in grasslands. In Massachusetts, Vickery et al. (1994) determined that its abundance was significantly negatively correlated with grassland area. It was positively correlated with the density of tall shrubs and trees. The proportion of shrubby habitat decreased with increasing grassland area, which probably explained the negative relationship with area. Johnson and Igl (2007) examined its area sensitivity in grasslands in Montana, South Dakota, North Dakota, and Minnesota. In most areas, field size had no effect on it. At 3 sites, it was negatively affected by field size, but its density was positively associated with size at 1 site. They concluded that there was a greater tendency for area sensitivity in regions with high densities of yellowthroats. Studies in forested habitat demonstrated that it is either unaffected by forest size or that it declines with increasing forest size. In North Dakota and Pennsylvania woodlots, size had no effect on it (Grant and Berkey 1999; Keller and Yahner 2007). In riparian forests in Maryland and Delaware, there was no difference in its probability of detection in forests 50, 100, 200, 300, and 800 m wide (Keller et al. 1993). In South Dakota, it was much more abundant in isolated woodlots 0.7-3.5 ha in area than in large, contiguous riparian woodlands (Gentry et al. 2006). In southern Ontario and the mid-Atlantic states, its abundance and probability of occurrence were significantly negatively correlated with woodlot size (Austen et al. 2001; Robbins et al. 1989).

Half of Ontario nests were on the ground and the remainder were 0.2-1.4 m above ground, mostly 0.2-0.3 m up. Nests were usually well concealed: among sedge or grass stems (54.1% of nests), among shrub stems (17.8%), attached to cattail or bulrush stems (11.1%), attached to both grasses and shrubs (5.9%), under boughs of shrubs or small trees (5.9%), among plant stalks (3.0%), beside fallen logs (1.5%), and near the top of a shrub (0.7%). Nests were in 9 species of deciduous shrubs and 1 coniferous tree species (Peck and James 1987).

Throughout its range, the yellowthroat places its well-concealed nest on or near the ground, usually within 7.6-10 cm of the ground, but occasionally as high as 1.8 m and rarely as high as 3 m. Higher nests tend to occur later in the season or be above water among emergent vegetation. Nests are typically in clumps of grasses or sedges, among herbaceous vegetation or shrubs, and, less frequently, above water in emergent vegetation. Nests are occasionally at the base of a tree or shrub, but these nests are also typically within clumps of grasses or sedges. Elevated nests may be simply wedged between dense stalks of vegetation without being attached to them. One nest was in a shoe on an exposed rafter under a house (Campbell et al. 2001; Chapman 1907; Graber et al. 1983; Gross in Bent 1953; Guzy and Ritichison 2020; Mousley 1916a; Stewart 1953).

Males establish territories immediately upon arrival and are aggressive toward other species such as Black-capped Chickadee, Yellow Warbler, Field Sparrow, and Henslow's Sparrow, but only until the females arrive. Latecomers have to be aggressive to obtain a territory, which typically involves a reduction in size of established territories and boundary shifting. In Wisconsin, larger dominant males established territories in coniferous bog communities with dense herbaceous cover and many small and dead trees. Smaller males established territories in areas dominated by

grass. Once territorial boundaries are established, trespassing seldom occurs, but intruders are quickly dispatched. Birds raising a second brood may adjust the territory boundaries after the first brood fledges. Territory boundaries are relaxed when the adults are feeding nestlings and when fledglings are present. Territoriality ceases with the onset of the postnuptial moult during the first half of August. Family groups may range unchallenged over boundaries while they are foraging. In Algonquin Park, territory size averaged 0.14 ha (range 0.02-0.64 ha) with a depth of 4.9 m. Five Illinois territories averaged 0.23 ha (range 0.01-0.44 ha). Eleven other Illinois territories averaged 0.57 ha and 3 others averaged 0.36 ha. In a 0.20-ha Illinois swamp, 17 nests were found, suggesting an average territory size of 0.01 ha. In Michigan, the territories of 10 monogamous males averaged 0.51 ha (range 0.32-0.73 ha). One Kentucky male defended 1.38 ha, but the habitat may have been marginal. Territory sizes of 0.8 ha were reported elsewhere in Kentucky. Other territory sizes include 0.2-2.9 ha in Michigan, 0.16-0.6 ha in Minnesota, 0.5 ha in Rhode Island, 0.29 ha in Maine, 0.5-0.93 ha in California, 0.1 ha in Texas, 2.20 ha in Colorado, and 0.3-0.4 ha in New York. Over 3 years in Massachusetts, territory densities were 1.8-1.9 per ha, suggesting territory sizes of 0.53-0.55 ha. A polygynous male in New York had a territory of 1.2 ha, approximately twice the size of those of monogamous males. In Michigan, a polygynous male had a territory of 1.38 ha; the average size for monogamous males was 0.51 ha. The 2 females in the polygynous mating had home ranges that were entirely separate and they were probably unaware of each other (Brewer 1955; Fitch 1958; Graber et al. 1983; Gross in Bent 1953; Guzy and Ritichison 2020; Kendeigh 1945; Létourneau and Lafontaine in Gauthier and Aubry 1996; Martin 1960; Morimoto and Wasserman 1991a; Morse 1977; Powell and Jones 1978; Stewart 1953).

In Ohio clear-cuts, 3 of 131 juveniles (2.3%) returned to their natal site. In Michigan and Minnesota, 1 of 85 nestlings (1.2%) was found 2 years later approximately 100 m from where she was banded. Another female bred the year after banding about 1,500 m from the natal site. In New Jersey, 1,083 yellowthroats were banded, but the number of juveniles and adults was not specified. Overall, 164 (15.1%) were recovered at the same area, including 125 adults and 39 juveniles (Guzy and Ritichison 2020; Lehnen and Rodewald 2009b; Suthers 1988). Schlossberg (2009) reported an average return rate of 2% for juveniles based on 216 birds and 2 studies. In a resident population at Brownsville, Texas, genetic analyses determined that young dispersed and did not defend territories near their natal area, and relatives did not appear to defend territories near each other (Roy et al. 2013).

Adult site fidelity appears to be low for migratory populations, possibly because the early successional habitat that it prefers is transitional. In Ohio, 41 of 128 adults (32.0%) returned to the same site. In Michigan and Minnesota, 1 male and 1 female of 11 adults (18.2%) returned the following year to the same territory. Adult return rate was 55% in the Rio Grande Valley where the yellowthroat is a year-round resident; 59% of males and 43% of females returned to breed at the same site. Between-year territory retention rates in 2 subpopulations of the resident subspecies in Texas were 45% and 89% (Guzy and Ritichison 2020; Lehnen and Rodewald 2009b). Schlossberg (2007) reported an average adult return rate of 47% based on 160 birds and 2 studies. In Texas, most males defended the same territory that they held the previous year. Birds defending another territory settled an average of 168 m from the previous year's territory (Roy et al. 2013).

Limiting Factors

Eggs have been reported in Ontario nests from mid-May to the end of July, with most present in the last 3 weeks of June (Peck and James 1987). In Algonquin Park, nests are under construction from early to late June, eggs are present from early June to late July, nestlings are present from late June to late July, and dependent fledglings have been observed from late June to late August (Tozer 2012).

Courtship begins as soon as females arrive and extends over 6-7 days. Females chose their mate within 1 or 2 days and select a nest site. Nest building may be completed in as little as 2 days or take as long as 7-10 days. Egg laying typically starts 2-4 days after the nest is complete, but as many as 8 days may elapse before an egg is laid. One egg is laid per day, but some days may rarely be skipped during periods of cold weather. Incubation begins with the laying of the last egg. The incubation period has been reported as 12 days, with a range of 11 days 3 hours to 12 days 19.75 hours in Michigan. The incubation period of 1 Ontario clutch was approximately 14 days. The nestling period is 8-9 days and is usually 7.8-9 days (Gross in Bent 1953; Guzy and Ritichison 2020; Kendeigh 1945; Peck and James 1987; Stewart 1953).

The Common Yellowthroat routinely raises 2 broods per season in southern Michigan and Texas, but is single brooded in northern Minnesota. Egg dates suggest that second broods may be common throughout its range. No second broods have been confirmed in Ontario or Quebec. Replacement clutches are common if a nest is lost. One Michigan pair made 3, and possibly 4, nesting attempts before successfully rearing a brood, which consisted of 2 cowbirds. It builds new nests for replacement clutches and second broods, with subsequent nests placed in the territory. The shortest reported interval between nest loss and building a new nest was 10 days and the interval between the start of 2 consecutive nests when the first was successful was 28 days in 1 case. Clutches of 2-5 eggs were reported in Ontario (average 3.97 eggs, mode 4 eggs). Elsewhere, clutches of 2-6 eggs were reported. The average size of 675 clutches, excluding those from Ontario, was 3.99 and 4 was the most frequent clutch size. In Michigan, early clutches were larger than later ones, with an average of 5.0 eggs in June and 4.2 in July. In other areas, no difference in clutch sizes occurred between early and late nests (Campbell et al. 2001; Chapman 1907; Graber et al. 1983; Guzy and Ritichison 2020; Hofslund 1957; Létourneau and Lafontaine in Gauthier and Aubry 1996; Gross in Bent 1953; Peck and James 1987; Stewart 1953).

The age at first breeding is 1 year. Both sexes can breed in their first year, but the incidence of this may vary individually and geographically. The yellowthroat is typically monogamous, but rare cases of polygyny have been documented. Polygyny is likely to occur only where there is a shortage of males so individuals can defend a larger than normal territory. Females exhibit no fidelity to their mates and may copulate with other males. The frequency of extra-pair copulations and paternity is unknown (Ford 1996; Guzy and Ritichison 2020; Powell and James 1978; Stewart 1953).

The yellowthroat is selective regarding the heights it forages at, and males forage at greater heights than females. In Massachusetts, females avoided foraging at heights of 1.5-3 m and above 6 m. Males foraged more opportunistically and used vegetation at different heights in proportion to their availability. Females foraged lower because they were associated with the nest, which was usually no more than a few centimetres from the ground. Males foraged and sang at a variety of

heights above 0.5 m. In June in Wyoming, mean foraging height was 0.18 m and this increased to 1.41 m in August. The increase in foraging height was attributed to the fact that other shrub-nesting warblers had left by this time. This study did not separate the sexes when calculating foraging heights. The increased height of foraging in August could also have been because females no longer had to tend to nests. In Massachusetts, there was no difference in plants used for foraging by the sexes. They exhibited a preference for feeding in scrub oak, used pitch pines and deciduous species according to their availability, and used ericaceous shrubs and herbaceous species less than their availability. There is no difference in the foraging techniques of the sexes and gleaning is the most frequent foraging technique, representing 93-100% of prey searches. Other less frequently used techniques include taking food from the ground, hovering, and hawking. Foraging occurs mostly at heights of 0-6.2 m, but occasionally as high as 15 m, predominantly on leaves, but also on the ground, on branches less than 1 cm in diameter, on bark, and on flowers and fruit. One study found that most prey captures were in the distal half of branches. Other studies found that it foraged equally on the inner and outer portions of trees. It prefers areas of dense vegetation for foraging. In Wyoming, 7% of foraging occurred where vegetation density was 50-85%, 27.3% at density of 85-100%, 22.7% at density of 15-50%, and 0% at density of 0-15%. In North Carolina, strata used for foraging included 6.2% in the canopy, 21.9% in low trees, 68.8% in shrubs, and 3.1% on the ground. In the canopy, 3.1% of all foraging occurred at the top of the crown, 3.1% in the lower crown, and 0% in the inner crown and on the bole. In low trees, 12.5% of foraging was at the top of the crown, 3.1% in the inner crown, 6.3% in the lower crown, and 0% on the bole. On shrubs, 12.5% of foraging occurred at the top of the crown, 3.1% in the inner crown, 0% in the lower crown, 43.8% in dense thickets, 3.1% in brush piles, and 6.3% in grasses. On the ground, 3.1% of foraging occurred in dense thickets and 0% occurred in grasses, at water's edge, or in the open (Guzy and Ritichison 2020; Hutto 1981; Lent and Capen 1995; Morimoto and Wasserman 1991b; Parnell 1969).

Young are initially fed small insects and larvae. By the age of 6 days, they are provided spiders and adult insects such as small moths, beetles, and grasshoppers. Food brought to an Iowa nest over an entire nesting season consisted of 22.2% unidentified insects, 20.5% moths, 17.1% larvae of various types, 16.5% spiders, 6.9% mayflies, 5.4% unrecognizable material, 3.6% flies, 3.2% damselflies, 1.2% caterpillars, 0.8% beetles, 0.8% chrysalises, 0.7% butterflies, 0.6% seeds, 0.4% grasshoppers, and 0.2% caddisflies. The adult diet consists of mostly insects and spiders. In Arizona, stomachs of 10 birds contained, in decreasing order of frequency, spiders, true bugs, flies, beetles, ants and termites, various larvae, hymenopterans, grasshoppers, and soft-winged bugs. In Illinois, 4 yellowthroats had consumed 80% lepidopterans (mostly cankerworms, but also other families), 8% beetles (weevils and rove, minute brown scavenger, and long-horned beetles), 4% flies (mostly gnats), 5% true bugs (mostly ash-gray leaf bugs), and a single hymenopteran, spider, and harvestman. It also eats katydids, gypsy moths, fall webworms, leafhoppers, aphids, grubs, plant lice, leafroller moths, dragonflies, locusts, insect eggs, and pokeweed (Graber et al. 1983; Gross in Bent 1953; Guzy and Ritichison 2020; Létourneau and Lafontaine in Gauthier and Aubry 1996; Stewart 1953; Suthers 1988; Whelan et al. 1989).

The yellowthroat is a common host of the Brown-headed Cowbird. It occasionally rejects cowbird eggs by abandoning the nest or building a second or even third nest over the cowbird eggs. In most cases, it accepts cowbird eggs. Most parasitism occurs in the first yellowthroat nest

with little to no parasitism of replacement and second clutches. Cowbird parasitism greatly reduces yellowthroat productivity and may be a limiting factor in some areas. At 1 Michigan study area, only 1 of 9 parasitized nests (11.1%) produced a yellowthroat fledgling. The average number of yellowthroat fledglings produced was 0.1 per parasitized nest compared with 1.9 per unparasitized nest. Another Michigan study determined that 3 of 20 parasitized nests (15%) produced yellowthroat fledglings. Fifty-eight percent of the total egg loss of yellowthroats was attributed to the cowbird. Of losses due to cowbirds, 33% were from removal of the host egg, 20% because of punctured eggs, 13% due to nest desertions caused by cowbird activity, and 33% to loss of incubation heat to the larger cowbird eggs. There was a direct relationship between hatching success and the number of cowbird eggs in the nest. No more than 2 cowbird eggs or 1 cowbird and 2 yellowthroat eggs hatched in any nest. If more than 1 cowbird egg was present, no yellowthroat eggs hatched. The heat of incubation each cowbird egg received was enough to prevent the hatching of 2 yellowthroat eggs. If yellowthroats successfully raise a cowbird, they do not renest. No loss of nestlings was attributed to cowbirds, and yellowthroat nestlings developed at the same rate in parasitized and unparasitized nests. Nine of 20 parasitized nests (45%) produced cowbirds. An average of 1.3 cowbirds fledged per successful nest, but only 0.6 were produced per parasitized nests. In Ontario, 36 of 187 nests (19.3%) were parasitized; 1 nest contained 2 yellowthroat eggs and 6 cowbird eggs. Parasitism rates vary considerably geographically: 7% in southern Quebec but 18.3% of all nests in Quebec; 18% of 35 British Columbia nests; 31.4% of 35 nests in Iowa; 10 of 22 (45.5%) and 20 of 52 nests (38.5%) in Michigan; 15 of 67 nests (22.4%) in Illinois; 19.7% of 84 Minnesota nests; 5 of 9 nests (55.6%) in Arizona; 42.0% of 88 nests in the Great Plains; and 0 of 7 nests in South Carolina (Campbell et al. 2001; Graber et al. 1983; Gross in Bent 1953; Guzy and Ritichison 2020; Hofslund 1957; Kilgo and Moorman 2003; Létourneau and Lafontaine in Gauthier and Aubry 1996; Lowther 1985; Peck and James 1987, 1998a; Sodhi 1995; Stewart 1953).

Habitat loss is not a significant limiting factor for the yellowthroat. Extensive deforestation in the mid-19th and early 20th centuries probably increased the amount of habitat available for it, although some forests that were removed were probably swamps that were suitable habitat. Significant wetland losses continued until the mid-1980s and this undoubtedly reduced habitat availability. Overbrowsing by deer and clearing of shrubs on cottage lots may render some habitats unsuitable. The replacement of shrub-lined drainage ditches with underground tile drainage results in habitat loss. Early mowing of hayfields, particularly those planted to alfalfa, usually results in the loss of nests, although this is poor habitat that is seldom inhabited (Guzy and Ritichison 2020; Létourneau and Lafontaine in Gauthier and Aubry 1996; Olechnowski and Debinski 2008; Stauffer and Best 1980).

Timmermans and McCracken (2001) examined population trends of the yellowthroat in relation to Great Lakes water levels. It was more abundant when lake levels were low and declined as levels increased. Higher water levels result in more open water, fewer emergents, and often a decrease in the amount of transitory meadow marsh between open-water marsh and upland habitats.

Forest thinning and clearing is beneficial for the yellowthroat and often creates habitat where none existed previously. Diseases, windstorms, ice storms, and other factors that reduce canopy closure are beneficial. The suitability of these habitats is short-lived, becoming unsuitable once the

canopy closes or young forests reach large sapling or pole size. Clear-cuts are most beneficial, followed by strip-cuts, shelterwood cuts, and selective thinning. In Pennsylvania timber improvement cuts where dead, dying, diseased, suppressed, and low-quality trees were removed, stands where snags were retained supported significantly higher densities of yellowthroats than those where snags were removed. Snag-retention areas had a more patchy and open canopy (52.9% canopy closure compared with 71.7% closure) and significantly more woody vegetation less than 1.5 m tall. In New York clear-cuts, it was the most abundant species and represented 30-40% of the entire avian population. It became abundant immediately after cutting and remained the dominant species until the study was terminated 6 years postharvest (Guzy and Ritichison 2020; Keller et al. 2003; Stribling et al. 1990). In the Canadian Shield of Ontario, there was no difference in its abundance in early successional and mid-successional clear-cuts and burns in the same seral stages. It was significantly more abundant in early successional than mature stands and equally abundant in mid-successional and mature stands (Zimmerling et al. 2017).

Two studies examined the effects of spraying clear-cuts with glyphosate, which suppresses deciduous woody species. In Nova Scotia and New Brunswick, there was no significant difference in the abundance of the yellowthroat on sprayed and control plots. It exhibited somewhat lower abundance on sprayed plots until the second postspray year but recovered by the fourth postspray year. In Maine, it was the most abundant species in untreated areas and second in abundance in treated areas. Its mean density was significantly less in treated sites than in control areas. Territories on treated sites were in areas where some uncontrolled shrubby vegetation remained, areas missed during the herbicide application. This was particularly evident 2-3 years after application. Invertebrates were much less abundant after spraying and were mostly in untreated skipped areas. Its density was positively correlated with the number of hardwood stems, vegetation height, total foliage density, and the foliage density contributed by each stratum (Freedman and Johnson 1999; Santillo et al. 1989).

The use of grasses for biofuel production may be beneficial to the yellowthroat. It is known to nest in fields planted to switch grass, reed canary grass, and Chinese silver grass (Robertson et al. 2012). It occasionally nests in hayfields dominated by alfalfa. In Iowa, density in that habitat was low. Males deserted their territories after mowing and never returned (Frawley and Best 1991).

Agricultural chemicals may be detrimental to the yellowthroat. One was found dead after granular carbofuran, an insecticide, was applied to a field. Poisoning can occur from direct ingestion of the granules or by consuming poisoned insects (Guzy and Ritichison 2020).

In Alberta, there were no significant differences in the yellowthroat's abundance at seismic lines, pipelines, or well pads than in forest interior adjacent to these facilities (Bayne et al. 2016). In West Virginia, it was significantly more abundant near well pads, access roads, and pipelines than in areas distant from these facilities (Farwell et al. 2019).

In Massachusetts, Zuckerberg and Vickery (2006) examined the effects of burning and mowing shrublands on the Common Yellowthroat. Shrubby areas were mowed 1-3 times or burned once in treatment areas, management that is undertaken to maintain habitat for grassland and shrubland species. It preferred control and burned shrublands and avoided shrublands that had been mowed. It was more abundant than expected in shrublands that had not been mowed, less abundant than

expected in shrublands that had been mowed once, and absent in shrublands that had been mowed 2 or 3 times. Shrublands that were left unmanaged or burned once were not noticeably different and were characterized by tall shrubs. Habitat preferred by the yellowthroat consisted of areas having shrubs 1-2 m tall and no litter cover. In North Dakota mixed-grass prairie, it was most abundant in grasslands that had not been burned for more than 80 years. Fire increased the amount of grasses and decreased shrub coverage. It showed a consistent and distinctly negative reaction to fire; it started to recover 7-8 years postfire (Madden et al. 1999). In grassland habitat in Indiana, Grundel and Pavlovic (2007a) found that it benefitted from burning at a frequency of about a fire every other year. In Illinois, daily nest survival was positively associated with distance to shrubs and negatively associated with vegetation height and density, suggesting that the reduction of woody vegetation and plant biomass by prescribed burns may benefit nest success (Glass and Eichholz 2023).

Drought may have adverse effects on the yellowthroat. In Wisconsin, its abundance decreased with increasing drought indices, with a 1-year time lag. In North Dakota, numbers fluctuated considerably over a 25-year period and were significantly associated with the number of ponds present in May (Blake et al. 1992; Niemuth et al. 2009).

In Pennsylvania and New Jersey over a 15-year period, hemlock declined from 56% of the total basal area to 46% due to mortality from the hemlock woolly adelgid. The amount of woody understorey increased as a result of the more open canopy. The yellowthroat increased because of these habitat modifications (Toenies et al. 2018).

Status

The Common Yellowthroat has always been common in Ontario and may be locally abundant. McIlwraith (1894) reported that it was widely but irregularly distributed, being an abundant breeder in some locations and mysteriously absent in other areas of suitable habitat, such as in Hamilton. Baillie and Harrington (1937) reported that it was a common breeder north to southern Kenora and northern Sudbury districts, and that it occurred sparingly further north to Moose Factory. The first atlas demonstrated that it bred from the southern boundary of the province north throughout the Boreal Forest Region and sparingly in the Hudson Bay Lowland where it was found in a few inland locations near Hudson Bay. It was the most abundant warbler in the province (McLaren in Cadman et al. 1987). In certain habitats, such as bogs and young clear-cuts, it may nest in high densities and be one of the dominant species (Martin 1960; Welsh and Fillman 1980). In large marshes in the south, it is often fourth in abundance (Tozer et al. 2006). James (1991) considered the yellowthroat a common breeder across the province north to Big Trout Lake and Attawapiskat, and probably occasional further north in the western portion of the province.

The second atlas confirmed that the range of the Common Yellowthroat included the entire province except for the northern portion of the Hudson Bay Lowland and Tundra Region. Although individual singing males were detected along the Hudson Bay coast, few occur within 100 km of the northern coast. It was detected in several squares north of Attawapiskat, which may represent a modest range expansion. Its probability of observation was similar province-wide during both atlases, although the tendency was toward an increase. Significant increases in its probability of observation occurred in the Boreal Forest Region and Hudson Bay Lowland. It attained its highest

abundance in the eastern portion of the Boreal Forest Region, north and east of Georgian Bay, and in a broad band along the southern edge of the Shield (McLaren in Cadman et al. 2007).

Marsh Monitoring Program results indicate that the Common Yellowthroat increased at a rate of 1.2% per year in the Great Lakes basin from 1995 to 2012 (Tozer 2013). In Great Lakes coastal wetlands, it decreased at an annual rate of 2.3% 2011-21 (Tozer et al. 2024). Breeding Bird Survey data indicate that it decreased at annual rates of 0.256% in Canada and 0.351% in Ontario 1970-2021. Trends 2011-21 were an annual increase of 0.438% in Canada and an annual decrease of 0.304% in Ontario. All results were highly reliable except for the Canadian long-term trend, which was of medium reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Recently fledged young do not move far unless they are disturbed, initially remaining within 1-2 m of the nest before moving to adjacent woods or thickets. One brood was still within a few feet of the nest 3 weeks after fledging. The parents and young may move in search of food and travel as far as 300 m from the territory (Guzy and Ritichison 2020). In Michigan, adults that nested in riparian forests remained there after the young fledged, and fledglings also remained there (Akresh et al. 2009). The adults continue to feed the young approximately 2 weeks after fledging. Fledglings continue to beg from the parents and may not be completely independent until 22-28 days after fledging. Young from second broods may be fed until it is time for autumn migration (Guzy and Ritichison 2020).

In Michigan, both adults and juveniles were captured in upland mature forests dominated by trembling aspen and large-toothed aspen, and in riparian trembling aspen forests with an understorey of honeysuckle and alder. Both age classes were significantly more abundant in riparian forests, where 79% of fledglings were captured (Akresh et al. 2009).

Both adults and juveniles frequently inhabit young regenerating clear-cuts during the postfledging period. In West Virginia clear-cuts, abundance of the yellowthroat was negatively correlated with increasing BA of retained trees. Residual trees inhibited understorey growth and limited stem density. Residual trees provided perches for raptors but did not offer protection from raptors. Within clear-cuts, it avoided residual trees and captures were greater in areas with few nearby trees. In Pennsylvania, it was 1 of the 5 most frequently caught species in clear-cuts that were considered early successional species. It was also 1 of the 10 most abundant species captured in forests during the postfledging season (McDermott and Wood 2010; Stoleson 2013; Streby et al. 2011b; Vitz and Rodewald 2006). In Missouri, Porneluzi et al. (2014) netted during the postfledging period 2-15 years after an oak-hickory-pine forest was clear-cut. Numbers captured were quite low and yellowthroats were netted in only years 3 and 4 after cutting.

On Pennsylvania hydro transmission line corridors through forested habitat, the yellowthroat was abundant during the postfledging period. In August, it was absent within the adjacent forest habitat, but occurred at densities of 200-347 per km^2 on the rights-of-way. In 1 year, an average of 2.50 families per day was observed; 5.83 per day were seen the following year. One year it was the most abundant species in this habitat; it was third in abundance the other year (Yahner et al. 2002).

MIGRATION

The Common Yellowthroat is a nocturnal migrant. All North American populations are migratory except for resident populations in Florida, along the Gulf Coast, in Texas, and in the southwest (Guzy and Ritichison 2020; Harrison 1984). Birds appear to migrate singly rather than in flocks (Campbell et al. 2001). Encounters of banded birds indicate a predominantly north-northwest-south-southeast orientation in Ontario. Two birds banded in Ontario were recovered in Florida during autumn migration (Brewer et al. 2018). Atwood (1992) used morphological measures to identify discrete breeding populations. Most birds measured at Toronto were associated with breeding populations along the Ottawa and St. Lawrence rivers near the Ontario-Quebec border, the Georgian Bay area, northeast of Sault Ste. Marie, and western Quebec. A few were associated with breeding populations in Newfoundland, Nova Scotia, and Anticosti Island. Toronto migrants represented predominantly birds breeding in southern Ontario and southwestern Quebec, and orientation appeared to be mostly north-south. The destinations of spring migrants were not confirmed.

Males arrive in spring before females. At Prince Edward Point, the mean date of arrival was 18.8 May for males compared with 23.0 May for females. Few birds were recaptured, indicating that most remained on site only 1 or 2 days (Francis and Cooke 1986). In Michigan, most females arrived about a week after the first appearance of males (Stewart 1953). In Massachusetts, the average difference in arrival by the sexes was 5.5 days. There were no significant changes in arrival times over a 33-year period or in the relative timing of arrival of the sexes. There were no significant relationships with any climate variables and timing of spring migration (Bauböck et al. 2012). In Maine, males arrived significantly earlier than females by 5.0 days. After-second-year birds arrived significantly earlier than second-year birds. Stopover lengths were not significantly different: 2.0-4.3 days for males and 1.8-6.1 days for females (Morris et al. 2003).

In southern and central Ontario, the yellowthroat typically arrives in early to mid-May, with the earliest migrants arriving in late April. Migration is mostly over by the end of May, but a few may remain into the first week of June (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008). At Long Point, the spring midpoint of migration is 20 May (Mills 2005).

During autumn, there is no difference in timing of migration by juveniles and adults. Woodrey and Chandler (1997) compared autumn migration timing of the 2 age classes at Long Point Bird Observatory (LPBO) and in Pennsylvania and Alabama in 1990 and 1991. In 1990, there were no differences in timing of migration of juveniles or adults at any of the sites. In 1991, the median passage of juveniles preceded that of adults by 14 days in Pennsylvania, but there was no difference in timing at the other sites. They concluded that timing of migration of adults and juveniles varied annually and by site.

At Ekwan, Wilson and McRae (1993) observed single migrants on 7, 9, and 11 September. In the southern Shield, the peak of autumn migration is in September and most are gone by the second or third week of October (Mills 1981; Tozer 2012). In southern Ontario, migration begins by mid-August and continues through September and much of October. Some remain into the first week of November, but there are numerous January and a few February records in the Hamilton area

(Black and Roy 2010; Curry 2006; Keast 1980; LaForest 1993; Lancaster et al. 1981; Weir 2008). At Long Point, the autumn midpoint of migration is 14 September (Mills 2005a).

Mills (2005b) compared timing of migration at Long Point from 1974 to 2002 in relation to climate change. When first date of arrival was considered, birds arrived earlier in spring in 2002 than in 1974, but not significantly. There were no differences when spring quartiles were examined. In autumn, it departed earlier in 1974, but not significantly. In spring, vanguard individuals may respond disproportionately to climate change, especially males in good condition. The yellowthroat may be breeding earlier and leaving earlier, but differences over time are not significant. In Pennsylvania, the average spring temperature did not change over an 18-year period, but the amount of precipitation received in May increased. It arrived earlier with time at a rate of 2.8 days per decade (R.J. Smith et al. 2023).

In spring, the yellowthroat is more restricted in its habitat use and may simply show up on breeding territories in the north. During spring,it is found mostly in habitats similar to those used for breeding, although a wider variety of habitats may be used at more southern stopover sites. In autumn, it occurs regularly away from wetlands and may be found in patches of dense vegetation and shrubs, such as raspberries, that retain leaves later into autumn. It also occurs along open creeks, at sewage lagoons, at forest edges, in bottomland forests, in flower gardens, along stagnant ditches and drains with emergents, in trembling aspen groves, in dense grassy areas, and even in upland forests (Campbell et al. 2001; Curry 2006; Graber et al. 1983; Guzy and Ritichison 2020; Sinclair et al. 2003; Tozer 2012).

Several studies examined habitat preferences of the yellowthroat during migration. In Illinois, Graber et al. (1983) did not examine marsh habitats, but found it to be most numerous in forest edges and shrubby areas. It also occurred in mature bottomland forests, but in inconsequential numbers. During spring migration in Wisconsin and Minnesota, it was significantly more abundant in floodplain forests than upland forests (Kirsch et al. 2013). During spring migration in North Carolina, it was most common in shrub habitat. Average numbers seen per hour were 3.28 in wet thickets, 2.00 in dry thickets, 1.55 in floodplain forests, 0.19 in pine and oak-hickory forests, 0.08 in pine-hardwoods forests, and 0 in beech forests (Parnell 1969). During spring migration in Pennsylvania, it was significantly more abundant in shrubs than forests. Detections per 100 m of transect were 0.08 in forests and 0.84 in shrubs; captures per 1,000 net-hours were 3.7 in forests and 32.8 in shrubs (Smith and Hatch 2008). In New Mexico, capture rates in willows shorter than 3 m tall were 4-fold greater than in any other habitat (agricultural edges, cottonwood–Russian olive stands, and cottonwood-mixed stands; Kelly et al. 2000). During autumn migration in Pennsylvania, its abundance was significantly higher in shrub-sapling-stage forests than forest-agricultural edge habitat. It was not observed in forest interior, suburban forests, or pole-stage forests. The shrub-sapling stage had the highest number of stems in the 0.25- and 2.5-8-cm diameter classes. In forest-agricultural edges, it usually used shrubby habitat at edges (Rodewald and Brittingham 2004). In open-canopied forests in Indiana, migrating yellowthroats were associated with low ground vegetation, high shrub density, and low tree density and were most abundant where there were frequent fires (Grundel and Pavlovic 2007a). During spring migration in Pennsylvania, it was more

likely to be detected in large than small patches, but there was no relationship between its abundance and patch size during autumn migration (Keller and Yahner 2007).

During migration, the yellowthroat usually forages singly and is seldom seen in mixed-species flocks of warblers (Campbell et al. 2001). During spring migration in North Carolina, 3.0% of foraging occurred in the canopy, 20.5% in low trees, 72.2% in shrubs, and 4.2% on the ground. In the canopy, 0% of foraging occurred at the top of the crown, 1.2% in the inner crown, 1.8% in the lower crown, and 0% on the bole. In low trees, 1.8% of foraging occurred at the top of the crown, 13.9% in the inner crown, 4.8% in the lower crown, and 0% on the bole. In shrubs, 8.4% of foraging occurred at the top of the crown, 10.8% in the inner crown, 2.4% in the lower crown, 51.0% in dense thickets, 6.6% in brush piles, and 3.0% in grasses. On the ground, 1.8% of foraging occurred in dense thickets, 0% in grasses, 1.2% at water's edge, and 1.2% in the open (Parnell 1969). In New York, Lebbin et al. (2007) observed yellowthroats foraging at night among the foliage of low shrubs in an area illuminated by football-stadium lights.

The yellowthroat is vulnerable to being killed by extremely adverse weather during migration. These may include cold fronts with headwinds, heavy rains, and tornados (Guzy and Ritichison 2020).

During migration, the yellowthroat is frequently killed by striking buildings, communication towers, and other human-made structures. From 1972 to 1982, 1,995 were killed at the Lennox generating station chimneys near Kingston, including 1,002 on the night of 6 September 1981. There is a record of 2 being killed by striking a fire tower in central Ontario. It is one of the species most vulnerable to striking high-rise buildings in Toronto. In Florida, 2,710 were killed at television towers over 3 years during autumn migration. In Illinois, it represented 5.1% of all warblers killed at television towers and was 11.4% of all birds killed at human-made structures in the United States and Canada (Chapman 1907; Colling et al. 2022; Graber et al. 1983; Gross in Bent 1953; Guzy and Ritichison 2020; Mills 1981; Weir 2008). Loss et al. (2014) examined bird-building collisions across the United States and determined that the yellowthroat was more vulnerable to striking buildings than average. For all types of buildings, it was 10.9 times more likely to strike a building than average. At low-rises, it was 18.4 times more likely to strike a building than average compared with 20.4 times at high-rises.

In Pennsylvania, an outbreak of the viburnum leaf beetle resulted in almost complete mortality of the southern arrowwood, which was formerly the third most abundant shrub species. Prior to the infestation, spring migrating yellowthroats gained significant mass after sunrise, but no weight gains occurred after the infestation (Smith and Hatch 2017).

James (1991) considered the yellowthroat a common to locally abundant migrant.

At LPBO, migration monitoring determined that the yellowthroat declined at a rate of 1.6% per year 1961-88. Trends by period were: −1.8% 1961-70, −1.9% 1970-79, and −1.1% 1979-88. All trends were nonsignificant, suggesting that populations were stable (Hussell et al. 1992).

WINTER

The winter range of the Common Yellowthroat covers most of the area where the frost-free period is longer than 240 days, generally north to the Virginia area in the east. Densest populations occur where the average minimum January temperature is higher than 7°C (Root 1988). Ontario is considerably north of its normal winter range. It is only occasional and rare during winter from Point

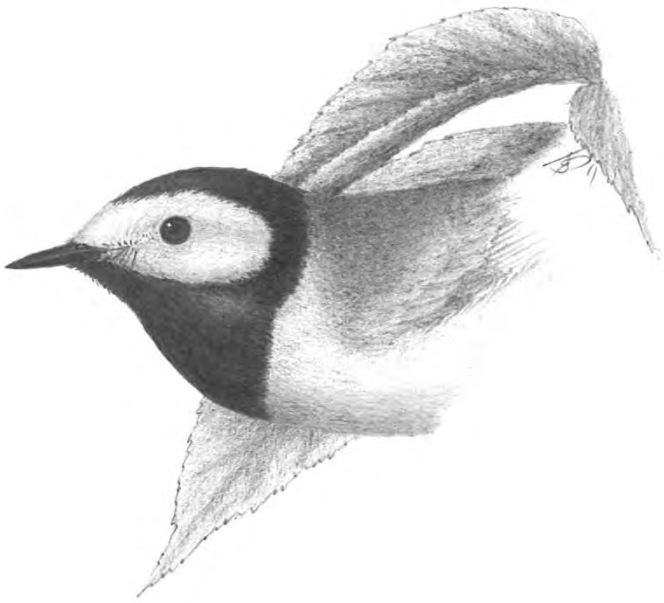
Pelee to Toronto (James 1991). The proportion of birds that attempt to overwinter that survive is unknown.

In the Hamilton area, the yellowthroat may successfully overwinter on occasion, and is usually observed among cattails in lakeside marshes (Curry 2006). Wintering birds in Ohio were also seen in cattail marshes (Gross in Bent 1953).

The yellowthroat commonly defends a territory in winter (Guzy and Ritichison 2020; Morse 1989). Due to its rarity in the province in winter, it is unlikely that any territorial defence is required.

Hooded Warbler

Setophaga citrina



BREEDING SEASON

Habitat Requirements

Ontario Hooded Warbler nests were in mixed (50.5% of nests), deciduous (47.3%), and coniferous (2.2%) forests. The coniferous stands were mature white pine plantations. Most forests it used for nesting were dry and all had characteristic understories of dense saplings, shrubs, and vascular plants (Peck and James 1987, 1998a). It occurs predominantly in tracts dominated by white oak, hickory, red maple, sugar maple, beech, and white pine. Common habitat associations that it uses include sugar maple–beech, oak-hickory, oak–sugar maple, and oak-pine stands. It occurs in white pine plantations only if they are mature and have an understorey of deciduous shrubs or saplings. It occurs less frequently in silver or red maple swamps and hemlock–yellow birch ravines (Austen et al. 1994; Page and Cadman 1994b; Sutherland and Gartshore in Cadman et al. 1987; Walters and Nol 2011b).

Potential occupancy of Ontario woodlands by the Hooded Warbler is affected by factors at the landscape level, by characteristics of the forest, and by microhabitat features. Habitat is not occupied if there are deficiencies at any level.

There appear to be 2 important factors at the landscape level that determine if a given woodlot has potential to support the Hooded Warbler. These include the amount of forest cover within the landscape and presence of sandy soils. In the Long Point area, the amount of forest cover within the local landscape was a significant predictor of Hooded Warbler occupancy. At the 3 major sites supporting it in southwestern Ontario, forest cover is 61-77% within 1 km of nest sites. Eastern Elgin County and Norfolk County, where the core of the population occurs, have 16-25% forest cover. In sand plains in western Chatham-Kent and Lambton where forest cover is as low as 3%, it was originally absent in otherwise suitable forest patches (Friesen et al. 2012; Gartshore 1988; Melles et al. 2012). With its recent range expansion, some forested areas in Chatham-Kent and Lambton have become occupied (Badzinski in Cadman et al. 2007).

Sutherland and Gartshore (in Cadman et al. 1987) and Gartshore (1988) were the first to notice that most occupied woodlands were on sand plains. Other records can mostly be explained by local sand deposits. Much of Haldimand County is dominated by the Haldimand Clay Plain, but a nest near Cayuga was at the end of the Oriskany sandstone formation where there is rich sandy soil. Even with the expanding population, the relationship with sandy soils appears to ring true. The recent expansion into the Ganaraska Forest occurred in areas of sandy soils (Heagy and Badzinski 2012; Walters and Nol 2011b).

In addition to having the appropriate dominant tree cover, forests must be mature and large or very close to a large forest to be occupied. Forests with trees smaller than timber size are avoided. At St. Williams and South Walsingham, forest maturity was an important factor in determining nest-site selection. Nesting areas had a higher basal area (BA) of large trees than unoccupied areas. Nest sites have a significantly lower BA of trees 7.5-15 cm diameter at breast height (DBH). Presence of large trees is essential because the Hooded Warbler relies on gaps in the canopy for nest sites. In undisturbed forests, these are created primarily by treefalls so presence of large trees is required to create large enough gaps. It is unlikely to use woodlots that lack mature growth (Bisson and Stutchbury 2000; Whittam et al. 2002).

The Hooded Warbler appears to be area-sensitive in Ontario. Extra-pair copulations are an important component of its mating system, so forests have to be large enough to support more than a single pair. It occasionally uses smaller woodlots, but only if they are close to larger tracts that support additional breeding pairs. The amount of habitat required to support it in Ontario is

uncertain, and is probably evolving as it increases in abundance. When a species is rare, it typically is restricted to the largest patches of optimum habitat, but may use smaller patches and those of somewhat lower quality as it becomes more common. The degree of isolation and the amount of local forest cover may also influence the size of forest required. Initially it was thought that contiguous woodlands exceeding 100 ha in size were required to support the Hooded Warbler in Ontario and 95% of known occurrences are still within forests of that size. It was subsequently concluded that 30 ha or more were required to support a viable population and later that it was consistently absent from woodlots smaller than 20 ha. More recently, it has been documented nesting in woodlots 8-10 ha in area, but only where they are near larger forests. Both forest size and connectivity are important (Friesen and Stabb 2001; Friesen et al. 2012; Heagy and Badzinski 2012; James 1984b; Page and Cadman 1994b).

Large, mature forests on sandy soils with suitable tree species composition are unlikely to be occupied unless they have canopy openings that promote growth of deciduous shrubs and saplings. Although the Hooded Warbler nests within mature woodlots, it does not nest within mature portions of woodlots and selects small patches of early successional habitat. It is a forest-gap specialist that nests in small openings in the canopy created by treefalls, windthrow, insect damage, diseases, or forest management. The importance of shrubby gaps has been demonstrated in the South Walsingham Forest in Norfolk County and the Springwater Conservation Area in Elgin County. It declined significantly or disappeared from these areas once forest gaps matured and filled in. Gaps used for nesting in Ontario range from 5 to 1,178 m^2. Gaps may be occupied 1-5 years after they are created until they are 12 or 13 years old. Gaps are abandoned once saplings reach 5-10 m in height. At this stage of succession, the ground is usually devoid of vegetation. Common shrub and sapling species found in gaps used for nesting include raspberries, red elderberry, maple-leaved viburnum, grape, gooseberry, chokecherry, red maple, sugar maple, white ash, and beaked hazel. Sixty-six woody species were found at nest sites in southwestern Ontario. To be suitable, gaps must have a high density of deciduous woody plants at the height that nests are usually placed, usually 0.5-1.3 m from the ground. Because gaps provide suitable nesting habitat for only a short period, the location of breeding territories and nests may be constantly shifting in large forests, and the number of breeding pairs may fluctuate considerably depending upon availability of suitable gaps. Populations in small woodlots may be ephemeral, being occupied for a few years after disturbance and absent when the canopy is closed (Allaire and Badzinski 2004; Bisson and Stutchbury 2000; Friesen et al. 2012; Gartshore 1988; Heagy 2008; Heagy and Badzinski 2012; Melles et al. 2012; Page and Cadman 1994b; Walters and Nol 2011b; Whittam 1999; Whittam et al. 2000, 2002). Although presence of suitable gaps for nesting is critical, presence of suitable nesting habitat within high-quality forests does not ensure occupancy. Occupancy declines with increasing distance from core populations indicating that connectivity at the landscape level is important. Forests with suitable nesting areas within the maximum gap-crossing distance for this species (50 m for females and 500 m for males) are frequently selected for nesting (Melles et al. 2012).

Several Ontario studies described the habitat characteristics of gaps used for nesting and compared them with unused areas within the same forest. Gartshore (1988) described the habitat at 6 nests in the Long Point area as having 88% canopy cover, 87% shrub cover, and an average of 10.5 shrub stems per m^2 (range 3.3-27.9 per m^2). In the same region, Melles et al. (2012) determined

that nest locations had fewer saplings with a DBH of less than 2.5 cm and more large saplings (2.5-9.9 cm DBH) than pseudo nest sites. Bisson and Stutchbury (2000) sampled 23 nest sites and 23 unoccupied sites in 7 woodlots in the Long Point area. Nest sites had a higher percentage of cover at all 4 vegetation profile heights (0-0.3 m, 0.3-1 m, 1-2 m, and 2-3 m) and a lower BA of trees in the smallest size class (7.5-15 cm DBH) than unoccupied areas. The percent vegetative cover at the 4 height intervals for occupied and unoccupied sites respectively were: 0-0.3 m, 90.4% and 79.8%; 0.3-1 m, 83.9% and 56.5%; 1-2 m, 72.2% and 46.8%; and 2-3 m, 65.3% and 49.6%. The BA of trees 7.5-15 cm DBH was 1.9 m^2 per ha at occupied sites compared with 3.0 at unoccupied sites. Nest sites had a lower percent canopy cover than unoccupied sites (79.0% compared with 89.0%), but the difference was not significant. The probability that a site would be occupied increased with height of the subcanopy and percent coverage by vegetation at the 1-2-m level. Whittam et al. (2002) examined 52 nest sites in South Walsingham Forest and 57 in St. Williams Forest and compared their vegetative structure to unoccupied sites and found that they were significantly different. Nest sites in both forests differed from controls by having denser vegetation (mostly raspberries, but also some herbaceous cover) 0-0.3 m from the ground and by having fewer tree stems per ha. In South Walsingham Forest, nest sites had denser vegetation at the other 3 levels above ground, more snags per ha, less BA of small trees, and greater BA of large trees than controls. In St. Williams Forest, nest sites had taller canopy, more stumps, and more BA of stumps than controls. In both forests, vegetation density below 1 m above ground discriminated nest sites from controls. At St. Williams Forest, 86% of nest sites were in gaps averaging 43 m^2 and 196 m^2 over 2 years, and 84% of gaps were created by timber harvesting. Nest gaps averaged 6.2 years old (range 1-13 years) in 1999 and 7.6 years (range 4-14 years) in 2000. Nests were found in coniferous stands more than expected due to more recent and widespread logging in plantations. Hooded Warblers were found in areas of low, moderate, and high logging intensity more than expected by chance. Significant habitat variables at St. Williams Forest compared with control areas were: canopy height, 25.9-27.9 m compared with 22.9 m; cover 0-0.3 m from ground, 90.8-91.3% compared with 78.6%; cover 0.3-1 m from ground, 68.5-76.1% compared with 57.5%; cover 1-2 m from ground, 40.4-61.0% compared with 46.8%; 564-614 tree stems per ha compared with 861 stems per ha; 17-139 logs per ha compared with 24 logs per ha; stump BA, 9.8-18.5 m^2 per ha compared with 35 m^2 per ha; and 46-93 stumps per ha compared with 27 per ha. Significant habitat variables at South Walsingham Forest nests compared with control areas were: cover 0-0.3 m from ground, 84.2% compared with 66.0%; cover 0.3-1 m from ground, 61.8% compared with 39.6%; cover 1-2 m from ground, 57.9% compared with 37.1%; cover 2-3 m from ground, 56.2% compared with 39.5%; tree stems per ha, 1,005 compared with 1,319; snags per ha, 105 compared with 177; BA of small trees, 13.3 m^2 per ha compared with 17.3 m^2 per ha; and BA of large trees, 12.3 m^2 per ha compared with 8.8 m^2 per ha. Walters and Nol (2011b) reported similar habitat at nest sites in the Ganaraska Forest. Nests were mostly in deciduous forest but 2 of 12 (16.7%) were in managed coniferous forests regenerating to mixed forest. Similar to the Long Point area, nests were in forest gaps and habitat of these gaps was also similar. Most nest sites had 26-75% coverage 0.5-1.3 m from the ground; most unoccupied sites had 1-25% coverage in this height range. Fifty percent of nest sites had 26-50% coverage 2.5-10 m from the ground; 71% of unused sites had 1-25% coverage at this height. At nest sites, there were significantly more living woody stems (27.9 compared with 9.3 per 50 m^2) and fewer dead stems (0.8 compared with 1.3 per 50 m^2) than at unoccupied sites. There were significantly more shrubs at nest sites (43, range 7-66)

than at unoccupied sites (3, range 0-125) per 50 m^2. Similar to the St. Williams Forest, canopy closure was less at nest sites than unoccupied sites, but not significantly.

Throughout its range, the Hooded Warbler nests in habitat similar to what it uses in Ontario. In addition, it frequently nests in deciduous swamps and this appears to be preferred habitat. In New Jersey, it was significantly more abundant in hardwood swamps than in oak-pine forest. It rarely nests in mature coniferous plantations in Wisconsin and pine barrens in New Jersey, where it nests at the interface between cedar and pine swamps. Nonetheless, it shows a decided preference for deciduous forests. Forests that it uses are intermediate in age or mature so that a treefall creates a large enough gap for nesting. In Pennsylvania, it occurred in 36.4% of old-growth forests, 28.8% of woodlots state-wide, and 31.3% of woodlots on the Appalachian Plateau. It had neutral affinity for old-growth forest, being neither more nor less likely to occur in old-growth stands. It is a gap specialist throughout its range, nesting in small canopy openings with dense deciduous shrubs and saplings. In North Carolina, its relative abundance was 3.19 in pine-hardwoods, 2.11 in beech forests, 1.76 in floodplain forests, 1.37 in pine forests, 0.95 in oak-hickory forests, and 0 in wet and dry thickets. Mist-netting during the breeding season resulted in captures per 100 net-hours of 2.1 in gaps, 4.0 in edge, and 2.0 in forest. Forest habitat was used most during the breeding season, but it was never the dominant habitat used. It nested and foraged in the mature forest, but often foraged in gap habitat in all seasons, and young remained in gaps during the postfledging period. In the mid-Atlantic states, habitat variables that defined suitability for the Hooded Warbler were identical to those identified in Ontario. Its abundance was significantly correlated with canopy height, the amount of forest within 2 km, foliage density 0.3-1.0 m from the ground, and percent ground cover. Habitat characteristics of nest-site gaps in Pennsylvania were: 23.7 stems per m^2; 19.7 branches per m^2; overall visibility, 50.4%; 57.9% visibility at nest height; 39.0% visibility at 1.5 m; and 31.0% visibility from above with considerable variation in all parameters. The dominant nest substrate corresponded to the dominant shrub species in the forest and included blackberry, beech, prickly gooseberry, and black cherry. In Tennessee, it was significantly negatively correlated with foliage, branch, and bole biomass of trees 1.2-8.4 cm DBH. The Hooded Warbler was closely associated with the Cerulean Warbler and Carolina Chickadee. The 3 species were separated vertically with the Cerulean Warbler inhabiting the canopy, the chickadee the subcanopy and understorey vegetation, and the Hooded Warbler with the layer closest to the ground. In Ohio, 7 of 23 vegetation variables varied significantly between nest sites and perches. Nest sites were characterized by a greater density of small coniferous and deciduous trees, a lower canopy closure percentage, more deciduous woody plants 1.0 cm and 1.1-2.5 cm DBH, and significantly more conifers smaller than 1.0 cm, 1.1-2.5 cm, 15.1-23 cm, and 30.1-38 cm DBH than perch sites. Both nest sites and perches were significantly correlated with percent ground cover and trees larger than 53 cm DBH. The Hooded Warbler exhibited a high degree of selectivity for nest sites, but nest sites and perches became more similar with increasing sample area. The difference between nest sites and perches may be related to the requirement to conceal nests compared with the desire of the male to sing from a conspicuous area. When selecting a nest site, it responds to vegetation in an area of less than 0.04 ha and more specifically to a 1-m radius, or 3 m^2 (Anderson and Shugart 1974; Bent 1953; Bielefeldt and Rosenfield 1994; Bowen et al. 2007; Brooks 1940; Brush 1987; Buffington et al. 1997; Bushman and Therres 1988; Graber et al. 1983; Haney 1999; Harrison 1984; Howlett and Stutchbury

1996; Kilgo et al. 1996; Mossman and Hoffman 1989; Mumme et al. 2023; Noon et al. 1979; Parnell 1969; Petit et al. 1988a; Powell and Rappole 1986; Rich et al. 1994; Robbins et al. 1989; Sargent et al. 1997).

In a Connecticut woodlot over a 59-year period, there was a progressive shift to larger trees, a sparser shrub layer, and a less diverse tree canopy dominated more by oaks and maples due to a severe decline in hemlock. The Hooded Warbler declined within the woodlot but populations increased statewide. The decline was likely due to the reduction in the shrub layer (Buchanan et al. 2016).

The Hooded Warbler appears to be area sensitive in some areas, but inhabits very small woodlots in other areas. Area sensitivity may vary considerably even in areas close to each other. In western Maryland, where it is uncommon, it is found only in woodlands larger than 4,000 ha, but it nests in woodlots as small as 5 ha in central Maryland (Bushman and Therres 1988). Robbins (1979) concluded that 30 ha were required to support a viable population, but Robbins et al. (1989) found that its abundance and occurrence were not related to forest size in the mid-Atlantic states, which include Maryland. Mumme et al. (2023) stated that it inhabited forests larger than 15 ha. In Pennsylvania, it regularly breeds successfully in woodlots smaller than 2 ha. Forest fragments where it was studied averaged 1.2 ha (range 0.7-1.8 ha). All fragments were close to larger habitat patches, and this probably contributed significantly to their habitat suitability. Only 19% of isolated forest fragments 0.5-5 ha were occupied (Norris and Stutchbury 2002; Norris et al. 2000). The degree of its area sensitivity probably depends on a number of factors such as its local abundance, the amount of suitable habitat in the landscape, and the proximity of suitable woodlots to each other. In Pennsylvania, both males and females regularly flew across open habitat into adjacent larger woodlots. No females crossed open gaps wider than 50 m, but males crossed gaps as wide as 465 m. In some cases, there were wooded corridors connecting the fragment to the larger forest patch. Only 1 of 3 females that had a corridor available to them used it. When males had corridors available, most (62.5%) used the corridor when leaving the woodlots but not when returning (16.7%). Seventy-seven percent of all forays to adjacent woodlands occurred despite the absence of corridors. Protection of corridors linking patches may not be as important as limiting the degree of isolation between forested areas. The added time and energetic costs of making forays in fragmented landscapes could explain the low occupancy rate of small woodlots (Norris and Stutchbury 2001, 2002).

Numerous authors considered the Hooded Warbler a forest-interior species that avoided edge habitat. Edges were considered detrimental due to anticipated higher levels of predation and parasitism by the Brown-headed Cowbird. Few of these studies based their conclusions on empirical data. Early status reports prepared for the Committee on the Status of Endangered Species in Canada (COSEWIC) emphasized the importance of forest interior to the Hooded Warbler. The first COSEWIC report suggested that the distance required from edge was probably closer to 600 m than 60 m and that large forests dominated by edge were of little use to it. It was thought that it rarely wandered to forest edge. The second COSEWIC report stated that it was unlikely to persist without large blocks of forest where much of their area was more than 200 m from edge. An earlier Environment Canada factsheet concluded that nesting success was often greater in forest interior

than at the edge. The third COSEWIC report acknowledged that it uses forest edges (Freemark and Collins 1992; Friesen and Stubb 2001; Heagy and Badzinski 2012; James 2000; Page and Cadman 1994b). Even prior to the preparation of the first COSEWIC report, the Hooded Warbler was known to nest at the edges of Vanessa Swamp and the St. Williams Forest (personal observations).

Some studies specifically examined presence of the Hooded Warbler in relation to forest edge. Although a few studies observed an apparent edge-avoidance reaction, more studies determined that it was either indifferent to edge or even more likely to occur near edge. Lynch (1987) mapped territories in Maryland and found that no territories included edge; 30 m was the closest it was observed to edge. In New Jersey, it was consistently more abundant in forest interior than at forest edge (Rich et al. 1994). In the St. Williams Forest, nest sites tended to be further from forest edge than pseudo nest sites. Nonetheless, it tended to nest in the northern and southwestern portions of this forest, fairly close to forest edges that bordered on roads and trails (Melles et al. 2009, 2012). Kroodsma (1984) examined the relationship between edge and the Hooded Warbler in Tennessee. It exhibited no edge-avoidance behaviour, with 7 pairs detected 0-268 m from edge and 0 pairs 268-488 m from edge. It was most abundant 40 m from edge, which consisted of a power-line right-of-way. Moorman et al. (2002) examined nest distribution and success relative to group selection and clear-cuts in South Carolina. Nests were clumped near edges of both types and there were approximately 2 times as many nests 0-50 m from edge than 51-100 m or further than 100 m from edge. Very few nests were further than 200 m from edge. Nest success was unrelated to distance from edge. In Pennsylvania, Howlett and Stutchbury (1996) found 1 nest within 10 m of a forest-field edge and 77% of 75 nests were near microedges such as deer trails, old logging roads, path edges, and gas well roads. In Pennsylvania, Norris et al. (2000) radiotracked males in small isolated woodlots and in a 150-ha woodland. Edge was defined as the area 0-20 m from the outer limit of the forest for birds in small fragments and the same distance from the territory edge for birds in contiguous forest. In fragments, males spent 34.5% of their time in edge, less than expected by chance. The amount of time spent by males at edges in contiguous forest was only 11.3%, significantly lower than for birds in fragments. Males in both habitats spent more time than expected in the core of their territory, consistent with the strategic-centre hypothesis that males should spend more time in the core of the territory because loss of this area is more likely to result in complete territory loss. Males with high numbers of neighbours in the large forest spent more time in the core of the territory. The single male that had only a single neighbour exhibited the highest use of territory edge (26%). The authors concluded that it avoided edges because of social factors and not because of higher predation or a reduction in prey availability. Males in isolated woodlots spent over a third of their time in edge. In the Birds of the World species account for the Hooded Warbler, Mumme et al. (2023) concluded that individuals do not avoid edge habitat.

Of nests reported to the Ontario Nest Records Scheme (ONRS), 79.5% were in deciduous saplings and shrubs, 8.4% were in conifers, 8.4% were in ferns, and 3.6% were in herbaceous plants: horse balm, mayapple, and sweet cicely. Nest height ranged from 0.2 to 1.5 m, with most 0.4-0.7 m from the ground. Two nests were in maple saplings, 2 were in crotches of maple-leaved viburnum, 2 were in raspberry canes, 1 was in the crotch of a sensitive fern, and 1 was joined to 3 basswood saplings (Peck and James 1987, 1998a). Several other nests have been described in the province. Nests are typically in or on the edge of a forest gap and may be in the middle of regenerating

logging roads, at edges of footpaths, and near lanes cut for mist nets. Nests are usually in the crotch of the supporting plant or on a platform created by branches. One nest was placed where a dead branch touched a sapling. Average height of 23 nests in Norfolk County was 46.3 cm and 10 nests in the Ganaraska Forest averaged 56 cm from the ground. In Norfolk County, 69.6% of nests were in raspberries, 13.0% in red elderberry, 4.3% in chokecherry, 4.3% in wild grape, 4.3% in sensitive fern, and 4.3% in gooseberry. In the Ganaraska Forest, 50% of nests were in sugar maple saplings, 25% in red elderberry, 17% in raspberries, and 8% in beaked hazel. In Elgin County, 1 nest was in a beech sapling (Baillie 1962; Bisson and Stutchbury 2000; Gartshore 1988; Lancaster et al. 2004; Walters and Nol 2011b).

Throughout its range, the Hooded Warbler nests a short distance above ground. Nests have been reported 0.15-5.5 m from ground, with the highest nest in a slender upright shoot growing from the trunk of a large beech tree. Excluding this nest, the highest other nests have been reported is 1.8 m, but most nests are 0.3-1.5 m from the ground. Nests higher from the ground are often just over the edge of a ravine such that the nest is just below the level of adjacent upland ground. Most nests are in a fork of the supporting vegetation and they often include a dead branch that has fallen across the fork. Nests are rarely in dead branches of fallen trees or in piles of debris. Most nests are in deciduous saplings or shrubs, but a few are in ferns and herbaceous species. In addition to the plant species reported in Ontario, it has nested in giant ragweed, jewelweed, swamp currant, Ohio buckeye, honeysuckle, buttonbush, huckleberry, Manitoba maple, oak, ash, spicebush, and blue cohosh, which is a preferred nest substrate in some areas. Selection of the species for nesting is site specific, with the local species that offers the best protection from weather and predators selected. Nests tend to be well concealed laterally and from above, but are fairly conspicuous from below. Nests built earlier in the season are rarely reused (Bent 1953; Chapman 1907; Mumme et al. 2023; Fall 1989; Graber et al. 1983; Harrison 1984; Howlett and Stutchbury 1997; Kilgo et al. 1996; Odum 1931; Powell and Rappole 1986).

The Hooded Warbler is territorial, with both sexes defending a territory. Some females nest at territory boundaries and appear to not have an extensive territory. Both sexes nest and feed within the territory, but may make extensive and frequent trips off the territory, apparently to seek extra-pair copulations. Birds nesting in small woodlots may visit adjacent larger woodlots, but the territory is confined to the smaller woodlot and movements to other woodlands are extra-territorial. Territories tend to be clumped and it has been considered semicolonial by some authors. Some areas of forest are inhabited by high densities of Hooded Warblers whereas nearby areas of apparently identical habitat are left almost vacant. At St. Williams Forest, nests were significantly clustered at the scale of 360-900 m. Above and below this scale, nests were randomly distributed, and nest clustering occurred specifically between 360 and 480 m. Clustering was not related to the distribution of suitable habitat or to the distribution of unmated males. Just below the 900-m scale, unmated males were more clustered than mated males, providing evidence that unmated males cluster their territories, but at a larger scale than mated males. Territories are non-overlapping, so nest avoidance occurs at the 30-m scale. Females nested randomly within available habitat at scales approximately equal to that of a male's territory (60-240 m), but there was clustering at 120 m and nests were clustered between 240 and 420 m. Nests may be selected to be closer to other females and their associated nests to facilitate obtaining extra-pair copulations from mated males. Nest

distribution was not associated with the distribution of unmated males because they are presumably lower-quality potential mates. In Pennsylvania, nearest-neighbour distances were 50-75 m where territories were close together, but 60-600 m when territories were spaced apart. Outside Ontario, territories tend to be 0.5-1.0 ha in larger forest patches that support several pairs, but may be as large as 2.2 ha in small forest fragments supporting a single pair. Territories in Ontario are much larger than reported elsewhere. The average size of 33 Ontario territories was 3.2 ha (range 0.3-11.4 ha). The complete range of territory sizes occurred at the St. Williams Forest. Territories were 1.1-2.4 ha in woodlots smaller than 50 ha. The larger territories in Ontario may be because the habitat is inferior or because the density of birds is low. The habitat in Ontario is typical for the species, so it is most likely that the large territories are a function of the habitat not being saturated. Territories are still clumped, but each male can defend a larger than normal territory because male density is low (Bent 1953; Evans Ogden and Stutchbury 1997; Friesen et al. 2012; Heagy and Badzinski 2012; Melles et al. 2009; Mumme et al. 2023; Neudorf et al. 1997; Norris 2000; Norris and Stutchbury 2002; Tarof et al. 1998).

Home ranges are consistently larger than territories. Throughout the breeding season, males leave the territory on a daily basis. In small woodlots in Pennsylvania, 85% of males left their woodlot at least once and some made extra-territorial forays more than once every 2 hours and spent an average of 16.5% of their time off territory. Twenty percent of males spent more than one third of their time off territory. Males travelled 40 m to 2.5 km from their territory. Over 50% of forays were less than 200 m, but 20% were further than 500 m and 5% were further than 1 km. In isolated woodlots, all forays involved flying over open habitat on a daily basis, with the maximum gap crossed being 465 m. Woodlots that the Hooded Warbler visited were significantly closer than woodlots that were not visited (213 m compared with 394 m). Approximately half of forays were to other territories. During these intrusions, 91% of males were silent and 71% visited the nest vicinity while the neighbouring female was fertile. Some males visited the same territory repeatedly and rarely or never visited other territories an equivalent distance away. Approximately 10% of males visited more than 1 woodlot during a foray and in all cases visited intervening woodlots to reach further destinations rather than flying over woodlots. Females also leave the territories, mostly when they are fertile. In Pennsylvania, 77% of fertile females left the territory compared with 10% of nonfertile females. Fertile females visited 1-4 territories of immediate neighbours. Nonfertile females visited neutral areas undefended by any males. The maximum open gap that females crossed was 50 m. Females travelled as far as 300 m from their territories (Neudorf et al. 1997; Norris 2000; Norris and Stutchbury 2001, 2002; Stutchbury et al. 2005b; Tarof et al. 1998).

Natal philopatry rates are fairly high in Ontario but low elsewhere. At the South Walsingham Forest, 11.0% of juvenile males and 10.8% of juvenile females returned. One male occupied its natal territory the following year. There were several instances of recruitment of birds banded as nestlings at other sites within 20 km. It is likely that dispersal of young and adults occurs at greater distances, but this has not been confirmed. In Pennsylvania, 2 of 232 nestlings (0.9%) returned to the natal area to nest. Juvenile birds banded later in summer away from the natal territory had higher return rates: 16.0% in Ontario and 15.4% in Pennsylvania. Juveniles may seek and select suitable nesting areas prior to migrating in autumn (Evans Ogden and Stutchbury 1996; Gartshore and Agro 1994; Heagy

and Badzinski 2012; Mumme et al. 2023). One Pennsylvania fledgling was captured 3 years later during the breeding season 50 km from his natal site (Mumme et al. 2023).

For Ontario adults, the return rates were 61.8% for males and 42.1% for females. There was no significant difference in the return rate of the sexes, although returning males always outnumbered females in every age class. Males tended to return to the same territories in subsequent years and one used the same general area in 6 consecutive years. One male occupied a territory from 1988 to 1991. His son, hatched in 1988, occupied the same territory in 1992 and in 1993, a grandson, hatched in 1992, occupied the territory. In each case, the male of the previous generation had disappeared. When the son occupied the territory in 1992, he had not been seen since 1988 and it was unknown where he had spent the intervening years. Several birds banded as adults nested 5-15 km away, which may be a reflection of the ephemeral nature of the habitat the Hooded Warbler occupies. Females appeared to have higher dispersal rates than males. The population in southwestern Ontario appears to be maintained by frequent dispersal into and out of the population, and this is probably typical of many populations (Gartshore and Agro 1994; Heagy and Badzinski 2012). In Pennsylvania, the overall return rate for adults was 47%, with 52% of males and 43% of females returning. Males exhibited greater territorial fidelity than females, with 58% of returning males occupying the same territory compared with 29% of females. Females that returned to the same area tended to have fledged more young the previous year than those that occupied different areas, but the difference was not significant. Birds that remated had higher territory fidelity (84.6%) than birds that divorced, with 47.1% of divorced males and 5.9% of divorced females occupying their previous territory. For birds whose mate from the previous year did not return, 50.8% of males and 22.2% of females occupied their previous territory, significantly less than for reunited pairs. Females that had extra-pair young the previous year were slightly more likely to return to their previous territory. Although prior nesting success and occurrence of extra-pair young had a positive effect on female site-fidelity, territory and mate fidelity was not influenced by these factors for males. Some females may disperse to improve breeding success or their chances for extra-pair copulations. Males may disperse to better habitat or to areas that are not as densely occupied (Howlett and Stutchbury 2003). In the same study area, females returning in a subsequent year nested significantly further from their previous nest (mean 239 m, median 151 m) than males (mean 93 m, median 51 m; Mumme 2024).

Limiting Factors

In Elgin County, males are on territory as early as the first week of May, and adults have been observed feeding nestlings in the first week of June. Eggs have been found in Ontario nests from mid-May to early August, but most contain eggs from mid-June until the first week of July (Allaire and Badzinski 2004; Lancaster et al. 2004; Peck and James 1998a).

The female settles on a male's territory within a few days of arrival. She selects the nest site and builds the nest in 2-7 days, typically 5-6 days. Egg laying commences once the nest is complete; eggs are laid at the rate of 1 a day. Incubation begins with laying of the last egg. The incubation period at 12 Ontario nests was 11-12 days, consistent with reports from elsewhere, with most eggs taking 12 days to hatch. In Ontario, most young leave the nest when they are 8 days old. The nestling period is 8 or 9 days throughout the Hooded Warbler's range (Baillie 1962; Bent 1953; Evans Ogden

and Stutchbury 1997; Friesen et al. 2012; Gartshore 1988; Harrison 1984; Mumme et al. 2023; Niven 1993; Odum 1931; Page and Cadman 1994b; Peck and James 1998a; Powell and Rappole 1986).

Some birds are double brooded and triple broods have been reported in Ontario. At St. Williams, 20% of pairs successfully raise 2 broods per year. In Pennsylvania, 43.9% of females with a successful first brood began a second brood. Double-brooded females nested significantly earlier than single-brooded females, with the average date of the first egg 26 May for those rearing 2 broods compared with 31 May for those raising a single brood. Eighty-two percent of females that began laying by 23 May and did not experience predation laid second clutches. Of birds that initiated laying by 31 May, 46% did not attempt a second brood. Yearlings are significantly less likely to attempt a second brood than older females. Time appears to be the main constraint to raising a second brood. Birds that attempted a second brood produced 63% more fledglings than those that raised a single brood. Raising a second brood has costs, with adults having to care for young well into August. They also have to delay their moult by approximately 3 weeks and are still on the breeding grounds while other birds are establishing winter territories. Having a second brood may reduce the likelihood of successfully establishing a winter territory. The average interval between young fledging from the first nest and laying eggs in the second nest was 11 days in Pennsylvania (range 3-22 days). Successful females that initiate a second nest did so in the same territory with the same mate, but nested significantly further from the first nest (60 m) than females laying replacement clutches after the first nest was depredated (48 m). Successful females may move their second nest further away to avoid their fledglings from the first nest. The Hooded Warbler is a persistent renester, renesting as many as 3 times in an attempt to raise young. Females usually remain within the same territory and retain their mate while renesting. In Pennsylvania, only 3 of 184 females (1.6%) deserted the territory to renest. A more recent study at the same location determined that 7 of 567 females (1.2%) changed mates and territories within a season. Usually a new nest is built for each nesting attempt, but 1 Ontario pair raised 2 clutches in the same nest. Nests reported to the ONRS contained 3-5 eggs (average 3.64 eggs, mode 4 eggs); there was only one 5-egg clutch. Twenty-three nests in Norfolk County had an average clutch size of 3.5 eggs and a mode of 4 eggs. In another sample of 43 nests from St. Williams and South Walsingham forests, overall clutch size averaged 2.81 and 3.47 eggs over 2 years. Mean clutch size for parasitized nests was 2.27 and 3.25 eggs compared with 3.40 and 3.60 eggs for unparasitized nests. Throughout its range, it lays 3-5 eggs per clutch, but mostly 4 eggs. Clutch size declines with season. In Pennsylvania, mean clutch size in late May was 4.0 eggs (range 2-5 eggs) compared with 3.5 in June (range 3-4 eggs); all July nests had 3-egg clutches (Allaire and Badzinski 2004; Bent 1953; Bisson and Stutchbury 2000; Chapman 1907; Evans Ogden and Stutchbury 1996, 1997; Friesen et al. 2012; Gartshore 1988; Graber et al. 1983; Heagy and Badzinski 2012; Howlett and Stutchbury 1997; Mumme 2024; Mumme et al. 2023; Peck and James 1998a; Whittam et al. 2002).

The age at first breeding is 1 year for both sexes and all yearling females apparently nest. There are some nonbreeding males in most populations, mostly yearlings that failed to attract a mate. At St. Williams Forest, an average of 25% of males was unmated (range 10-40%). In smaller Ontario woodlots near the St. Williams Forest, 17-24% of males were unpaired. In Pennsylvania, 25-27% of males were unmated in small woodlots but less than 1% were unmated in a 150-ha forest. Overall, about 6% of males remain unmated. Once a bird has bred, it presumably nests every year thereafter

(Bisson and Stutchbury 2000; Heagy and Badzinski 2012; Mumme et al. 2023; Norris 2000; Norris and Stutchbury 2002). The Hooded Warbler is typically monogamous but approximately 4% of males are polygynous. Polygyny has been documented in Ontario (Mumme et al. 2023; Walters and Nol 2011b). Pairs remain together for an entire breeding season, including for second broods and replacement clutches. In Pennsylvania, 60 of 175 returning birds (34.3%) had mates that also returned. Of the 60, 26 (43.3%) paired with the same mate to form 13 pairs that had been previously mated. Eleven of the 13 females (84.6%) remated with a former mate that was defending their previous territory. In the other 2 cases, the male was defending a new territory (Howlett and Stutchbury 2003; Mumme et al. 2023). Cooperative breeding by the Hooded Warbler is rare. At 1 of 60 Pennsylvania nests (17%), a second male helped feed nestlings. The second male had been mated with the female the previous year on a nearby territory, but was genetically unrelated to his offspring that year (Tarof and Stutchbury 1996). In 2 of 17 cases (11.8%) in Pennsylvania, males fed young on their own territory that had fledged from a neighbour's territory. In both cases, the social father was no longer on his territory at the time of adoption and the social mother had renested in an attempt to raise a second brood. Both males were unrelated to their adopted fledglings, but 1 male was the genetic father of 2 of 3 nestlings in the social mother's second brood. By adopting fledglings, males increase the availability of fertile females on neighbouring territories by increasing the likelihood that females will renest. Fledgling adoption may be a widespread behaviour (Stutchbury and Evans Ogden 1996).

Extra-pair copulations are an important component of the Hooded Warbler's mating system. It is likely that territories are clustered to facilitate extra-pair copulations. Even in isolated woodlots supporting only a single pair, young in the nest may be extra-pair. Both males and females seek extra-pair copulations. All females mated to younger males moved off their territories, presumably to seek extra-pair copulations, compared with 50% of females mated with older males. A similar proportion of young (60%) and old (99%) females left their territory. In Pennsylvania, 55 of 57 intrusions (96.5%) by males were to adjacent territories, but males occasionally travelled as far as 150 m to intrude. Seventy-six percent of intrusions occurred when the resident female was nest building; only 2% occurred in territories where there was no female or when the female was egg laying (8%) or incubating (14%). In 78% of intrusions, the male entered a territory when the female was chipping, and females chip only 20% of the time. One of 10 males made only 2 intrusions within 10 hours, both to a single territory. Another male made 9 intrusions in 12 hours into 4 different territories. The mean rate of intrusion of males into adjacent territories was 0.4 per hour. Males with the highest intrusion rates into adjacent territories had the lowest intrusion rates into their own territories. In a high-density population in Pennsylvania, 66.7% of broods contained at least 1 extra-pair young and 53.7% of nestlings were extra-pair. In a low-density population, 26.1% of broods contained extra-pair young and 22.0% of nestlings were extra-pair. The frequency of extra-pair young declines with the season, with 40% of nestlings being extra-pair in late May compared with 15% in late June. There was no difference in the frequency of extra-pair fertilizations between replacement clutches (14.0% of young and 22.2% of broods) and second broods (19.6% of young and 31.3% of broods). Over 95% of extra-pair fathers were adjacent neighbours, but some birds travelled as far as 600 m for extra-pair copulations. For broods with more than 1 extra-pair young, all young had the same genetic father in 13 of 17 cases (76.5%). Eighty percent of males were not known to father extra-pair young,

but 5.7% of males had 3 or more extra-pair young per year. Younger females had significantly more extra-pair young in their broods than older females: 41.9% for yearlings, 17.7% for 2-year-olds, and 6.2% for 3-year-olds. Younger females arrive later in spring and might be expected to obtain lower-quality mates and be more likely to seek extra-pair copulations. The proportion of extra-pair young per nest ranged from 0% to 100% with a strongly bimodal distribution. Females either had no extra-pair young or most of the brood was extra-pair. It appears as though females are actively selecting genetically superior males to sire their young (Evans Ogden and Stutchbury 1997; Mumme et al. 2023; Neudorf et al. 1997; Norris and Stutchbury 2001; Stutchbury 1988; Stutchbury et al. 1994, 1997, 2005b; Tarof et al. 1998).

Parnell (1969) observed foraging locations of the Hooded Warbler during the breeding season in North Carolina. Of all observations, 24.5% were in the canopy, 51.0% were in low trees, 24.5% were in shrubs, and 0% were on the ground. In the canopy, 0% of observations were in the top of the crown, 6.1% in the inner crown, 18.4% in the lower crown, and 0% on the bole. In low trees, 2.1% of observations were in the top of the crown, 20.8% in the inner crown, 20.8% in the lower crown, and 0% on the bole. In shrubs, 0% of observations were in the top of the crown, 16.3% in the inner crown, 0% in the lower crown, 6.1% in dense thickets, 2.1% in brush piles, and 0% in grasses. Singing males occurred at heights of 0-15 m (average 6.0 m). Other birds were seen at heights of 0-15 m (average 3.0 m). Males forage higher because they use the canopy for singing and the females remain lower in association with the nest. The Hooded Warbler is an excellent flycatcher that obtains much of its prey from the forest subcanopy, including aerial insects it captures in flight. It captures a high proportion of prey by hovering or gleaning insects from leaves and stems. While foraging, it flicks its tail to reveal the white tail spots. This flushes prey and enhances the foraging performance of warblers. Females with experimentally darkened tail spots had significantly reduced foraging success related to decreased frequency of aerial prey attacks. These females delivered significantly fewer winged insects to nestlings and proportionately more insect larvae than control females (Bent 1953; Harrison 1984; Mumme 2014; Mumme et al. 2023).

Young are fed crane flies and other flies, moths and their larvae, beetles, and spiders. In Pennsylvania, the mean size of prey fed to nestlings was greater than those found by sweep netting; 16.0% of prey delivered to nestlings was more than 20 mm long. Females initiating a second brood discontinue feeding their first fledglings once they begin incubation, leaving care of the fledglings to the male. When first learning to feed on their own, fledglings attack moths most frequently. Adults feed exclusively on arthropods. It eats spiders, weevils and other beetles, and adult and larval lepidopterans in proportion to their abundance. Other food items include grasshoppers, locusts, plant lice, flies, ants, wasps, bugs, caddisflies, and nematodes (Bent 1953; Buehler et al. 2002; Evans Ogden and Stutchbury 1997; Mumme et al. 2023; Odum 1931).

The Hooded Warbler is a frequent host of the Brown-headed Cowbird. It appears to be preferentially selected as a host, possibly because of the chipping calls made by the female while building the nest. In Pennsylvania, 54% of Hooded Warbler nests were parasitized in 1 year compared with 3% of nests of other songbirds nesting within 3 m of the ground. Females respond aggressively toward cowbirds, but this appears to be ineffective given the high rate of parasitism. It usually accepts cowbird eggs, but occasionally abandons a parasitized nest. Despite the high rate

of parasitism throughout its range, most authors concur that cowbird parasitism has little effect on the reproductive success of the Hooded Warbler. This is because replacement clutches and second broods are seldom parasitized. Experimental removal of cowbirds at a Pennsylvania site drastically reduced parasitism, but did not result in a significant increase in reproductive success. Cowbird removal resulted in an average increase of only 0.12 young fledged per nest, or about 5 extra fledglings from a breeding population of 40 pairs. The reason for the minimal increase in productivity was that many unparasitized nests were depredated. Cowbird parasitism in Norfolk County resulted in warbler clutches that were 0.8 egg smaller than unparasitized nests. Nesting success was 35.0-58.3% for unparasitized nests compared with 18.2-41.5% for parasitized nests. Nestling survival rate was 55% in parasitized nests compared with 81% in unparasitized nests. In South Carolina, the costs of parasitism were clutches 0.8 egg smaller and 0.9 fledgling fewer per nest. In Ontario, parasitism rates are significantly higher in recently logged sites and in forests smaller than 75 ha. In South Carolina, the probability of parasitism was greater near clear-cut edges and at nests with less ground cover. Female cowbirds concentrated their nest-searching activities near edges of openings that were larger than 0.26 ha. Gaps created by group-selection harvesting did not increase parasitism rates. In Ontario, 54 of 114 nests (47.4%) reported to the ONRS were parasitized. Over a 2-year period in St. Williams Forest, 11 of 21 nests (52.4%) and 13 of 33 nests (39.4%) were parasitized. In South Walsingham Forest, a parasitism rate of 45% was reported compared with 18% at other scattered sites in southern Ontario. Annual parasitism rates are highly variable, ranging from 13-52% 1999-2010 at St. Williams. Over this period, 35% of 497 nests were parasitized. At the Ganaraska Forest, 1 of 13 nests (7.7%) was parasitized 2006-10. Parasitism rates reported from other areas include 61.5%, 64.3%, and 62% in Pennsylvania; 13.1%, 14.4%, and 18.2% in South Carolina; 75% in Illinois; 18%, 30%, and 50% in Ohio; and 5% and 39% in Arkansas (Bent 1953; Bisson and Stutchbury 2000; Heagy and Badzinski 2012; Kilgo and Moorman 2003; Mark and Stutchbury 1994; Moorman et al. 2002; Mumme et al. 2023; Peck and James 1998a; Rush and Stutchbury 2008; Sargent et al. 1997; Stutchbury 1997; Walters and Nol 2011b; Whittam 1999; Whittam et al. 2002).

Predation appears to be the greatest limiting factor for the Hooded Warbler. Ontario nest predation rates vary considerably annually, but are typically high at 30-50%. Predation is the primary cause of nest failure in Ontario and most other locations, and has a much larger influence on overall productivity than parasitism or any other factor. Predation rates during the egg and nestling periods are around 50% in much of its range. A high proportion of fledglings are also lost to predation, with most losses occurring within the first 5 days after fledging. In Ontario, 49% of fledglings survived to independence compared with only 19% in Pennsylvania. Even in large contiguous forests, females only produce 0.2-0.4 females per year and would have to live 4 seasons to replace themselves. There appear to be no differences in predation rates in small woodlots compared with large woodlots, with distance from edge, or from recent logging. Most authors found no relationships between predation rates and nest-site parameters. In a Pennsylvania experiment, vegetation was removed around some nests and the degree of concealment did not affect predation rates. The least visible nest (90% concealed by vegetation) was depredated while the most visible nest (22% concealed) was successful. Two South Carolina studies found vegetation variables at nest sites that affected predation. In 1 study, successful nests had a higher percent coverage by ferns than unsuccessful

nests. In the other study, nests that were better concealed from below were more successful. Snakes were the primary predators in this area (Allaire and Badzinski 2004; Bisson and Stutchbury 2000; Bowen et al. 2007; Evans Ogden and Stutchbury 1996; Heagy and Badzinski 2012; Howlett and Stutchbury 1996, 1997; Kilgo et al. 1996; Moorman et al. 2002; Mumme et al. 2023; Rush and Stutchbury 2008; Sargent et al. 1997; Whittam 1999).

Several studies concluded that the greatest threats to the Hooded Warbler in Ontario are habitat loss and fragmentation, and that this resulted in a significant decline in the species (Friesen et al. 2012; James 2000; Mumme et al. 2023; Page and Cadman 1994b). Bushman and Therres (1988) cited the same factors as being detrimental in Maryland. In the eastern United States, only about 20% of detections of the Hooded Warbler on Breeding Bird Survey (BBS) routes were in fragmented landscapes (Donovan and Flather 2002). The risk from habitat loss and fragmentation appears to be minimal in Ontario, and the amount of available habitat is stable or increasing. In general, the amount of forest cover is increasing and woodlands are becoming more mature. More coniferous plantations are maturing and being thinned, thereby creating suitable potential habitat (Heagy 2008; Heagy and Badzinski 2012). Loss of forests supporting it is unlikely as larger woodlots are typically designated significant woodlands by municipalities and development is usually prohibited in them. At greater risk are smaller woodlots that support the species because they may not be afforded the same level of protection. Isolation of smaller woodlots that support small populations may be detrimental. Females may avoid settling in small fragments due to lowered chances of receiving extra-pair copulations. For those that must leave the woodlot where the nest is located to seek extra-pair copulations, gaps between woodlots greater than 50 m will inhibit female movement and gaps greater than 500 m will inhibit males. Creating larger open gaps may result in smaller woodlots being abandoned (Norris 2000; Norris and Stutchbury 2002).

Diameter-limit tree cutting is usually detrimental because this removes the large trees that the Hooded Warbler requires. One Ontario study found no difference in its abundance in uncut forests and those than had been harvested using standard thinning practices and diameter-limits cuts; densities were low in all stands. Clear-cutting does not occur within its range in Ontario, but this practice can provide suitable postfledging habitat, albeit for a short period. Suitable nesting gaps within the canopy are a limiting factor and single-tree and group-selection harvesting is highly beneficial. In Norfolk County, it declined over time in a lightly logged forest and increased significantly in a nearby heavily logged forest. Eighty-four percent of gaps used for nesting were created by timber harvesting. In small woodlots, the entire area is typically logged at once, so the benefits may last only a decade at most. In larger woodlands, staggering the harvest over several years can create more permanent habitat. Management suggestions for Ontario include creating gaps no larger than 0.05 ha (a diameter of 25 m), leaving the shrub layer intact, retaining at least 12 m^2 per ha BA of trees larger than 38 cm, and creating 2-3 group-selection gaps per ha. The importance of selective harvesting for the Hooded Warbler has been identified throughout its range and in some areas it nests only in sites that have been harvested. In Illinois, openings of 0.02-0.4 ha were created in a 2,000-ha forest using group- and single-tree selection. It was absent in uncut forest, common in cuts 1-2 years old, and absent to rare in cuts 11-12 years old (Allaire and Badzinski 2004; Bisson and Stutchbury 2000; Bushman and Therres 1988; Friesen and Stabb 2001; Friesen et al. 2012; Gartshore 1988; Heagy 2008; Heagy and Badzinski 2012; Holmes et al. 2004; McCracken 1999a;

Mumme et al. 2023; Page and Cadman 1994b; Robinson and Robinson 1999; Walters and Nol 2011b; Whittam 1999; Whittam et al. 2000, 2002).

Timber harvesting may be discouraged or prohibited in some woodlands that support endangered species, and this could be detrimental to the Hooded Warbler. Page and Cadman (1994b) recommended that timber harvesting not take place in forests occupied by the endangered Acadian Flycatcher, and the 2 species often occur in the same woodland. Similarly, the presence of the endangered Jefferson salamander may inhibit or prevent timber harvesting in woodlands inhabited by the Hooded Warbler.

In New Jersey and Pennsylvania over a 15-year period, hemlock declined from representing 56% of the total basal area to 46% due to the hemlock woolly adelgid. This resulted in an increase in deciduous understorey. The Hooded Warbler increased, probably in response to the increase in deciduous shrubs and saplings (Toenies et al. 2018).

Farwell et al. (2019) examined the effects of shale gas infrastructure in West Virginia. These included pipelines, access roads, and well pads. The Hooded Warbler increased significantly with distance from well pads. In West Virginia, it was more abundant in intact forests than remnant forests near strip mines. Remnant forests were bordered by strip mines on 3 sides but were not directly affected by them (Margeneau et al. 2019).

Severe weather events that create gaps in the forest canopy may be beneficial. Insects and diseases (emerald ash borer, hemlock woolly adelgid, beech bark canker fungus, dogwood anthracnose fungus) may be beneficial provided that the canopy is not opened up too much and that some large trees remain (Friesen et al. 2012; Heagy and Badzinski 2012; Heckscher 2000).

Factors that reduce shrub coverage in woodlands are detrimental. Prescribed burns in forests may kill the low deciduous layer. This is a standard practice in pine stands in the southeastern United States. In North Carolina pine-oak forests, the Hooded Warbler occurred most frequently at points that had not been burned for more than 15 years following low severity fires, and longer following high severity fires. Woodlots grazed by sheep in Illinois were abandoned by the Hooded Warbler. Sheep grazing is not an issue in southern Ontario, but overbrowsing by white-tailed deer could have deleterious effects (Gartshore 1988; Graber et al. 1983; Rose and Simons 2016).

In Arkansas, Nagy and Smith (1997) examined the effects of spraying the larvicide Bt to eradicate gypsy moths, which results in a reduction in the number of all caterpillars. An 85% reduction in the amount of caterpillars affected few aspects of the Hooded Warbler's reproductive biology. Nest success was not affected by food limitation. Nestling mass was lower in the treatment zone for birds that hatched shortly after application, so survivorship may be reduced for these individuals. There were no differences in feeding rates between control and treatment areas. Bt application appeared to have minimal effects.

Deforestation of winter habitat is occurring to create pasture for cattle, and burning occurs regularly. This results in habitat loss and habitat that is burned becomes unsuitable. Loss of winter habitat may be a significant limiting factor (Mumme et al. 2023; Powell and Rappole 1986).

All-terrain vehicles and snowmobiles could introduce invasive species and destroy the understorey vegetation required by the Hooded Warbler (Friesen et al. 2012).

The effects of climate change on the Hooded Warbler are uncertain. Melles et al. (2011) examined factors that led to its increase in Ontario. There has been a significant and gradual lengthening of the growing season in Ontario, with the number of growing-degree days above 5°C at northern breeding sites increasing by 162 since 1940. Its mean probability of occurrence in Ontario has been increasing since 1975. Seventy-seven percent of variation in its probability of occurrence was related to increasing mean temperature and the growing season length. An additional 14% in variation was correlated with reduced amounts of precipitation. Changes in climate over the past 20 years were a better predictor of range expansion than were gradual shifts in distribution due to immigration. Forest connectivity was only marginally significant and amount of forest cover was not significant. Establishment probability, based on the number of occupied neighbouring atlas squares, and immigration from the south, estimated from BBS results, were also important predictors of range expansion. Increased growing season and July temperatures and decreased precipitation were the most important predictors. Price (2004) predicted that the Hooded Warbler could become extirpated as a breeding species in southern Ontario if the average summer temperature increased by 2°C.

Status

The status of the Hooded Warbler prior to European settlement is uncertain. It was originally thought that it probably inhabited most of the Carolinian Forest Region and portions of the southern Great Lakes–St. Lawrence Forest Region prior to deforestation of the southern portion of the province. It was postulated that it was virtually extirpated from the province as a result of forest clearing and that its recent increase in population represents recovery of the species within its original range. There were no early records from the province to substantiate this theory, but there were few ornithologists present during this era and there are also few to no records of some species that clearly were here prior to European settlement. The only evidence to support the hypothesis that it originally occurred in Ontario is that it was abundant prior to settlement at similar latitudes in southern Michigan, where it declined precipitously due to deforestation and subsequently recovered at approximately the same time frame as in Ontario. The alternate theory is that the Hooded Warbler is a recent immigrant to Ontario. This appears to be more plausible because there were very few records of the species in the late 19th and early 20th centuries. In addition, the entire range of the species increased in the mid- to late 20th century, consistent with its first breeding records in the province and subsequent increase. BBS data indicate that the northern margin of the breeding range shifted 115 km north over a 26-year period. The currently accepted explanation is that the Hooded Warbler is a recent colonist to the province rather than a species that was extirpated and is now recovering. A review of its status in the province in 1925 concluded that it was a rare migrant but acknowledged that an observation of a young bird in autumn suggested breeding (Austen et al. 1994; Baillie 1925; Heagy and Badzinski 2012; Page and Cadman 1994b).

The first record of the Hooded Warbler for the province was a spring migrant seen at Hamilton prior to 1860. It would be another 60 years before another one was seen in Hamilton during the spring of 1920. The first breeding season record came from Chatham-Kent in 1878, followed by

records from Essex in 1912; Elgin in 1940, Hamilton in 1941 and 1953; York in 1947, 1951, and 1953; Lambton in 1947 and 1957; Halton in 1954 and 1955; Niagara in 1954; and Oxford in 1957. The first nest was found in the province on 27 July 1949 in the Springwater Conservation Area in Elgin County and additional nests were found there in 1950 and 1952. Records from Elgin County give a good historical perspective of its breeding status. In 1891, it was unknown to have occurred in the county. By 1954, it was known only from the Springwater area. By 2000, it was essentially extirpated from the main forest at Springwater due to the lack of timber harvesting, but occurred near there in recently logged woodlots. At that time, it was a local breeder that was becoming increasingly common and widespread. In 1957, the first nest for Oxford County was discovered near Tilsonburg. Prior to the first atlas, the Hooded Warbler was considered a straggler that bred only occasionally in Ontario. The second atlas and intensive studies on the Norfolk Sand Plain in 1985 and 1986 revealed that it was uncommon on this geographic feature in Elgin, Oxford, and Norfolk counties, and rare elsewhere with scattered records in Chatham-Kent, Elgin, Middlesex, Niagara, Hamilton, and York. Because much suitable habitat remained uninvestigated, it was concluded that the province could potentially support 100 breeding pairs. For the next 10-15 years, breeding records increased substantially, but it was difficult to determine if it had actually increased or if the apparent increase was an artifact of more observers and more targeted searches (Austen et al. 1994; Baillie 1962, 1967; Curry 2006; Gartshore 1988; James 2000; Lancaster et al. 2004; McIlwraith 1894; Page and Cadman 1994b; Sutherland and Gartshore in Cadman et al. 1987).

Between the atlases, several targeted inventories were completed for the Hooded Warbler, and these highlighted the dramatic increase during this period. Estimates of numbers of breeding pairs were: 80-176 in 1988, 144-207 in 1998, 150-210 in 2001, and 242 in 2002. At the St. Williams Forest, which now supports much of the core population, it was apparently absent in 1994, 8 pairs were present in 1995, and there were 43 pairs in 1999 (Friesen and Stabb 2001; Gartshore 1988; Heagy 2008; James 2000; McCracken 1999a; Whittam 1999; Whittam et al. 2002).

The second atlas showed an expansion in the range of the Hooded Warbler, with several breeding records in the Great Lakes–St. Lawrence Forest Region south of the Canadian Shield and one in the Shield. It expanded its range within the Carolinian Forest Region, with concentrations in Norfolk County and Niagara Region and lesser numbers in Hamilton, Chatham-Kent, and Lambton. It was detected in 81 squares compared with 21 during the first atlas. Its probability of observation increased significantly by almost 400% between atlases (Badzinski in Cadman et al. 2007).

Numbers continued to increase after the second atlas. In 2006, a small population was detected in Ganaraska Forest, about 200 km north of its previously known range. As of 2011, this population remained stable at approximately 5 pairs. In 2007, at least 436 territorial males were detected at 89 sites in Ontario and the population increased by more than 300% from 1997 to 2007. The 2011 population was estimated at 1,000-2,000 mature birds. The population continues to be concentrated in Norfolk County where counts have at least doubled every 5 years. Numbers have also increased in Hamilton and Niagara, but not in other areas of southwestern Ontario. A small isolated population near Midland has persisted at low levels for 20 years and the Hooded Warbler has expanded in the Greater Toronto Area, especially in Durham Region, and Northumberland County. In 2012, it was concluded that there was no reason to expect that the population would

not continue to grow, at least over the next decade. There is a high probability of regular immigration from northern United States populations and this is considered essential because Ontario populations may be unable to sustain themselves without continued immigration. Small changes in the large United States population could have a significant ripple effect on the small Canadian population (Heagy 2008; Heagy and Badzinski 2012; Walters and Nol 2011b).

Early status reports assumed that the Hooded Warbler had been widespread in southern Ontario prior to European settlement and subsequently extirpated due to deforestation. At the federal level, it was first ascribed a status of special concern in 1994. A review in 1994 resulted in its status being upgraded to threatened, and this status designation was reaffirmed in 2000. At this time, it was also designated special concern provincially. A recovery strategy and another status report were prepared in 2012. The recovery strategy identified the population objective as increasing the number of breeding pairs to 500, but the status report observed that this objective had already been realized. In 2012, the status of the Hooded Warbler was downgraded to not at risk nationally and provincially (Friesen et al. 2012; Heagy and Badzinski 2012; James 2000; Page and Cadman 1994b).

BBS data indicate a nonsignificant continental increase from 1966 to 1991. During this period, there was a significant increase of 1.58% per year in the east and a nonsignificant decline of 5.43% per year centrally (Mumme et al. 2023). The global population of the Hooded Warbler has doubled since the 1970s, due in part to climate change (Mumme et al. 2023). There are insufficient BBS data to estimate population trends in Canada and Ontario (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Brood division by the adults occurs once the young fledge, with the female taking care of the extra chick in broods with odd numbers. The 2 sub-broods remain distant from each other except when the female attempts a second brood. When this occurs, the female's portion of the first brood reunites with those being cared for by the male once she starts incubating the second clutch. The young are unable to fly when they first leave the nest but can fly about 3 days later. They seek dense cover near the nest for the first 6 days out of the nest. This may consist of fallen treetops, tangles of decaying logs, or dense deciduous shrub or sapling cover. The vertical cover of vegetation 2-4 m from the ground is significantly greater at sites used by fledglings than at nest sites. Once the young are capable of flight, they follow the adult that is caring for them and move further from the nest site. During the first 6 days after fledging, the mean distance moved from the nest in Pennsylvania was 37 m compared with 70 m during days 7-15. Those that hatched in small woodlots never left the forest fragment. During days 7-28 after fledging, young in small fragments used locations with a greater proportion of cover 0-2 m and 2-4 m from the ground than those in large forests. In Pennsylvania, males and their fledglings averaged 104 m from females with their charges. Fledglings attended by females were led an average of 155 m from the centre of the territory compared with 46 m for males. Females took their broods as far as 650 m from the territory. Males usually remained within the territory or very close to it. Young first attempt to feed themselves 5 days after fledging, usually unsuccessfully, and may not be independent for 5-6 weeks after fledging. In southern Ontario, adults attend young into early September (Bent 1953; Evans Ogden and Stutchbury 1994, 1997; Mumme et al. 2023; Rush and Stutchbury 2008).

Within forests, adults with fledglings seek dense deciduous growth either in small woodland gaps or in forest edges. They are also common in non-forested early successional habitats such as clear-cuts. Juveniles, adults, and family groups have inhabited young clear-cuts during the postfledging period in Ohio, Pennsylvania, Virginia, Missouri, and West Virginia. In Ohio, the Hooded Warbler was the fourth-most abundant forest-breeding species captured in clear-cuts. It was twice as abundant in small (4.0-9.3 ha) than large (13.3-18.1 ha) clear-cuts and there was no significant difference in the number of captures 20, 50, or 80 m from the edge of adjacent mature forest. In West Virginia, its abundance in clear-cuts declined with increasing BA of retained timber. Retained trees inhibit understorey growth, limit stem density, and provide perches for raptors. Capture rates increased with increasing understorey stem density, total arthropod biomass, and total lepidopteran larvae biomass. During the postfledging period in South Carolina bottomland forests, 2% of mist-netted birds were in forests, 47% were in forest gaps, and 51% were in forest edges (Bowen et al. 2007; Evans Ogden and Stutchbury 1997; Friesen et al. 2012; Marshall et al. 2003; McDermott and Wood 2010; Porneluzi et al. 2014; Stoleson 2013; Vitz and Rodewald 2006, 2007).

In Missouri, Porneluzi et al. (2014) netted during the postfledging period 2-15 years after an oak-pine-hickory forest was clear-cut. The Hooded Warbler was the second-most abundant species captured. Its numbers increased gradually to a peak 7-9 years after cutting and then declined.

Juvenile males that immigrate to new areas outside the natal site sing and appear to establish territories. These birds may return to the same site to breed the following year (Mumme et al. 2023).

In late August and September, Ontario birds join mixed flocks before migrating (Friesen et al. 2012).

MIGRATION

Although the Hooded Warbler is a nocturnal migrant, it rarely strikes tall structures (Graber et al. 1983; Mumme et al. 2023).

Males typically arrive a week earlier than females in spring and occasionally as much as 2 weeks in advance of females. Adult females arrive 7-10 days before yearlings. In Louisiana, the average length of stopover was 2 days after birds had crossed the Gulf of Mexico. In Norfolk County, males are on territory as early as 9 May, but typically arrive 11-18 May. Elsewhere in the south, early migrants arrive in late April, but most arrive in mid-May (Black and Roy 2010; Curry 2006; Gartshore 1988; LaForest 1993; Lancaster et al. 2004; Moore and Kerlinger 1987; Mumme et al. 2023; Page and Cadman 1994b; Stutchbury et al. 1997; Weir 2008).

Autumn migrants occur throughout September and rarely into the first week of October. The latest autumn records are often of birds that are still on their breeding territories (Curry 2006; Gartshore 1988; Lancaster et al. 2004; Weir 2008).

During both spring and autumn migration, the Hooded Warbler occurs most often in edge habitat within logged forests. During spring migration in South Carolina, 5% of mist-netted birds were captured in forest, 47% were in forest gaps, and 48% were in forest edge. During autumn migration, 8% were captured in forest, 40% in gaps, and 52% in forest edge. Relative abundance in North Carolina habitats during spring migration were 1.98 in oak-hickory forests, 1.60 in floodplain

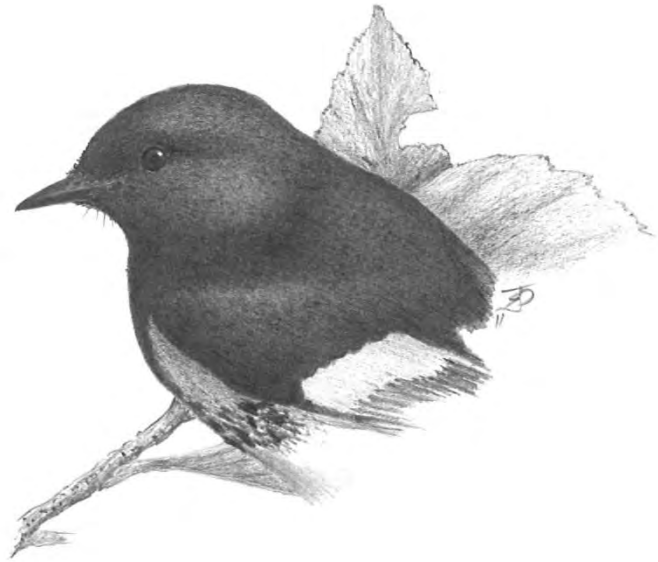
forests, 1.54 in pine forests, 1.42 in pine-hardwood forests, 0 in wet and dry thickets, and 0 in beech forests (Bowen et al. 2007; Kilgo 2005; Mumme et al. 2023; Parnell 1969).

In New York, Lebbin et al. (2007) suspected that Hooded Warblers were foraging at night under artificial lights, but could not confirm this. During spring migration in North Carolina, 18.6% of foraging occurred in the canopy, 48.3% in low trees, 30.9% in shrubs, and 2.2% on the ground. In the canopy, 0% of foraging was at the top of the crown, 2.3% in the inner crown, 16.3% in the lower crown, and 0% on the bole. In low trees, 4.5% of foraging was at the top of the crown, 11.2% in the inner crown, 32.6% in the lower crown, and 0% on the bole. In shrubs, 3.9% of foraging was in the top of the crown, 10.1% in the inner crown, 4.5% in the lower crown, 10.1% in dense thickets, 2.3% in brush piles, and 0% in grasses. On the ground, 1.1% of foraging was in dense thickets, 0% in grasses and at water's edge, and 1.1% in the open (Parnell 1969).

The Hooded Warbler is a rare migrant and is occasionally observed considerable distances from the breeding range. It has been observed during spring and autumn migration in areas such as Moosonee (James 1991). Although it continues to be a rare migrant, numbers are increasing significantly. During the mid-1990s, approximately 50 were seen at Long Point Bird Observatory (LPBO) during spring migration. During 1961-2010, numbers of spring migrants at LPBO increased significantly at a rate of 3.4% per year. The rate of increase is augmenting. The increase 1970-2010 was 2.7% per year compared with 6.2% for 2000-10. The 10-year trend indicates an 80% increase in spring migrants (Heagy and Badzinski 2012; Page and Cadman 1994b).

American Redstart

Setophaga ruticilla



BREEDING SEASON

Habitat Requirements

Most Ontario American Redstart nests were in woodlands (75.0% of nests). The remainder were in shrubby fields (19.0%), dense stands of deciduous shrubs (5.0%), and in a garden (1.0%). Of nests in woodlands, 52.1% were in deciduous stands, 37.0% were in mixed stands, 2.7% were in coniferous stands, and 8.2% were in unspecified stands. It preferred second-growth woodlands and those with a dense deciduous understorey of shrubs or saplings to mature forests. Many nests were near woodland or swamp edges, or beside roads or shorelines (Peck and James 1987). A nest in Grey County was in a small urban apple orchard (Peck and Peck 2010). James (1984b) reported that it bred in deciduous and mixed woods where it requires a closed canopy. The canopy may consist of only tall shrubs or dense young trees but may also include mature forests with dense shrub coverage within the forest or at its edges. The redstart may occur in either dry or wet forests, usually where there are some trees amongst growth close to the ground.

The range of the American Redstart barely extends into the southern portion of the Hudson Bay Lowland. It is a fairly common breeder in the Moosonee area where it inhabits riparian lichen-rich spruce forests (Wilson and McRae 1993).

In the Boreal Forest Region, the redstart nests both in forested and shrubby areas, including regenerating clear-cuts and burns. Clear-cuts may provide important habitat in extensively forested landscapes. Near Hearst, Welsh and Fillman (1980) reported it in 3-17-year-old clear-cuts in upland mixed forests and in 3- and 24-year-old clear-cuts in lowland coniferous forests. Near White River in jack pine stands, it was most abundant in clear-cuts 13-15-years old and occurred in all stand ages from young clear-cuts to mature forests (Venier and Pearce 2005). Welsh (1993) considered it a mid-successional species in the Boreal Forest Region. It occurred in stands 6-27 years old but not those 1-5 or 33-220 years old. In the Clay Belt, it occurred in all forest types, but was most abundant in those dominated by balsam poplar, followed by trembling aspen, white birch–white spruce, tamarack or white cedar, jack pine, and white spruce. It was significantly associated with nutrient-rich stands. It occurred throughout the moisture regime, from the wettest to driest stands and averaged near the midpoint on the moisture axis (Welsh and Lougheed 1996).

In the Great Lakes–St. Lawrence Forest Region in the Canadian Shield near Gogama, the redstart was common in younger mixed woods where some deciduous trees reached a height of 6-7 m. It also occurred in dense deciduous groves. It avoided older forests where the trees formed a closed canopy. It was restricted to mixed forests 17-20 years old (James and Peck 1995a). In northern hardwoods near Sault St. Marie, it increased after single-tree selection harvesting occurred. The increase occurred 6-7 years after harvest once a shrub layer became established (Holmes and Pitt 2007). Near Parry Sound, it was absent in pure jack pine stands, but occurred in low densities in young, open-canopied, mixed jack pine–deciduous stands (James 1979a). In Muskoka and Parry Sound districts, it was most abundant in deciduous or mixed forests or in the deciduous understorey of more mature forests (Mills 1981). In Algonquin Park, it was most abundant in poplar-birch stands, followed by balsam fir–spruce-hardwood stands, poplar-birch-fir-spruce stands, and hardwoods. It was also common in shrubby plots at forest edges; it was the most abundant species in border plots. It was absent in bogs, young white pine stands, and hemlock stands. In poplar-birch stands, it restricted its activities from the ground upward to the lower tree branches, a height of approximately 6 m. In hardwoods, it ranged from the ground to 8.8 m, just below the bottom of the canopy. In balsam fir–spruce forests, it occupied the central portion of the canopy. Martin (1960) considered it a species of pioneer deciduous forests. In white pine stands in Algonquin Park, Kingsley

and Nol (1999) found it in all age classes that they examined: 2-9-year-old shelterwood cuts, 10-16-year-old cuts, and forests with no recent history of cutting. It was most abundant in 10-16-year-old cuts, but not significantly. In Algonquin Park, it was associated with sapling density in the 2-5-m stratum (Jobes et al. 2004). In Muskoka District and Haliburton County, nest sites were associated with moderate canopy volume, moderate tree density, and high densities of woody understorey (Clark et al. 1983).

In Presqu'ile Park, the redstart nests in deciduous forests, especially in areas with a thick understorey (LaForest 1993). In Durham Region, Speirs and Orenstein (1975) observed it in a mature maple-oak forest on a floodplain rising to rocky ridges. Most of the plot had a full canopy, but trees were sparse on the ridges.

In the Carolinian Forest Region, the redstart was a significant indicator of diameter-limit cuts and was more abundant in heavily harvested forests than those that had been selectively cut or had no recent history of cutting. It was more abundant in recent than older cuts and was absent in selectively thinned and uncut forests (Holmes et al. 2004).

Throughout its range, presence of deciduous shrubs or saplings appears to be the most important component of the redstart's habitat requirements. In forested habitat, it is associated with edges, gaps in the canopy, or open-canopied woodlands where light penetration promotes growth of a woody understorey. Breeding habitat is not restricted to woodlands and it may be locally abundant in shrubby areas, particularly those dominated by willows and alders. Regenerating clear-cuts may provide high-quality habitat from the young sapling and shrub stage until the trees become pole-sized. Clear-cutting and other types of timber management that promote shrub and sapling growth can be beneficial, especially in forest-dominated landscapes where habitat is limited. Less frequently or rarely used habitats include orchards, fencerows, pine and oak barrens, and suburban parks and woodlots.

Because the presence of a woody understorey is the key habitat parameter, the redstart inhabits a variety of forest types. Virtually every type of deciduous forest may be used. In the northeast, it occurs equally in deciduous treed swamps and dry forests such as those dominated by maple-oak or maple-beech. In the southern and western portion of its range, it is more restricted to treed swamps, bottomland forests, and riparian thickets of willow and alder or, to a lesser extent, red-osier dogwood. It occurs in a variety of mixed forests provided that there are suitable patches of deciduous trees and undergrowth. In most mixed forests, its abundance declines with increasing coverage by coniferous species. One study concluded that it was associated with increasing abundance of pine or spruce-fir, but this does not appear to be the norm. It avoids pure coniferous forests and plantations. On islands dominated by spruce in Maine, most male redstarts failed to attract a mate. Where deciduous cover was available, it was used significantly more than its abundance. In New Hampshire and Maine, it was not recorded in balsam fir–spruce stands, but occurred in all other forest types. It was most abundant in northern hardwoods and aspen stands, followed by stands dominated by swamp hardwoods, white birch, hemlock, and white pine. In North Carolina, its relative abundance during the breeding season was 1.81 in floodplain forests, 1.41 in beech forests, 0.43 in pine-hardwoods, 0.20 in oak-hickory forests, and 0 in pine forests and wet and dry thickets. In British Columbia and Quebec eastward, it frequently breeds in coniferous

forests where it is restricted to riparian areas that support deciduous shrubs such as willows and alders. Examples of forest types that it has nested in include white pine or spruce mixed with hardwoods, almost pure spruce or balsam fir stands, sugar maple–basswood-hackberry, sugar maple, trembling or large-toothed aspen, balsam poplar, maple-beech, red maple–birch-conifers, bur oak, sycamore, white cedar–balsam fir, oak-pine, hardwood swamp, white birch–red oak, silver maple swamp, yellow birch–white birch–white cedar, sugar maple–yellow birch, hemlock–yellow birch, ash-basswood lowland forest, red maple swamp, white spruce–trembling aspen, pin oak swamp, and lowland white spruce interspersed with aspen, poplar, and white birch. In the west and northeast, the redstart shows a preference for stands dominated by trembling aspen or balsam poplar, or riparian thickets of willow and alder along margins of ponds, lakes, rivers, and wetlands. In the Boreal Forest Region, it is typical of aspen-birch stands and may be a dominant species in these stands where there is a dense subcanopy at a height of 3-9 m; elsewhere it may be scarce or lacking. In many areas, it nests predominantly in forests along streams and rivers. In Illinois, some of the highest densities occurred on wooded islands (Beals 1960; Campbell et al. 2001; Capen 1979; Chapman 1907; DeGraaf and Chadwick 1987; DeGraaf et al. 1998; Erskine 1977; Faanes and Andrew 1983; Ficken and Ficken 1967; Golet et al. 2001; Graber et al. 1983; Gross in Bent 1953; Harrison 1984; Hobson and Bayne 2000; Howe 1974; Hunt 1996; Kirk et al. 1996; LaRue et al. 1995; Morse 1973; Mossman 1988; Mossman and Hoffman 1989; Parnell 1969; Rich et al. 1994; Robbins et al. 1989; Sabo 1980; Sherry and Holmes 1997; Sinclair et al. 2003; Sturm 1945; Temple et al. 1979; Wiebe and Martin 1998).

The redstart is an adaptable species that may use different habitats in different regions. On a broad scale, this is evident in its preference for forested swamps in the south and poplar stands and willow or alder thickets in the west. Collins (1983a) compared its habitat usage in Maine and Minnesota. Maine birds occurred in areas with a high percent canopy cover, variable coniferous cover, and many trees in smaller size classes. Minnesota birds occurred in areas with dense shrub cover, moderate canopy cover, and low percentage of conifers in the canopy. Its habitat structure was significantly different from random for shrub cover, canopy cover, number of tree species, and number of trees 7.5-23 cm diameter at breast height (DBH). It selected the most optimal habitat at each site from what was available. Ficken and Ficken (1967) observed habitat differences in areas used by the redstart in New York and Maine. The New York study area was a deciduous swamp with a nearly closed canopy and an understorey of saplings 6 m tall. There were dense stands of saplings where the canopy was interrupted and it nested within both habitat types within the swamp. The Maine landscape was dominated by coniferous forests, and it selected 5 distinct habitats for breeding. The first was deciduous forest with some trees taller than 9 m, understorey saplings as tall as 6 m, and occasionally as much as 10% coverage by conifers (white pine and spruce). The second habitat type was immature deciduous forest with trees taller than 9 m, but with the understorey not as well developed and often more open. The third habitat was dense alder thickets growing to a height of 4.6 m, often with willows and some deciduous growth. The fourth habitat was mixed forest with 10-60% coverage by white pine and/or spruce and the remainder deciduous coverage. The final habitat used was coniferous cover with more than 60% coverage by conifers, including some stands that were pure spruce.

In New Hampshire, Hunt (1996) investigated areas that were defended first in spring and by adult males, which are socially dominant to yearling males, to assess which areas were preferred habitat. The site supported 3 habitats: early successional stands 4-22 years old (mean 10.8 years), mature deciduous stands 20-122 years old (mean 72.4 years), and mature coniferous stands 36-102 years old (mean 73.0 years). Early successional areas were characterized by high redstart densities; a high proportion of adult males; high mating success, even of yearling males; and smaller territories. Coniferous stands were occupied last in spring, and the proportion of adult males decreased with increasing stand age. Early successional stands were important to the redstart. It could decline as these stands matured. Coniferous stands may support lower densities.

The redstart has been variously described as an early, mid-, or late successional species or preferring early to late seral stages. This is due in part to the broad habitat range that it occupies, but also to the varying manners in which successional and seral stages have been defined. There is good evidence for it being associated with early successional areas because it occurs in recent clear-cuts, regenerating old fields, and shrubby utility rights-of-way, particularly those passing through forested habitat. Its response to habitat succession in Maine clear-cuts is typical of its usage of this habitat type. It was absent in the first 2 years after cutting when cuts were dominated by open ground covered with slash. It was most abundant 3-6 years after cutting when habitat consisted of dense coverage by raspberries and regenerating hardwoods less than 2 m tall. It was slightly less abundant in the next stage of succession, but was one of the dominant species. At this stage, the hardwood regeneration was taller than 2 m and there was a well-developed but slower growing softwood regeneration layer. It was even less common once hardwood regeneration was taller than 4.5 m and trees were 10-15 cm DBH. The final seral stage was a dense coniferous canopy with an open forest floor; it was absent in this stage. Its abundance was positively correlated with the number of deciduous trees less than 10 cm DBH that were 2.1-4.5 m tall and the number of dead tree stems larger than 10 cm DBH. It was negatively correlated with the number of conifers larger than 20 cm DBH. In many other areas, it exhibits an absence immediately after cutting, high populations during the early shrub and sapling stages, and a decline once trees become larger and shade out the lower layers of woody vegetation. In Vermont, territories included mostly forests, but some included forest and clear-cut and some were entirely in clear-cuts (Back 1979; Falardeau et al. 1999; Freedman and Johnson 1999; Hanowski et al. 2005; Lent and Capen 1995; Morgan and Freedman 1986; Sabo 1980; Thompson and Capen 1988; Titterington et al. 1979; Yahner 1993). On hydro transmission line corridors in Pennsylvania, the redstart was one of the most abundant species during the breeding season. It occurred in all types of management plots, which included combinations of hand cutting, mowing, and herbicides, but was uncommon directly under the wires where there were few shrubs. Yahner et al. (2002) considered it adapted to both early succession and forested habitat.

Most authors consider the redstart a mid-successional species associated with second-growth hardwoods or medium-aged stands. Presence of woody growth in the 1.5-6-m range is important. On South Bass Island in western Lake Erie, it was more abundant in a second-growth woodland dominated by sugar maple, basswood, and hackberry than in a mature forest of the same composition a short distance away. In New Hampshire and Maine, it was significantly more abundant in sapling-sized stands than in other tree-size classes. It was next in abundance in large

sawtimber stands with trees averaging larger than 60 cm DBH followed by sawtimber-sized and pole-sized stands (Baker 1944; Collins et al. 1982; Cyr and Darveau in Gauthier and Aubry 1996; DeGraaf and Chadwick 1987; DeGraaf et al. 1998; Ficken 1962a; Hoffman 1989a; Litwin and Smith 1992; Noon et al. 1979; Sturm 1945). Long-term studies in New York and New Hampshire found that the redstart declined significantly with time and it became extirpated at 1 site. For both sites, the declines were a result of forest maturation. During this period, areas of low shrub and sapling growth disappeared or declined, rendering the habitat less suitable (Holmes and Sherry 2001; Litwin and Smith 1992). Bond (1957) examined the distribution of birds in Wisconsin in a series of woodlots that spanned the entire successional range, a wide range of age classes, different sizes, and a range of moisture regimes. The redstart exhibited one of the most striking curves along the vegetational gradient. It reached a definite peak in the middle portion of the gradient and was uncommon in all other continuum intervals. The trend was marked regardless of the size of woods, although it was more pronounced in large than small woods. Small woodlots appeared to present more pioneer conditions to avifauna than larger woodlands with a similar continuum interval, possibly due to more light and wind penetration. It was most abundant in stands midpoint on the moisture scale where saplings were dense and well branched.

In western Canada, the redstart is significantly more abundant in mature stands, but these are typically early successional stands dominated by aspen or aspen birch. In these stands, it is associated with high shrub density and large, sparse trees. It was also present where there were large numbers of snags larger than 20 cm DBH; conifers were avoided (Kirk et al. 1996; Schieck et al. 1995). In Pennsylvania, it had a negative affinity for old-growth forest. It occurred in 18.2% of old-growth stands, 60.7% of stands within the state, and 79.6% of forests on the Appalachian Plateau (Haney 1999).

Several studies identified microhabitat preferences of the redstart, and virtually all confirmed the importance of deciduous shrubs or saplings in the understorey. In Illinois, its abundance was associated with silver maple trees larger than 10 cm DBH and a shrub understorey. In the mid-Atlantic states, its abundance was correlated with trees larger than 38 cm DBH and percent ground cover. In Iowa, it was correlated with shrub coverage and negatively correlated with grass cover (Graber et al. 1983; Robbins et al. 1989; Stauffer and Best 1980; Vanderwel et al. 2009). In Alberta, Sodhi et al. (1999) compared habitats of trembling aspen forests that were occupied and unoccupied by the redstart, and habitats within and outside territories. Unoccupied woodlots and areas outside territories contained larger trees and higher densities of trembling aspen, accompanied by prickly rose, red-osier dogwood, and honeysuckle. Areas within territories were characterized by high densities of willow trees and shrubs, cherries, Saskatoon, and balsam fir saplings, as well as a tall shrub layer. Nest sites were associated with a high density of white birch trees and saplings, willows, cherry, and balsam poplar saplings, as well as viburnums that contributed to a tall shrub layer. Territories were not established randomly and were characterized by a high abundance of willow and other tall shrub species. Nest sites also supported high densities of white birch. Trembling aspen was underrepresented in occupied sites, even though this was the dominant tree in the community. It preferred early successional forests or disturbed areas embedded within older stands, but might also choose territories based on soil moisture or food availability. In Vermont, average habitat variables for the redstart were 37.2% green ground cover,

8.7% cover by slash on the ground, 77.0% canopy closure, 22.9 m canopy height, 12.5 m canopy depth, 17.0 m^2 per ha basal area (BA) of deciduous species, 3.5 m^2 per ha BA of coniferous species, 16.4 cm DBH for deciduous species, and 15.9 cm DBH for conifers. It was in the closed-canopy deciduous association (Thompson and Capen 1988). In Minnesota, average habitat characteristics were 67.7% ground coverage, 70.7% shrub coverage, 66.3% canopy cover, 14.5 m canopy height, and 4.7% coniferous cover. It was in a guild with the Black-and-white Warbler, Nashville Warbler, Magnolia Warbler, and Canada Warbler. It was separated from other warblers in this guild by preferring more medium-sized deciduous trees and conifers (Collins et al. 1982). In subalpine areas of New Hampshire, it preferred areas midway between sheltered valleys and exposed slopes, areas with wet depressions, average canopy height 10.4 m, 74% canopy closure, 38% coniferous foliage volume, and an average DBH of 10 cm for live trees (Sabo 1980). In New Hampshire and Maine, it was positively associated with the number of coniferous trees larger than 10 cm DBH, the number of deciduous trees 2-10 cm DBH, the number of woody stems per ha, and total foliage volume of both deciduous and coniferous trees larger than 10 cm DBH. It was negatively correlated with the number of coniferous trees 2-10 cm DBH (DeGraaf et al. 1998).

Several authors considered the redstart a forest-interior species, but provided no data to support this (Freemark and Collins 1992; Grant and Berkey 1999; Hobson and Bayne 2000; Sherry et al. 2020). It does not avoid edge in New Hampshire or Alberta (Sherry et al. 2020). In southern Ontario, it was negatively correlated with the amount of forest further than 100 m from edge, although this relationship was not significant (Austen et al. 2001). There appears to be no evidence that the redstart is a forest-interior species. If anything, the opposite is more likely because shrubby areas at edges of woodlands may provide superior habitat to forest interior.

The American Redstart appears to be area-sensitive in some areas and not in others. Area sensitivity in this species may be complex, with sensitivity being exhibited where it is uncommon, where there is limited forest cover in the landscape, and where woodlots are isolated from each other. Where woodlots are close together or the landscape is largely forested, area sensitivity may completely break down. Extra-pair fertilizations are an important component of its mating behaviour and the requirement for neighbours to accomplish this may be 1 factor that affects area sensitivity. Because of the variables that affect area sensitivity, various studies have concluded that the redstart is mildly or highly area sensitive, or unaffected by forest size. Certain authors (Freemark and Collins 1992; Mossman and Hoffman 1989; Robbins 1979) considered the redstart an area-sensitive species without providing any supporting documentation. Some studies determined that it is not area sensitive. In Alberta, Sodhi et al. (1999) found it nesting in woodlots as small as 2 ha. In Pennsylvania, it was not area sensitive during the breeding season (Keller and Yahner 2007). In North Dakota, it was not influenced by forest size or isolation, and was present in woodlots smaller than 2 ha (Grant and Berkey 1999). In Wisconsin, it was not restricted to larger islands (Beals 1960). Robbins et al. (1989) did not find a relationship between redstart abundance or occurrence and forest size in the mid-Atlantic states, but it was positively correlated with the percent forest coverage within 2 km. In red maple swamps in Rhode Island, there was no significant difference in its abundance in swamps smaller than 1 ha and those 11-20 ha. These swamps were surrounded by upland forests, so this may not have been a true test of area sensitivity (Golet et al. 2001). In Maine, it nested on islands where the forest cover was only 0.16-1.50 ha (Morse 1973). Other studies concluded that the

redstart is area sensitive. In Saskatchewan, it was significantly correlated with forest size and only occurred in woodlots 15 ha or larger (Johns 1993). Also in Saskatchewan, it was significantly correlated with forest size and amount of forest cover within 5 km (Hobson and Bayne 2000). In western Maryland, where it is uncommon, it was found only in forests larger than 4,000 ha and, in other areas of the state, it was not found in woodlots smaller than 70 ha (Bushman and Therres 1988). In South Dakota, it was absent in 3.5-ha woodlots, but common in large riparian woodlands. Gentry et al. (2006) were uncertain if woodlot size precluded usage by the redstart or if other factors contributed such as vegetation structure or distance from other wooded areas. In Wisconsin, Bond (1957) found the redstart in woodlots as small as 6.5 ha, near the minimum woodlot size that he examined. Its frequency of occurrence increased with forest size: 7.3% in woodlots 6.1-14.2 ha, 16.6% in woodlots 16.2-32.4 ha, and 29.0% in woodlots larger than 32.4 ha. It was at least 50% more common in large than small woodlots. There are 4 studies relevant to redstart area sensitivity in Ontario. James (1984b) did not identify it as being area-sensitive but Coleman et al. (2000) concluded that it was highly area sensitive and required forests 100 ha or larger. No fieldwork was undertaken as part of these studies. South of the Canadian Shield, its presence was positively correlated with woodlot size, but not significantly. It was negatively correlated with the amount of forest cover within 2 km and the amount of regional forest cover, but these relationships were also not significant (Austen et al. 2001). A study in Grey County on the Niagara Escarpment found redstarts in small woodlots 1-2 ha in size. This area was extensively forested and all woodlots were very close together (personal observation). The distribution map in the second atlas (McLaren in Cadman et al. 2007) indicates that it occurred in most squares in southern Ontario, except for a few in Essex, Lambton, Chatham-Kent, and Haldimand. This suggests that it is not particularly area sensitive in Ontario, but this needs more study.

Adult-plumaged males are socially dominant to males with juvenile plumage, so yearling males may be forced to breed in suboptimal habitat that differs from that of adult males. Some woodlands may be split into 2 neighbourhoods, one occupied by adult males and the other by yearlings. As individuals age, they tend to move from the yearling to the adult neighbourhood, thereby keeping the age classes separate. In New Brunswick, territories of adult males had high density of ground cover, large black cherries and poplars, and many deciduous trees taller than 8 m. Territories of yearlings had high contributions of deciduous trees in the 2.5-m layer. There were highly significant differences in the floristic features of territories of adults and yearlings, but there were also differences within age classes. Redstarts selected territories in a variety of habitats and which were better was not readily identifiable by which age class used it. Studies on the distribution of age classes in New York, Maine, and Michigan had conflicting results. All study areas contained deciduous forests and alder thicket swamps. In Maine, yearlings were least common in alder thickets and mature deciduous forests and more common than older adults in immature deciduous, mixed, and coniferous forests. The distribution of age classes appeared to be related to the amount of deciduous foliage, with the frequency of adult males higher where deciduous foliage density was higher. Highest deciduous foliage density occurred in alder and mature deciduous stands. The percentage of yearling males in Maine habitats were 7% in alder, 21% in mature deciduous forest, 71% in immature forest, 60% in mixed forest, and 82% in coniferous forest. In Michigan, 0% of males in deciduous forest were yearlings compared with 25% in alder thickets. The Michigan deciduous

forest was more mature than the one in Maine which might explain why yearlings were more common in this habitat type in Maine than Michigan. Complete separation of the age classes has also been documented in New Hampshire (Ficken and Ficken 1967; Howe 1974; Lemon et al. 1996; Morris and Lemon 1988a; Sherry and Holmes 1988).

Ontario nests were in saplings, shrubs, mature trees, and vines, predominantly in live woody vegetation but 8 nest trees or shrubs were dead. The redstart greatly preferred saplings and shrubs to mature trees for nesting, and deciduous species (22 species, 92.5% of nests) were used more often than coniferous species (6 species, 7.5%). The species chosen most frequently were maples (53 nests), birches (28 nests), ashes (15 nests), hawthorns (12 nests), alders (12 nests), and white cedar (8 nests). On the Bruce Peninsula, 42 of 55 nests (76.4%) were in coniferous species: 42 in white cedar, 5 in balsam fir, and 2 in American yew. This was markedly different to the preference shown for deciduous species elsewhere. The DBH of 9 trees and saplings supporting nests ranged from 3.8 to 17.8 cm, mostly 5-10 cm. A total of 93.9% of nests were in upright crotches, 5.1% were on horizontal branches, and 1.0% were between 2 upright trunks. They were mostly placed against the main trunk, but 4 were 0.6-1.8 m from the trunk. Nest heights ranged from 0.3 to 15 m, with most 1.8-3.7 m up (Peck and James 1987, 1998a). Near Kingston, 1 pair renested for the second time in an old Red-eyed Vireo nest. This was the latest redstart nest attempt that season, and usage of an existing nest may save time. Usage of other species' nests appears to be rare. This was the only observed case out of more than 750 nests (McKellar 2010). Nests in Algonquin Park were in vegetation ranging from shrubs to tall trees at an average height of 2.8 m (Tozer 2012).

Throughout its range, the redstart typically nests in tree saplings, less frequently in shrubs and mature trees, and seldom in vines. Nests are at the juncture of 3 or more small branches, usually at the trunk of the nest tree. Where nests were built on horizontal limbs, they were almost always where several branches grew upright. It rarely builds in crotches formed by 2 branches. These nests are vulnerable to being blown out of the tree. In New Brunswick, nests were at an average of 52.0% of the nest-tree height (range 41.8-58.7%). Nest height did not appear to be influenced by seasonal foliage development. Nests were often built in deciduous species before they fully leafed out despite the presence of coniferous trees. Most tree species are used according to their availability, but some are underutilized. Trembling aspen, balsam poplar, and striped maple are seldom used, possibly because the bark is too smooth and the branch structure is inadequate to support a nest. Conifers other than white cedar are seldom used, possibly because the branch structure is unsuitable. In New Brunswick there was a difference in nest-tree selection by adult and yearling males. Nests of yearlings were located more often in chokecherry and a variety of other tree species than those of adults; 4.2% of yearlings' nests were in white cedar compared with 14.8% of adults' nests. Nests are frequently placed in grey alder, beaked willow and other willow species, white birch, yellow birch, sugar maple, beech, white cedar, cherry, and hawthorns. Other species that have supported nests include ash, dogwood, gooseberry, elm, hackberry, hazelnut, silver maple, white oak, bur oak, raspberry, sycamore, hophornbeam, balsam poplar, trembling aspen, hobblebush, striped maple, spruce, and tamarack. In New Hampshire, 37.8% of nests were in sugar maple, 31.0% were in yellow birch, and 28.4% were in beech. Overall, nests have been reported 0-28 m from the ground. Ground nests are rare, and most nests are 2-5 m up. In Maine, 4% of nests were 0-1.5 m from the ground, 12% were 1.5-3 m up, 36% were 3-4.6 m up, 22% were 4.6-6.1 m up, 10% were 6.1-9.1

m up, 12% were 9.1-12.2 m up, and 4% were higher than 12.2 m from the ground. In New Brunswick, nest height averaged 3.5 m but differed by plant species: 2.7 m in alder, 5.3 m in white birch, 3.9 m in white cedar, 2.2 m in cherry, 3.4 m in hawthorn, and 3.4 m in other species. In New Hampshire, mean nest height was 8.2 m with a strong mode at 1.5-3 m and a second shallow mode 10-20 m from the ground. Nests were higher in yellow birch (median height 15 m) and only 1-4 m in other species. In the western and southern portion of the redstart's range, the nest is often built over or near water. The redstart has used old nests of the Yellow-throated Vireo, Red-eyed Vireo, and Yellow Warbler. These nests may be used as is or additional material may be added to the interior to bring the cup to the proper dimensions. Material from old redstart nests may be incorporated into a new nest, but there are no records of redstart nests being reused. Several unusual nests have been reported. One was built on a metal bracket at the front door of a house; one was in a lilac shrub 30 cm from a front window of a house; one was partially sunken into the ground at the base of a gooseberry between 2 logs; one was 1.5 m up in the fork of a dead branch that had fallen and was leaning against a sapling; and one was on a U-shaped grapevine hanging from a tree, saddled on the vine at the bottom of the U where it swung 1.5 m with the wind (Baker 1944; Campbell et al. 2001; Chapman 1907; Cruickshank 1956; Ficken 1964; Graber et al. 1983; Gross in Bent 1953; Harrison 1984; Morris and Lemon 1988a, 1988b; Mousley 1916a; Sherry et al. 2020; Sodhi et al. 1999; Stauffer and Best 1980; Sturm 1945; Yezerimac 1993).

The male does not tolerate any other males in his territory. Males are also aggressive toward females and females defend the territory from both sexes, except when accepting extra-pair copulations. Territories may be defended from spring arrival until autumn migration. Territory size shrinks during the nestling period and expands again during the fledgling period. At this time, territoriality may be somewhat relaxed. Most activity is confined to the territory, although both sexes make occasional off-territory forays. When densities are high, all suitable habitat is defended but when densities are low, there may be an undefended gap of about 15 m between territories. There are no differences in territory sizes of yearling and adult males or in the size of area used by females. Yearling males that are unsuccessful in attracting a mate abandon their territories after about 2 weeks and may travel several kilometres to establish a new territory. When adults shift their territorial boundaries later in the nesting season, yearlings may be successful in defending a territory. Occasionally a female builds a nest at or outside the boundary of the male's territory and he is forced to try and shift the boundaries. The American Redstart may maintain multiple territories simultaneously when it mates polygynously. These areas are not contiguous and individuals may have as many as 3 discrete advertising areas 120-450 m apart. Other polygynous males have large territories that can accommodate 2 nesting females. Nests of females mated to the same male may be as close together as 120 m; nests of different pairs may be separated by only 9 m. Territories near Quebec City were significantly clustered at scales of 250, 350, 450, and 550 m. The purpose of this may be to facilitate extra-pair copulations. This may also contribute to area sensitivity. In Algonquin Park, territories averaged 0.15 ha (range 0.03-0.74 ha). Most territories are 0.4-0.6 ha, but some are quite small and others are twice this size. In Illinois, territories averaged 0.57 ha in 1 area; another single territory was 1.29 ha. In New York, territories averaged 0.30 ha or less than 0.4 ha; most Maine territories were larger than 0.4 ha. In New York, average territory size in the early stages of nesting was 0.41 ha and declined to 0.07 ha during the nestling period. On South Bass Island in western Lake

Erie, most territories were 0.2-0.4 ha, but one was only 0.06 ha. Average territory size in subalpine areas of New Hampshire was 0.6 ha. In New Hampshire, territory sizes averaged 0.17 ha in 8- and 22-year-old stands and 0.54 ha in mature forest. Quebec territories averaged 0.64 ha (range 0.35-0.93 ha); average size in maple stands was 0.39 ha (range 0.17-0.61 ha). A polygynous male in New York had a territory that was 1.25 ha (Bourque and Desrochers 2006; Cyr and Darveau in Gauthier and Aubry 1996; Ficken 1962a; Ficken and Ficken 1967; Ford 1996; Graber et al. 1983; Hickey 1940; Hunt 1996; Kendeigh 1945; Martin 1960; Sabo 1980; Secunda and Sherry 1991; Sherry et al. 2020; Sturm 1945; Yarrow 1970).

In Ontario, 26 of 632 nestlings (4.1%) returned to the natal area (Sherry et al. 2020). In New Brunswick, 9 of 172 nestlings (5.2%) returned, including 5 males and 4 females. Three of the 5 males remained on the study area briefly and were not seen again, probably having been unsuccessful in attracting a mate. The other 2 males established territories 0.5 km from their natal site. Three of the returning female yearlings nested 300 m from their natal site (Lemon et al. 1996). In New Hampshire, 1 of 161 nestlings (0.6%) returned (Sherry et al. 2020). Using stable isotopes in Maryland, Rushing et al. (2015) determined that long-distance dispersal of yearlings was rare. Long-distance natal dispersal was influenced by habitat quality experienced during the previous winter. Birds were more likely to disperse northward following years of low food abundance and habitat quality. Yearlings were more likely to disperse southward in years when cherry trees blossomed early. The quality of an individual's winter territory did not affect long-distance dispersal. The long-distance immigration rate of yearlings to the site was 18.1%.

Adult site fidelity varies geographically, annually, by sex, by age class, and may be affected by how late birds remain in autumn and if they were successful in raising young. In Saskatchewan, Bayne and Hobson (2002b) found no difference in survival rates of males and females, and 55% of birds returned the following year. In New Hampshire, 49 of 182 adults (26.9%) returned the following year. Males returned at a significantly higher rate (30%) than females (19%). Yearling males banded in the year of their first breeding season returned at a lower rate than older males (16% compared with 39%). Returning males nested significantly closer to their previous year's territory (average 68 m, range 17-617 m) than females (average 171 m, range 22-236 m). There were no significant differences in the distances between subsequent territories for returning yearling and older males. There was a tendency for successfully returning individuals of all sexes and ages to return more frequently than unsuccessful birds (Holmes and Sherry 1992). In New Brunswick, 44% of adult birds returned compared with 26% of yearlings. Males that were banded as yearling breeders returned to their previous territory significantly less (26.7%) than returning adult males (84.6%). Over half of returning yearlings settled on the same or an adjacent territory. Reproductive success of males the previous year was not a significant predictor of territory change and some previously successful males switched territories. Twenty-four of 119 females (20.2%) returned. Of returning females, 5 returned to the same territory, 8 to an adjoining territory, and 3 no further than 2 territories from the original territory. One female that returned 5 years nested as far as 400 m from the original territory some years, but returned to it in the final year. Breeding success was a strong predictor of return of females, with 30.8% of successful and 21.0% of unsuccessful females returning. The date that a bird was last seen on the study area was a significant predictor of return for both yearling and adult males, suggesting that the decision to return is made in the autumn of the previous year (Lemon et

al. 1996). Fifteen percent of Maryland redstarts made long-distance movements between breeding sites or natal sites and first breeding sites. In 3 of 4 years, 78.4% of immigrants to the site originated from the north; 70% originated from the south in the other year. The odds of birds originating from the south increased with earlier cherry blossom dates. The rate of long-distance dispersal to the site was less for adults (11.2%) than for yearlings (18.1%), but adult dispersal was greater than that for yearlings in the year of early cherry blossoming. There were no significant differences in dispersal rates between the sexes. Both age classes may disperse further north in years of early phenology when food resources are available further north than usual during the spring migration period (Rushing et al. 2015).

Limiting Factors

Eggs have been reported in Ontario nests from late May to late July, with most present during the last 3 weeks of June (Peck and James 1987). In Algonquin Park, nests are under construction from late May to late June, eggs are present from late May to mid-July, nestlings are present from mid-June to late July, and dependent fledglings have been observed from late June to mid-August (Tozer 2012).

Females arrive at night and usually select a male and territory the following morning. Females visit very few males before selecting one as a mate and, if a female remains in a male's territory for more than an hour, she does not leave. The female spends 12-60 hours exploring the territory, with early arriving females taking more time. She finally restricts her activities to a few locations and searches them for suitable nest sites. This may take from a few hours to 1.5 days. As soon as the female selects a nest site, she begins to build the nest. Nests typically take 2.5-4 days to complete, but some take as long as 7-10 days. Nests built later in the season may be completed within a day, particularly if material is taken from an old nest. Egg laying started the day after the nest was completed in 2 of 3 Ohio nests and 1 day later in the third nest. Eggs are laid at the rate of 1 a day. Incubation begins in earnest with laying of the last egg, although some time may be spent incubating after the penultimate egg is laid. The incubation period of 17 Ontario clutches was 10-13 days; most clutches hatched in about 11 days. Similar incubation periods have been reported throughout the redstart's range, although 1 Yukon clutch took 14 days to hatch. Young hatch over a 24-hour period. The young typically fledge when they are approximately 9 days old, but may fledge when they are only 7 or 8 days old if they are disturbed. At nests with a single adult, young may not fledge until they are 10-13 days old (Baker 1944; M.S. Ficken 1962b, 1963, 1964; Gross in Bent 1953; Kendeigh 1945; Peck and James 1987, 1998a; Secunda and Sherry 1991; Sherry et al. 2020; Sinclair et al. 2003; Sturm 1945).

The redstart raises a single brood in a breeding season. Second broods are expected in the southern portion of its range where the season is longer, but this has not been confirmed. It is a persistent renester that routinely lays as many as 4 clutches in an attempt to raise a brood; 6 nests per season have been reported. Over an 11-year period near Kingston, fewer than 25% of pairs were successful in fledging any young on their first nesting attempt. Replacement nests are usually in the same territory but occasionally pairs move and establish another territory. Clutches of 2-5 eggs have been reported in Ontario (average 3.69 eggs). The most frequent clutch size was 4 eggs, with 67.7% of nests containing 4 eggs. Throughout its range, clutches of 1-5 eggs have been documented. One-

and 2-egg clutches are uncommon and tend to occur toward the end of the breeding season. Five-egg clutches (5.5% of Ontario nests) are also uncommon and occur at the beginning of the breeding season and at more northerly latitudes. In Alberta, 43% of clutches contained 5 eggs. Most clutches contain 4 eggs. Replacement clutches typically have 3 eggs or occasionally only 2. In New Hampshire, females mated to yearling males had an average clutch size of 3.63 eggs compared with 3.86 eggs for females mated to older males. The difference was due to yearlings initiating nesting later (Campbell et al. 2001; Chapman 1907; Ficken 1962a; Graber et al. 1983; Gross in Bent 1953; McKellar et al. 2013; Peck and James 1987; Sherry et al. 2020; Sodhi et al. 1995; Sturm 1945).

Both sexes are capable of breeding when they are 1 year old. All females of all age classes breed each year, but many males do not breed until they are 2 years old. This is because yearling males arrive later than adult males. There is a surplus of males in the population, so females may all be mated by the time yearling males arrive. In addition, yearling males may be relegated to suboptimal habitat where females are less likely to settle on a territory. In some populations, 100% of adult males are mated, but this percentage may be as low as 70% in some areas. In New Brunswick, 71.9% of adult and 57.4% of yearling males were mated. Another New Brunswick study reported 85.1% of adult and 48.3% of yearling males mated. In New York, 100% of adult and 43% of yearling males were mated. In New Hampshire, less than 50% of yearling males were mated. Some unmated males may hold territories for about 2 weeks and then move considerable distances to repeat the process. Other unmated males are floaters that wander through the habitat. Occasionally a female arrives late and mates with one of the later-arriving yearling males. Yearling males that are mated tend to have smaller clutches because of the lateness of the season, but have similarly sized territories and fledging success rates as older males. Near Kingston, adult males that had successfully mated were temporarily removed from their territories. Those that lost their territory to another male and re-established another territory nested on approximately the same schedule as yearlings. They also had a similar reproductive output as yearlings, indicating that the delay in nesting was the main factor in reducing the number of young fledged. Pairs typically remain mated for the entire breeding season but divorce rarely occurs. Remating of the same birds in subsequent years is rare. In New Brunswick, the probability of both members of a pair reuniting was 8%. Two of 8 previous pairs remated and this involved the same birds twice (Ficken 1962a; Ficken and Ficken 1967; Hickey 1940; Hunt 1996; Kendeigh 1945; Lemon et al. 1996; Lozano et al. 1996; McKellar et al. 2013; Morris and Lemon 1988a; Omland and Sherry 1994; Sherry and Holmes 1982; Sherry et al. 2020).

The American Redstart is typically monogamous, but may be polygynous when ecological and social circumstances allow it. For polygyny to occur, territory density must be low so that a polygynous male can defend an extra-large territory or have multiple territories. In New Brunswick, 0-4% of males were polygynous. In New Hampshire, 6 cases of polygyny were confirmed and others were suspected. Males defended as many as 3 territories and 1 male was successful in attracting a mate to each of his territories. Polygyny appears to be practised mainly by older males (Secunda and Sherry 1991; Sherry et al. 2020). Extra-pair fertilizations may be an important component of the redstart's breeding strategy. In New Brunswick, 55.3% of nestlings were related to the adults caring for them and all nestlings were related to their attending female. Of 32 broods, 41.1% were sired by their putative father, 41.1% were partially sired by their putative father, and 18.8% were sired entirely by extra-pair fertilizations. A total of 41.7% of nestlings were not attended by their biological father.

Subadult males attended a greater proportion of extra-pair young (68%) than adult males (37%). Nine of 10 extra-pair fathers were from neighbouring territories; the other territory was 200 m away. Nestlings in 2 broods were sired by undetermined males that either had distant territories or were floaters. Two of 7 broods were sired by 2 extra-pair males. The number of broods fathered by a single male was greater than expected, suggesting that females were selecting for good genes (Ficken 1962a; Perreault et al. 1997). In Pennsylvania, 44.4% of young were from extra-pair fertilizations and 30% of the extra-pair males were not mated (Kappes et al. 2009). In an Ontario study, 40% of 100 nests contained extra-pair young and 23% of 313 nestlings were extra-pair (Sherry et al. 2020). Near Kingston, females appeared to be mating with extra-pair males that were more genetically similar to themselves than their social mates (Hajdasz et al. 2019).

Numerous studies summarized the foraging strategies of the American Redstart. It is the only warbler that is a true aerial forager. It is intermediate in its foraging techniques between warblers and flycatchers and is significantly different from both. Unlike flycatchers that hunt stationarily from a perch and often return to the same perch after attacking prey, the redstart is constantly in motion. It flashes its wings and spreads its tail, causing soft-winged bugs to drop to the ground, and it flutters downward to capture them. Aerial foraging and gleaning are its primary tactics for obtaining food. It may rarely forage briefly on the ground and as high as the top of the canopy, but most foraging occurs in the mid- to lower portion of the canopy and in the subcanopy. It is highly adaptable in its foraging heights and use of different foraging techniques. Foraging height depends upon the structure of the woodlot, time of day, and sex of the bird. Individuals of the same sex occurring on different territories within the same woodlot use significantly different methods at the same time of day. Birds select areas within their territory and the forest that have more open vegetation that facilitates aerial foraging. Redstarts forage at lower levels at midday than in the morning. There may be an increase in foraging height again later in the afternoon, but there are no consistent patterns to this. Between early morning and midday, the frequency of hawking increases and the amount of hovering declines, and there is a general downward shift in foraging heights. This is related to insect abundance and behaviour. Flying insects increase from a low early in the morning to a peak at midday and are most abundant in the lower strata of the forest, with another concentration near the top of the canopy. The overall abundance of insects differs significantly depending upon time of day and height, and the redstart adjusts its foraging techniques to access the most abundant prey. In New Hampshire, it foraged at heights of 0-24 m, mostly at 5-14 m, except in late afternoon when it foraged at heights of 0-4 m. The only difference in foraging techniques between the sexes in 1 study was that females gleaned more often at midday than males. In most pairs, the sexes foraged at the same heights during the same period. In the 39% of pairs where foraging height differed between sexes, the male foraged higher than the female in all but 1 case. Females may forage lower because they are associated with the nest. The primary foraging techniques are gleaning, hovering, and mid-air captures. Another New Hampshire study found significant differences between the sexes, with males hovering at leaves less and hawking more than females. Males foraged more on yellow birch and less on sugar maple than females. In all tree species in New Hampshire, it attacked prey more on lower leaf surfaces in relation to caterpillar abundance than expected, and less on upper leaf surfaces, petioles, and twigs. More caterpillars were present in beech than sugar maple or yellow birch. The redstart attacked prey in proportion to their availability

only in beech. Caterpillars on beech were mostly leaf miners and leafrollers. Those on the other 2 tree species were mostly free-living and more available. Most of these occurred on leaf blades and undersides of leaves. It may temporarily concentrate on taking adult moths and other prey from tree trunks when such prey is abundant. While moulting, it forages using more inactive behaviours such as hopping with infrequent sallies and few aerial flights. At this time, it tends to stay in dense vegetation, sometimes high in the canopy. In yellow birch in New Hampshire, the redstart fanned its tail more frequently both in the canopy and subcanopy than in ash, maple, or beech. It encountered prey most frequently in yellow birch and also used the flush-chase manoeuvre most often in this tree species. In Parry Sound District, it used a variety of tree species in early successional woods for foraging, but white birch was favoured in spring and autumn. During the breeding season, it foraged 3.9-12 m from the ground compared with 3.8-10 m in autumn (Chapman 1907; Ficken 1962b; Greenberg et al. 1999; Gross in Bent 1953; Holmes 1986; Holmes and Schultz 1988; Holmes and Sturges 1975; Holmes et al. 1978; Keast et al. 1995; Lent and Capen 1995; Mills 2007; Morse 1989; Parnell 1969; Robinson and Holmes 1982, 1984; Sabo 1980; Seidel and Whitmore 1982; Sherry et al. 2020; Williamson 1971).

Morse (1973) compared the foraging strategies of the American Redstart to the Yellow Warbler and spruce-woods warblers on small islands in Maine. In most cases, redstarts used dead limbs more frequently and deciduous foliage less frequently than the Yellow Warbler. Redstarts used manoeuvres other than gleaning, particularly flycatching, more frequently than the Yellow Warbler. Both species preferred to forage on deciduous foliage, using it more than its availability. Most foraging by the redstart occurred on small limbs of deciduous species. There was little overlap in the foraging of the redstart and Yellow Warbler with the spruce-woods warblers due to the heavy usage of deciduous vegetation by the former 2 species. There was no relationship between abundance of defoliating insects and redstart abundance, possibly due to the small size of the islands which prevented establishment of large numbers of territories. In Louisiana, the diet of the redstart overlapped considerably (74-89%) with other insectivorous birds, including the White-eyed Vireo, Hooded Warbler, Carolina Wren, Acadian Flycatcher, Prothonotary Warbler, and other warblers that do not breed in Ontario. Despite high dietary overlap, the species exhibited modest resource specialization in their foraging techniques and substrates with some differences among species in all communities. These small distinctive differences appear to be critical to species coexistence (Kent et al. 2022).

In New Hampshire, the diet of nestlings consisted mostly of 2 orders of insects: lepidopterans (caterpillars and adult moths) and flies (predominantly crane flies). Young are also often fed spiders and mayflies. During a mayfly hatch, 90% of insects brought to young at nests near Lake Michigan were burrowing mayflies. House flies and rosy maple moth caterpillars were fed to young, and gnats have been reported as part of nestlings' diets (Baker 1944; Chapman 1907; Kappes et al. 2009; Omland and Sherry 1994; Secunda and Sherry 1991).

Adults prey predominantly on small winged insects 2-5 mm long. These are mostly flies and hymenopterans, beetles, soft-winged bugs (especially leafhoppers and planthoppers), and moths (both adults and caterpillars). Other prey include aphids, small wasps, stoneflies, spiders and harvestmen, mayflies, caddisflies, ichneumonid wasps, midges, mosquitoes, black flies, dance flies,

cankerworms, spittle bugs, scale insects, and plant lice. Beetles it consumes include weevils, flea beetles, and long-horned beetles. The redstart rarely eats berries and seeds, including those of barberry, juneberry, and magnolia. Near Manitouwadge, it increased in numbers in young and intermediate-aged stands in response to increasing numbers of spruce budworms. In New Brunswick and other locations, no response to budworm numbers was observed. In an aviary study, it preferred cabbage looper moths, followed by mealworms, and gypsy moth larvae. The latter were largely avoided and it would be less likely to eat gypsy moth caterpillars when alternate prey was available. In New Hampshire, redstart populations increased then declined in concert with saddled prominent caterpillar populations. North of Lake Nipigon, stomachs of 5 redstarts contained 41.9% flies (including dance flies), 23.2% lepidopterans, 12.4% beetles (including weevils), 7.3% hymenopterans (including ichneumonid wasps), 6.8% soft-winged bugs (including leafhoppers and aphids), 3.8% spiders, 3.0% mayflies, and 1.5% caddisflies. Stomach samples from New Hampshire contained 34.7% soft-winged bugs (mostly leafhoppers and planthoppers), 30.2% flies, 13.1% beetles, 11.9% hymenopterans, 4.5% caterpillars, 1.1% adult lepidopterans, 1.1% spiders, and 3.4% unidentified. The diet at the same location based on visual observations consisted of 67.3% caterpillars, 25.5% adult lepidopterans, 1.8% beetles, 1.8% flies, 1.8% hymenopterans, and 1.8% spiders. A later analysis of 41 stomachs from the same location determined that the diet consisted of 35.3% flies, 34.5% bugs, 9.7% caterpillars and moths in equal proportions, 6.3% ants and parasitic wasps (including sawflies), 6.3% beetles, 4.1% spiders, 2.6% stoneflies, and less than 1% each of mayflies, bark lice, lacewings, caddisflies, and scorpionflies. In some forests, food availability may be an important factor with birds depleting caterpillar resources during parts of the breeding season (Graber et al. 1983; Gross in Bent 1953; Holmes and Sturges 1975; Holmes et al. 1978; Kendeigh 1947; Morris et al. 1958; Robinson and Holmes 1982; Sherry and Holmes 1992; Sherry et al. 2020; Sturm 1945; Venier et al. 2009; Whelan et al. 1989).

The redstart is a common host of the Brown-headed Cowbird. The redstart usually accepts cowbird eggs, but occasionally abandons the nest or builds another layer over the foreign egg. In Wisconsin, Minnesota, and Iowa, 1.87 fledglings were produced in unparasitized nests compared with 1.48 in parasitized nests. In Ontario, 61 of 364 nests (16.8%) were parasitized; 0 of 47 nests on the more heavily forested Bruce Peninsula were parasitized. Parasitism rates vary considerably geographically and with the amount of forest cover in the landscape. Parasitism rates from elsewhere are: 15.8% of 145 nests in Quebec; 6.2% in the Prairie Provinces; 18% in Alberta; 9% of 131 nests in British Columbia; 17% in Wisconsin, Minnesota, and Iowa; 30.6%, 68%, 74%, and 6% in New York; 5.6% and 32% in Ohio; and 0% in Pennsylvania. In Illinois, 7.4% of 27 nests were parasitized prior to 1900 compared with 36.6% of 41 nests after 1900 (Campbell et al. 2001; Cyr and Darveau in Gauthier and Aubry 1996; Ficken 1962a; Graber et al. 1983; Gross in Bent 1953; Hahn and Hatfield 1995; Hobson and Villard 1998; Peck and James 1998a; Powell and Knutson 2006; Sherry et al. 2020; Sodhi 1995; Sodhi et al. 1999; Sturm 1945).

The species of tree that is selected for the nest site can affect nest success. In New Brunswick, nests in white cedar had a 100% fledging success compared with 37% in the other 4 main nest-tree species. In New Hampshire, nests in yellow birch were significantly less likely to be depredated due to better concealment (Morris and Lemon 1988a; Sherry et al. 2020).

A population near Kingston experienced a 50% rate of nest loss, and this is fairly typical for the redstart. In New Hampshire, nest success was increased from 50% to 77% by placing baffles around tree trunks beneath active nests, thereby reducing access by red squirrels and chipmunks. Weather can also affect nest success. Wind frequently destroys nests or damages them sufficiently that they are abandoned. Rain may also remove material from nests, resulting in abandonment. Heavy rainfall during the nestling period may result in starvation due to depressed insect availability, reduced foraging time, or both. In New Hampshire, daily nest survival increased with increasing May temperatures. June rainfall also had a positive effect on survival. The adverse effects of these factors are often mitigated by renesting, and later nests are less likely to be parasitized (McKellar et al. 2013; Sherry and Holmes 1992; Sherry et al. 2020; Sturm 1945).

Habitat loss and degradation do not appear to be significant issues for the redstart. Nonetheless, some habitat is being lost south of the Canadian Shield due to urban development and clearing for agriculture. Forests that mature and lose their woody understorey growth eventually become unsuitable.

Activities that reduce the amount of woody vegetation in the understorey are detrimental, such as clearing brush on cottage lots. Along the Michigan shoreline of Lake Superior, the redstart was detected more frequently on the forested inland side of cottage roads than on the cottage side of the road (Ford and Flaspohler 2010; Stauffer and Best 1980).

The effects of timber harvesting on the American Redstart vary depending upon the harvest methods. Certain studies concluded that the redstart benefits from forest management; others concluded the opposite. Management that converts deciduous stands to conifers is universally detrimental. Clear-cutting in occupied stands initially results in a short-term loss of the redstart until sapling growth becomes established. Clear-cutting or strip-cutting in coniferous stands can provide short-term habitat where none previously existed. In the Boreal Forest Region of Ontario, it had a negative response to partial timber harvesting. It declined by 25% when 45% of trees were removed, by 50% when 50% of trees were removed, and by 75% when 65% of trees were removed. In the Great Lakes–St. Lawrence Forest Region of Ontario, partial timber harvesting either has no effect or a positive effect. Near Sault Ste. Marie in northern hardwood communities, it responded positively to harvest, with postharvest numbers inversely related to the amount of residual BA. Three studies on group-selection and shelterwood cutting in Algonquin Park found that it was unaffected by harvesting. In the Carolinian Forest Region of Ontario, it was more abundant in diameter-limit cuts that removed all large trees than in forests that experienced single-tree selection or had not been cut for at least 24 years. It was most abundant in recent cuts indicating that it temporarily benefits from opening the canopy. Trends in response to timber harvesting are similar in other portions of its range. In the Boreal Forest Region, it tends to decline as a result of partial harvest, or occasionally there is no effect or a temporary small increase. In northern hardwoods, it may increase with increasing levels of harvest, but in some areas no change was documented. In Pennsylvania, clear-cutting of 75% of aspen and 50% of oak stands resulted in a decline. In Maryland, forest management that opened the canopy was detrimental, but selective cutting and thinning of competing understorey trees was beneficial (Bushman and Therres 1988; Haché et al. 2013; Hanowski et al. 2005; Harrison et al. 2005; Holmes et al. 2004; Jobes et al. 2004; Kingsley and Nol 1999; Sherry et al. 2020;

Tittler et al. 2001; Tozer et al. 2010; Vanderwel et al. 2007, 2009; Webb et al. 1977; Yahner 1993). In the Canadian Shield of Ontario, there was no difference in its abundance in burned and clear-cut forests in early successional stands, but it was significantly more abundant in harvested than burned mid-successional stands. It was significantly less abundant in early successional and mid-successional than mature stands (Zimmerling et al. 2017).

Hunter and Witham (1985) examined the effects of carbyl spraying in Maine. The first year, spraying was spotty, and only 30% of the area was sprayed, but spraying was complete the following year. The spray reduced numbers of caterpillars, particularly in the upper portions of trees. In the first year, there was a sharp drop in warbler numbers after spraying followed by a gradual recovery a week later, but numbers of redstarts did not decline significantly. The average foraging height of all warblers decreased after spraying, but returned to prespray levels during the recovery period, although foraging heights in the control areas increased even further. Use of conifers by foraging warblers decreased from 53% to 24% after spraying but stayed constant at 62-63% in the control area. Because spraying was spotty, birds were able to travel to unsprayed areas to forage. When spraying was complete the following year, there were no changes in numbers, foraging height, or tree selection. The overall impact of the spraying appeared to be negligible.

Presence of the Least Flycatcher can affect habitat selection and use by the American Redstart. The 2 species share similar habitat preferences and have similar foraging tactics and substrates, with an overlap of 49.8%. Their diets are dominated by flies, hymenopterans, and beetles, constituting 79% of the redstart's diet and 92% of the flycatcher's diet. The redstart has a broader diet, also eating substantial numbers of caterpillars and soft-winged bugs. There is considerable aggression between the 2 species, with the flycatcher usually being the aggressor and winning conflicts. During the nestling period, redstarts may be attacked several times a day, and attacks continue throughout the breeding season. Where the territories of the 2 species overlap, they may use different horizontal strata without interspecific territoriality. Because of its broader foraging niche, the redstart may use gaps and margins of niche space left vacant by the Least Flycatcher. In a New Hampshire study area, Least Flycatchers occupied 1 area of a woodlot and adult redstarts occupied much of the remainder of the area. Due to aggression from older males, yearling redstarts occupied the portion of the woodlot that was occupied by the flycatchers. Flycatchers subsequently disappeared from the area and adult redstarts settled throughout, but most frequently in the area formerly occupied by the flycatchers and they clearly preferred this habitat. At the same time, yearling redstarts declined where the flycatchers resided. The flycatchers later recolonized the same area, and the redstart distribution returned to what it was originally. These patterns strongly suggested that the Least Flycatcher directly kept the American Redstart from settling in otherwise preferred habitat and that behaviourally subordinate yearling redstarts settled where adult male redstarts were absent (Sherry 1979; Sherry and Holmes 1988).

In Pennsylvania and New Jersey, hemlock declined from 56% of the total basal area to 46% because of the hemlock woolly adelgid; this resulted in an increase in deciduous understorey. The American Redstart population increased as a result, probably in response to the increased coverage by deciduous undergrowth (Toenies et al. 2018).

In Alberta, there was no difference in abundance of the redstart at noisy compressor stations and quiet well pads. It did not appear to be affected by chronic noise (Bayne et al. 2008).

In Alberta, there was no difference in the abundance of the redstart at seismic lines, pipelines, or well pads than in forest interior adjacent to these features (Bayne et al. 2016). In West Virginia, it was significantly more abundant near well pads than in areas distant from them. It exhibited no response to pipelines and access roads (Farwell et al. 2019).

Factors on the wintering ground may be more significant in limiting redstart populations than those on the breeding grounds. Loss of wintering habitat is the most important concern (Morse 1989).

Status

McIlwraith (1894) concluded that the redstart was generally distributed throughout Ontario. Fleming (1907) considered it common in the Toronto area. Baillie and Harrington (1937) stated that it bred from the southern border of the province north to James Bay and west to the southern Manitoba boundary. In 1891 in Elgin County, it was a very common summer resident; by 1954, it was observed less frequently in the summer. In 2000, it was an uncommon breeder that continued to decline (Lancaster et al. 2004). During the first atlas, its range included the entire area south of the Canadian Shield, where it was spottily distributed in areas of intensive agriculture and urbanization. Its range included all the Great Lakes–St. Lawrence Forest Region in the Shield and most of the Boreal Forest Region, although it was absent or scarce in the western portion of that area. Breeding in the Hudson Bay Lowland was confirmed to the southern portion of the James Bay shoreline and a bit westward. Highest numbers were in the Great Lakes–St. Lawrence Forest Region (Cartwright in Cadman et al. 1987). James (1991) considered the redstart a common breeder across the province north to Sandy Lake and Attawapiskat.

The second atlas demonstrated that there had been no change in the distribution of the redstart since the first atlas. It was seen in a few more locations in the northwestern portion of its range, but it is unlikely that this represented a range expansion. There was no significant difference in its probability of observation province-wide, although the trend was positive. Significant increases were documented in the Boreal Forest Region and in the Great Lakes–St. Lawrence Forest Region south of the Shield. It was most abundant in the Great Lakes–St. Lawrence Forest Region on the Bruce Peninsula, on Manitoulin Island, the northeastern shore of Georgian Bay east to the Quebec border, and around the northern shore of Lake Superior. It was also abundant along the Quebec border northward to the southern extent of the Hudson Bay Lowland (McLaren in Cadman et al. 2007).

Breeding Bird Survey (BBS) results indicated that the redstart declined continentally in the latter half of the 20th century, but not significantly. This decline was attributed to forest maturation, forest fragmentation that resulted in an increase in predation rates, increases in cowbird populations, and habitat loss in the wintering grounds (Sherry and Holmes 1992; Sherry et al. 2020). BBS results indicate that it increased at an annual rate of 0.015% in Canada and decreased at an annual rate of 0.134% in Ontario 1970-2021. Trends 2011-21 were annual increases of 1.02% in Canada and 0.713% in Ontario. All results were highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Once the young fledge, the brood is divided with each adult caring for half the brood. The adults provide fledglings with most of their food for the first week after fledging and continue to feed them for as long as 2-3 weeks after this (Sherry et al. 2020).

During the postfledging period, adults and juveniles occur in deciduous forests and shrubby areas such as regenerating clear-cuts and utility rights-of-way through forested habitat. In Michigan, Akresh et al. (2009) compared redstart usage of upland and riparian forests during the postfledging period. The upland forests were mature trembling aspen–large-toothed aspen stands. Riparian stands had a mixture of alder, honeysuckle, and trembling aspen, and a greater diversity of vegetative cover in the understorey. Captures per 100 net-hours were 4.2 in upland and 15.7 in riparian forests; 89% of juveniles were captured in riparian forests. There was no apparent trend in adult usage of habitat by time; 5 moved from upland to riparian habitat and 5 did the opposite.

Two Pennsylvania studies compared redstart usage of forests and early successional areas during the postfledging period. Stoleson (2013) captured 53 adults and 15 juveniles in 3-6-year-old regenerating clear-cuts and 1 adult and 0 juvenile in adjacent mature forest. There was no difference in shrub and sapling coverage in the 2 habitats. In August over a 2-year period, Yahner et al. (2002) observed 124 redstarts on a shrubby hydro right-of-way and 7 in the adjacent forest. No family groups were observed in the forest but the average number seen per day on the right-of-way was 0.67. In Quebec, Major and Desrochers (2012) netted in small clear-cuts among mature forests. All redstarts were caught in nets set parallel to forest edge, suggesting that they were moving through the clear-cut from 1 mature forest to another.

Both adults and juveniles commonly occur in clear-cuts during the postfledging period. Use of clear-cuts has been confirmed in West Virginia, Virginia, Ohio, Minnesota, Pennsylvania, Missouri, and Quebec. It is likely that this habitat is used wherever it is available. Although the redstart may breed in clear-cuts, there appears to be active movement to these areas during the postfledging period. In Minnesota, 11 were netted during a single breeding season; 315 (184 adults and 131 juveniles) were captured during the postfledging period over 4 years. Adults were captured at a consistent rate but very few juveniles were captured prior to August (Marshall et al. 2003; McDermott and Wood 2010; Porneluzi et al. 2014; Streby et al. 2011a, 2011b; Vitz and Rodewald 2006, 2007).

Porneluzi et al. (2014) netted in a Missouri oak-pine-hickory forest during the postfledging period for 2-15 years after it was clear-cut. The numbers of redstarts gradually increased with time after cutting, but the increase was not significant.

Two studies examined redstart usage of habitat within clear-cuts. Both found that presence of adults was correlated with the abundance of arthropods. One study determined that adults were associated with the vertical complexity of vegetation and negatively correlated with understorey stem density. The other study found that canopy height was a significant predictor of adult abundance, but vegetation density was unrelated to captures of adults. In both studies, availability of invertebrates was the most important predictor of juvenile abundance, although at 1 site juveniles were positively correlated with the biomass of caterpillars and negatively correlated with total arthropod biomass. At 1 site, canopy height was a significant predictor of juvenile abundance. At the other site, juveniles were positively correlated with vertical complexity of the vegetation,

density of understorey stems, and residual BA. For both age classes, food availability was the most important predictor of abundance (McDermott and Wood 2010; Streby et al. 2011a).

MIGRATION

The American Redstart is a nocturnal migrant. During migration, it may join mixed flocks of chickadees, nuthatches, and other warblers, particularly in autumn, but also during inclement weather in spring. There is seldom more than a single redstart in these mixed flocks (Brewer et al. 2018; Graber et al. 1983; Morris et al. 1994; Norris et al. 2006; Sherry et al. 2020; Tozer 2012). Gesicki et al. (2016) monitored nocturnal calls of the redstart during spring migration at 2 sites on the Ohio shoreline of Lake Erie and at 2 offshore sites. The number of calls decreased from the coast into the lake in both the western and central basins. It appeared to partially avoid crossing the lake in both basins.

Adult males are first to arrive in spring, followed by adult females a few days to a week later, then by yearling males and finally by yearling females. At Long Point, mean capture dates were 17.0 May for adult males, 22.1 May for yearling males, and 17.6 May for males of undetermined age. Average arrival for males was 3.0-3.6 days earlier than for females. The difference in arrival dates between the sexes was greatest in years when males arrived earlier. The midpoint of migration for all redstarts at Long Point was 21 May. At Prince Edward Point, mean arrival times were 22.7 May for males and 25.7 May for females. Mean arrival date for adult males was 20.7 May compared with 25.1 May for yearling males. In New York and Maine, 2 weeks may elapse between the arrival of adult and yearling males. In New Hampshire 1 year, females arrived 9 days after adult males and yearling males followed females 3 days later. During spring migration at 3 stopover sites in Texas, Louisiana, and Florida, males migrated 5 days earlier than females and older birds migrated 3-4 days earlier than yearling males. In some years and locations, there may be overlaps in the arrival of adult females and yearlings of both sexes. During spring, birds stop at staging areas 1-11 days, but most frequently only a single day with mean stopover times of 2.0-2.6 days. Recapture rates and stopover times are lower in spring than autumn. Spring migration is concentrated with few stopover areas. Autumn migration is extended with more frequent stopovers. On 2 islands separated by less than 1 km in the Gulf of Maine, 1 redstart was caught on both islands in spring and 2 were caught on both islands in autumn indicating daytime movements (Campbell et al. 2001; Cohen et al. 2019; Ficken 1962a; Ficken and Ficken 1967; Flockhart 2010; Francis and Cooke 1986; Gross in Bent 1953; Lozano et al. 1996; McKellar et al. 2013; Mills 2005a, 2005b; Morris and Glasgow 2001; Morris et al. 1994; Procter-Gray 1991; Smith et al. 2009; Stewart et al. 2002; Suomala et al. 2012).

Spring arrival dates may be affected by precipitation and the quality of habitat that an individual used during winter, by increasing temperatures in the breeding grounds, and by local weather conditions. Higher precipitation rates in the wintering grounds are associated with greater food availability, improved body condition, and earlier departure date from the nonbreeding areas. Ontario arrival and egg-laying dates were earlier when rainfall in Jamaica was greater. Egg-laying dates in Alberta were earlier when rainfall in Mexico was greater. Birds occupying wetter winter habitats, such as mangrove swamps, were more likely to arrive earlier in New Hampshire. Arrival time was a significant predictor of nest success with successful males arriving an average of 3.5 days earlier than unsuccessful males. For every day that a male arrived after the first male, he was 11%

less likely to fledge young. Yearling males wintering in mangrove swamps have significantly more black breast plumage than those wintering in scrub habitat. Near Kingston, early arriving yearling males had more extensively black breasts than late arrivals. These earlier arriving yearlings are more likely to attract a mate (Germain et al. 2010; McKellar 2012; Tonro et al. 2011). At Delta Marsh in Manitoba, Murphy-Klassen et al. (2005) compared first observation dates over a period of 63 years. The redstart arrived 0.67 days earlier for every 1°C increase in temperature. Over a 25-year period at Long Point, there was no significant difference in spring arrival times or autumn departure times. Similar results were reported in Massachusetts over 32 years, and there was no change in the relative timing of arrival of the sexes. Males arrived significantly earlier in warmer years, but females followed the same trends. It is possible that the warming in Canada, which would promote earlier migration, is offset by drying in the wintering areas (Bauböck et al. 2012; Mills 2005a). Strode (2003) examined migration dates in relation to climate change in Illinois and North Dakota. Over 100 years in Illinois, there was no significant change in spring temperature or timing of redstart arrival. This resulted in migrants having 20 fewer days to travel between southern Illinois and northern Minnesota, where springs are arriving earlier. In North Dakota, spring advanced by an average of 8.6 days since 1961, but the redstart did not arrive earlier. In Michigan, arrival date was correlated with aspen leaf development and the relationship between arrival date and temperature approached significance. All age and sex classes arrived earlier during warm, food-abundant springs and later during cold, food-poor springs. Migration rate may be adjusted in response to temperature and food availability once it approaches its breeding area (Smith et al. 2009).

In southern and central Ontario, the peak of migration extends from mid-May to the first week of June, with the earliest migrants arriving in early May (Black and Roy 2010; Curry 2006; Keast 1980; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008). Kendeigh (1947) first observed the redstart north of Lake Nipigon on 28 May.

It is uncertain if there is differential timing of the sexes and age classes in autumn. Some studies state that there are differences in timing; others have concluded that there is not. It is possible that timing of migration of the sexes and age classes varies geographically. Sherry et al. (2020) reported that the 2 year classes arrived synchronously in Ontario, Pennsylvania, and West Virginia banding stations, but yearlings arrived earlier than adults in 1 of 3 years in coastal Alabama. In Illinois, Graber et al. (1983) reported that females and juveniles preceded adult males southward. In Alberta, females initiated autumn migration 2 days before males (Flockhart 2010). In Mississippi, juveniles are the first to appear in autumn, followed by females and adult males (Gross in Bent 1953). In Maine, there was no significant difference in timing of migration between the sexes and age classes. When the sexes were analyzed separately, there was no difference in the autumn arrival dates of adult and juvenile males, but adult females arrived 6 days later than juvenile females (Morris and Glasgow 2001). In Virginia and West Virginia, adults and juveniles started their migration in the same 5-day period (Stewart 1986). The length of autumn stopovers tends to be longer than those in spring, but not significantly. Most birds stay over a single day, but some stay as long as 6 days. Juveniles have longer stopover periods than adults (Morris and Glasgow 2001; Morris et al. 1994).

Wilson and McRae (1993) observed a migrant at Longridge on 7 September. In the southern Shield, most redstarts leave by the end of September, with some remaining into early October (Mills

1981; Tozer 2012). Autumn migrants move through most of southern Ontario from mid-August to mid-October, with late birds remaining until late November or mid-December (Black and Roy 2010; Curry 2006; Keast 1980; LaForest 1993; Lancaster et al. 2004; Weir 2008). The midpoint of autumn migration at Long Point is 6 September (Mills 2005a, 2005b).

During migration, the redstart may occur in a variety of habitats such as forests, shrubby areas, and miscellaneous areas such as orchards, residential yards, university campuses, city parks, cemeteries, and windbreaks. In woodlots, it is more likely to select tree-fall gaps and edges than forest interior, and it may prefer bottomland and riparian forests to upland forests. In Illinois, highest numbers occurred in bottomland forests, forest edges, and shrubby areas. Where forested habitat was scarce, upland forests were heavily used. Relative abundance by habitat during spring migration in North Carolina was 1.73 in floodplain forests, 1.63 in beech forests, 0.77 in pine-hardwood forests, 0.66 in oak-hickory forests, 0.56 in wet thickets, 0.14 in pine forests, and 0 in dry thickets. During spring migration in Wisconsin and Minnesota, it was more common in floodplain than upland forests, but not significantly. In British Columbia coniferous forests, it was more common in riparian areas in both spring and autumn. During spring migration in Ohio, the redstart was significantly more abundant in mature upland forest than mature riparian forests. The two forest types were similar except that upland sites had a higher density of shrubs. A study of autumn habitat usage in Pennsylvania found no significant differences among habitats in 1 year. When the study was repeated, it was most abundant in forest-agricultural edges and shrub-sapling-stage forests, followed by suburban forests. It was not observed in forest interior or pole-stage forests. These latter 2 habitats were used least in the earlier study indicating that they are not preferred habitat. During migration, the redstart shows a decided preference for shrubby areas over forest cover. During spring migration in Pennsylvania, detections per 100 m were 0.007 in forest and 0.060 in shrubs; captures per 1,000 net-hours were 0.1 in forest and 3.6 in shrubs. In many other areas, it actively selects shrubby areas, particularly along edges of watercourses, ponds, lakes, and wetlands. It selects shrubby areas within forest cover, explaining why it is more common in forest edges and tree-fall gaps. Two studies tested to determine if the redstart is area sensitive during migration. During spring migration in Pennsylvania, it was significantly more likely to be observed in larger patches within fragmented landscapes, but it did not exhibit area sensitivity in autumn. A South Carolina study found the opposite. There was no significant difference in its abundance in differently sized oak hammocks within coastal marshes in spring, but it was detected significantly more often in large hammocks in autumn. Hammocks smaller than 0.5 ha may not have provided sufficient habitat (Campbell et al. 2001; Graber et al. 1983; Keller and Yahner 2007; Kirsch et al. 2013; Leighton et al. 2002; Parnell 1969; Rodewald and Brittingham 2002, 2004; Rodewald and Matthews 2005; Sherry et al. 2020; Sinclair et al. 2003; Smith and Hatch 2008; Somershoe and Chandler 2004; Suomala et al. 2010; Wiebe and Martin 1998).

Just prior to autumn migration, males demonstrate a slight increase in aggression and agonistic encounters may occur between males, although there is no evidence of territorial defence at this time. Older birds are dominant to juveniles, who may be relegated to suboptimal habitat. The increase in aggression prior to and during autumn migration may be a precursor to behaviour on the wintering grounds where birds defend territories. Aggression during spring migration does not appear to have been documented (Ficken 1962a; Sherry et al. 2020).

During migration, the American Redstart forages using similar techniques to those used during the breeding season, predominantly aerial attacks and gleaning. There are no differences in foraging strategies or heights used by the sexes or age classes during migration. During autumn migration, it fed at heights of 1.5-17 m at Prince Edward Point, with a peak around 10 m. Foraging was characterized by aerial pursuits of flying insects and was directed 22% to the air, 11% to outer leaves, 5% to twigs and inner leaves, 17% to outer branches, 17% to inner branches, 0% to trunks, 19% to sapling foliage, 11% to sapling branches, and 0% to low shrubs and the ground. During spring migration in North Carolina, 37.2% of redstart foraging occurred in the canopy, 58.1% in low trees, 4.6% in shrubs, and 0% on the ground. In the canopy, 3.8% of foraging occurred at the top of the crown, 14.6% in the inner crown, 18.8% in the lower crown, and 0% on the bole. In low trees, 5.4% of foraging occurred at the top of trees, 23.0% in the inner crown, 29.7% in the lower crown, and 0% on the bole. In shrubs, 0.4% of foraging occurred at the top of the crown, 1.7% in the inner crown, 1.3% in dense thicket, 0.8% in brush piles, and 0% in grass. It readily adapts its foraging strategy in response to prey availability. There are 2 records of it foraging at night in areas lit by artificial lights. In an area illuminated by stadium lights, it used aerial sallying manoeuvres to capture insects on foliage or in the air. In another area, it was attracted at 0300 hours to a window lit by lights in the room. It alternately hovered and perched on the window screen, selecting the larger insects that were predominantly mayflies, moths, and caddisflies. During spring migration in Michigan, midges are abundant within 0.4 km of the shoreline of Lake Huron. Spiders are also more abundant near the shoreline because they prey upon the midges. There was no difference in the total biomass of arthropods inland and near the shore, but midges were essentially absent inland and spiders were less common. Both sexes of redstarts gleaned more at the shoreline than inland and more sallying occurred inland. Near the shore, redstarts foraged heavily on resting midges and spiders. They foraged predominantly on flying insects inland. White cedar was used for foraging according to its availability near the shore but was used significantly less than expected inland. Near the shore, midges rested on white cedar but few insects used it inland. Foraging rates were much higher near the shoreline. Foraging was most intense in the early morning when temperatures were below 10°C. These temperatures inhibited midge swarming until later in the day and made them readily abundant on vegetation. Midges may be important prey for the redstart during spring migration in areas near the Great Lakes. Spiders may also be important in the diet on shorelines (Bakkan and Bakkan 1977; Keast 1980; Lebbin et al. 2007; Parnell 1969; R.J. Smith et al. 2004, 2007).

The diet during migration consists mainly of insects and spiders. Migrants collected in Texas and Louisiana had eaten 40.1% flies (including 13.5% midges), 17.2% leafhoppers and planthoppers, 11.6% wasps and ants, 10.6% beetles, 8.9% bark lice, 2.9% spiders, 2.7% caterpillars and moths, 1.4% mayflies, 1.3% lacewings, and less than 1% each of odonates, orthopterans, and mites. During cold periods in autumn, the redstart may resort to eating vegetable matter. In Ohio, it was observed inspecting yew and honeysuckle fruit but was not seen eating the berries. Two were observed plucking foxtail and crabgrass seeds from their stalks and 10 others foraged within 2 m of the ground on the trunks of large trees. There were essentially no insects available at that time (Sherry et al. 2020; Tramer and Tramer 1977).

The redstart is commonly killed at television towers and other tall structures during migration, predominantly in autumn, but a few kills occur during spring. From 1972 to 1982, 625 were killed at

the Lennox generating station chimneys near Kingston. At 2 towers in Florida, 908 and 728 were killed over the course of 4 years. Between 2 September and 12 October, 537 were killed at Illinois towers (Graber et al. 1983; Leighton et al. 2002; Sherry et al. 2020; Weir 2008).

James (1991) considered the redstart a common migrant. Daily maxima are in the order of 40-60 birds, but more than 600 have been reported during spring at Presqu'ile (Curry 2006; LaForest 1993; Weir 2008).

At Long Point, the redstart declined significantly during migration at an annual rate of 2.2% 1961-88. Trends during other periods were: 1961-70, −6.7%; 1970-79, +4.8%; and 1979-88, −3.3% (Hussell et al. 1992). More recent data indicate that the redstart population at Long Point increased significantly during both spring and autumn migration 1961-2004 (McLaren in Cadman et al. 2007).

Kirtland's Warbler

Setophaga kirtlandii

BREEDING SEASON

Habitat Requirements

The Kirtland's Warbler has nested in Ontario only at Garrison Petawawa and near Sudbury. Nesting habitat at Petawawa consists of young stands of mixed jack pine and red pine or pure jack pine stands in sandy soils. It inhabited stands less than 20 years old that were mostly 1.5-4 m tall, but as tall as 6 m. Occupied stands had openings vegetated with lowbush blueberry, velvetleaf blueberry, sweet fern, bluestem, sedges, mosses, and lichens. One nest was in a 820-m^2 clearing dominated by these plant species, but there were 4 jack pines in the centre of the clearing (Richard 2008, 2013). A comparison of vegetation in occupied and unoccupied sites revealed that occupied habitats were associated with greater percent ground cover of lowbush blueberry, star-tipped lichen, reindeer lichen, and waxyleaf moss. Blueberries are important ground cover because they conceal nests from predators, provide protection from the elements, and supply berries for food. Unoccupied areas were associated with greater percent cover of bare ground, sheep laurel, red maple saplings, common strawberry, bluestem grasses, juneberry, wintergreen, blackberry, red raspberry, and

whorled loosestrife. There was no significant difference in the percent composition of poplar, red maple, jack pine, white pine, and red pine in occupied and unoccupied sites. There was a significant difference in ages of stands, with occupied stands averaging 14.8 years compared with 32.4 years for unoccupied sites. These sites had as much as 70.9% red pine in the canopy, suggesting that Kirtland's Warbler will occupy stands with a lower percentage of jack pine, higher percentage of red pine, and less oak than typical habitats in Michigan (Richard 2014).

The Kirtland's Warbler has highly specialized habitat requirements that significantly curtail its breeding distribution. It nests only in flat or gently rolling areas with well-drained, nutrient-poor sandy soils. Within this restricted physiographic type, it nests almost exclusively in jack pine stands created by wildfires or in jack pine plantations managed specifically for it. Occasionally it uses red pine stands. To be suitable, pine stands must be dense, young, and even aged but they must also include openings. In addition, it is area sensitive, requiring large tracts of suitable habitat.

The Kirtland's Warbler appears to avoid hilly areas and nests predominantly in flat areas or where the topography is gently rolling. It nests on the ground in porous well-drained sandy soils so that the nest does not become flooded during heavy rains. The sandy soils that it selects for nesting are acidic and nutrient-poor. This allows establishment of the preferred ground cover which may include lowbush blueberry, velvetleaf blueberry, bearberry, little bluestem, big bluestem, poverty grass, Pennsylvania sedge, wintergreen, trailing arbutus, sweet fern, bracken fern, sand cherry, juneberry, reindeer moss, flowering spurge, frostweed, sheep sorrel, and starry false solomon's-seal. More fertile sandy soils are unsuitable because these promote growth of deciduous tree species rather than jack pines. Fertile sands also support denser and taller ground-cover species, such as goldenrods and asters that are not preferred by the Kirtland's Warbler. Only a small area within eastern North America has soil types that are potentially suitable. This includes the Lower and Upper peninsulas of Michigan and a band across central Ontario through Sault Ste. Marie, Thessalon, and Chapleau to Petawawa (Anich et al. 2011; Bocetti et al. 2020; Bowman and Chamberlain 1980; Chamberlain 1978; Kashian and Barnes 2000; Kirk and Pearce 2008; Marshall et al. 1998; Mayfield 1960, 1962; Probst 1985; Van Tyne in Bent 1953; Walkinshaw 1983).

Historically, the Kirtland's Warbler nested in jack pine forests that resulted from wildfires. Jack pine cones open only when exposed to heat and this conifer typically needs fire to propagate. If the fire is too intense, jack pine seeds fail to germinate and they also fail to germinate if the fire is

followed by a period of drought. To be suitable, jack pine stands need to be even-aged but patchy in distribution, with areas of dense tree coverage interspersed with openings. If the stand lacks openings, it usually is not used. Optimum habitat structure consists of a minimum of 3,500 jack pine stems per ha, 35-65% canopy cover, and small openings. Areas with less than 20% tree canopy cover are rarely used. The Kirtland's Warbler may initially occupy a stand when there are more than 2,000 stems per ha and peak occupancy occurs at 5,000 stems per ha. Only young jack pine stands are inhabited because it typically nests on the ground under the lower living branches of pines. The lowest live branches of pines should be less than 1 m from the ground. Once pines become more mature and the lower branches die, the habitat becomes unsuitable. Initial colonization of stands occurs when pines are 3-5 years old and trees are 0.3-1.8 m tall. Populations increase rapidly when stands are 8-11 years old, remain constant when stands are 12-17 years old, decline at stand age of 18-21 years and then disappear. In Michigan, it has been detected in stands 3-24 years old. During years of highest occupancy, stands support trees 2.4-3.8 m tall with as high as 60% tree coverage. The number of years that a site is occupied varies depending upon the growth rate of the pines, but the pattern is consistent with rapid colonization and population growth, a short peak, and then a decline until the site is abandoned. Stands tend to be occupied for 14-18 years, with high populations for only 7-8 years. During the years of decline, average tree height is 4.0-4.5 m in natural stands and 4.5-5.6 m in plantations, and live foliage is absent below about 1.2 m in height. In Michigan where almost all the Kirtland's Warbler population breeds, jack pine stands may contain almost equal numbers of Hill's oak and lesser numbers of red maple and trembling aspen. It has been estimated that less than 10% of natural jack pine stands are suitable habitat due to the exacting requirements of the Kirtland's Warbler. Due to fire suppression, natural jack pine stands are becoming scarce. Jack pine plantations are being planted and managed specifically for this species in Michigan. Pines are planted 1.2 m apart in rows 1.8 m apart; 10 rows are planted, then 15 rows are skipped to provide openings 27.4 m wide and a tree density of about 4,500 trees per ha. In Michigan, more than 90% of the Kirtland's Warbler populations nest in jack pine plantations managed specifically for it. On rare occasions, it nests in red pine plantations (Anonymous 1988; Bickerton et al. 2006; Bocetti et al. 2020; Bowman and Chamberlain 1980; Chamberlain 1978; Eliason 1989; Kashian and Barnes 2000; Kirk and Pearce 2008; Marshall et al. 1998; Mayfield 1953, 1960, 1962, 1963; Morse 1989; Probst 1986, 1988; Probst and Weinrich 1993; Walkinshaw 1983).

Zou et al. (1992) described 11 ecosystems within a large burn in Michigan, and the Kirtland's Warbler colonized 5 of these ecosystems. Habitats used by warblers were characterized by a physiography of level or rolling terrain; well-sorted sandy or sandy loam to silt loam soils; uplands with relatively warm temperatures during the breeding season; vegetation dominated by lowbush blueberry, bearberry, wintergreen, Hill's oak, bluestem grasses, and haircap moss; and a canopy of tall, dense, and patchy jack pine and oak.

Natural red pine stands are unsuitable breeding habitat for the Kirtland's Warbler because these pines seldom, if ever, grow closely enough together to create thickets. Red pine plantations may provide suitable habitat, and it has nested in this habitat in Wisconsin and in red pine plantations specifically planted for it in Michigan. Occupied red pine plantations in Wisconsin were 11-13 years old. They had a tree density of 1,876 per ha of which 66.9% were red pine, 20.6% were Hill's oak, and 12.5% were jack pine; mean tree height was 3.2 m. The lowest live branch of red pine was an average

of 8 cm from the ground compared with 35 cm for jack pine in Michigan and Wisconsin. Canopy closure in occupied red pine plantations was 46%, dominated by red pine but with 9% coverage by oak and 6% by jack pine. Although red pine is not a common breeding habitat for the Kirtland's Warbler, persistent occupancy, annual return rates similar to birds in jack pine, and good nesting success indicate that red pine stands can provide suitable habitat. Nonetheless, most red pine plantations are not suitable. Extensive die-offs of red pine occurred in the occupied plantations in Wisconsin and substantial regeneration by jack pine created the necessary mosaic of openings and thickets (Anich et al. 2011; Mayfield 1953). Olah et al. (2022) determined that nest sites in red pine plantations had greater dead herbaceous vegetation depth, vegetation-height density at 0.25 and 1.0 m, and tree cover than random sites in the territory. Average density of trees within territories (1,577 per ha) was greater than outside territories (1,094 trees per ha). Occupied patches consisted of 70% red pine, 28% jack pine, and 2% oak. The average tree height of both species of pines was 4.1 m.

The Kirtland's Warbler seldom nests in woodlands smaller than 32 ha and jack pine stands larger than 80 ha support 90% of nests that fledge young. It appears to be most successful in stands that are larger than 200 ha. Occupied red pine plantations in Wisconsin ranged in size from 36 to 70 ha. In Michigan, it occasionally uses smaller tracts. In some cases, 2 or 3 males will settle in a stand of 20-25 ha; in a 24-ha stand, there were 4-5 males and nesting occurred. Males have been found in jack pine stands as small as 3 and 4.9 ha but it is uncertain whether they were mated. All occupied stands smaller than 32 ha have been surrounded by taller stands of jack pine (Anich et al. 2011; Bickerton et al. 2006; Bocetti et al. 2020; Mayfield 1960, 1962, 1993; Walkinshaw 1983).

Only 1 nest has been described for Ontario. It was on the ground under a 3.5-m-tall jack pine at the end of a row, 81 cm beneath a lower branch of the tree and 2.1 m from its base. The nest was on the side of a small hummock and well concealed by blueberries and grasses (Richard 2008).

More than 300 nests have been described from Michigan and all were on the ground well concealed in vegetation 8-20 cm tall. Nests are never on steep slopes and are in flat areas or gently rolling topography. Vegetation in a 4-m^2 area centred on the nest was comprised of 40% lowbush blueberry, 20% wintergreen, and 12% sweet fern, and the ground was typically littered with pine needles and oak leaves. Blueberries and/or grasses comprised the major ground cover at 84.8% of nests. Vegetation in the vicinity of the nest is usually 30 cm or less tall. Nests may be completely arched over by vegetation with a single entrance. Nests were 0-305 cm from the base of the nearest live tree. Near large trees, nests tend to be further from the trunk where the branches droop near the ground. Of 146 nests, 139 (95.2%) had jack pine as the nearest tree, 2 (1.4%) had trembling aspen, and 5 (3.4%) had a small Hill's oak. When a nest was closer to a tree species other than jack pine, there were always jack pines present nearby. Nests are often at the edge or near the edge of a dense group of jack pines. Of 126 nests in natural burns, 22 were exactly on the edge of an opening and 40 were within the pine growth. Sixty-four nests were an average of 60 cm (range 1-366 cm) from the edge of trees in an opening. In plantations with 10-row strips, nests tended to be on or near edges. Of 79 nests, 40 (50.6%) were between or very close to the first and second outside rows, 10 (12.7%) were located away from edge in the open, and 33 (41.8%) were deeper in the plantation, but often near an area where several trees had died, creating a small opening. One atypical nest was

under a fallen dead jack pine where the live pines were only 5 cm tall. Nearly all nests have a specific entrance with directional orientation. In Michigan, 134 nests faced south, 134 faced east, 103 faced west, and 102 faced north. Nest sites are not known to be reused, but 1 nest was only 35 cm from a previous year's nest (Bocetti et al. 2020; Chapman 1907; Mayfield 1960; Van Tyne in Bent 1953; Walkinshaw 1983).

The male establishes a territory immediately upon arrival on the breeding ground. Territories are defended well into the summer during the incubation and nestling stages. Both sexes may challenge other species well away from the nest, including Black-capped Chickadees, Nashville Warblers, Chipping Sparrows, and Vesper Sparrows. A single pair may be the only occupants in an area as large as 12-16 ha, but much of this area is unused. The extreme boundaries of the territory are seldom visited once they are established. Grassy clearings within the territory are avoided and infrequently flown over. Territories in natural habitat are approximately circular in shape. Those in plantations are rectangular, conforming to the row pattern of the trees. Territories are clustered into groups with solitary pairs being rare and usually representative of a declining population. Large areas of suitable habitat remain unoccupied with territories grouped together in what may be a small proportion of the available habitat. Although all suitable habitat is not occupied, marginal habitat is occasionally used. Despite being clumped, the territories are rarely contiguous. Territories may be loosely distributed over the habitat in a manner similar to a bunch of grapes, not always touching each other and not filling in the intervening spaces. The Kirtland's Warbler has a large territory for a warbler. Territory size may be affected by tree density and tends to be larger in areas of lower tree density. At Petawawa, males defended territories of 0.47-12.1 ha. One bird defended 3 small territories close to each other and these were 1.4, 2.0, and 3.0 ha within an overall area of 39 ha. Another male had a territory of 7 ha. During the nestling period, 1 pair confined their activities to 1.27 ha. In Michigan, territory sizes of 0.4 ha to more than 12 ha have been reported. In different locations and years in Michigan, average territory sizes ranged from 3.4 to 8.4 ha. Territories were larger where the tree growth was more open and smaller if they were bordered closely by neighbouring territories (Anonymous 1988; Berger and Radabaugh 1968; Bocetti et al. 2020; Richard 2008, 2013; Mayfield 1953, 1960, 1962, 1983; Walkinshaw 1983). Nonbreeders exhibit territorialism at multiple successive locations 200-1,000 m apart rather than at a single location. After 11-58 days (mean 33 days), some nonbreeders moved 5-77 km to other breeding areas (Cooper and Marra 2020).

The Kirtland's Warbler exhibits low natal philopatry, but return rates for it are higher than for many species. From 1931 to 1965, 296 nestlings and fledglings were banded in Michigan, and 8 (2.7%) were seen again. Five returned to their natal colony and the other 3 were in other colonies 6.4-8.0 km distant. These represent minimum return rates because fieldwork was sporadic in the early years. Returning birds could have been missed simply because no one looked for them. Of 57 nestlings banded in 1977, none were seen again, probably due to limited time spent looking for them. Of 446 nestlings banded prior to 1978, 40 (9.0%) returned, including 24 males and 16 females. The rate of return was 12.3% for males and 8.2% for females, which are more difficult to find. At another Michigan site, 25 of 298 nestlings (8.4%) returned. Return rates were 10.6% of young from first nests and 1.4% for second broods. Of 27 returning males banded as nestlings the previous year, 12 (44.4%) were found within 1.6 km of the natal nest and 13 (48.1%) were found an average distance

of 20.4 km from the natal site. The other 2 males were found considerable distances away: 1 at Petawawa 676 km from where he fledged and the other 579 km away in Wisconsin. Five of 9 male nestlings returned to their natal plantation an average of 728 m from the natal site (range 395-1,208 m). Three of these bred in 2 different areas during their lifetime, as far as 14.5 km from each other. A male nestling banded in Michigan in 1974 was found in Quebec in 1978. Of 25 banded nestlings returning to Michigan the following year, 24 returned in 2 or more seasons. Twenty bred in the same vicinity each year and 4 bred in 2 different locations 13.8, 19.7, 21.0, and 36.2 km away. Returning young tend to nest in younger stands than where they were hatched, settling first in very young pine stands. This may be to avoid competition from older males. Returning young tend to avoid settling near territories occupied by adult males (Berger and Radabaugh 1968; Mayfield 1983; Probst 1986; Walkinshaw 1983). Settling into young pine stands may be beneficial for returning young for another reason. Once an individual breeds, it may continue to do so in the same location for several years. Because habitat remains suitable for only a few years, it is advantageous to settle in younger habitat that will not become unsuitable during the individual's lifespan.

Once a bird nests at an area, its site fidelity is very high and most continue to nest in the same area as long as they are alive. Sixty percent of birds observed 1 year are typically seen the next year. Given that some returning birds may be missed, it has been assumed that the annual return rate is about 65%. At a Wisconsin site, 71.4% of males returned the following year. In Michigan, 18 of 23 control males (56.3%) and 28 of 60 males (46.7%) with geolocators returned. The return rates were not significantly different. At Petawawa, most males returned in at least 1 subsequent year. An adult male banded in 2006 returned in 6 consecutive years, but was not observed in 2013. In 2010, 1 male moved to a second territory 100 m away midway through the breeding season, possibly because he failed to attract a mate on the first territory. In Michigan, some females are not seen in 1 year and then return the next, but no males skipped a year and were found later. One Michigan female returned in 7 consecutive years and 1 male returned in 8 consecutive years. Of 28 returning males, 18 (64.3%) returned to the same breeding territory. Fourteen returned exclusively to the same territory but 4 also returned in other seasons to a different territory within the same colony. Nine of the 28 returning males (32.1%) returned to different territories in the same colony. Five remained exclusively on the same territory; 4 switched territories in subsequent years. One of the 18 returning males returned to a different colony and his 2 nests were 6.1 km apart. The average distance between nests of males returning to different territories in the same colony was 437 m (range 229-800 m), and the overall average distance between subsequent nests of returning males was 358 m. Of 41 returning females, 12 (29.2%) returned to the same territory, 23 (56.1%) returned to different territories within the same colony, and 5 (12.2%) returned to distant colonies. Average distances between subsequent nests for the first 2 groups were 115 m (range 3.7-192 m) and 668 m (range 229-1710 m), with an overall average of 475 m if birds moving to other colonies are excluded. Another study in Michigan determined that the average distance between nests in subsequent years was 215 m for males that returned to the same colony. The average for females was 263 m (range 15.9-3,031 m). Four females moved to other colonies 1.7, 2.0, 15.3, and 25.8 km away. Both sexes return at a similar rate and most return to the same colony, but females are more prone to change locations than males. Males that failed to obtain a mate also tend to return to the same territory. As a pine stand ages, the percentage of birds that return increases because older stands

fail to attract new recruits (Anich et al. 2011; Berger and Radabaugh 1968; Bocetti et al. 2020; Cooper et al. 2017; Mayfield 1977b, 1983; Richard 2008, 2013, 2014; Walkinshaw 1983).

Limiting Factors

Upon arrival, the female inspects the territory for suitable nest sites. This may take only a few hours, but more typically 4 or more days for first nests and 1-2 days for replacement or second nests. First nests in Michigan took 2-3 days to build (average 2.8 days). Subsequent nests also took 2-3 days (average 2.25 days). Also in Michigan, first nests were reported to take 6-8 days to build; 4 days were required for replacement nests. Nest building is suspended during cold, wet weather. For first nests, an average of 2.7 days (range 1-4 days, but occasionally as long as 8 days during inclement weather) elapses between completion of the nest and laying of the first egg. The average is 1.6 days (range 1-3 days) for second nests. In Michigan, females laid eggs in the last week of May through to 10 June, except for yearling females which may not initiate nesting until late June. One egg is laid per day and incubation begins the afternoon before the last egg is laid or with the laying of the penultimate egg. The incubation period is 13-16 days (average 14.2 days). Larger clutches and those containing cowbird eggs tend to have a longer incubation period because individual eggs get less heat from the incubating female. Hatching usually occurs within a 24-hour period, and averages 12.6 hours (range 2-25 hours). In Michigan, the first eggs hatch 9-26 June. If disturbed, the young may leave the nest when they are 8 days old, but typically remain in the nest another 1-2 days, with young fledging at an average age of 9.4 days (Anonymous 1988; Bocetti et al. 2020; Mayfield 1960; Richard 2008; Sykes et al. 1989, 1993; Van Tyne in Bent 1953; Walkinshaw 1983).

Early publications stated that the Kirtland's Warbler raised only a single brood per season and it was not until 1954 that double brooding was confirmed. It is now considered a fully double-brooded species, with all pairs that nest successfully early enough attempting to rear a second brood. The latest date for the first brood fledging and a second nesting attempt was 28 June in Michigan. Four to 15 days may elapse between fledging of the first brood and laying of the first egg in the second clutch (average 7 days). The average distance between nests when the first one was successful was 72.4 m (range 16-137.5 m). Renesting typically occurs if the first nest fails. The time between loss of the first nest and laying of the first egg in a replacement nest is 6 days (range 4-14 days). The average distance between failed and replacement nests was 115 m (range 31.1-323 m). The single Ontario nest contained 2 eggs and 2 nestlings, indicating a probable clutch size of 4 eggs. Five eggs are usually laid in the first nest and 4 eggs in second and replacement nests. Clutches may range in size from 3 to 6 eggs, with 3- and 6-egg clutches rare. Yearling females had an average clutch size of 4.82 eggs, which was not significantly different from clutch sizes of older females. In Michigan, mean clutch size of first nests was 4.87 eggs compared with 4.00 eggs for replacement clutches (Anonymous 1988; Berger and Radabaugh 1968; Bocetti et al. 2020; Mayfield 1960; Probst 1986; Richard 2008; Van Tyne in Bent 1953; Walkinshaw 1983).

Both sexes are capable of breeding in their first year. It is probable that all females in every age class breed annually, but the proportion of young males that breed is unknown. Of 63 adults in Michigan, 32% did not breed. In young or poorly stocked areas, only 25-67% of males obtain mates compared with 95% pairing success in more suitable habitat. It is unknown what proportion of unmated males are yearling birds. The mating system is predominantly monogamous, but as many

as 15% of males may be polygynous and some are polyterritorial. One male at Petawawa defended 3 discrete territories, suggesting that it may have had more than 1 mate. Females may be more selective in their choice of habitat, resulting in an excess of females in prime habitat and a scarcity in marginal habitat. Some males in good habitat have more than 1 mate; some males in marginal habitat remain unmated. Clustering of territories may facilitate finding mates. It may also be important if extra-pair copulations are part of the breeding strategy, but this has not been investigated. There is a floating population of males that are either exploring from nearby territories, relocating from remote areas, or both. Most pairs remain mated throughout the breeding season, but some males may mate with 2 females successively within a breeding season. Fourteen of 18 pairs (77.8%) that could remate in a subsequent year did so and 1 pair remated in 3 consecutive years. Of the 4 pairs that did not remate, the males had nests the second year 137, 165, 209, and 217 m from the previous year's nest. All 4 of the females nested on territories adjoining the one occupied by their former mate. None of these pairs remated once they had separated (Anonymous 1988; Berger and Radabaugh 1968; Bocetti et al. 2020; Cooper and Marra 2020; Ford 1996; Probst 1986; Probst and Weinrich 1993; Walkinshaw 1983).

During the breeding season, most foraging occurs within 120 m of the nest, and a large proportion of prey is obtained within 9-12 m of the nest. Foraging occurs mostly in small jack pines and oaks at mid-level, usually 0.9-2.4 m from the ground. The Kirtland's Warbler also feeds in the ground cover and occasionally on the ground, especially in dense pine thickets where the ground is nearly bare. It may also occur at the top of jack pines 15 m from the ground, but these are typically singing males that may not be foraging. It obtains prey mostly by gleaning among pine needles, deciduous leaves, and ground vegetation. It sometimes hovers to snatch insects and capture prey in terminal clusters of pine branches. It often flies out from a tree to capture an insect on the wing (Bocetti et al. 2020; Van Tyne in Bent 1953).

The Kirtland's Warbler appears to eat whatever is most abundant at the time and shows no particular prey preferences. Young are fed caterpillars, moths, flies, cicadas, sawfly adults and larvae, grasshopper nymphs, ant-lions, and other small crawling and flying insects. Young in second and replacement nests may be fed blueberries. The adults' diet is similar to that of the young, and may also include spiders, butterflies, mayflies, true bugs, deer and horse flies, cicadas, crickets, centipedes, and springtails. An analysis of fecal material collected on the breeding grounds determined that 61% of samples contained soft-winged bugs (36% frequency by spittlebugs and 21% by aphids), 45% contained ants and wasps, 42% contained blueberries, 25% contained beetles, and 22% contained moth caterpillars. Miscellaneous food items included spiders (20% occurrence), flies (18%), true bugs (6%), and traces of springtails and neuropterans. In August, both juveniles and adults consume large quantities of blueberries (Bocetti et al. 2020; Deloria-Sheffield et al. 2001; Mayfield 1960; Van Tyne in Bent 1953; Walkinshaw 1983).

Brown-headed Cowbird parasitism is currently not a limiting factor for the Kirtland's Warbler in Ontario. At Petawawa, the cowbird was not observed during 2 years of study. The cowbird is rare in this area, and also infrequent in the Thessalon area where the warbler has been previously documented during the breeding season. If the Kirtland's Warbler becomes established in the Sudbury, Barrie, and Orillia areas where it has previously occurred, parasitism is potentially more of

a threat (Falk in Cadman et al. 2007; Richard 2008), and it has since nested in the Sudbury area. In the core breeding grounds in Michigan, cowbird parasitism is considered a major and significant limiting factor to the Kirtland's Warbler. It appears to be a preferential host for the cowbird because it suffers very high rates of parasitism, in excess of 70% of nests in some years. In contrast, examination of several hundred nests of other suitable hosts in the same area revealed only 7 parasitized nests. The cowbird was formerly absent within the Michigan breeding grounds of the Kirtland's Warbler. As forests were cleared for agriculture, the range of the cowbird moved northward in Michigan to overlap with this warbler's range. The cowbird first reached that area in the 1870s and continued to increase for the next century. From 1903 to 1948, 48% of nests were parasitized compared with 67% from 1963 to 1971; parasitism rates reached 75% some years. The female cowbird typically removes 1 or more warbler eggs for every egg that she lays, but occasionally no warbler eggs are removed. Warbler clutch size in first nests declined from 5 to 3.73 eggs. Nests with 2 cowbird eggs fledge no warblers and the probability that a warbler will fledge from a parasitized nest is only 7%. Warblers typically accept cowbird eggs, but occasionally abandon the nest or rarely build another nest layer over the cowbird egg. At the rate of parasitism that was being experienced, it was projected that the Kirtland's Warbler would become extinct by 1980. Cowbird control began in Michigan in portions of the breeding area in 1972 and the program was expanded the next year to include the entire breeding range. The program was highly successful, with parasitism rates averaging 3.4% from 1972 to 1981. The number of fledglings produced per nest increased from 0.81 to 2.76 during this period. Taking replacement nests and second broods into account, each pair fledges an average of slightly more than 3 young per year. In order to maintain Kirtland's Warbler populations, it was suggested that the cowbird removal program in Michigan, and now also Wisconsin, would have to be continued indefinitely (Anonymous 1988; Bocetti et al. 2020; Kelly and DeCapita 1982; Mayfield 1960, 1961, 1972, 1977b; Probst 1986; Walkinshaw 1983). Although those studying the Kirtland's Warbler are of the opinion that cowbird control is essential to its continued survival, those studying the cowbird disagree. They point out that the warbler population did not increase as a result of cowbird control and that the Kirtland's Warbler only increased once the amount of habitat increased. Most warbler nest losses were due to predation and parasitism accounted for only 16.8% of the losses (Chace et al. 2005; Ortega et al. 2005; Rothstein and Peer 2005).

Another major limiting habitat is the scarcity of suitable breeding habitat. Cowbird control successfully increased reproductive output, but this served only to stabilize the population and the predicted increase did not transpire. Young jack pine stands on nutrient-poor, well-drained soils are rare. With increasing fire suppression, natural stands regenerated by wildfires are becoming increasingly scarce. Fires that do occur are much smaller than they were historically. In Michigan, serious efforts to control fires began in 1927. Prior to that the average size of fires was more than 125 ha, but this decreased to less than 6 ha in the 1940s. Consequently, the amount of habitat created by fire dwindled and many of the resulting pine stands were too small to support a warbler population. From 1961 to 1971, the amount of suitable habitat declined by 40% in Michigan. Once it was realized that habitat availability was a major limiting factor, jack pine stands in Michigan were managed specifically for the Kirtland's Warbler. This involves commercial logging, prescribed burns, and planting of plantations with habitat managed on a 50-year rotation. Approximately 76,000 ha

of habitat are managed for the Kirtland's Warbler in Michigan, with a goal of providing a minimum of 15,200 ha of suitable habitat at any given time. Military exercises at Petawawa create a mosaic of pine stands of differing ages. A lightning strike in 2012 caused a fire that consumed 200 ha, so this should provide suitable future habitat. Habitat may become unsuitable or lost due to stand fragmentation and conversion of jack pine stands to other more desirable species from a forestry perspective. Planting pines at unsuitable densities may make plantations uninhabitable (Bickerton et al. 2006; Marshall et al. 1998; Mayfield 1962, 1983, 1993; Probst 1986; Richard 2013; Walkinshaw 1983).

Habitat quality affects male pairing success. Probst and Hayes (1987) determined pairing success in suitable habitat, young marginal habitat, and open marginal habitat. Young marginal habitats were those that were adequately stocked but that had been used by Kirtland's Warblers for less than 3 years. Open marginal sites were unburned, poorly stocked areas. At 1 burn, 83.3% of males were mated where the trees were dense compared with 41.7% where the trees were more sparse. Male pairing success averaged 96.7% in suitable habitat and 59.1% in marginal habitat, with an overall average of 85%. Earlier slow recovery of the population may have been due in part to low pairing success. Males may not pair successfully in new colonies, old colonies, marginal habitat, and peripheral habitat. It is unknown to what extent polygyny in good habitat offsets low pairing rates in marginal habitat (Probst 1985, 1986; Probst and Hayes 1987). During earlier census years for this species, it was assumed that the sex ratio was equal and that all males were paired. This may have led to an overestimate of the population.

The rarity of suitable breeding habitat and the dispersal behaviour of juveniles continue to create an additional limiting factor. Returning juveniles often disperse to areas other than their natal site, thus decreasing the probability that they will find suitable habitat. Juvenile males that colonize new sites may not be successful in acquiring a mate. The reproductive potential of many juveniles is probably lost (Mayfield 1983; Morse 1989; Probst 1985, 1986).

Nests may rarely be flooded. This typically occurs only when there is extremely heavy rain and nests are in a depression where water accumulates. These nests are not used further even if they are undamaged (Mayfield 1960).

Predation is another significant limiting factor. As many as a third or more of nests are lost to predators. In Michigan, the Blue Jay may be a significant predator of nestlings. Nesting success tends to be higher where there are no hills or snags that offer vantage points for cowbirds and predators searching for nests. Nest success increased significantly where large trees and snags were present after cowbirds were removed. It has been recommended that new habitat be established in extensive flat regions free of large trees and snags. At 1 site, presence of a valley resulted in differential growth rates of pines on the tableland and in the valley. This extended the occupancy of the site by 4-6 years (Kashian and Barnes 2000; Probst 1986; Walkinshaw 1983).

If a nest site is examined by a human shortly after the female selects it, she may abandon it. Otherwise, the Kirtland's Warbler is very tolerant of moderate levels of disturbance. Some individuals will allow themselves to be picked off a branch or the nest, and they may land on humans (Berger and Radabaugh 1968; Bocetti et al. 2020; Van Tyne in Bent 1953; Walkinshaw 1983).

Habitat loss and degradation on the wintering grounds in the Bahamas does not appear to be an issue for the Kirtland's Warbler. Climate change in the wintering area has the potential to affect the size of the breeding population and reproductive success. Many climate models predict significant drying trends in the Caribbean. Numbers of breeding males in Michigan are strongly correlated with the amount of rainfall received in the Bahamas from November until April. Drought on the wintering grounds results in a scarcity of food and poorer physical condition of warblers, except for older males that may be able to defend territories that contain water. All males fledged significantly more young following Marches with more rainfall, with an average increase of 0.23 fledgling for every 1 cm increase in March rainfall. Adult male arrival on the breeding grounds was not related to March rainfall, but arrival of yearlings was delayed by 1.4 days for every centimetre reduction in March rainfall. A 10-day delay in arrival was associated with 0.74 fewer fledgling raised. Although adult males were in better condition than juvenile males and their arrival date was unaffected by winter precipitation, they also experienced reduced reproductive output following dry winters. This is likely because females arrived later and in poorer condition. They frequent the same winter habitats as juveniles (Mayfield 1983; Rockwell et al. 2012). As a result of projected climate changes in North America, Botkin et al. (1991) concluded that jack pine forests in central Michigan will soon be growing at a significantly slower rate than they have in the recent past. Consequently, these forests may become unsuitable for the Kirtland's Warbler within 30-60 years, suggesting that it may be subject to a greatly increased risk of extinction.

Status

The Kirtland's Warbler is one of the most critically endangered bird species in North America. Without active human intervention in the form of habitat management, it is likely that it would become extinct within a short period. Prior to European settlement, it was probably much more abundant and its range may have included Wisconsin and Ontario on the sandy outwash plains following the Wisconsin glaciations. Peak populations may have occurred about 500 years ago. Originally wildfires burned unchecked and there were no cowbirds within the breeding range. Within recorded history, peak populations occurred in the 1880 and 1890s. Around that time, 3 events occurred that greatly affected populations. In the 1870s, a fire burned 500,000 ha in the core of the breeding range, thereby creating extensive suitable habitat. Logging of virgin pine forests also occurred near the end of the 19th century. Both these events were beneficial but short term. The third event was that forest clearing created habitat for the Brown-headed Cowbird, and this was a permanent negative effect. During the late 19th and early 20th centuries, there were numerous reports of migrants and wintering birds in the Bahamas at a time when there were few observers using inferior optical equipment. By the mid-20th century when there were more observers with better equipment, it was rarely observed during migration and winter. The Kirtland's Warbler was first described in 1851 when a migrant was collected in Ohio, but the breeding grounds in Michigan were not found until 1903. The first breeding survey, which was more of a census since it is probable that most males were detected, was completed in Michigan in 1951. During this census, 432 males were discovered and in the next census, in 1961, there were 502 males present. The entire population was confined to 6 counties in a single watershed in the northern part of Michigan's Lower Peninsula. The 1971 census revealed that the population had dropped to 201 singing males with the entire global population within a circle 56 km in diameter. Cowbird control was initiated

the following year but populations remained stable for the first decade of control, with an average of 207 males per year (range 167-243). The first modest increase occurred in 1991 with 347 males recorded. The habitat management program was successful with 804 males in 1998. In 2007, nesting outside Michigan was finally confirmed in Wisconsin and Ontario. Populations continue to increase, with 1,828 singing males in 2011 and 2,014 in 2013 (Anich et al. 2011; Anonymous 1988, 2009a; Bickerton et al. 2006; Bocetti et al. 2020; Graber et al. 1983; Harlon 1995; James 1999d; Kelly and DeCapita 1982; Kirk and Pearce 2008; Marshall et al. 1998; Mayfield 1953, 1962, 1972, 1973, 1977b, 1993; Probst 1986; Richard 2013; Tozer 2012; Weinrich 1989).

There is a band of suitable breeding habitat across central Ontario bounded by Thessalon, Sault Ste. Marie, Chapleau, North Bay, and Petawawa. The Kirtland's Warbler may have nested historically in this area, but this was never confirmed. In 1919, it was fairly common over a large area in jack pines at Petawawa. Nesting was not confirmed at this time and no estimates of numbers were made. At the same site in 1939, only single birds were noted on 2 occasions. The first reported breeding record was from the Barrie area when adults were found feeding a juvenile during August. Although the identification of the adults was accepted by the Ontario Bird Records Committee, the identity of the juvenile was uncertain. It was noted that the bill was quite stout for that of a warbler's and it may have been a cowbird. The Natural Heritage Information Centre did not accept this breeding record, considering it ambiguous and unverified. Until breeding was finally confirmed at Petawawa, the Kirtland's Warbler was officially considered a hypothetical breeder in the province. As of 1999, there were only 8 other subsequent records for it during the breeding season: the Bruce Peninsula in 1958 and 1990, Point au Basil in 1961, Barrie in 1964, Petawawa in 1977 and 1978, Orillia in 1985, and near Thessalon in 1997. Later targeted surveys were completed near Thessalon, Sault Ste. Marie, and Chapleau and these were all negative. After finding the singing male near Orillia, suitable habitat was searched near Orillia, the Chapleau-Cartier area, the Bruce Peninsula, and Manitoulin Island and these surveys were also negative. Searches at Petawawa were negative in 2002 and 2004, but 2 singing males were found there in 2007. The first Ontario nest was found at Petawawa on 28 June 2007. The population at Petawawa appears to be stable, with 2 or 3 males documented each year from 2006 to 2013, except in 2012 when 4 males were present. At least 27 fledglings had been produced by the end of the 2013 breeding season, but some may have been overlooked (Austen et al. 1994; Bickerton et al. 2006; Bowman and Chamberlain 1980; Chamberlain 1978; James 1999d; Kirk and Pearce 2008; Natural Heritage Information Centre 2008; Richard 2008, 2013; Speirs 1984). In 2012, Holmes et al. (2015) deployed song meters at 38 locations in central Ontario in potentially suitable habitat. In 1,631 hours of recording, they documented 66 Kirtland's Warbler songs on a single day at 1 site in eastern Algoma District. It was in a 20.4-ha stand that was 6 years old with 80% jack pine and 20% red pine coverage. Because it was detected on only 1 of 28 dates of surveying at this site, the authors suggested that either the recording location was outside the core range of a territorial bird or that it was prospecting for a mate, but was unsuccessful and moved to another location. The latter explanation seems more likely.

The Kirtland's Warbler was designated endangered in Ontario in 1971 and in Canada in 1979. Recovery of the species in Ontario is considered feasible, but this is dependent upon dispersal from Michigan. If the Michigan population continues to grow, the Ontario population may either remain stable or increase slightly, provided that suitable habitat is maintained. If the Michigan population

declines, the Ontario population may not be able to sustain itself (Bickerton et al. 2006; Chamberlain 1978; James 1999d).

The prognosis for the Kirtland's Warbler currently looks promising. It was delisted from the United States Endangered Species Act in 2019. The goal of the United States conservation plan was to eventually reach 1,000 nesting pairs per year. That goal has been surpassed with approximately 2,000 pairs present in 2020. The population has expanded from the Lower Peninsula of Michigan to the Upper Peninsula, Wisconsin, and Ontario (Anonymous 2019). In Ontario, a 42-ha site in Simcoe County is being established as a pine-oak forest specifically to create and manage habitat for the Kirtland's Warbler. In 2018, more than 100 km^2 of jack pine rock barrens was burned by Parry Sound Fire 33 and this area has high potential to provide suitable habitat for the Kirtland's Warbler (Burke 2020). In 2022, males were documented in Simcoe County, but no females were present. Tuininga and Burke (2023) concluded that the Ontario population had likely been approximately 20 pairs for the last decade. Several birds and a nest were found in the Sudbury area in 2024.

POSTFLEDGING PERIOD

Young fledged from an Ontario nest on 2 July. Fledglings may be fed by adults until they are 26-44 days old, but start obtaining their own food when they are 23 days old. At this time, they are almost as proficient at flight as adults. Adults have been seen feeding young as late as mid-August, but these may be second broods (Bocetti et al. 2020; Richard 2008).

As soon as young fledge, they immediately flutter to concealment in ground cover. At first, they can fly only 2-3 m but can fly 10-20 m within a week. During this time, fledglings sit for long periods of time under ground cover or on a low twig in a pine thicket. By the second day, fledglings may have moved 100-200 m from the nest but remain in undergrowth and low branches for about 2 weeks. During this period, they remain in an area not much larger than the original territory, but not identical with it. Brood division occurs, with each adult caring exclusively for half the brood. The 2 sub-broods move about separately but remain in close association with each other. If a second brood is started, the female may initiate the second nest while feeding the first brood. Once incubation of the second clutch begins, the male takes charge of the entire first brood. In late summer, family groups tend to concentrate in a few areas, leaving the remainder of the breeding habitat devoid of warblers. Fledglings chose perches close to one another for sleeping until they are about 9 months old then chose isolated perches (Anich et al. 2011; Anonymous 1988; Bocetti et al. 2020; Mayfield 1960; Walkinshaw 1983).

Most observations of fledglings have been in breeding habitat and young may remain in the natal area until autumn migration (Anich et al. 2011; Bocetti et al. 2020). Bocetti (1993) reported an exception after finding a juvenile in Michigan 4.8 km from the nearest occupied breeding area. It was in a second-growth mixed forest surrounded by mature coniferous forest. The canopy was dominated by black cherry, trembling aspen, Hill's oak, and jack pine. Canopy closure was 70% with openings patchily distributed; average tree height was 4.5 m (range 2-6 m). The ground was completely covered with vegetation, predominantly by little bluestem and sweet fern, with some areas of lowbush blueberry, snowberry, and Pennsylvania sedge. In Wisconsin, fledglings used areas with lower foliage-height diversity and bare ground and greater herbaceous vegetation height than unoccupied areas. The probability of fledgling use increased from 24% to 75% when vegetation

height increased from 0 to 52 cm. Probability of use decreased from 74% to 0.5% as foliage-height diversity increased from 0 to 3.24. All fledgling locations had bare ground coverage of 50% or greater. The probability of fledgling use increased from 37% to 49% when bare ground coverage changed from 0 to 1-50% cover (Olah et al. 2023).

Sixty percent of nonbreeders and 11% of breeders made long-distance movements after the nestling and fledgling periods. Both breeders and nonbreeders made an average of 3 movements (1-7 for breeders and 1-13 for nonbreeders). Mean distances moved were 59 km for breeders (range 10-183 km) and 65 km for nonbreeders (range 5-166 km). The mean distance moved by all birds was 63 km (Cooper and Marra 2020).

Fledgling survival rates in Wisconsin red pine plantations were much lower than for fledglings in young jack pine forests in Michigan. Populations breeding in red pine plantations with low pine densities may be sinks. These plantations may be suitable for breeding but have low fledgling survival rates (Olah et al. 2023).

MIGRATION

Migration is presumably nocturnal and birds move solitarily or occasionally in the company of other warblers. Cooper et al. (2017) used geolocators to determine the wintering areas, migration routes, and stopover locations of Kirtland's Warblers breeding in Michigan. Almost all tracked males wintered in the Caribbean, mostly in the central Bahamas but also in eastern and western Bahamas. One male wintered in Cuba. After leaving the breeding grounds in an easterly direction, 25 of 27 males (92.6%) stopped over in southern Ontario or the northwestern mid-Atlantic states. Most stopped again on the coastline of either North or South Carolina prior to initiating over-water migration. During spring migration, males spent an average of 58% of their time at 1-5 stopover sites. Most used 3 main stopovers. Most (74%) made a stopover of an average of 4.8 days shortly after making landfall in Florida. The remaining birds travelled further north before their first stopover. Ninety-six percent of males spent 1.5-14.5 days (mean 4.7 days) in northern Florida, southeastern Georgia, or southwestern South Carolina before crossing the Appalachians. Southwestern Ontario and the region directly to the south also appeared to be important, with 33% of males spending 1-3.5 days (mean 2.2 days) there before reaching Michigan. Cooper et al. (2018) banded 220 Kirtland's Warblers at a site in the central Bahamas. They resighted 56 of these (25.5%) on the breeding grounds: 87.5% in the Lower Peninsula of Michigan, 7.1% in the Upper Peninsula of Michigan, 3.6% in Wisconsin, and 1.8% in Ontario. Loss of wintering habitat at a single location could have a diffuse effect across the entire breeding population.

Adult males arrive at the breeding grounds before juvenile males and females. The earliest record at Petawawa is 9 May. In Michigan, males arrive from 2 May to 5 June (mean 14.6 May). First arrivals of males usually occur 2-7 May. Females do not arrive until after 18 May. Some males arrive at new locations as late as 23 June. These birds may have abandoned territories established earlier elsewhere, or they may be late-arriving yearlings (Anonymous 1988; Berger and Radabaugh 1968; Bocetti et al. 2020; Ewert et al. 2012; Probst 1985; Richard 2013; Rockwell et al. 2012; Walkinshaw 1983).

By August, the first Kirtland's Warblers have returned to the wintering grounds. On the Michigan breeding grounds, there is a significant decline in both age classes from late August to late

September, with significantly greater declines for juveniles than adults. Juveniles comprised 49% of all birds captured during the postbreeding period. They represented 60% of birds netted 16-31 August, 42% 1-15 September, and 0% 16-30 September. A substantial portion of the population remained on the breeding grounds at least through September, but a few birds remain during the first half of October. Juveniles leave earlier than adults. They complete their moult by the end of August but the moult for adults extends through September (Sykes et al. 1989). The latest observation at Petawawa was 4 August (Richard 2014).

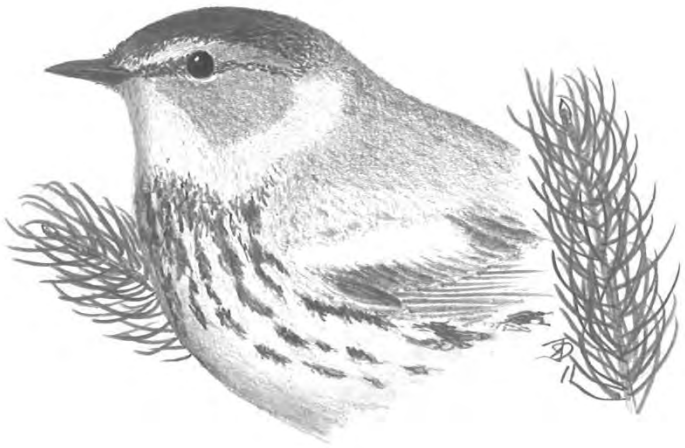
In Pennsylvania, an autumn migrant was captured in an old field with dense coverage by hawthorn and crabapple. It was recaptured twice in the same year in the same 45-m stretch of net despite being released 250 m and 850 m from this area. It appeared to prefer this habitat type over willow thickets bordering a pond, old fields in varying stages of succession, and second-growth forest. This bird remained at the same location for a minimum of 11 days. In 2 other years, single Kirtland's Warblers were observed at this site foraging in birches on abandoned strip-mine spoil. Migration habitat is dissimilar to breeding habitat and consists of low deciduous scrub in open situations (Bocetti et al. 2020; Clench 1973).

During migration, the Kirtland's Warbler has collided with windows and lighthouses (Walkinshaw 1983).

The Kirtland's Warbler is a rare migrant in Ontario. The first Ontario record was from Toronto in May 1900. With the population increase in Michigan, there has been an increase in the number of migrants observed in Ontario since 1990. There is now an average of just over 1 sighting per year, predominantly in May. From 1900 to 2005, there were a total of 47 spring and 7 autumn records (Austen et al. 1994; James 1999d; Kirk and Pearce 2008; Richard 2013).

Cape May Warbler

Setophaga tigrina



BREEDING SEASON

Habitat Requirements

Ontario Cape May Warbler nests were found in white spruce forests and second-growth mixed forests of birch and spruce (Peck and James 1987). In Ontario, it prefers mature coniferous and mixed forests. Although it occasionally inhabits dense woods, it prefers open forests and forest edges and openings. Conifers at least 10 m tall are an important habitat component. It is typically associated with white spruce and/or balsam fir and with black spruce to a lesser extent. It is one of the spruce budworm specialists, typically increasing as budworm populations increase. When budworms are absent or scarce, large tracts of suitable habitat are unoccupied, but it uses marginal habitat when budworms are abundant. At Manitouwadge, it was not observed in young (1-21 years) or intermediate-aged (24-36 years) stands when budworms were scarce and was restricted to stands 60-223 years old. When budworms became abundant, it occupied all age classes of forest. Near Quetico Park, it was found only in stands 112-176 years old. Near Hearst, it occurred in uncut upland mixed and lowland coniferous stands, and in clear-cuts in these forest types 17-24 years old. In Algonquin Park white pine stands, it was absent to rare in clear-cuts 10-16 years old and was absent

in younger cuts. North of Lake Nipigon, it preferred white or black spruce stands with trees as tall as 30 or more metres, with balsam fir in the canopy and grey alder, Labrador tea, and raspberries in the shrub layer. In the Clay Belt, it was most common, in decreasing order of abundance, in stands dominated by trembling aspen, trembling aspen mixed with conifers, trembling aspen–balsam poplar, white spruce–balsam fir, black spruce–trembling aspen, black spruce, and jack pine. It occurred in both wet and dry stands and those that were moderate to rich in nutrients. It appears to nest only in spruce and balsam fir, so it is associated with these species even in stands dominated by deciduous trees. Along the James Bay coast in 1978, the Cape May Warbler occurred exclusively in mature coniferous stands (Apfelbaum and Haney 1999; James 1984b; Kendeigh 1947; Kingsley and Nol 1999; Tozer 2012; Vanderwel et al. 2009; Venier et al. 2008; Welsh in Cadman et al. 1987; Welsh and Fillman 1980; Welsh and Lougheed 1996).

The Cape May Warbler is one of only 14 passerines whose breeding range is confined or nearly restricted to boreal conifer forests, although its Ontario range includes the northern portion of the Great Lakes–St. Lawrence Forest Region. It is regular in spruce forests only in the presence of spruce budworms, and also occurs in mature spruce–balsam fir stands. The stands it uses may include a mix of intolerant hardwood species such as trembling aspen, balsam poplar, white birch, and yellow birch. In most cases, it is restricted to intermediate-aged, mature, and old-growth stands dominated by spruce and balsam fir, but may use younger stands when budworms are abundant. It prefers spruce stands where trees are a minimum of 10 m tall with well-developed crowns and some supercanopy trees that provide song perches. Sites it uses tend to have an open understorey comprised of low shrubs. It prefers large isolated white spruce for nesting, but it is also attracted to open stands. In dense stands, it is associated with edges or small openings. The Cape May Warbler tends to occur more frequently on drier sites. Wet sites are dominated by black spruce which is seldom attacked by the spruce budworm. In addition to spruce and spruce–balsam fir stands, it has nested in black spruce bogs, 50-year-old white spruce plantations with sparse understorey and 2.4 m between trees, in mature balsam fir–white cedar stands, and occasionally in recent clear-cuts. In spruce–balsam fir stands in Maine, it occurred only in mature forests and clear-cuts 1-2 years old dominated by dense slash coverage and considerable bare ground. In Quebec, it was equally abundant in riparian and nonriparian stands of mature balsam fir–white cedar. In the northeast, it was in a guild of species that was most common in mature coniferous lowland forests. In the western Canadian boreal forest, it was in a guild of birds associated predominantly with coniferous

species. In Quebec, its breeding distribution corresponds closely with the distribution of the spruce budworm. In the Boreal Forest Region of Saskatchewan, it was significantly more abundant in white spruce stands within contiguous forest than in fragmented forests. In fragmented landscapes, it was more common than expected by chance in mature white spruce stands that were larger but isolated (Baltz and Latta 2020; Bent 1953; Campbell et al. 2001; Chapman 1907; Crawford and Titterington 1979; Dawson 1979; Erskine 1977; Hobson and Bayne 2000; Kirk et al. 1996; Lamoue and Morrier in Gauthier and Aubry 1996; LaRue et al. 1994; Morse 1978; Niemi and Pfannmuller 1979; Sinclair et al. 2003; Temple et al. 1979; Titterington et al. 1979).

Peck and James (1987) described 5 Ontario nests, although a few more have been found subsequently. All were near the top of either white or black spruce and placed against the trunk or as far as 5 cm from it. Nests were 0.3-0.75 m from the top of nest trees at heights of 7.6-15 m.

Few nests of the Cape May Warbler have been described. Nests are very difficult to find because of their position and the female's behaviour when returning to the nest. Nests are in dense vegetation very close to the top of a conifer and cannot be detected from the ground. One nest was so well hidden that the researcher could not see it even when he was even with it in the tree, and only found it by feeling for it in the dense vegetation with his hand. When the female returns to the nest, she lands low in the tree and hops branch to branch in the interior of the tree to reach the nest. Consequently, she is very difficult to detect. All nests were 0.6-1.8 m from the top of a conifer, usually spruce (white, black, or red) but occasionally balsam fir. Most nest trees are in the open, at least on 1 side. Nests tend to be at the trunk or as far as 23 cm from it. Most nests are affixed to a branch with insect silk but one was simply sitting on a branch. Nests have been found 10.7-18.3 m from the ground (Baltz and Latta 2020; Bent 1953; Philipp and Bowdish 1919).

Kendeigh (1947) mapped Cape May Warbler territories north of Lake Nipigon during a spruce budworm outbreak when warblers were present at a supersaturated level. The average size of 22 territories was 0.4 ha (range 0.16-0.97 ha). These were based on few observations, so territories may have been larger. Most territories were isolated or barely touched each other and some contained considerable amounts of grey alder swamp. There appear to be no other estimates of territory size, but others have noted that territories mostly do not adjoin each other. Territory size may be determined by food availability, with larger territories prevalent when food resources are low (MacArthur 1958; Morse 1978).

No information is available on natal philopatry (Baltz and Latta 2020). In the Gaspé Peninsula of Québec, 1 of 28 adults (3.6%) returned to the site where it was banded (Moisan Perrier et al. 2020).

Limiting Factors

Peck and James (1987) concluded that nests with eggs could occur in Ontario throughout June. In Algonquin Park, dependent fledglings have been seen from late June to mid-July (Tozer 2012). No information is available on how long it takes to build the nest, if time elapses between nest completion and initiation of egg laying, rate of egg laying (although it is probably 1 per day), when incubation is initiated and how long it takes, the nestling period, or how long fledglings are dependent upon the adults (Baltz and Latta 2020; Bent 1953).

It is likely that a single brood is raised in a season, but this has not been confirmed. It is unknown if replacement clutches are laid if the first one is lost. One Ontario nest contained 6 eggs and another held 4 young. The Cape May Warbler, along with the other budworm specialist warblers, lays the largest clutch of the warblers. The clutch size ranges from 4 to 9 eggs. Six eggs is the most frequent clutch size and the average across its breeding range is 5.8 eggs. It has been assumed that clutch size increases during spruce budworm outbreaks resulting in an increase in population, and that smaller clutches are laid when budworms are scarce, resulting in a declining population. These relationships have never been positively confirmed (Baltz and Latta 2020; Bent 1953; MacArthur 1958; McCracken 2004; Peck and James 1987; Philipp and Bowdish 1919).

The mating system is probably monogamous, but this has not been studied. It is likely that both sexes are capable of breeding when they are 1 year old. Removal studies demonstrated that there is a large floating population suggesting that some individuals may delay breeding until they are older (Baltz and Latta 2020; Hensley and Cope 1950).

Kendeigh (1947) observed the Cape May Warbler's foraging strategies north of Lake Nipigon. Feeding was done at the same levels where males sang, typically within 2.1 m of the top of a conifer. The average height of song perches and male feeding areas was 10.7 m (range 2.7-16.8 m). One male sang from the top of a 16.8-m dead tree but all other observations were of birds in live conifers. It occasionally flew out to capture an insect in the manner of flycatchers. In the Boreal Forest Region of Ontario, 95% of foraging occurred in conifers, 79.0% occurred in foliage, 17.6% of attacks were aerial and 3.4% were by hanging; average foraging height was 15.3 m (Greenberg et al. 1999). There are 5 warbler species that coexist in homogeneous mature boreal forests: Cape May, Yellow-rumped, Black-throated Green, Blackburnian, and Bay-breasted warblers. These species are very similar in their ecological preferences, suggesting that they have different microhabitat requirements. The Cape May Warbler forages more consistently near the top of trees than any other species except the Blackburnian Warbler, from which it differs principally in the type of feeding action. The Cape May Warbler not only hawks more than the Blackburnian Warbler but moves vertically rather than radially in trees, causing its feeding zone to be more restricted to the outer shell of the trees. Of observations of feeding Cape May Warblers, 43.8% were in the terminal zone of new needles and buds in the top 3 m of the trees, 21.3% were in the terminal zone in the next lowest 3 m, 13.8% were in the middle zone of old needles in the top 3 m, 11.2% were in the middle zone 3-6 m from the top, and 6.2% were in the middle and terminal zones 6-9 m from the top. No birds foraged in the lower 6 m of trees. During windy, rainy, and cold days, it did not occur at the top of conifers and instead foraged in low willows and among flowers of pin cherries. The Cape May Warbler has a noticeably different bill than the other 4 species, being more slender, especially near the tip. In addition, it has a semitubular tongue that is unique to warblers. It may occasionally forage on the ground and often forages from the undersurface of fir needles. In Maine, approximately 77% of foraging occurred on outer limbs, 12% at tips of branches, 10% on inner limbs, and 9% on dead limbs and in deciduous species. Fifty percent of foraging occurred at heights of 15-18 m, 30% at 18-21 m, 11% at 21-24 m, 5% at 12-15 m, 2% each at 9-12 m and 6-9 m, and 0 below 6 m. Almost all foraging was by gleaning with only 2 observations of hawking. It foraged 71.2% of the time in red spruce, significantly more than the 52.0% of time spent in this species by the Bay-breasted Warbler (Baltz and Latta 2020; Campbell et al. 2001; MacArthur 1958; Morse 1978, 1989).

During a spruce budworm outbreak north of Lake Nipigon, the stomach of 1 male contained 60 spiders, 25 aphids and 15 beetles (Kendeigh 1947). Near Longlac during a budworm outbreak, McMartin et al. (2002) quantified the diet of the Cape May Warbler and compared it with that of the other 2 budworm specialists (Tennessee Warbler, Bay-breasted Warbler). The diet was examined during 2 periods: 7-11 June and 18-24 June. During the early period, only small instars of budworms were available and these are seldom eaten by birds. In the later period, large larvae and pupae of budworms were present. The diet of the Cape May Warbler during the early period consisted of 52.7% adult beetles, 18.9% flies, 17.6% caterpillars, 8.1% other invertebrates, and 2.7% spiders. Other invertebrates included soft-winged bugs, hymenopteran adults and larvae, true bugs, beetle larvae, snails, odonates, caddisflies, and neuropterans. The late-season diet consisted of 79.1% caterpillars, 8.8% adult beetles, 5.5% spiders, 4.4% flies, and 2.2% others. The food-niche breadth of the Cape May Warbler declined by two thirds from the early to the late period. The 3 warblers differed significantly in their consumption of beetles and caterpillars early in the season. At that time, the Bay-breasted Warbler ate more beetles, the Cape May Warbler ate more flies, and the Tennessee Warbler ate more caterpillars than the other species. Later in the season, the only difference in diets was that the Bay-breasted Warbler continued to eat more beetles than the other 2 warblers. All 3 warblers fed on budworms in the later sampling period and these were so abundant that there was no competition for food resources. Twenty-four Cape May Warbler stomachs collected during a moderate budworm outbreak in Maine averaged 48% and 39% budworm larvae and pupae by volume in 2 years (Baltz and Latta 2020; Mitchell 1952). Crawford and Jennings (1989) examined predation on the spruce budworm by the Cape May Warbler in New Hampshire and Maine. Large larvae and pupae of budworms were available to birds from 11 June to 21 July. An average of 5.7 budworms was found in stomachs, second highest to the Purple Finch. The 4 species that ate the most budworms were Blackburnian Warbler, Cape May Warbler, Bay-breasted Warbler, and Magnolia Warbler, but they exhibited only a weak feeding response to increasing numbers of budworms. Although not confirmed, the authors expected that nestling consumption of budworm larvae and pupae would equal or exceed adult consumption. High densities of budworms far exceeded the food requirements of all of the woodland birds that were present. It was estimated that birds consumed only 22% of the budworms.

Food availability appears to be the main limiting factor to Cape May Warbler populations. It depends upon occasional outbreaks of superabundant food, such as the spruce budworm, for its continued existence. It may immigrate to areas experiencing outbreaks and is a good example of a fugitive species. Between outbreaks, it suffers reductions in numbers and may experience local extirpations. North of Lake Nipigon, densities approached 100 pairs per km^2 during a budworm outbreak but it was absent in the same location 2 decades later when budworms were scarce. Near Manitouwadge, numbers of Cape May Warblers increased by 10.4-fold over a 4-year period during a budworm outbreak. It was initially 35th in abundance of the bird species present, but increased to 10th as budworm populations increased. These results confirmed that the Cape May Warbler is a budworm specialist, so that factors that affect budworm populations may have an impact on it. These may include climate change, changing forest species composition due to forestry, forest fire suppression, and use of insecticides such as Bt. Most other studies have found a positive response to budworm populations, but 2 in New Brunswick and Maine did not. This may have been because

warbler populations increased gradually over several years (Baltz and Latta 2020; Crawford and Jennings 1989; Kendeigh 1947; MacArthur 1958; Morris et al. 1958; Sanders 1970; Venier et al. 2009).

The Cape May Warbler is a rare host of the Brown-headed Cowbird. There are few locations where the distribution of the 2 species overlaps. In addition, the warbler nests in habitat that is rarely visited by cowbirds. There are no records of cowbird parasitism in Ontario, but few warbler nests have been found. In British Columbia, there is 1 record of an adult warbler feeding a fledgling cowbird (Baltz and Latta 2020; Campbell et al. 2001; Peck and James 1987).

The effects of spraying for spruce budworms are uncertain. In 1975, 2.7 million ha were sprayed in New Brunswick and 4 million ha were sprayed the following year with similar coverage in Quebec. In 1975, it was estimated that there were several million bird casualties due to spraying, primarily from exposure to phosphamidon. In 1977, aminocarb was used solely and there was no convincing evidence of spray effects on songbird populations. More recently, Bt is used, which attacks only lepidopteran caterpillars. Modifications to spruce budworm spraying programs appear to have reduced mortality, although studies are limited. In some areas, Cape May Warbler populations have stabilized over several decades because budworm control programs keep budworm numbers at low to medium levels over long periods of time (Baltz and Latta 2020; Morse 1989).

Repeated fires and logging may limit the Cape May Warbler by preventing development of the mature forests required both by the warbler and budworms. Effects of partial timber harvesting are uncertain and have not been extensively studied. Based upon the results of several studies in the Boreal Forest Region, with particular emphasis on Ontario, it appeared to increase when 30%, 50%, or 70% of trees were removed from a stand. The reliability of these data was low. In Alberta, no effect was noticed on the Cape May Warbler as a result of partial harvest. In British Columbia, it often inhabits stands where only the largest spruces have been removed. Creating openings in dense stands is probably beneficial but excessive thinning that promotes growth of deciduous trees and shrubs may be detrimental (Baltz and Latta 2020; Campbell et al. 2001; Harrison et al. 2005; Vanderwel et al. 2009). In the Canadian Shield of Ontario, there was no difference in its abundance in early successional and mid-successional clear-cuts compared with burns in the same seral stages. It was equally abundant in early successional, mid-successional, and mature stands (Zimmerling et al. 2017).

In Alberta, there were no significant differences in the abundance of the Cape May Warbler at seismic lines, pipelines, well pads, or in forest interior adjacent to these features (Bayne et al. 2017).

DesGranges and LeBlanc (2012) determined that the Cape May Warbler was found mostly in warmer microclimates in the Boreal Forest Region of central Quebec and Labrador. Warblers in this area may benefit from climate change. This study was conducted near the northern extent of the warbler's range. Studies conducted further south may have differing results.

Status

The Cape May Warbler appears to have been rare in Ontario and throughout its range in the late 19th century. McIlwraith (1894) considered it very rare and had only 6 records of migrants from the Hamilton area. In the Toronto area, there were only 4 records of migrants from 1889 to 1897. An increase began in 1898 and in 1900 they were fairly common in the city during migration (Fleming

1907). Although these early records were only of migrants, they give a general picture of the breeding status of the species. Baillie and Harrington (1937) considered it a very rare summer resident between the Bruce Peninsula and James Bay west to Lac Seul, but noted that it was a fairly common breeder in Sudbury District. Baillie and Hope (1947) reported that the only known nesting locations were Sudbury District, Moosonee, Lac Seul, and Dorcas Bay on the Bruce Peninsula. James (1984b) reported that it probably bred north to Sandy Lake and Moosonee south to the tip of the Bruce Peninsula and Algonquin Park. Tozer (2012) summarized trends in populations in Algonquin Park, and these are probably indicative of province-wide populations. It was first observed in the park in 1921, became common as a breeder and migrant in the 1940s, was uncommon in the 1960s, and common again in the 1970s. Since the 1990s, numbers of migrants and breeders have been low. The first atlas extended the known range slightly northward to Sachigo Lake and a bit north of Moosonee. Its range probably included all the Boreal Forest Region. It was not reported in some northern blocks where it was likely present but overlooked. In the south, it nested on Manitoulin Island, the Bruce Peninsula, throughout Algonquin Park, and a bit south of the park (Welsh in Cadman et al. 1987). James (1991) considered the Cape May Warbler a locally common breeder north to Big Trout Lake and Moosonee, south to the Algonquin Park area. He considered it occasional and rare on Manitoulin Island and the Bruce Peninsula.

The second atlas indicated few changes in the range of the Cape May Warbler. It occurred in a few squares in the Hudson Bay Lowland north to the Sachigo River and Swan River. It continued to be concentrated in the Boreal Forest Region where it was apparently absent in some squares. In the south, it nested to the southern edge of the Canadian Shield, although sparingly. South of the Shield, it was confirmed breeding east of Ottawa, but was not detected on the Bruce Peninsula and it apparently disappeared from many squares on Manitoulin Island. There was no change in its overall probability of observation between the 2 atlases. A significant decline occurred in the Great Lakes–St. Lawrence Forest Region in the Canadian Shield. This was due to its disappearance from many squares in Algonquin Park and in the Sudbury area. Budworms were about twice as common in Algonquin Park during the first atlas compared with the second atlas, and this probably had a direct effect on its local abundance. It was not particularly common anywhere despite its broad distribution. It was most common in the northern Boreal Forest Region. There was little spruce budworm activity in Ontario during the second atlas, so the densities and distribution recorded represent baseline population data. Highest abundance areas for the Cape May Warbler did not correspond to those for the Tennessee, Bay-breasted, or Blackburnian warblers, suggesting that the observed densities were not linked to budworm outbreaks (McLaren in Cadman et al. 2007).

The Cape May Warbler was universally rare in the 19th century, but experienced a marked increase early in the 20th century. In Ontario, the first signs of increase occurred in 1898. It did not become common in New England until 1909, but it was among the most common species in Maine by the late 1940s (Bent 1953; Fleming 1907; MacArthur 1958). McCracken (2004) compared the abundance of migrating Cape May Warblers at Long Point Bird Observatory (LPBO) with the timing of spruce budworm outbreaks in the province. No budworm outbreaks of any consequence occurred during the 1960s, but massive outbreaks began in the 1970s, peaking in 1980. Infestations fell off dramatically after that except for 2 resurgences in the mid-1980s and early 1990s. In 1980, approximately 19,000,000 ha of forests were affected by budworms compared with 131,000 ha in

2002, similar to the 1960s levels. Banding of Cape May Warblers at LPBO closely tracked the extent of insect infestations in boreal Ontario. Peak populations of the 3 primary budworm warblers combined occurred in 1977, with an index value of 4.7. Numbers dropped to an index level of 1.4 in 2002, a level slightly below the prebudworm era of the 1960s. For North America, Breeding Bird Survey (BBS) results indicated an annual increase of 3.1% 1966-91, but a decrease of 9.4% 1982-91 (Baltz and Latta 2020). BBS results indicate that the Cape May Warbler increased at annual rates of 2.39% in Canada and 0.637% in Ontario 1970-2022 and 7.58% in Canada and 3.02% in Ontario 2012-22 (A.C. Smith et al. 2023).

MIGRATION

Judging by kills at tall structures, the Cape May Warbler appears to be a nocturnal migrant (Baltz and Latta 2020).

Males arrive before females in spring, and the duration of spring migration is shorter than in the autumn. At Long Point, mean capture dates for males were 12.7 May for adults, 14.6 May for yearlings, and 13.1 May for males of undetermined age. For females, average arrival dates were 16 May for adults, 17.5 May for yearlings, and 19.3 May for those of undetermined age. Differences in timing between age classes were significant for males but not for females. In southern and central Ontario, migrants begin to arrive in the first week of May or rarely, the last week of April, and almost have passed through by the end of May (Baltz and Latta 2020; Black and Roy 2010; Curry 2006; Fleming 1907; Francis and Cooke 1986; Keast 1980; LaForest 1993; Lancaster et al. 2004; Mills 1981; Stewart et al. 2002; Tozer 2012; Weir 2008). North of Lake Nipigon, it was first observed on 24 May (Kendeigh 1947). A bird observed at Shagamu on 2 June was probably a spring overshoot because this is well north of the known breeding range (Wilson and McRae 1993).

Autumn migration may begin in late July after nesting is complete, but more typically in late August, and most birds have left the breeding grounds by late September. The sexes may travel together and older birds tend to migrate earlier than juveniles, although there were no differences in timing of migration of the age classes in Virginia (Baltz and Latta 2020; Campbell et al. 2001; Stewart 1986). Wilson and McRae (1993) observed an autumn migrant at Moosonee on 2 September. Autumn records in the southern Shield are from early August to late September, with birds rarely remaining into the second week of October. Peak autumn passage is from mid-August until the end of the third week of September (Mills 1981; Tozer 2012). Lawrence (1950) observed one at her feeder at Pimisi Bay on 23 November 1949. Although this was autumn according to the calendar, there were 25 cm of snow on the ground and the low temperature was –23°C. It travelled with a flock of chickadees and appeared to be in excellent health until a Northern Shrike killed it 4 days later. Six years previously, one was seen in Weston on 3 December. In southern Ontario, average arrival is in mid-August and average departure is late September. Birds may arrive as early as mid-July and remain until mid-October, with rare records into early December (Black and Roy 2010; Curry 2006; Keast 1980; Lancaster et al. 2004; Weir 2008).

During migration, the Cape May Warbler frequents coniferous and mixed forests and often forages in nearby shrubs. These habitats become scarce once it travels south of the Canadian Shield. South of the Shield, it may still seek conifers in mixed woods and anthropogenic areas such as residential plantings, university campuses, golf courses, tree nurseries, and plantations. Presence of

conifers is not essential during migration, and they become increasingly rare further south. It may frequent deciduous woodlands, flowering shade and fruit trees, overgrown fencerows, weedy roadsides, orchards, suburban parks and residential areas, riparian vegetation, bottomland forests, and weedy patches in fields and dried lake beds. In Maine, it is common on treeless coastal islands where it forages in the grass. It has been observed along drainage ditches and the high-tide line on the Atlantic coast. In Indiana, it often occurs in drier woodlands such as those dominated by oaks. In spring in Illinois, it was most abundant in mature upland forests, but also occurred in forest edges and shrubs. In autumn, it is most abundant in forest edges and shrubs followed by mature bottomland forests and pastures. During autumn migration in Pennsylvania, there were no differences in its abundance in forest interior, forest edges, forest-agricultural edges, suburban forests, pole-stage forests, or shrub-sapling-stage forests (Baltz and Latta 2020; Bohlen and Oehmke 1993; Campbell et al. 2001; Chapman 1907; Dawn 1957; Graber et al. 1983; Leighton et al. 2002; Morse 1989; Rodewald and Brittingham 2002; Sealy 1988).

The Cape May Warbler frequently forages in mixed-species flocks of warblers during migration (Baltz and Latta 2020; Tozer 2012), but it also forages solitarily in territories that it defends from other Cape May Warblers and other species. It has been observed expelling the Ruby-throated Hummingbird, Yellow-bellied Sapsucker, Least Flycatcher, Philadelphia Vireo, Swainson's Thrush, Northern House Wren, Northern Waterthrush, Tennessee Warbler, Orange-crowned Warbler, Black-and-white Warbler, Yellow Warbler, Yellow-rumped Warbler, Common Yellowthroat, American Redstart, Blackpoll Warbler, Palm Warbler, and Black-throated Blue Warbler. It defends territories only when food resources are scarce, such as during inclement weather or extreme drought conditions. At other times, it forages with other species and other Cape May Warblers without aggression. In peach-leaved willow forest in Manitoba, these warblers were spaced 1.5-2 m apart in tree crowns and individual birds remained in the same territory for about 2 days. In 1 tree, 2 warblers each defended territories of 3 m^2 on opposite sides of the tree. They appeared to be feeding on the nectar of the willows. During a storm in another spring in Manitoba, warblers defended fixed territories about 8 m long along a water-filled ditch. Some held their territories as long as 4 days until the weather improved. Birds walked the shoreline and perched on bent-over and floating branches to access prey on the surface of the water. During autumn migration in Illinois, 1 defended an area 3-7.6 m above ground in the lower branches of a black maple and held this territory for at least 15 days. During spring migration in Florida, a male defended flowers on a plant and chased all birds that approached it, although it ignored birds in a pine a few feet away and the leaves of the same plant. Territorial birds most often defend flowers and other nectar sources, but may also defend unusually abundant prey in an area where food is otherwise scarce, and occasionally unusual prey is defended. The Illinois territorial birds were defending portions of trees that were heavily infested with aphids. This was during a drought and food was very scarce away from the infested trees. The birds that defended territories along a ditch in Manitoba foraged on springtails, an apparently rare prey item. During the storm when these territories were defended, it is unlikely that traditional insect prey were available (Bohlen and Oehmke 1993; Kale 1967; Sealy 1988, 1989).

During migration, foraging typically occurs in the upper, outer canopy of trees. In spring in North Carolina, 71.4% of foraging was in the canopy and the Cape May Warbler foraged higher than any other warbler species; 28.6% of foraging occurred in low trees and none occurred in shrubs or on

the ground. In the canopy, 14.3% of foraging occurred at the top of the crown and 57.1% was in the inner crown. In low trees, 14.3% of foraging was at the top of the crown and 14.3% was in the inner crown. No foraging occurred in the lower crown or on the bole in either the canopy or low trees. During cold spells, it may forage lower in the vegetation, on tree trunks, and on the ground. During such weather during spring at Point Pelee, limited aerial foraging occurred. Of other substrates, 50% were bare twigs, 40% were branches, and 10% were sapling trunks. No birds foraged more than 17 m from the ground, 40% foraged at 13 m, 30% foraged at 10 m, 20% foraged at 7 m, and 10% foraged at 3 m. Foraging was not observed at heights of 5, 0.6-1.8, and 0 m from the ground. It searched for most food on bare trunks and branches. Of 231 prey captures in Manitoba, 67.1% were arthropods gleaned from vegetation and the remainder were aerially hawked. There are several records of it feeding at hummingbird feeders and sapsucker wells (Baltz and Latta 2020; Keast 1980; Kilham 1953; Marvel 1948; Parnell 1969; Sealy 1989).

During migration, the Cape May Warbler eats a mix of insects, nectar, and fruit. Four stomachs examined in autumn near Prince Edward Point each contained about 15 beetles. Ten stomachs collected in autumn in Pennsylvania contained 57.5% hymenopterans (parasitic wasps, ants, and small bees), 16.7% flies, 16.7% small moths, 7.8% beetles, and small numbers of true bugs, spiders, and miscellaneous insects. Other prey items include small crickets, leafhoppers, bark lice, termites, moth larvae, dragonflies, and harvestmen. On the Atlantic shoreline of New York, it ate amphipods approximately 14 mm in length. In spring in Illinois, it is especially attracted to flowers, particularly those of hawthorns. In Manitoba it favours willow catkins. It has fed on orange slices. In autumn, it regularly pierces grapes with its bill and sucks out the juice with its tubular tongue. It may be quite destructive to commercial grape crops (Baltz and Latta 2020; Bent 1953; Dawn 1957; Graber et al. 1983; Keast 1980; Sealy 1989).

The Cape May Warbler frequently strikes communication towers and other tall structures during migration. Although mortality at Illinois television towers is rare, predation and collisions are the primary sources of mortality during migration. Hundreds are killed at towers in the United States but few strikes involve more than 100 birds in a night. At the Lennox generating station chimneys, 231 were killed the night of 5 September 1981 and an additional 176 were killed the following night (Baltz and Latta 2020; Graber et al. 1983; Weir 2008). Loss et al. (2014) analyzed bird collisions with buildings in the United States. The Cape May Warbler was highly vulnerable to striking high-rises and was 16.7 times more likely to strike this type of building than birds on average. It was not on the lists of the 20 most vulnerable species for striking residences 1-3 stories tall or low-rises.

In New York, Zelt et al. (2017) compared spring arrival dates, autumn departure dates, and length of the breeding season for 1888-1939 and 1967-2012. There was little climate change during the first period but significant warming occurred during the second period. Autumn departure of the Cape May Warbler was significantly later in the second period, but there were no differences in spring arrival dates or length of the breeding season.

James (1991) considered the Cape May Warbler an uncommon to common migrant in Ontario. Numbers in individual locations vary considerably depending upon spruce budworm populations. Its numbers have experienced long-term trends as well as short-term changes and these are all likely related to budworm numbers. It was a very rare migrant in the province prior to 1900: McIlwraith

(1896) had only seen 6; none had been observed in Elgin County by 1891 (Lancaster et al. 2004); and Fleming (1907) considered it one of the rarest warblers prior to 1898. Peak numbers of migrant Cape May Warblers occurred in the 1970s and early 1980s, with a continuing decline since then (Hussell et al. 1992; McCracken 2004). In Niagara Region, Black and Roy (2010) considered the Cape May Warbler a rare spring migrant that had clearly declined since 1970 when it was common during migration. Black (2017) reported that numbers of Cape May Warblers observed during May at the Port Weller pier declined 1993-2017. LPBO data indicate significant declines during spring and autumn migration of 4.4% per year from 1981-86 to 2001-06 (Venier et al. 2009).

Cerulean Warbler

Setophaga cerulea

BREEDING SEASON

Habitat Requirements

Ontario Cerulean Warbler nests were in deciduous second-growth and mature forests, but one was in a mixed woods. The stands that it occupied were usually open, and nests were often at edges or near clearings (Peck and James 1998a). It requires dense and tall second-growth or mature woodlands. It prefers swamps and floodplain forests, but also occurs in moist upland forests. It requires extensive areas of forest and seems to be area sensitive (James 1984b). Austen et al. (1994) summarized its habitat requirements as mature deciduous forests in extensive woodlands, particularly in floodplains or other mesic habitats characterized by large mature trees and closed or semiopen forest canopies. It also occurs in drier, open upland forest. The largest Ontario population of the Cerulean Warbler is in the Canadian Shield north of Kingston. The landscape in this area consists of extensive forest with embedded beaver meadows, abandoned farm fields, and dry rocky ridges. The forest cover is 80-90 years old and dominated by sugar maple, bitternut hickory, and white ash, with occasional oaks, elms, basswoods, and birches. The mid- and understorey is dominated by sugar maple and hophornbeam saplings. Two study areas north of Kingston that

supported large populations experienced different land-use strategies. The Lake Opinicon site was mature sugar maple–beech-oak forest that has remained undisturbed since the early 1900s. The Canoe Lake site experienced extensive grazing by cattle in the late 1950s and has also experienced selective thinning of large oaks and poplars. The eastern Ontario population breeds in a broad range of habitats from deciduous forests to sumac-juniper thickets, although it is typically associated with forests (Barg et al. 2005; Jones and Robertson 1997, 2001; Oliarnyk 1995; Oliarnyk and Robertson 1996a). In Durham Region, it nested in a mature sugar maple–oak forest arising from the floodplain of the St. John River. Tree growth was sparse on rocky ridges, but most of the plot had an upper canopy (Speirs and Orenstein 1975). In southwestern Ontario, predominantly in the Carolinian Forest Region, it preferred tall canopies in late-successional wet to mesic deciduous woodlands. McCracken (1993) stated that canopy height and structure were probably critical habitat features. He also noted that it required large forests in excess of 100 ha, and concluded that it was a forest-interior species. It occurs in Vanessa Swamp, a 700-ha tract in the Carolinian Forest Region, predominantly in areas dominated by oaks and, to a lesser extent, maples. It also occurs in the extensively forested floodplains of the Grand River from Paris to Cambridge and in large woods adjacent to them. These forests are dominated by sugar maple, but contain a mixture of oaks, hickories, and other deciduous species as well as white pine. The forest cover in both these areas is mature second growth (personal observation).

A good proportion of what is known about the Cerulean Warbler's habitat requirements and breeding biology is a result of intensive studies in eastern Ontario in the Kingston region. From this and other research, it is apparent that it has distinct habitat preferences at several scales: the landscape, the structure and composition of the forest, the territory, the core of the territory, the singing perches, and the nest site.

The Cerulean Warbler nests both in extensively forested habitat north of Kingston and in agricultural landscapes in most of its remaining range in Ontario. Landscape type affects the suitability of individual forest patches for the species and its degree of area sensitivity. In the Kingston area, it breeds successfully in woodlots as small as 10 ha. It may require woodlands larger than 100 ha in the agricultural areas of southwestern Ontario. In these agricultural areas, the spatial distribution of forest patches and especially the distance between suitable patches undoubtedly play an important role in settlement patterns and area sensitivity, but this requires more study. Even in eastern Ontario, the minimum patch size used is considerably larger than a single territory,

suggesting that area sensitivity is occurring to some degree even within extensively forested landscapes. This may be due to its habit of clumping territories, requiring stands to be large enough to accommodate multiple territories (Barg et al. 2003; Jones 2000; McCracken 1993). The Cerulean Warbler is area sensitive throughout its United States range but, similar to Ontario, the size of tract that is required varies geographically. In Wisconsin and Minnesota, it occurs only in stands larger than 16 ha. In Ohio, it prefers tracts that are at least 20-30 ha and avoids tracts smaller than 8-10 ha. These tract sizes may be similar to what is used in New York. In the mid-Atlantic states, maximum probability of occurrence occurred in woodlots larger than 3,000 ha, probability was reduced to 50% at 700 ha, and the 3 smallest woodlands it was detected in were 1,500, 637, and 138 ha. In Connecticut, the average size of patches where it was observed was 1,634 ha; the minimum-sized forest it occurred in was 647 ha. In Tennessee in the Mississippi River valley it appear to require 1,600 ha and forests as large as 8,000 ha may be required to support a viable population. Despite these numbers, it was documented breeding in a grove of trees at a church in 1925, but no information is available on the landscape context. In Arkansas, it occurred in a 3-ha 100-year-old forest. In Illinois, it nested in a 7-ha woodlot (Askins et al. 1987; Buehler et al. 2020; Hamel 2000; Robbins et al. 1989; Thogmartin et al. 2004). Thompson et al. (2012) related Cerulean Warbler abundance to landscape levels of forest cover in Missouri and Arkansas. They surveyed along rivers in landscapes containing 30.7-97.3% forest cover within 10 km. Its abundance increased 390.7 times over the observed range of forest cover within 10 km, 8.7 times over the range of riparian forest within 250 m, and 4.1 times over the range of upland forest within 250 m. Their results were consistent with the theory that habitat selection is hierarchical and that landscape conditions provide important cues to breeding warblers. In other areas, suitable riparian forest surrounded by agricultural land is often unoccupied (Hamel 2000). In West Virginia, fewer territories than expected by availability occurred in forest fragments and more than expected occurred in intact forests. Seventy-three percent of territories occurred in intact forests although only 28% of the area surveyed was in intact forest (Weakland and Wood 2005). There is strong evidence that habitat selection at the landscape level and area sensitivity are linked to precipitation and moisture regimes. Thogmartin et al. (2004) modelled its abundance in the Prairie-Hardwood Transition Area that includes all or portions of Minnesota, Wisconsin, Michigan, Iowa, Illinois, and Indiana. Its greatest abundance occurred where precipitation rates and forest patch size were coincidentally higher. It was abundant in small deciduous patches if the mean precipitation was high. Small, dry deciduous patches contained few Cerulean Warblers. It increased as the percentage of the landscape in forested wetland increased, but chose forested uplands within this matrix of moist bottomland forest. In Wisconsin upland forests, Bond (1957) recorded it in woodlots ranging in size from 6.1 ha to more than 200 ha. Its frequency of occurrence was 4.0% in woodlots 6.1-14.2 ha, 17.4% in woodlots 16.2-32.4 ha, and 23.6% in woodlots larger than 32.4 ha. There was a close relationship between the effects of forest size and the seral stage. It was most common in the most mesic forests regardless of the size class. It appeared in xeric stands only if they were large or in smaller stands only if they were mesic. It was responding simultaneously to patch size and moisture regime. Small woodlots appeared to present more pioneer conditions to birds than larger woods of a similar seral stage. Insect density on foliage may have been greater in the moister stands because the main foliage gleaners were more common in these stands.

At the forest patch scale, the Cerulean Warbler is selective in the forest types that it inhabits. In Ontario, the primary habitat components are that the woodland must be deciduous, although it tolerates scattered white pine and hemlock are tolerated. The forest must be dominated by late-successional tree species such as sugar maple and oaks; and it must contain large, tall trees such as sugar maple, oak, and elm. Old-growth forest is not essential, but mature woods that are more than 80 years old are required for successful breeding. It may breed in riparian forests that range from wet to dry, in swamps dominated by maples or oaks, and in upland forests dominated by either maples or oaks or a mixture of these. Large forest patches dominated by early successional tree species or those that do not contain large trees are usually unoccupied (Austen et al. 1994; Oliarnyk 1995; Savignac 2010b).

In the core of its range, the Cerulean Warbler prefers mature deciduous bottomland forests. These forests are dominated by species such as hackberry, sycamore, black walnut, green ash, bur oak, silver maple, tulip tree, elms, and Manitoba maple. It has been suggested that its occurrence in floodplain forests may be an artifact because many of the potentially suitable upland forests have been destroyed. In North Carolina and Kentucky, it selected floodplain forests and avoided upland forests. In many areas, it nests in upland forests dominated by oak-hickory, sugar maple–beech, and occasionally black locust–black cherry. It highly prefers ridgetops in mountainous areas and slopes facing north or east. To be suitable, woodlands must be a minimum of 21 m tall and support some taller, large-diameter trees. Along rivers in Missouri, presence of tall sycamores was a significant predictor of presence of the Cerulean Warbler. Floodplain forests in North Carolina that are even-aged and support no old-growth trees support few, if any, breeding pairs. Habitat requirements at the forest level include a closed canopy (usually greater than 85% but as low as 65%), but often with gaps; presence of scattered, very tall (24-30 m) old-growth canopy trees; and varied vegetation strata with a distinct zonation of canopy, subcanopy, shrub, and ground-cover layers. Woodlands that it occupies tend to have large, well-spaced trees, a moderately complex canopy structure, small canopy gaps, an open understorey with few saplings or shrubs, and almost complete coverage by ground flora. There are some exceptions: it has nested in black locusts in regenerating old fields; in an old field overgrown with sumac, blackberry, and black gum; areas with a large proportion of pines in the canopy; and in 15-18-year-old clear-cuts that were 10-12 m tall with a closed canopy (Bannon and Robert in Gauthier and Aubry 1996; Bent 1953; Bond 1957; Boves et al. 2013; Buehler et al. 2020; Carpenter et al. 2011; Chapman 1907; Graber et al. 1983; Hamel 2000; Hamel et al. 2004; Hands et al. 1989d; Hartman et al. 2009; Linehan 1973; Mossman 1988; Mossman and Hoffman 1989; Noon et al. 1979; Register and Islam 2008; Robbins et al. 1992, 1998; Rogers 2006; Samson 1979; Savignac 2010b; Schukman 1996; Temple et al. 1979; Wood et al. 2005, 2006).

Habitat within territories is often different from that of the occupied woodland. Several studies on this level of habitat selection have been conducted in eastern Ontario. Territories are usually characterized by well-spaced large trees with high canopies and dense foliage cover in the upper mid-canopy and canopy. The Cerulean Warbler tends to avoid areas of dense understorey. Territories had significantly higher mean basal area (BA) (0.23 m^2 compared with 0.17 m^2), higher BA per stem (0.02 m^2 compared with 0.01 m^2), and higher foliage cover at 12-18 m from the ground (4.4-4.5 compared with 3.0) than unoccupied sites within the same forest. There was a tendency for territories to have higher maximum tree heights (15.7-17.3 m compared with 13.3 m) and fewer

saplings (38.9-42.5 compared with 50.2; Barg et al. 2003; Jones and Robertson 2001). The detailed work on territory selection in Ontario is very important because other authors have observed that data collected in 1 area may not be representative of conditions throughout the Cerulean Warbler's range. A single range-wide management strategy for this species may not be effective in stabilizing or enhancing populations. In most cases, territories are characterized by larger diameter trees than are present in unoccupied areas of the same woodland, but in at least 1 case the opposite was true. Canopy height is typically taller in territories, but not always. Basal area of deciduous trees is usually higher in territories than in unoccupied areas. Results from Alabama are typical for the species. Compared with unused habitats, territories had significantly fewer trees 3 cm or smaller diameter at breast height (DBH) (840.4 compared with 1,305.3 per ha); higher ratio of BA to the number of stems (0.04 compared with 0.03); greater percent BA by deciduous trees (100.0 compared with 96.2%); taller lower, middle, and upper canopy heights (5.8 m compared with 5.2 m, 17.0 m compared with 15.5 m, and 29.4 m compared with 26.2 m, respectively); greater canopy cover (90.0% compared with 82.5%); larger diameter trees (22.0 cm compared with 13.5 cm), and larger canopy gaps (31-40 m^2 compared with 10-20 m^2). Much of the variability in territorial habitat occurs in the Appalachians. This variability suggests that habitat selection by the male may be quite plastic and may be affected by landscape characteristics. In the least-forested landscapes (74-75% forested), males selected areas with greater BA and greater canopy cover, features normally associated with closed-canopy, undisturbed mature forests. Where the surrounding forest cover was greater, it selected territories with lower BA, greater understorey cover, and closer proximity to canopy gaps. Presence of canopy gaps appears to be an important habitat component, particularly in extensively forested landscapes. They may be of lesser importance in forest fragments. Some analyses determined that presence of small snags is important, possibly because these create gaps in the canopy. In the Appalachians, it strongly selected ridges for territories and presence of slopes was also important. Territories tended to be on slopes facing north and east; these support the most productive forests. In the Appalachians, territories supported more sugar maple and the red oak group of species. It avoided red maple, chestnut oak, and ash (Boves et al. 2013; Buehler et al. 2020; Carpenter et al. 2011; Robbins et al. 1992; Roth and Islam 2008; Weakland and Wood 2005; Wood et al. 2006). In the Cumberland Mountains of Tennessee, males selected locations with less average solar exposure (based on elevation), greater distance to streams, higher elevations, and sites that occurred more on ridge tops, upper slopes, and on steeper slopes than what was available on average. More than 90% of territories were in mature deciduous forests, but this habitat represented only 50.7% of the study area. No selection was made for terrain moisture (Buehler et al. 2006). In Arkansas, it preferred forests with larger trees averaging 40 cm DBH. These trees were significantly larger than those in males' territories (35 cm DBH) and at random sites (32 cm DBH). Males preferred areas closer to canopy gaps characterized by greater BA and understorey cover (Wessels and Boves 2021).

In eastern Ontario, males have distinct areas of high use in territories called the core. These are vegetatively and structurally different from the rest of the territory, and are used predominantly for singing. Compared with the remainder of the territory, core areas were characterized by lower stem densities and higher average canopy heights. Territories of all males examined were dominated by sugar maple (38-63% coverage), but core areas of 6 of 7 males were dominated by species other than sugar maple: 4 by bitternut hickory, 1 by white ash, and 1 by hophornbeam. At the territory

scale, the Cerulean Warbler used canopy trees in proportion to their availability, but core areas contained more bitternut hickory and oak than the remainder of the territory. The 5 most commonly used trees for singing posts were: sugar maple, 36.5%; bitternut hickory, 30.0%; white oak, 12.1%; oaks, 8.1%; and white elm, 5.7%. Song post densities were 9 times greater in core than noncore areas (303.9 compared with 34.0 song posts per ha). In noncore areas, males predominantly used sugar maple (34.4% of observations); bitternut hickory was used most often in core areas (36.8% of observations). Distance between the core area centre to the nearest canopy gap averaged 12.2 m compared with 13.6 m for random sites within the territory. Only 3 of 14 core areas encompassed a gap. Bitternut hickory was highly selected, representing 45% of all song posts but only 9% of available trees. This tree's distribution was not clustered so this was not the reason for territory clustering. Males appeared to select tree species for song posts that have delayed leaf-out in spring. Bitternut hickory and white ash (the second-most used species) were late to leaf out and had less leaf cover than the other species. Males with less densely foliaged song perches will both send and receive clearer song messages. When a male failed to return the subsequent year, the new male tended to use the same song perches. It selected tree species at random for nesting, but highly selected hickories for singing perches. Bitternut hickories support significantly more arthropods in their canopies than other species. No core areas contained a nest, but they were located significantly closer to the within-territory nest than to neighbour's nests. Because core areas are close to the nest, they may be advantageous to nest defence (Barg et al. 2003, 2006a).

Studies in other areas confirmed significant differences between core areas and entire territories, and the preferences for hickories or other species or features that maximize song projection. In West Virginia, gap densities were 3 times higher in core areas than in entire territories. Seventy percent of all observations occurred in the lower and mid-canopy strata; males were rarely detected in the understorey. The upper canopy was used more frequently than expected for singing and less than expected for foraging, perching, and preening. The lower canopy was used more frequently than expected for perching and the mid-canopy was used more than expected for preening. Singing occurred more in the upper canopy than expected in core areas and less than expected outside core areas. Midstorey singing occurred more than expected outside core areas and less than expected in core areas. Singing locations in the upper canopy were associated with canopy gaps more than expected. Foraging occurred more frequently than expected in the midcanopy in core areas and less than expected in noncore areas. Males were associated with canopy gaps for 34% and 19% of observations at 2 sites. At 1 site, black cherry was used more in core than noncore areas; hickory was used more in core areas at the other site. Males foraged more than expected outside core areas and these areas were used predominantly for singing and opportunistic foraging in the midcanopy. The high use of canopy gaps may be due to higher insect prey in the openings but is more likely related to superior transmission of song in areas unimpeded by leaf cover (Wood and Perkins 2012). In Kentucky, potential indicators of singing posts, presumably within core areas, were large diameter trees, an east-facing aspect, and understorey density. Song perches averaged 54 cm DBH compared with 40 cm DBH for random trees. This supports the hypothesis that the size of song-perch trees relative to other trees in the stand is important. More than 85% of Cerulean Warblers and 95% of song perches were on east-facing slopes that coincided with more mesic and protected sites that allowed birds to take advantage of the morning sun while avoiding midday heat stress

(Hartman et al. 2009). In Illinois, the Cerulean Warbler had definite preferences for tree species. Species used more than expected given their availability, from greatest to least preferred, included shellbark hickory, bitternut hickory, silver maple, green ash, overcup oak, sweet gum, black gum, and sycamore. Species used less than expected included silver maple, blue beech, pumpkin ash, Shumard oak, swamp chestnut oak, bald cypress, cherrybark oak, pin oak, and white elm. The 2 hickories were strongly preferred, as in Ontario, but were only 11th and 19th in tree species abundance (Gabbe et al. 2002). In Missouri, 1 study observed it 70% of the time in pecan (a type of hickory), and 15% of the time in sycamore. Other studies have found it strongly associated with sycamore (Ball 1948; Robbins et al. 1998; Schukman 1996). Sycamores are typically tall supercanopy trees that would offer ideal perches for broadcasting songs. Throughout the Cerulean Warbler's range, hickories and oaks in the white oak group appear to be preferred for foraging and song posts. It avoids red maple and oaks in the red oak group (Buehler et al. 2020).

Studies in eastern Ontario demonstrated that habitat at Cerulean Warbler nest patches and nest sites differed from each other and from other areas within the territory. Nest patches consisted of 5 5-m radius circles with 1 at the nest and 4 11.4 m away in cardinal directions. There were 2 significant differences between nest patches and random sites, with nest patches having fewer trees and a higher BA per stem. There were 3 significant differences between nest sites and other locations within the territory. Nest sites had more foliage cover 12-18 m from ground, more foliage cover above 18 m, and taller and fewer trees. There were 5 significant differences between nest sites and random sites. Nest sites had a higher BA, higher BA to stem ratio, more foliage cover at 12-18 m, less foliage cover above 18 m, and taller trees. There were no significant differences between nest sites and nest patches, but there were 3 suggestive differences. Nest patches tended to have fewer trees, more foliage cover above 18 m, and taller trees than nest sites. The small differences between nest sites and other areas within the territory suggested that important nest-patch and nest-site decisions were made by the male when selecting the territory, thereby maximizing the probability that a female would settle on the territory (Jones and Robertson 2001). Females may choose nest sites outside but close to the male's core area allowing the male to be vigilant over the nest while advertising (Barg et al. 2006a). Boves et al. (2013) examined habitat within nest patches within the Appalachians. Nest patches had taller canopies than other areas within the territory at 2 sites and lower canopies at another 2 sites. Females consistently selected nest sites characterized by fewer but larger-diameter trees with a high amount of understorey cover and low amount of midstorey cover. Overall habitat characteristics at all sites for nest sites compared with territories included: lower average DBH in nest patches, lower BA at nest patches, higher percent understorey cover in nest patches, lower midstorey canopy cover, and greater distance to a canopy gap in nest patches. At the nest-patch level, sugar maple was avoided at 1 site, tulip tree was preferred at 2 sites, and white oak was preferred at 1 site. At the nest-site level, preferred species were cucumber tree at 1 site, sugar maple at 1 site, tulip tree at 1 site, and white oak at 4 sites. Black cherry was avoided at 1 site, hickory at 1 site, and the red oak group at 3 sites. Across all study areas, females consistently selected nest patches with large, well-spaced trees, increased understorey cover, decreased midstorey cover, a high proportion of white oak, and a low proportion of sugar maple. These areas were usually within or near edges of small-scale canopy disruptions in mature forest. Sugar maple was avoided at the nest-patch scale but preferred at the territory and nest-tree scales. Differences in

preferences for the different species of maple and oak may be related to differences in bark or foliage structure that may influence insect availability or suitability for nest attachment or concealment. Nest-patch selection by females was more consistent than territory selection by the male.

In West Virginia, Wood et al. (2006) examined the effects of edge on the Cerulean Warbler. The study area consisted of large patches of second-growth oak-hickory forests surrounded by extensive grasslands. The remaining forests had also been subjected to periodic disturbances such as natural canopy gaps, old timber harvests, jeep and all-terrain vehicle trails, and utility rights-of-way. There was an abrupt change from mature forest to reclaimed grassland and edge shape was convoluted, resulting in a high edge-to-area ratio. Occurrence of the Cerulean Warbler did not vary with distance from edge suggesting a degree of tolerance to edge. Territory density and abundance increased significantly from edge leading the authors to speculate that habitat near the edge was less suitable for breeding. They were not able to test this hypothesis. Effects on abundance of the Cerulean Warbler extended 340 m from edge. In the same area, Weakland and Wood (2005) found that territory placement in relation to the closest edge type differed from the expected distribution. Fewer territories than expected were adjacent to streams and valleys filled with mine waste and more than expected were adjacent to roads with open or semi-open canopies. The proportion of territories adjacent to natural gaps did not vary from availability with 63% of territories crossing either a road or trail. Distance to mine edge had no relation to territory density when all distances were plotted. When plots further than 400 m from edge were excluded from the analysis, density increased beyond 100 m of mine edge suggesting that edge effects extended about 100 m into the forest. Internal edges were not avoided and territorial placement was closer than expected to these. In both West Virginia studies, the Cerulean Warbler did not avoid hard edges but had lower densities near edge suggesting that edge habitat may be inferior. In another West Virginia study, Perkins and Wood (2014) examined selection of forest canopy gaps by males. One study area supported only gaps created by fallen trees. The other also had gaps created by a trail and 3 wildlife openings 0.17-0.32 ha. Gap densities were greater within core areas than in territories or random plots. The size of gaps that intersected territories ranged from 12 to 3,163 m^2, but 86% of gaps were less than 500 m^2. Small gaps in the 50-100 m^2 range occurred more frequently within territories and less frequently on the periphery of territories. The largest gap-size class (larger than 300 m^2) occurred more frequently than expected on peripheries and less frequently in territories. The most common type of gap within territories was created by tree falls, representing 68% of gaps within territories. Trail and wildlife gaps occurred only on the periphery of territories. Tree-fall gaps occurred more than expected within territories and less than expected in the periphery of territories. Trail gaps were often used as territorial boundaries. A 4-year study at Vanessa Swamp determined that the Cerulean Warbler was most abundant on plots 120 and 180 m from edge, although a few were recorded on edges and 60 m from edge. A county road bisects this swamp and it was common along the road in the centre of the swamp but not at its edges. The centre of the swamp was characterized by very tall trees with canopies that overhung the road, with only about a 5-m gap between the treetops on each side. The main area inhabited by this warbler consisted of tall, well-spaced sugar maples and oaks. Single-tree selection occurred during the study, and this had no effect on the number of Cerulean Warblers present. Habitat around the agricultural edges of the forest consisted of shorter trees with greater coverage by shrubs and saplings (personal observation). It appears as though the

Cerulean Warbler does not actively avoid edges but that habitat conditions are often superior distant from edges.

Ontario nests were in medium to large deciduous trees, including maples, oaks, elms, basswood, American chestnut, and bitternut hickory. In 1 eastern Ontario study, 66.7% of nests were in maples, 11.1% were in bur oak, 7.4% were in white oak, and 3.7% were in each of red oak, hophornbeam, bitternut hickory, and elm. Another study in the same area determined that 56.3% of nests were in maples, 16.9% were in elms, and 18.3% were in bitternut hickory. Nests near and west of London were mostly in basswood and elms. There appeared to be no selection for nest-tree species, although the high number in bitternut hickory reported by 1 study suggests that this may be a preferred nest tree. In eastern Ontario, 70% of nests were within 10 m of a territorial boundary and 59% were within 30 m of a canopy gap compared with 23% of random sites. Most nests were in contiguous forest and only 1 nest occurred near a gap between differing adjacent habitats. At this site, the most commonly used nest trees (maples and oaks) were those with the greatest overall BA. In eastern Ontario, the average DBH of nest trees was 40.2 cm (range 11.2-49.8 cm). Average nest height was 11.8 m (range 7.0-18.6 cm), and overall heights in the province range from 4.6 to 19.8 m, with most 8.8-13.1 m from the ground. Seventy-one percent of nests were in the lower canopy of trees, 59% had no other vegetation between the nest and ground, and 77% were on the outer edge of a lateral branch. Distance of nests from the trunk averaged 3.62 m (range 0-4.69 m), but some Ontario nests were as far as 6 m from the tree trunk. The nest resembles a knot and is saddled on a horizontal branch 1.3-5 cm in diameter. The nest is a very shallow cup attached to the limb by nest fibres; often the nest is simply saddled on the branch but it may also be supported by a small twig. Materials from the first nest are used to build replacement nests. Cerulean Warblers may also take nesting materials from neighbours' nests and from other species' nests. In eastern Ontario, Cerulean Warblers stole nesting materials from nests of the Red-winged Vireo and Blue-gray Gnatcatcher (Jones and Robertson 2001; K.C. Jones et al. 2007; Oliarnyk and Robertson 1996a; Peck and James 1987, 1998a; Saunders 1900; Savignac 2010b).

Throughout its range, the Cerulean Warbler nests in the canopy of tall deciduous trees. In addition to the nest-tree species used in Ontario, it has nested in sycamore, cottonwood, shagbark hickory, Osage orange, white ash, cucumber tree, black walnut, black cherry, tulip tree, black locust, black oak, red oak, and white pine. It appears to select the largest available trees for nesting. In some areas, there appear to be no preferences for nest-tree species, but sycamore, white elm, cucumber tree, white oak, and sugar maple have been selected in some areas. Sugar maple may be preferred for nesting because of its early leaf-out and thick foliage, and areas dominated by this species tend to have suppressed midstorey vegetation. In certain areas, it tends to avoid trees in the red oak group, red maple, and tulip tree as nest trees. Many nests are near a stream, a small artificial gap created by internal roads or selective harvest, or natural openings such as tree falls, snags, or small wetlands. One Delaware nest was only 5.2 m from the ground and overhung a busy road and parking lot. Nests have been reported at heights of 4.5-30 m, but mostly higher than 10 m. Average nest height in Indiana was 18 m. Similar to Ontario, nests are on a horizontal branch in the mid- to upper canopy concealed from above by leaves or Virginia creeper vines. One Michigan nest was completely encircled by Virginia creeper. Nests are characteristically over an open space that may be as small as 1 m between the nest branch and a lower branch of the same tree. More frequently,

the open space is 5-20 m from the nest to tops of trees below the nest branch, to shrubs below the tree, or to the herbaceous layer or bare ground. When leaving the nest, the female drops vertically before flying away horizontally, so the open space below the nest accommodates this behaviour (Bent 1953; Boves et al. 2013; Buehler et al. 2020; Chapman 1907; Graber et al. 1983; Hamel 2000; Hands et al. 1989d; Harrison 1984; Linehan 1973; Nemes et al. 2005; Rogers 2006; Roth and Islam 2008; Wagner and Islam 2014; Weakland and Wood 2005).

The Cerulean Warbler is aggressively territorial. Males may attack each other at heights of 20 m or more and flutter to the ground while grappling with each other. Females are equally aggressive. Male territorial boundaries shift considerably prior to the arrival of females. Territorial boundaries broke down in eastern Ontario in mid- to late July. If a pair has a successful first nest, the maximum time that a territory is held is 22 days. Despite the aggressiveness of the birds, territories appear to be clumped and areas of apparently suitable habitat are unoccupied. In eastern Ontario, territories may either be aggregated or cover most of an area with boundaries of several territories abutting each other. In Missouri and Arkansas, territories are arranged linearly where riparian forests are narrow but are more densely packed in broader floodplain forests. In Indiana, territories were clustered on 3 plots, regularly spaced on 1 plot, and randomly located in another plot. Territories were clustered in areas with significantly more vertical stratification and a greater number of smaller trees. Clusters of territories in West Virginia were also associated with numbers of small trees. It is possible that the Cerulean Warbler clusters territories in areas of forest with large amounts of foliage where there would be greater food availability. Territories also tended to be near streams and ravines in areas with more slope. Habitat selection therefore plays a role in aggregation of territories but clustering occurred even in areas of uniform high quality habitat. This suggests that social factors may also be involved in territorial clustering, such as settling where a neighbour could be heard. Presence of other singing birds may signal high reproductive success potential because birds that fail to raise young in 1 year seldom return the subsequent year. Another potential reason for clustering is to facilitate extra-pair copulations (Barg et al. 2003, 2005; Buehler et al. 2020; Hamel 2000; McCracken 1993; Oliarnyk and Robertson 1996a; Robbins et al. 2009; Roth and Islam 2007; Weakland and Wood 2005).

Several estimates of territory size are available from eastern Ontario. Oliarnyk and Robertson (1996a) reported that territories averaged 1.04 ha (range 0.38-2.4 ha). Jones et al. (2001) reported average territory sizes of 0.74 ha in 1996 and 0.63 ha in 1997, 2 years prior to a severe ice storm, 0.57 ha in 1998 during the first breeding season after the ice storm, and 1.17 ha in 1999. There were no significant correlations between territory size and the amount of storm damage in either poststorm year. Territory size does not appear to be directly related to pair density. Using minimum convex polygon estimates, eastern Ontario territories averaged 0.96 ha (range 0.23-2.21 ha). The kernel (or core) territory size averaged 0.70 ha (range 0.12-2.35 ha). Overall, territory sizes of 0.1-2.4 ha have been documented in eastern Ontario. Males occasionally made long direct flights without song or other territorial behaviour. These were probably extra-territorial forays, possibly to seek extra-pair copulations (Barg et al. 2003, 2005). Average territory sizes reported elsewhere include 0.9 ha in Missouri, 0.21 ha in Indiana, 0.31 ha in West Virginia, 1.14 ha in Arkansas, and 0.45 ha in Tennessee. In another West Virginia study, territory size averaged 0.30-0.42 ha and core areas averaged 345-680 m^2 (Buehler et al. 2020; Perkins and Wood 2014; Robbins et al. 2009; Wessels and Boves 2021).

Limited information is available on natal philopatry. Three of 20 (15%) nestlings banded at Lake Opinicon returned in subsequent years. Long-distance dispersal of juveniles may occur in eastern North America. Three of 32 nestlings (9.4%) subsequently bred in a Bird Conservation Region other than their natal area. Some breeding birds in eastern Ontario hatched in Illinois and Arkansas (Girvan et al. 2007; Savignac 2010b).

Earlier workers assumed that adult site fidelity was high and this led to the conclusion that mortality rates were higher than they actually are, suggesting that most populations were not replacing themselves with their annual recruitment rate. The misinterpretation resulted from the fact that certain birds returning to a given area may exhibit high site tenacity, with certain individuals nesting in the same territory for as many as 7 breeding seasons. Adult males may disperse widely between breeding seasons, which contributes to underestimates of survivorship. In some areas, breeding success effects return rates with failed breeders seldom returning. In other areas, breeding success appears to have no effect on return rates. At Lake Opinicon, an attempt was made to band all males, but each year 40-70% of the older breeding males were unbanded. These birds may represent local recruitment and only a few of these were long-distance immigrants. In eastern Ontario, only 1 adult male was recorded moving more than 500 m between breeding seasons over a period of 7 years. In the Appalachians, site fidelity was very low, with fewer than 20% of males returning to their former breeding territories. In Arkansas, 26% of adults returned. Four males returned to the same territory; 2 shifted their territories a few hundred metres. One returning female nested 6.64 km from her previous year's nest (Wessels and Boves 2021). In Michigan, 74% of returning males chose territories within 500 m of the previous year's territory. Seven males moved a mean of 1.7 km (range 1.1-2.2 km) between nesting seasons. Long-range movements of adult males also occur as determined by stable hydrogen isotopes, with as many as 28% dispersing long distances between breeding seasons. Populations varied in the number of immigrants they received, from 4% in Ontario to 38% in West Virginia. The eastern Ontario population may be acting as a source to United States populations (Barg et al. 2005; Boves et al. 2013; Buehler et al. 2020; Girvan et al. 2007; Jones and Islam 2023; Jones et al. 2004, 2008; Rogers 2013; Roth and Islam 2007). In Pennsylvania, Arkansas, and Missouri, return rates of birds fitted with geolocators were 16% compared with 35% for birds without geolocators (Raybuck et al. 2017).

Limiting Factors

Egg dates for nests reported to the Ontario Nest Records Scheme (ONRS) ranged from the last week of May until the end of June, with most eggs present in the first half of June (Peck and James 1998a). In eastern Ontario, initiation of nest construction for first nests was 18-24 May; replacement nests were initiated from 31 May to 4 June. The extreme dates for incubation were 30 May to 23 June and fledging typically occurs in the first week of July (Oliarnyk and Robertson 1996a; Savignac 2010b).

Pair formation commences shortly after females arrive and nest-site selection and initiation of nest construction occurs 1-2 days after the females arrive. Nests may take 3 to more than 8 days to build, with first nests typically taking 4-6 days to complete. Nest building may be expedited if the female gathers material from an old nest or steals material from another species' nest. Nest building may be prolonged if other species rob material from the nest while it is being built. No information is available on whether there is a gap between nest completion and initiation of egg laying.

Presumably, eggs are laid at the rate of 1 a day. Incubation takes 10-13 days in Ontario, most frequently 11-12 days (mean 11.4 days). The nestling period is typically 10-11 days, but young may leave the nest at age 7-9 days if they are disturbed (Barg et al. 2005, 2006b; Buehler et al. 2020; Graber et al. 1983; Hamel 2000; Hands et al. 1989d; Jones et al. 2007; Oliarnyk and Robertson 1996a; Peck and James 1998a; Wagner and Islam 2014).

One brood is typically raised per breeding season. The only record of a second brood is from eastern Ontario and it occurred under unusual circumstances. The female was the secondary female of a bigamous male who provided very little care to her brood. She moved her fledglings 800 m (4 territory widths) and remated with a different male. This male adopted her fledglings, the only known case of brood adoption by this species, while she laid a second clutch. The Cerulean Warbler readily renests if a clutch is lost and may make as many as 3 attempts to fledge young. Nests reported to the ONRS had clutches of 3-5 eggs (mostly 3 or 4 eggs, average 3.69). In eastern Ontario clutches contained 2-5 eggs with most clutches containing 5 eggs (average 3.8 eggs). Throughout its range, the clutch size is 3-5 eggs with 4 eggs most frequent. Mean clutch sizes reported elsewhere include 5.00 in Illinois, 4.33 in Michigan, 3.58 in New York, 3.82 in Pennsylvania, and 3.78 range-wide (Barg et al. 2003, 2006b; Bent 1953; Buehler et al. 2020; Graber et al. 1983; Hamel 2000; Oliarnyk and Robertson 1996a; Peck and James 1998a; Savignac 2010b).

The mating system is typically monogamous, but 10% of Ontario males and 7% of Tennessee males were bigamous. The pair bond is maintained for the duration of the breeding season, even when renesting occurs. Both sexes are capable of breeding at age 1 year. Some populations contain unmated males that are presumably yearlings. Unpaired males comprised 20.5% of a Missouri population, 38.7% of an Indiana population, and 35% in another Indiana population. These numbers probably represent maxima as some females may not have been detected in these studies. Once a bird breeds, it typically does so for the remainder of its life. Northern populations may be dominated by adult males. Only 15% of Ontario breeding males were yearlings and 10-20% of Michigan birds were yearlings. Extra-pair copulations may be common, but this has not been studied extensively. In eastern Ontario, extra-pair copulations were observed and blood samples from 2 families revealed that 4 of 7 young were sired by a male other than the social male (Barg et al. 2005, 2006b; Buehler et al. 2020; McKillip and Islam 2009; Robbins et al. 2009; Rogers 2006).

Foraging occurs in the canopy of tall trees. In eastern Ontario, males foraged significantly lower than where they sang (12.8 m compared with 15.0 m). Singing and foraging both occurred within the canopy at 83.9% and 71.9% of the tree height. In Arkansas and Tennessee, average perching and foraging height was 15 m in trees averaging 22 m (68.2% of tree height). In Ohio, males foraged at an average height of 16.9 m (76% of tree height); females foraged at 14.4 m (72% of tree height). The Cerulean Warbler has been documented foraging at heights of 2 m to more than 45 m, but mostly in the lower to midcanopy, particularly in dense foliage. Males forage in larger trees in higher canopy positions than females. In Indiana, males foraged at an average height of 19.2 m compared with 16.9 m for females. Females in the Mississippi River valley often foraged extensively in poison ivy vines that encircled the bole of canopy trees, working in a spiral around the tree trunk. In Illinois, it preferred hickories, silver maple, green ash, black gum, and sycamore for foraging. It used red maple, blue beech, pumpkin ash, white elm, and oaks in the red oak group significantly less than

their availability. In Ohio, males foraged in hickories 27% more than expected, but were not observed foraging in black oak. White oak and tulip tree were used in proportion to their availability. Hickory trees supported twice the number of greenish-coloured caterpillars as oaks. Most foraging occurs by hopping along twigs peering at the upper and lower surfaces of leaves, petioles, and twigs and gleaning insects from these surfaces. It may infrequently capture prey by hovering or sallying. In West Virginia, males leaf-picked 73.3% of the time, wood-picked 19.3% of the time, sally-gleaned 6.8% of the time, and aerially hawked less than 1% of the time (Barg et al. 2006a; Buehler et al. 2020; Gabbe et al. 2002; Hands et al. 1989d; Newell et al. 2014).

In eastern Ontario, 35% of males fed incubating females, mostly caterpillars. Nestlings are fed mostly caterpillars, but also adult lepidopterans, crane flies, smaller flies, beetle larvae, and spiders. In Ohio, adults fed nestlings predominantly greenish caterpillars, accounting for 69% of prey items. Other food provided to young included 12% caterpillars with darkish colouration, and 19% winged insects. Adults brought large prey that extended beyond the bill on 56% of deliveries. In Indiana, young were fed predominantly green-coloured caterpillars. These constituted 53% of nestling food items; caterpillars represented only 14% of potentially available prey. The nestling diet was comprised of 83% caterpillars in the early part of the season during the peak nestling period. The proportion of caterpillars in the nestling diet decreased with the season, and was 80% less for the last nest of the season compared with the first nest. Caterpillars of prominent and owlet moths dominated the diet. Nestlings were also fed flies, adult lepidopterans, harvestmen, spiders, true bugs, hymenopterans, beetles, and walkingsticks. Most flies fed to young were crane flies. The mean length of prey provided to nestlings (14.7 mm) was significantly longer than the mean length of prey on branches (6.1 mm). Adults are predominantly insectivorous during the breeding season, but also eat some spiders. Four Alabama stomachs contained 42% hymenopterans by frequency, 35% lepidopterans, and 23% beetles, including weevils. In West Virginia during a gypsy moth outbreak, 14 adults consumed 52% soft-winged bugs by volume, 37% lepidopterans (mostly caterpillars), 7% beetles, and small amounts of hymenopterans, flies, true bugs, spiders, and other arthropods. Diet was investigated at a site that was treated with diflubenzuron, an insecticide that interferes with moulting of larval insects. Birds in control plots ate 2 times more lepidopterans than soft-winged bugs. Those in treatment plots ate 3 times more soft-winged bugs than lepidopterans. Prior to and a month after treatment, more lepidopterans than bugs were consumed (Auer et al. 2016; Barg et al. 2003, 2006b; Buehler et al. 2020; Hands et al. 1989d; Newell et al. 2014).

Cowbird parasitism rates of the Cerulean Warbler are almost zero in extensively forested landscapes and moderate in agricultural landscapes. Peck and James (1987) reported that 7 of 39 Ontario nests (17.9%) were parasitized, and all these nests were from the agricultural southwest. Peck and James (1998a) reported 8 of 57 nests (14.0%) parasitized, and this sample included a mix of nests from the southwestern and eastern portions of the province. Nest parasitism is rare in the Kingston area. From 1994 to 2006, cowbird eggs were found in only 2 Cerulean Warbler nests; both were abandoned. No cowbirds fledged from eastern Ontario nests out of a few hundred nests (Barg et al. 2003, 2006a; Oliarnyk 1995; Oliarnyk and Robertson 1996a, 1996b). Similar results have been reported from elsewhere. Parasitism rates in Indiana were 0% in extensive forest and 15.4% elsewhere, very low at 1 Michigan site and 25% at another. In the Cumberland Mountains of Tennessee, 1 of 52 nests (1.9%) was parasitized and 9 of 66 nests (13.6%) were parasitized in the

Mississippi Alluvial Valley. In Illinois, no parasitized nests were found (Buehler et al. 2008, 2020; Graber et al. 1983; Hamel 2000; Rogers 2006; Roth and Islam 2008; Savignac 2010b). Some authors stated that cowbird parasitism posed a potential significant threat to the Cerulean Warbler. Parasitism is more prevalent where human activities have fragmented forests. The actual impacts of parasitism on the Cerulean Warbler require additional study. In Michigan, the effects of parasitism were considered low, with few nests parasitized whereas more than 60% of Hooded Warbler nests were parasitized. The Cerulean Warbler appeared to be a poor host for the cowbird in this region (Buehler et al. 2020; McCracken 1993; Robbins et al. 1992; Rogers 2006).

Habitat loss is the greatest threat to the Cerulean Warbler. The extensive deforestation associated with European settlement undoubtedly resulted in the loss of habitat in southwestern Ontario. More recently, the amount of forest cover in the province has increased due to abandonment of former agricultural land. The more recent forest cover may not be suitable habitat because it often occurs in small patches, has inappropriate tree species composition, or is too immature. Most of the gains in forest cover have been due to creation of coniferous plantations which are unsuitable habitat. Most large forest patches that support the Cerulean Warbler are protected from development, but there is no protection from agricultural activities. With the current high value of row crops, there is an increasing tendency to attempt to farm marginal land and this is resulting in some loss of habitat. In the core of its range, a high proportion of upland forests in the Mississippi Alluvial Valley have been eradicated and there has been serious encroachment into floodplain forests. In the Appalachian Mountains, ridgetop mining has resulted in the loss of thousands of hectares of prime habitat. In several states, the Cerulean Warbler was once the most abundant warbler species and it is now rare and declining in many of these states (Barg et al. 2003; Brett 2011; Buehler et al. 2020; Hamel 2000; Hamel et al. 2004; Hands et al. 1989d; McCracken 1993; Robbins et al. 1992; Savignac 2010b; Thogmartin et al. 2004; Weakland and Wood 2005).

Habitat fragmentation is another significant limiting factor to the Cerulean Warbler. Loss of woodlots that do not even support this species can have significant detrimental effects by reducing the amount of overall forest cover in the landscape. This may have the effect of increasing the minimum size threshold for forests. In the core of its range, it appears to be more restricted to large tracts now than it was from 1930 to 1960. The minimum forest size requirement is larger in the western portion of its range where forest coverage is less than in the east. Fragmentation of the landscape creates better habitat conditions for many nest predators and the Brown-headed Cowbird. Woodlands in fragmented habitats may not produce enough young to sustain populations without immigration. In West Virginia, density of the Cerulean Warbler was 6.6 times higher in contiguous forest than in forest fragments of similar habitat quality (Barg et al. 2003; Brett 2011; Buehler et al. 2020; Hamel 2000; Robbins et al. 1992; Savignac 2010b; Weakland and Wood 2005).

Human activities can degrade occupied habitat in a number of manners. Partial removal of a forest may drop it below the minimum threshold size, reduce territorial density, and improve habitat for predators and the cowbird. Drainage of swamps and mesic woods may make them less attractive to the Cerulean Warbler. Acid precipitation has been identified as a threat in some areas. This is unlikely to be an issue in southwestern Ontario where soils neutralize the effects of acid

precipitation, but it is a possible issue on the Frontenac Axis and the southern Canadian Shield. Forest harvesting and other forest management activities may have no apparent effects, possible benefits, or be very destructive to habitat depending upon the type and intensity of management. In eastern Ontario, the Cerulean Warbler population was robust in areas that were managed for sugar maple productivity. This activity appeared to have no effect nor did shelterwood cuts. In extensively forested areas, harvests that create small openings may be beneficial because it is attracted to gaps for nesting. In eastern Ontario, nest success was lower near canopy gaps than distant from them, so this may potentially be a form of ecological trap. Forest management that removes all mature and old-growth timber is detrimental and is considered responsible for the species' eradication in large areas of its core range. Short rotations that do not allow persistence of mature and supercanopy trees essentially render the habitat unsuitable. In southwestern Ontario, single-tree selection may be acceptable in large tracts if portions of the forest remain unharvested during each rotation. Cuts that include an entire tract and diameter-limit cuts have the potential to eradicate the species. For the most part, current forest management practices in southwestern Ontario are not conducive to maintaining Cerulean Warbler populations and there are few mature to old-growth stands remaining. Even in the Appalachians, timber harvest often results in lower daily nest survival rates and numbers of young fledged (Barg et al. 2003, 2006a; Boves et al. 2013; Brett 2011; Buehler et al. 2020; Hamel 2000; Jones and Robertson 2001; McCracken 1993; Robbins et al. 1992; Savignac 2010b; Wood et al. 2005).

Farwell et al. (2019) studied the effects of shale gas infrastructure (well pads, access roads, and pipelines) on the Cerulean Warbler in West Virginia. Initially, it occurred in least-developed areas of the forest but began to occur in greater abundance near pipelines and access roads as the development expanded. It increased closer to linear infrastructure but not well pads. Nonetheless, it still declined across the site by 34%. They considered it a forest-interior gap specialist. In West Virginia, Margeneau et al. (2019) determined that it was more abundant in intact than remnant forests associated with strip mines. Remnant forests were surrounded by strip mines on 3 sides but were not directly affected by them.

Severe weather events may significantly alter habitat and result in declines in the Cerulean Warbler or a decrease in productivity. A severe ice storm in eastern Ontario in 1998 affected approximately 60% of its habitat, reducing the canopy foliage structure; average cover was reduced by as much as 60%. Warblers nested in the same areas and same territories as in the previous year. The nest success rate declined from 75.7% in prestorm years to 8.9% in the breeding season after the storm, and the number of fledglings per nest fell from 2.0 to 0.4. The reason for the decline in productivity appeared to be related to a decline in insect availability. The following year, warblers expanded their territory sizes and shifted their locations and productivity increased. There was another severe ice storm in southern Ontario in December 2013 but it is uncertain what effects it had on Cerulean Warbler habitat and populations. It was observed regularly in the Montreal area in the 1960s and 1970s. A severe ice storm hit this area in the early 1980s and it has been seen only rarely since. A severe ice storm in Arkansas resulted in a significant decline in the population, to the point where it disappeared from the area where it was being studied. A large thunderstorm altered the forest structure in 1 location in Point Pelee National Park, and the Cerulean Warbler has not been

seen at that site since 1977 (Bannon and Robert in Gauthier and Aubry 1996; Barg et al. 2003; Brett 2011; Buehler et al. 2020; Hamel et al. 2004; Jones 2000; Jones et al. 2000a, 2001).

Certain key tree species for nesting and foraging for the Cerulean Warbler may be at risk due to disease or insects. The European oak borer has recently been discovered in Ontario and it may pose a threat given that oaks constitute about 50% of nest trees in certain areas. The potential effects of the emerald ash borer are unknown. Other potential threats in Ontario include the Asian longhorned beetle, gypsy moth, beech bark canker fungus, and forest tent caterpillar. In other areas, oak wilt, sycamore anthracnose, and Dutch elm disease have been identified as potential threats (Brett 2011; Hamel 2000; Robbins et al. 1992; Savignac 2010b).

Microhabitat features may affect reproductive success. In eastern Ontario, nests in areas with larger than average trees and denser foliage 6-12 m and higher than 18 m from ground were more likely to be successful. Nests near small canopy gaps and where there was a dense understorey were less likely to be successful. At 1 site in the Appalachians, white oak was a preferred nest tree species, but daily survival rates were significantly lower in these trees (Barg et al. 2006a; Boves et al. 2013; Hamel 2000; Jones and Robertson 2001; Oliarnyk and Robertson 1996b).

Habitat loss in migration areas in Central America and the wintering area in South America is a concern. The wintering area is increasingly being inhabited by humans and deforested for agriculture (Brett 2011; Hamel 2000; Savignac 2010b).

In Ontario, aggressive interactions between the Cerulean Warbler and the Least Flycatcher, Red-eyed Vireo, and American Redstart are common, and aggression has also been noted between the White-breasted Nuthatch and Cerulean Warbler. Most of these species are dominant to the Cerulean Warbler, but an Ontario study concluded that the frequency of aggression was too low to have detrimental effects. Aggression toward the Cerulean Warbler has been observed elsewhere by all these species except the nuthatch. In addition, aggression has been observed from the Blue-gray Gnatcatcher, Northern Parula, Hooded Warbler, Black-throated Blue Warbler, Black-throated Green Warbler, and Scarlet Tanager. The reasons for the aggressive interactions are unknown. The resource selection of these species may overlap or it may be related to nest-material kleptoparasitism (Barg et al. 2003; Buehler et al. 2020; Carpenter et al. 2011; Hamel 2000; K.C. Jones et al. 2007; Varey and Robertson 1997; Wood and Perkins 2012).

The eastern Ontario population experiences high nesting success and reproductive output, although annual productivity may vary considerably (Barg et al. 2003; Jones 2000; Jones and Robertson 1996; Oliarnyk 1995; Oliarnyk and Jones 1997; Oliarnyk and Robertson 1996a, 1996b). It was initially assumed that eastern Ontario and Tennessee were source populations, contributing birds to other areas within the Cerulean Warbler's range. Jones et al. (2004) conducted a demographic study on the eastern Ontario population and concluded that it may not be self-sustaining because of apparent high mortality rates during migration and winter. The calculated mortality rate was based on the premise that adults exhibited high site fidelity and that return rates were representative of survival rate. This was a reasonable assumption because this is generally the case for most passerines. These authors concluded that the outlook for the species was potentially grim, but acknowledged that they had no estimates of survivorship for females or juveniles. Several other studies were conducted on populations in the United States using the survival rates calculated

in Ontario, and all were deemed to be declining sink populations. Concerns were raised in both Canada and the United States that populations in their jurisdiction would decline due to lack of immigration from the other country. Only 1 Michigan study concluded that site-specific demographic information was required to determine if the local population was a source or a sink (Buehler et al. 2005; Rogers 2006, 2013; Savignac 2010b). Girvan et al. (2007) studied adult male dispersal patterns in Ontario and 4 states using stable hydrogen isotopes. They discovered that 28.2% of males nested in a location geographically distant from their capture site the previous year. This countered the earlier findings by Jones et al. (2004) that the Ontario population was not reproducing at replacement rates and was likely not a source population. Their study demonstrated that Jones et al. (2004) significantly underestimated adult male survival due to breeding dispersal. Consequently, the Ontario population is a source, and other populations in the United States may be as well. Another conclusion of the study by Girvan et al. (2007) was that the size of a given population was not a good indicator of population health or habitat quality.

DNA studies of birds from Ontario and many of the states confirmed that the entire population should be considered a single genetic population. A possible exception is the New England population which has not been studied. No genetic structure was observed in the population even between birds at the extreme northern and southern limits of the range. Lack of structure is related in part to ongoing gene flow with birds throughout having a 4% probability of being immigrants or descendents of immigrants. Most birds that were sampled were males and female dispersal rates tend to be higher than those of males, so dispersal rates may be higher than suggested by these data (Deane et al. 2013; Veit et al. 2005). The genetic study results support the conclusions of Girvan et al. (2007) that there is a high rate of dispersal among populations.

In Pennsylvania, Alabama, and Missouri, Raybuck et al. (2017) determined that fitting Cerulean Warblers with geolocators had no effect on breeding season survival, daily nest survival, or nestling provisioning rates. Birds with geolocators were less likely to return to their breeding grounds in the following year than control birds. Geolocators may cause one or more of the following: displacement from the previous year's territory, potentially due to later arrival on the breeding grounds or decreased aggression toward territorial intruders; reduced site fidelity; and decreased annual survival rates.

Price (2004) concluded that the breeding range of the Cerulean Warbler might expand in southern Ontario if the average summer temperature increased by 2°C.

Status

The historical status of the Cerulean Warbler is uncertain, with most of the uncertainty focused upon whether its original range included eastern Ontario. McIlwraith (1894) considered it a regular but local summer resident in southern Ontario, but provided no details on its range. Saunders (1900) considered it uncommon near London and noted that it was seldom observed in the Toronto area. Macoun and Macoun (1909) concurred, stating that it was common in southwestern Ontario, but not found much north of London. Baillie and Harrington (1937) stated that it bred only in southwestern Ontario in Chatham-Kent, Middlesex, Hamilton, Lambton, and Niagara Region, and that it was rather common in some locations. At that time, it occurred rarely in the Ottawa area and there was an indefinite nesting record for Leeds County. It is probable that the Cerulean Warbler

was more common in at least the Carolinian Forest Region prior to extensive deforestation by European settlers (Austen et al. 1994; McCracken 1993). There are some historical trends within this forest region, suggesting that it continued to decline after the original clearing. In Elgin County, it was a tolerably common summer resident in 1891; in 1954, it was considered a regular but not very common summer resident; and by 2000 only 3 woodlands supported the Cerulean Warbler (Lancaster et al. 2004). Curry (2006) recounted a bicycle trip undertaken by George North in the 1930s along Highway 3 from St. Thomas to Point Pelee when he estimated he heard more than 100 singing Cerulean Warblers. Former major breeding locations in the Hamilton area and their last known years of occupation were: Rock Chapel Woods, 1966; Westdale Ravine, 1969; Glen Morris, 1993; Six Nations, 1995; Caister-Canborough Slough Forests, 2001; and the Halton Region Forest, 1998. In Niagara Region, it was a rare and local breeder in the 1960s but, as of 2010, there had been only 1 confirmed breeding record in the past 24 years (Black and Roy 2010). The population in eastern Ontario increased recently. The first record for the Cerulean Warbler in the Kingston area was in 1928 and the next record was in 1950. It has been seen there annually since 1961 and the first nest was found in 1963 (Austen et al. 1994; Weir 2008). The first atlas documented a significant expansion of its known breeding range. It continued to occur in the Carolinian Forest Region, with notable concentrations in the Long Point area and in the lower Grand River watershed. A second northern band was occupied from the Bruce Peninsula along the southern edge of the Canadian Shield, with a high concentration on the Frontenac Axis north of Kingston, where there were an estimated 130 pairs. During the first atlas, 372-1,580 breeding pairs were estimated to occur in the province (Austen et al. 1994; Eagles in Cadman et al. 1987). James (1991) considered the Cerulean Warbler a rare to locally uncommon summer resident in the south, north to Bruce County and to northern Leeds and Grenville County.

There are 2 plausible explanations for the recent increase in population in eastern Ontario: the Cerulean Warbler was formerly present there, became very rare or extirpated with early deforestation, and returned when second-growth forests matured; or it has recently extended its range to include eastern Ontario. The latter explanation appears more likely despite the 2 records from eastern Ontario prior to the mid-1930s. It was not observed regularly in the Kingston area until 1961, an area with a very active naturalists' club. It is also unlikely that forest clearing by the settlers would have completely eradicated it. It was not eradicated in the Carolinian Forest Region where deforestation was probably more extensive. The entire expansion into the Great Lakes–St. Lawrence Forest Region in southern Ontario appears to be recent. Possibly most convincing is the fact that it has expanded its range northward and eastward over a widespread area. It was first reported in Quebec in 1950 and the population in the province expanded slightly eastward until 1960. There has been no recent change in range or numbers since then. This was considered to be a range extension from Ontario's eastern population rather than recolonization of historical range. In 1929, it was rare or accidental in New England and extremely rare east of the Appalachians. It has increased its range and abundance in Massachusetts, Connecticut, Rhode Island, Pennsylvania, and New York (Bannon and Robert in Gauthier and Aubry 1996; Barg et al. 2003; Buehler et al. 2020; Chapman 1907; McCracken 1993; Oliarnyk and Jones 1997; Oliarnyk and Robertson 1996a; Ouellet 1967; Robbins et al. 1992; Savignac 2010b). Buehler et al. (2020) concluded that the eastern Ontario population represented a range expansion rather than recolonization of an area where it formerly occurred.

The second atlas demonstrated that there had been no change in the distribution of the Cerulean Warbler since the first atlas. There was no evidence of a continued range expansion to the north or east. Its probability of observation decreased significantly in the Carolinian Forest Region and did not change significantly in other regions or province-wide, although all trends were negative. It was observed in 108 squares during the first atlas and 86 during the second. The number of squares it was observed in within the Carolinian Forest Region declined from 46 to 28 between atlases. The largest population continued to be in the Kingston area on the Frontenac Axis followed by the Long Point area. Densities of 5 or more pairs per atlas square were documented in these 2 locations as well as at Skunk's Misery, Pinery Provincial Park, and Awenda Provincial Park (Francis in Cadman et al. 2007).

The atlases suggest that the population in the Frontenac Axis is stable but the Carolinian population is declining. Approximately 20% of the Ontario population resides in the Carolinian Forest Region and a 47% proportional decline occurred in that area. This decline was significant at the 0.10 level and the data suggest a 16% decadal decline that is not significant. It was concluded that there was also a positive bias in the second atlas because participants were asked to look for it at known historical sites and disappearance from a single square would have involved more than 1 pair (Savignac 2010b). A possible negative bias in the atlas results is that only those species found within a square within the first 20 hours of atlassing were considered when comparing abundance between atlases. All squares where the Cerulean Warbler was documented after 20 hours would have been considered devoid of this warbler.

Additional population estimates were made since the attempt during the first atlas to estimate the size of the Ontario Cerulean Warbler population. The estimate provided by McCracken (1993) was 680-2,880 pairs. Population sizes in different areas ranged from a few pairs to 58 in Minesing Swamp near Barrie in 1974. Barg et al. (2003) reported the Canadian population, which includes a few in Quebec, at 500-1,000 pairs. The largest cluster was approximately 250 pairs in the Kingston area where the population has remained constant over the past 20 years. The largest clusters in southwestern Ontario consisted of 20-30 pairs and it was estimated that this entire area supported fewer than 100 pairs. After the second atlas, a targeted survey was completed for the Cerulean Warbler. This resulted in a more refined estimate of 408-493 pairs in Ontario. This included approximately 300 pairs on the Frontenac Axis and 80 pairs combined in Middlesex and Norfolk counties, Georgian Bay National Park, Awenda and Pinery Provincial Parks, and Minesing Swamp. It was estimated that the remainder of Ontario held no more than 50-150 pairs in scattered locations (Brett 2011; Savignac 2010b). Due to the differing survey methods used each time population estimates were made, the various estimates cannot be used to estimate trends. The results reported in 2010 were the most accurate surveys and also represent the most current knowledge.

The Committee on the Status of Endangered Wildlife in Canada has evaluated the Cerulean Warbler 3 times and a federal management plan and recovery strategy were prepared for it. It was initially designated special concern in 1993 and this status was confirmed in 2003. In 2010, its status was upgraded to endangered. In Ontario, it was also originally designated special concern and its status was upgraded to threatened. The objective of the 2010 management plan was to maintain the population at its current rate until 2015 (Barg et al. 2003; Brett 2011; McCracken 1993; Savignac

2010b). The 10-year objective of the recovery strategy was to halt the population decline. The 30-year objectives were to maintain a stable population of at least 1,000 mature individuals and to maintain its range, or where possible, increase its area of occupancy within its current range (Brett 2021).

The Breeding Bird Survey (BBS) determined that the Cerulean Warbler decreased in Ontario at annual rates of 2.22% 1970-2021 and 0.917% 2011-21. The trends were of low reliability (A.C. Smith et al. 2023). BBS data indicate that the Cerulean Warbler has declined rangewide at a rate of about 3% per year since 1966. This is one of the most precipitous declines recorded by this survey, with only 6 other passerines exhibiting a higher rate of decline (Buehler et al. 2008, 2020; Hamel 2000; Hamel et al. 2004; Hands et al. 1989d; Robbins et al. 1992). The BBS has significant limitations and its adequacy to monitor Cerulean Warblers has been seriously questioned. The number of BBS routes recording the species is too low in most areas such that trends can be estimated in only approximately 50% of its range. The fact that the BBS is a volunteer program creates problems in certain areas. It is particularly abundant in eastern Kentucky and West Virginia where there are few volunteers. A BBS survey consists of a roadside survey where 50 point counts are taken at evenly spaced intervals on 1 day in June. The roadside count method may be biased against forest-dwelling species such as the Cerulean Warbler. In West Virginia, it is most common on mountainous ridges, but all roads are in valleys. In Missouri, the average number of Cerulean Warblers recorded is only 0.2 birds per route. Canoe-float surveys along rivers determined that it was one of the most abundant riparian species, and unprecedented numbers were detected. The BBS suggested an annual decline of 3.1% in that state but canoe surveys noted either constant trends or possibly an increase. BBS data analysis involves averaging the number of birds observed on the 50 points of the route, thereby including data from points where there is no suitable habitat. Most routes with birds typically support only 1 or 2 birds and rarely 3 or more. A study in the Appalachians analyzed BBS data using only points where it was recorded and compared the results to the standard BBS results for 2 periods. The number of detections did not change between 1982 and 2001 across 1,375 BBS stops that were analyzed. There was an increase from 14% to 17% of stops where the species was detected and this approached significance. During the same period, the BBS reported declines of 4.1-6.8%. One of the main reasons for the disparity in results was that the study was done in the core of the species' range whereas the BBS results were based on 75 routes that included areas near the periphery of its range. Another limitation of the roadside survey technique is that changes in habitat along roadsides would reduce the detectability of birds in greater proportion than their actual decline. In all cases where detailed studies have been conducted, rates of population declines have been lower than estimated by the BBS. In some areas, populations were stable where the BBS indicated precipitous declines (Buehler et al. 2020; Hamel 2000; Link and Sauer 2002; McElhone et al. 2011; Robbins et al. 2009; Weakland and Wood 2005).

BBS data are also used to estimate the size of the Cerulean Warbler population. Point counts conducted on the BBS are of 3 minutes duration, and it is assumed that all birds present are detected. In Missouri, Robbins et al. (2009) estimated that 52.5% of Cerulean Warblers would be missed on a point count of 5 minutes or less. Even doubling the sample time to 10 minutes resulted in significant proportions of males not being detected. These authors concluded that the assumption that 100% of birds would be detected in a 10-minute point count was seriously flawed and that numbers may

be underestimated by 2-4 times. In addition, unmated males sang at twice the rate of mated males, so there is a lower probability of detecting mated males. Jones et al. (2000b) compared results from 50-m and 100-m fixed radius points and variable circular plots to known densities of Cerulean Warblers in eastern Ontario. They found that results from all 3 methods correlated with actual densities. The 50-m plots consistently overestimated densities; the other 2 plot types underestimated densities. The magnitude of the error increased significantly with actual density in both years for the latter 2 plot types but in only 1 year for the 50-m fixed radius plot. They concluded that it was better to underestimate than overestimate densities and recommended the variable distance plot as being easiest to employ. They noted that detailed information on a population, such as its extent, habitat, and population trend, is required before the appropriate survey technique is selected. They also cautioned that well-trained observers who studied the site year to year were required.

The current population estimates and trends for the Cerulean Warbler are deficient in many areas. It may be necessary to refine data collection techniques or change methods of analyzing existing data to obtain more reliable results. There are now several detailed studies available on discrete populations and it may be necessary to conduct more of these throughout its range to obtain better information on population demographics.

POSTFLEDGING PERIOD

In eastern Ontario, a pair was observed feeding fledglings 19 days after they left the nest. Elsewhere, a male was observed feeding 2 fledglings 30 days after they fledged. In eastern Ontario, fledglings used all parts of the canopy and often hid under leaves. In other areas, adults took fledglings into deep tangles of grape vines. In eastern Ontario, adults fed chicks within the territory for at least 10 days after fledging in half of successful territories. One male was observed feeding a fledgling 100 m outside his territory in the territory of an unpaired male. In the Appalachians, adults and young often dispersed outside their territories (Boves et al. 2013; Buehler et al. 2020; Hamel 2000; Oliarnyk and Robertson 1996a).

In Pennsylvania, fledglings remained within an average of 45 m of the nest for the first 2 days. Brood division occurred 3-6 days after fledging, with adults and fledglings moving as far as 150 m from the nest. By 7-12 days, most had moved as far as 305 m, beyond the male's territory. After 13-20 days, they were as far as 717 m from the nest. By the end of the tracking period (average 28.1 days after fledging), young had moved an average of 2.4 km from the nest. Fledglings were usually in the mid- to upper canopy and selected areas with greater sapling cover, less BA, and areas closer to water bodies than random sites. Until 2 days after fledging, young selected areas with greater sapling cover and less BA, but as they matured, they selected areas further from canopy gaps with greater mid-canopy cover. Compared with habitat selected by their parents, fledglings used areas with smaller and more numerous trees, fewer canopy gaps, and greater mid-storey cover (Raybuck et al. 2020).

In Missouri, Porneluzi et al. (2014) netted during the postfledging period in an oak-pine-hickory forest 2-15 years after it had been clear-cut and captured a total of 4 Cerulean Warblers.

MIGRATION

The Cerulean Warbler is a nocturnal migrant that travels alone or in small groups. During the day, it may occur in flocks with other warblers and resident species (Buehler et al. 2020).

Males arrive in spring about a week in advance of females. In eastern Ontario, males began to arrive in the first week of May and females arrived in the second week of May. Most Cerulean Warblers move through Long Point between 18 April and 25 May. In most of southern Ontario, it arrives in early to mid-May and migrants are present to the end of May; it has been recorded into early June. At Lake Opinicon, there appears to have been a shift toward earlier arrival, with first arrival on 13 May in 1994 and on 2 May in 2001 (Barg et al. 2003; Black and Roy 2010; Buehler et al. 2020; Curry 2006; Hamel 2000; LaForest 1993; Lancaster et al. 2004; Oliarnyk and Robertson 1996a; Weir 2008).

The Cerulean Warbler ceases singing in July and is very difficult to detect after that, hindering migration monitoring. It is an early autumn migrant and most leave the Ontario breeding grounds by the end of August. It is one of the earliest warblers to reach the Mississippi coast. In the Kingston area, the average date of the last sighting is 21 July and the latest record is 7 September. There are no autumn records from Prince Edward Point, suggesting that birds move early during late July and early August. Birds may also have an aversion to the Great Lakes shoreline. It is a rare to uncommon migrant at Long Point despite the presence of a fairly large population a short distance north of there, but it occurs more frequently at Point Pelee. There are only 2 autumn records for Presqu'ile, between 10 and 17 September. Average autumn departure in the Hamilton area is 23 August and the latest record is 27 October. The 3 autumn records from Elgin County are from 11 August to 28 September (Barg et al. 2003; Curry 2006; LaForest 1993; Lancaster et al. 2004; McCracken 1993; Robbins et al. 1992; Weir 2008).

During migration, the Cerulean Warbler occurs in the canopy of deciduous second-growth or mature trees. During spring migration in Illinois, it was most frequent in bottomland forests in the south and in upland forests in the central portion of the state. It has also been observed in orchards and shrubby areas during migration. It usually uses areas of lower vegetation only under adverse weather conditions such as strong winds and rain (Barg et al. 2003; Graber et al. 1983; Hamel 2000).

The Cerulean Warbler remains predominantly insectivorous during migration but also eats small amounts of plant material (Buehler et al. 2020; Hamel 2000).

During migration, the Cerulean Warbler is occasionally killed at communication towers and other tall structures. Numbers killed are relatively modest, but the population is small so it is unknown whether this is a significant impact. At the Lennox generating station chimneys near Kingston, 2 of 22,779 mortalities were Cerulean Warblers. Over 25 years at Florida television towers 141 Cerulean Warbler casualties were documented; over the first 11 years, 93 were killed of a total of 29,451 birds. No spring casualties were documented at Florida television towers. Two were killed at towers in spring in Illinois and there were no autumn casualties (Brett 2011; Buehler et al. 2020; Graber et al. 1983; Hands et al. 1989d; Robbins et al. 1992; Savignac 2010b; Weir 2008).

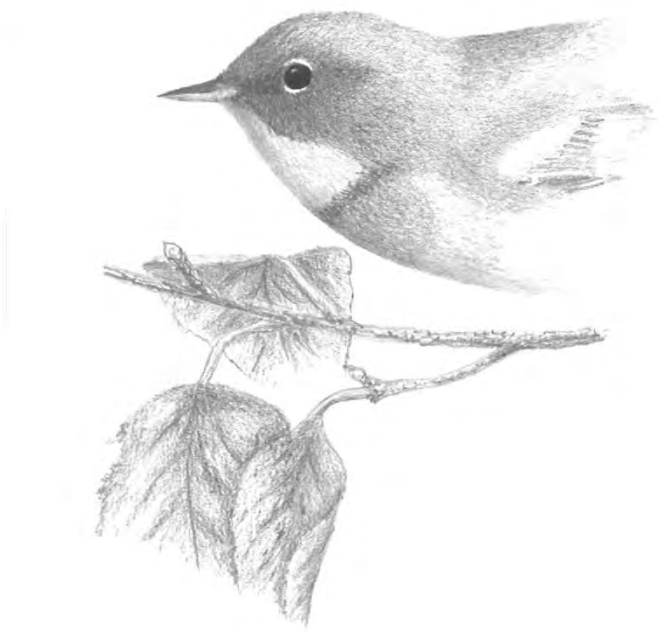
Before it was known that considerable dispersal of adults occurred on the breeding grounds, it was concluded that significant mortality must occur during migration and winter. Migration was

considered the time of maximum mortality because the species travels as far as 4,000 km 1 way and the migration period spans 2 months in spring and 4 months in autumn (Barg et al. 2003; Buehler et al. 2008; Jones et al. 2004). It is now known that annual mortality rates are not excessive. Undoubtedly some mortality occurs during migration, but it may not be a significant limiting factor. There are several other passerines that travel just as far. Although the species may spend extended periods migrating, it is unlikely that individuals do. The length of the Cerulean Warbler's migration period is similar to that of many neotropical migrants.

James (1991) considered the Cerulean Warbler a rare migrant. Only 30 were detected on daily surveys at Long Point Bird Observatory since 1960. The maximum daily count there is 3; the maximum recorded at Point Pelee is 25 (McCracken 1993). In Niagara Region, the high count of 3 was on 11 May; it has not been documented there in autumn (Black and Roy 2010). At Presqu'ile, the high count of 3 was on 19 May and usually only 1-4 birds are reported all spring (LaForest 1993).

Northern Parula

Setophaga americana



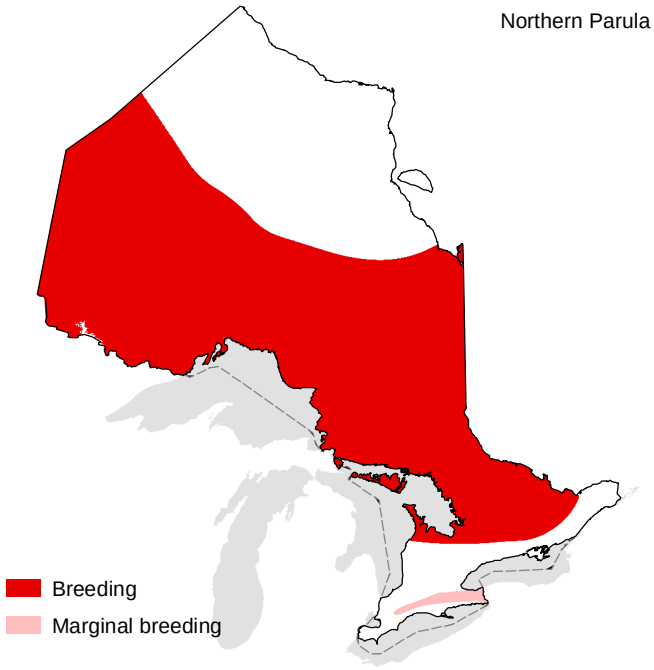
BREEDING SEASON

Habitat Requirements

Limited information is available on the breeding season habitat requirements of the Northern Parula in Ontario. James (1984b) observed that it was characteristic of sugar maple–beech forests but that it also occurred in mixed and deciduous forests. He noted that it required mature and dense upland forests.

In the Boreal Forest Region, the Northern Parula occurred in hemlock stands but was more characteristic of transitional sugar maple–beech forests. It sometimes extended far into the boreal region in deciduous or mixed woods. It is also characteristic of swamps and floodplains dominated by balsam poplar and tree-sized willows and alders (Erskine 1977). In the Clay Belt, Welsh and Lougheed (1996) detected it in only 2 stands. Both were dominated by balsam poplar on moist soils in areas rich in nutrients. Near Quetico Park, it tended to be associated with old-growth forests with scattered old red pines or white pines that formed an overstorey in a somewhat open forest of spruce and balsam fir. It also occurred in some forests 1-23 years old (Apfelbaum and Haney 1985). Near Manitouwadge, Venier et al. (2009) found it only in stands 60-223 years old; it was absent in

stands 1-21 and 24-36 years old. Near Hearst, Welsh and Fillman (1980) reported it breeding in 6-year-old clear-cuts in upland mixed forests.



In Algonquin Park, the Northern Parula is characteristic of hemlock stands. It also nests in spruce swamps and tall, mature coniferous and mixed swamp and bog forests where beard lichen is abundant. In addition, it nests in drier coniferous forests with white spruce and balsam fir where this lichen is often absent (Martin 1960; MacLulich 1938; Tozer 2012). In Ontario and much of its range, its distribution is closely linked to beard lichen or other epiphytes growing on trees. Nests are frequently placed in these and also constructed of them. It is not entirely constrained by lichens and mosses and will nest in areas where they are absent.

In the northern portion of its range, presence of the Northern Parula is often associated with beard lichen. This species is found most frequently in damp habitats where it grows predominantly on branches of conifers, although it also occurs on deciduous trees. The Northern Parula frequently breeds in mixed and coniferous lowland forests and swamps. These are most frequently dominated by white, red, or black spruce or balsam fir, but it also inhabits stands dominated by white cedar, tamarack, and hemlock. It nests not only in coniferous inclusions in deciduous forest stands, but also in pure deciduous forests. In Manitoba, typical habitat is mixed forests of trembling aspen, balsam poplar, white birch, white spruce, and balsam fir with profuse growth of beard lichen. It has also nested in white cedar–tamarack swamps and is locally distributed in dense coniferous and mixed forests containing a high proportion of black spruce, tamarack, white cedar, or balsam fir. In the Maritime Provinces, it is common in northern hardwood communities, including tolerant hardwoods dominated by sugar maple and intolerant hardwoods dominated by trembling aspen and balsam poplar. Densities are higher in deciduous than mixed or coniferous stands. It is less abundant in stands with increasing amounts of beech where it needs larger territories for food resources, but it prefers beech forests in South Carolina. In Maine, it is found mostly in forests dominated by spruce. In Illinois, it was more common in bottomland forests than upland forests. In 1 Illinois study, its abundance was correlated with presence of sycamore which it often used as a singing perch. Another Illinois study examined tree species preferences by the Northern Parula. Preferred species, in order of preference, were shellbark hickory, sycamore, silver maple, cherrybark oak, bitternut hickory, pin oak, and green ash. Avoided species, in decreasing order of avoidance, were overcup oak, sugar hackberry, pumpkin ash, blue beech, bald cypress, red maple, white elm, sweetgum, swamp chestnut oak, black gum, and Manitoba maple. Of the preferred trees, shellbark hickory was 11th in abundance, silver maple was 18th in abundance, and bitternut hickory was 19th

in abundance. Of the avoided trees, pumpkin ash was the second-most abundant tree, sweetgum was third in abundance, overcup oak was fourth in abundance, and blue beech was seventh in abundance. In Massachusetts, the Northern Parula nested in old apple orchards where the trees were covered profusely with beard lichen. As the apple trees died, the beard lichen declined as did the parula. Eventually both the lichen and warbler disappeared entirely. In many areas, it may be widely distributed despite the absence of beard lichen. In the more northern portions of its range, it has nested in stands dominated by oak-chestnut-hickory, oak-pine, white pine, red pine, white birch, balsam fir–white cedar, birch-basswood, white birch–yellow birch–white cedar, hemlock–yellow birch, sugar maple–yellow birch, and elm–Manitoba maple–sycamore in addition to the more traditional habitats (Beals 1960; Bent 1953; Brooks 1940, 1947b; Chapman 1907; Cruickshank 1956; Dawson 1979; Freedman and Johnson 1999; Gabbe et al. 2002; Graber and Graber 1951; Graber et al. 1983; LaRue et al. 1995; Lemieux et al. in Gauthier and Aubry 1996; McNicholl and Taylor 1982; Moldenhauer and Regelski 2020; Morgan and Freedman 1986; Morse 1967; Pagen et al. 2000; Parker et al. 1999; Parnell 1969; Rich et al. 1994; Samson 1979; Temple et al. 1979).

In the southern portion of its range, the Northern Parula nests most frequently in bottomland forests, often along rivers and lakes where Spanish moss grows on the trees. It also occurs in areas where this moss and other epiphytes are absent, and in upland forests. Stand types it has been reported using in the south include those dominated by hackberry, black walnut, sweetgum-oak, beech, oak-hickory, pine, pine-hardwoods, hemlock in moist ravines, hemlock–tulip tree, hemlock-hardwoods, black willow, and bald cypress. In upland habitats, it is associated with the more mesic portions of stands. In Missouri, preferred tree species included sycamore, hackberry, cottonwood, pecan, and green ash (Brittain et al. 2010; Brooks 1947b; Buffington et al. 1997; Bushman and Therres 1988; Chapman 1907; Harrison 1984; Hayden et al. 1985; Moldenhauer and Regelski 2020; Morse 1967; Parnell 1969; Schukman 1996).

The Northern Parula nests most frequently in mature forests with a closed canopy. It occasionally nests in younger or more open stands. Small canopy openings may be attractive to it and it frequently nests around these. Canopy closure of occupied forests ranges from poorly developed to an average of 70%. In northern hardwood stands in New Brunswick, it was one of the 6 most dominant species in stands 20 and more years old. It is also a dominant species in unharvested deciduous forests in Nova Scotia. In New Hampshire and Maine, it was significantly more abundant in the large-sawtimber size-class of forest that was dominated by trees larger than 60 cm diameter at breast height (DBH). It was equally abundant in sapling-sized forests and sawtimber-sized forests and uncommon in poletimber-sized forests. The Northern Parula is not an obligate old-growth forest species. In Pennsylvania, it occurred in 9.1% of old-growth forests compared with 10.1% of forests statewide and 9.9% of forests on the Appalachian Plateau. In South Carolina, it occurred in black willow stands 6, 27, and 60 years and older, but was most frequent in the oldest stand. It exhibited neither a positive or negative affinity for old-growth. In Maine, Minnesota, and New Brunswick, it consistently selected areas where there were highest densities of large trees. In the 2 states, these were coniferous species but they were deciduous species in New Brunswick. In South Carolina, breeding density was 4.5 times higher at edges of gaps 0.13-0.50 ha created by group-selection harvest than in unbroken canopy in the same forests. In Maine spruce forests, it also frequently nests around canopy gaps (Bowen et al. 2007; Buffington et al. 1997; Bushman and

Therres 1988; Collins 1983a; DeGraaf et al. 1998; Freedman et al. 1981; Haney 1999; Morgan and Freedman 1986; Morse 1967; Parker et al. 1999).

Collins (1983a) compared habitat usage by the Northern Parula in Maine and Minnesota. There were 3 habitat variables that were significantly different in the 2 states: number of tree species, number of trees 7.5-15 cm DBH, and number of trees 15.1-23 cm DBH. In Minnesota, it was in a forest–forest edge guild that occurred in habitats with tall canopies, moderate coniferous cover, few small trees, and more larger trees. In Maine, it was in a guild inhabiting areas with high percent canopy cover, variable coniferous cover, and many trees in the smaller size classes. In both states, it consistently selected larger trees and areas of conifers. The author concluded that it may not have different habitat preferences in the 2 areas but may simply be selecting the most optimal available habitat.

Some studies examined microhabitat requirements of the Northern Parula. In Arkansas, its density was correlated with the number of tree species, the number of small trees, and canopy height. In Nova Scotia, its density was correlated with tree density, basal area (BA), percent canopy cover, and canopy height. In the mid-Atlantic states, its abundance was positively correlated with BA and moisture gradient and negatively correlated with slope and percent coverage by conifers. In Maryland, its abundance was correlated with the total number of plant species. Average habitat characteristics in Minnesota were 60.3% ground cover, 50.0% shrub cover, 76.4% canopy cover, canopy height 16.8 m, 49.3% coniferous cover, and 6 tree species within a 0.04-ha circle. Numbers of trees of different size classes in 0.04-ha circles were: 10.0 that were 7.5-15 cm DBH; 11.0 that were 15.1-23 cm DBH; 7.3 that were 23.1-30 cm DBH; 3.6 that were 30.1-38 cm DBH; 2.8 that were 38.1-53 cm DBH; 0.4 that were 53.1-68 cm DBH; and 0.2 larger than 68 cm DBH. Habitat was characterized as mature forest with moderate ground and shrub coverage and greater than 75% canopy closure. Territories consistently contained more than 50% coniferous coverage, mostly in the large tree-size categories. It was associated with moderate amounts of large trees, more canopy cover, and less ground cover. In Georgia, the Northern Parula showed a strong positive association with shrub height and a weaker association with shrub density, canopy cover, and BA. It was negatively correlated with herbaceous cover. In New Hampshire and Maine, its presence was significantly correlated with the number of snags larger than 10 cm DBH and taller than 5 m and the total foliage volume of coniferous trees larger than 10 cm DBH. It was negatively correlated with the total foliage volume of deciduous trees larger than 10 cm DBH (Collins et al. 1982; DeGraaf et al. 1998; Klaus et al. 2010; Lynch 1987; Moldenhauer and Regelski 2020; Robbins et al. 1989).

In Minnesota, Collins (1981) compared the vegetation at Northern Parula nest sites and perch sites. Nests were in forest and forest-edge habitat with variable numbers of large deciduous and coniferous trees and an open canopy. Perches were also variable, but were most often in forest rather than at forest edge. Perch sites had significantly higher ground and shrub coverage and a higher percent coverage by conifers than nest sites.

Some studies reported that the Northern Parula is area sensitive and others have found it nesting in small patches with no indication of area sensitivity. Most reports of area sensitivity are from Maryland and other mid-Atlantic states and Missouri. In Maryland, Lynch (1987) reported that it was area sensitive and Bushman and Therres (1988) concurred. They reported that it was found in

few woodlots smaller than 70 ha. Robbins (1979) concluded that 100 ha were required to support a viable population in Maryland. In the mid-Atlantic states, its probability of detection was at its maximum in forests larger than 3,000 ha. Its probability of detection declined to 50% at 520 ha and the 3 smallest forests it inhabited were 516.0, 415.0, and 10.1 ha. In Missouri, Hayden et al. (1985) estimated that the minimum patch size required to support the Northern Parula was 53.6 ha. James (1984b) reported that it appeared to be area sensitive in Ontario, probably requiring 100 ha or more of continuous forest in order to maintain a viable population. In Maine, the Northern Parula regularly nested on small islands 0.2-1.5 ha. It nested on smaller islands than any other warbler species (Morse 1971b). Beals (1960) studied the avifauna on islands in Wisconsin and found that it was not confined to larger islands. In Georgia, Hodges and Krementz (1996) compared the densities of breeding Northern Parulas in corridors less than 350 m in width and those 400-700 m and wider than 1,000 m. It did not show a positive association with corridor width, with highest density in the medium-sized corridor and least in the widest.

Bushman and Therres (1988) considered the Northern Parula a forest-interior species, but provided no supporting documentation. In many areas, the opposite is true and it is an edge species. Hayden et al. (1985) considered it an edge species in Missouri as did Bowen et al. (2007) in South Carolina. In Maine spruce forests, it was confined to forest edge and rarely ventured into unbroken forest. It occasionally occurred in forest gaps created by blowdown and bedrock outcrops. Avoidance of forest interior appeared to be a response to competition with the Golden-crowned Kinglet. Both species have very similar foraging strategies, foraging on the outer tips of limbs, and the kinglet is socially dominant to the parula. There were few kinglets foraging at the forest edge, so the Northern Parula could forage there without competitive interference. In Louisiana, it was evenly distributed throughout the forest; there were no other species present that foraged in a similar manner (Morse 1967, 1989). In Quebec balsam fir–white cedar stands, it was more than 3 times abundant in riparian than nonriparian stands. In riparian stands, there was an edge effect due to a band of deciduous thicket swamp (LaRue et al. 1995). In northern Michigan, it was most abundant in mature riparian zones where it responded positively to even narrow riparian strips (Moldenhauer and Regelski 2020).

Only 4 empty nests have been described from Ontario and all were in mixed wooded areas. Nest-tree species included yellow birch, white birch, balsam fir, and white spruce. One nest was above the roof of a tourist lodge. One nest was built in hanging beard lichen. Another nest was in a curl of bark attached to the trunk of a white birch at a height of 8 m (Peck and James 1987).

Nests are invariably in trees, typically in forest or at forest edge, and rarely in isolated trees. Nest trees may be either coniferous or deciduous, including spruce, balsam fir, red cedar, birches, white oak, sycamore, and apple. Nests may be in live or dead trees, with dead trees used only if they support beard lichen. Nests have been reported 12.7 cm to 30 m from the ground, with most 3 or more metres up. Seventy-one Maine nests were 1.6-16.5 m from the ground, mostly 3-12 m up. In the north, most nests are built in and of beard lichen but Spanish moss is used in the south. Nests may be free-swinging in trailing lichen or moss or hung from small branches in a pendant or semipensile manner, similar to oriole or vireo nests. Although most northern nests are in beard lichen, there is no relationship between the density of warblers and lichens. The presence of the

lichen is important but lichen abundance is not. One nest in a spruce tree in Minnesota was built entirely of beard lichen, which was not known to occur within 1.6 km of the nest. The female must have travelled a considerable distance to find it. Of 81 nests reported in Maine, all were in beard lichen and constructed of it. Most nests constructed of lichen or moss are at the extreme tips of branches. Pendant nests attached to twigs usually open at the top. Nests in free-hanging lichens or moss have an entrance in the side at the level of the nest bowl. Some nests have 2 holes at this level. One is used as an entrance and the other as an exit. Where beard lichen and Spanish moss are absent, the Northern Parula may nest in clumps of leaves at the tips of oaks, sycamore, hemlock, and spruces. Nests may also be in debris deposited by flood waters in shrubs and trees along watercourses. Other nests have been on the horizontal limb of a spruce, in the crotch of a hackberry tree, in ivy within a tree, in witches'-brooms in hardwood trees, and burlap deposited by flood water on the branch of a Manitoba maple limb. Nests that survive the winter may be used in subsequent years. One Maine nest was used in 4 successive years (Bent 1953; Brooks 1940, 1947b; Chapman 1907; Cruickshank 1956; Graber and Graber 1951; Graber et al. 1983; Harrison 1984; Lemieux et al. in Gauthier and Aubry 1996; Moldenhauer and Regelski 2020; Morse 1967; Mousley 1916a, 1924, 1926, 1928; Parmelee 1973; Peterson 1946).

In Nova Scotia, average territory size was 0.32 ha (range 0.08-0.65 ha). Territory size increased with increasing abundance of beech and stand size, suggesting that it was more common in small stands without beech. In mainland forests in Maine, territories averaged 0.4 ha (range 0.30-0.51 ha). This area supported its main competitors (Golden-crowned Kinglet and Black-throated Green Warbler) as well as other Northern Parulas. On small islands, territories averaged 0.17 ha and were as small as 0.16 ha. The main competitors were absent on these islands and they supported only a single pair of Northern Parulas. There are 2 reports of colonial or semicolonial nesting. A Connecticut swamp was reported to support 75 breeding pairs and as many as 200 were reported nesting in trees surrounding a small lake in Virginia. Details of both of these observations are rather sketchy and the area of the habitat was not provided in either case so that densities could be estimated (Bent 1953; Chapman 1907; Moldenhauer and Regelski 2020; Morse 1967, 1977, 1989).

No information is available on natal philopatry or return rates of adults. One adult male was recaptured in the same area in Maine the following year. Two adult females were recaptured in the same 10-minute block in Maryland 3 years later (Moldenhauer and Regelski 2020).

Limiting Factors

Peck and James (1987) concluded that eggs could be present throughout June until mid-July. In Algonquin Park, nests are under construction from mid-May to early June, eggs are present from early to mid-June, nestlings are present from late June to late July, and dependent fledglings have been observed from late June to mid-August (Tozer 2012).

Nests may take 4-10 days to build. At 1 nest, the first egg was laid the day after the nest was completed, but this was an unusually late nest. One egg is laid per day. At a nest with a single egg, incubation began with laying of the egg but incubation started with laying of the penultimate egg in more traditionally sized clutches. Limited data suggest that the incubation period is 12-14 days. No information is available on the nestling period. One nestling left a nest prematurely when it was

disturbed at age 10 days (Bent 1953; Graber and Graber 1951; Moldenhauer and Regelski 2020; Mousley 1924, 1926, 1928).

Two clutches per season have been confirmed in the Carolinas and egg and nestling dates in Florida, Georgia, Alabama, and Texas suggest double brooding. It is unknown if second broods are raised in Ontario. Renesting after nest loss occurred in Maine. Typical clutches contain 3-5 eggs (range 2-7, mean 3.94). Clutches initiated near mid-July in Illinois contained only 1-3 eggs (Bent 1953; Chapman 1907; Graber and Graber 1951; Moldenhauer and Regelski 2020; Morse 1971b; Mousley 1916a).

Both sexes are capable of breeding at age 1 year. In Maine, individuals occasionally appeared on islands where they did not breed, indicating a floater population. The mating system is monogamous, although there is at least 1 record of polygyny. Extra-pair copulation is considered rare, but this warrants further study (Moldenhauer and Regelski 2020; Morse 1971b).

Considerable information is available on the foraging strategies of the Northern Parula and how they change in the presence of competitors. In South Carolina, it foraged from twigs and small branches 77% of the time and 20% of the time on larger branches (Moldenhauer and Regelski 2020). It typically gleans insects in the upper and mid-canopy, but occasionally forages along tree trunks similar to a nuthatch or searches for insects on the ground (Lemieux et al. in Gauthier and Aubry 1996). It often feeds chickadee-like by hanging upside down (Chapman 1907). During the breeding season in North Carolina, 53.8% of foraging occurred in the canopy and 46.2% in low trees, with no observations of it in shrubs or on the ground. In the canopy, 23.0% of foraging occurred in the inner crown and 30.8% in the lower crown with none in the upper crown or on the bole. In low trees, 7.7% of foraging occurred in the inner crown and 38.5% in the lower crown, with none in the upper crown or on the bole. Singing males were observed at heights of 1.5 to more than 15 m (average 11 m). Nonsinging birds occupied the same range of heights, but averaged 7.6 m from the ground (Parnell 1969). Morse (1967, 1971b, 1989) studied the foraging habits of the Northern Parula in Maine and Louisiana. Its foraging strategies are suggestive both of kinglets and the larger warblers in the genus *Setophaga*, although no other species forages exactly as it does. In Maine, it foraged at moderate heights an average of 10.0 m from the ground (range 1.5-18.3 m). It appeared to minimize overlap in foraging with the other warblers by feeding heavily in the extreme tips of foliage. There was considerable overlap with Ruby-crowned and Golden-crowned kinglets. Potential competition with kinglets was minimized by feeding mainly on disturbed edges; the kinglets concentrated on spruce in undisturbed areas. There were also some differences in the techniques of the Northern Parula and Golden-crowned Kinglet. The kinglet foraged more heavily on inner portions of spruce (more than 20% of the time) than the parula (6%). The kinglet also concentrated its foraging at a lower height (average of 8.0 m compared with 10.0 m), although there was considerable overlap in foraging heights of all species examined. Nonetheless, a considerable amount of foraging was done by the Golden-crowned Kinglet in the same areas as the Northern Parula, and some of the same types of movements were made in the tips of foliage. The Northern Parula spent 91.7% of its foraging time in spruce trees, 2.5% by flycatching, 8% in deciduous trees, and 0% on the ground. In spruce, 48.3% of its time was spent at the tip of foliage: 32.9% by gleaning, 5.0% by stretching, 7.5% by hovering, 2.1% by hover-walking, and 0.8% by hanging. In addition, 23.3% of time was spent on twigs 5 mm

or smaller in diameter, 2.9% on dead twigs (2.5% gleaning and 0.4% hovering), 2.1% gleaning on dead branches, 5.0% on lichen-covered branches, 3.8% on the distal portion of branches, 6.3% on the proximal portion of branches, and 0% on the trunk. The Black-throated Green Warbler showed more similarities in foraging to the Northern Parula than any other warbler. It foraged at the most similar height (average 11.8 m), hovered more frequently than any other warblers, and also attained the highest density of any of the warblers. The Black-throated Green, Blackburnian, and Yellow-rumped warblers did not use the tips of foliage as much as the Northern Parula, but the use of this habitat by the 3 warblers combined was heavy. In an area with equal numbers of spruce and birch, the Northern Parula foraged significantly more frequently on spruce (119 times) than birch (23 times) in the first half of June. By mid-July, it foraged somewhat less in conifers (51 times) than birches (66 times). By this time, the young had fledged and birch leafminer sawflies probably resulted in a superabundant food supply. Use of deciduous trees minimized competition with the Golden-crowned Kinglet which foraged solely in conifers. In Louisiana, the Northern Parula had no competitors and ranged widely through the canopy and also in the understorey once the young fledged. In spruce forests in Maine, the Golden-crowned Kinglet was the primary competitor, followed by the Black-throated Green Warbler and Blackburnian Warbler. The Yellow-rumped and Magnolia warblers did not appear to be significant competitors. Morse (1971b) studied the foraging strategies of warblers on small islands in Maine. Islands supported either 3 species of warblers (Black-throated Green Warbler, Yellow-rumped Warbler, and Northern Parula), the Yellow-rumped Warbler and Northern Parula, or just the Northern Parula. The parula showed a stronger tendency than the other 2 species to use deciduous foliage and to forage at the tips of vegetation. It preferentially selected birch trees infected with defoliating insects. Males foraged higher than females, but both sexes foraged lower in vegetation when the Black-throated Green Warbler was present. Where the Black-throated Green Warbler was absent, female Northern Parulas and male Yellow-rumped Warblers had higher foraging diversity, but no clear-cut relationship was detected for male parulas. When the Northern Parula was the only warbler species on an island, it exhibited much greater foraging diversity to include both coniferous and deciduous trees, a wider range of heights, and small limbs as well as the tips of branches. Foraging diversity declined on 1 island where it was the sole occupant because it concentrated on foraging in deciduous trees with high concentrations of insects. The Black-throated Green and Yellow-rumped warblers may restrict the foraging strategies of the Northern Parula, but it exhibits a greater level of foraging plasticity and was therefore able to occupy the smallest islands. Morse (1989) concluded that the Northern Parula may be more limited by the presence of kinglets and other warblers than by the availability of beard lichen for nesting.

Although the foraging strategies of the Northern Parula are well documented, there is limited information on its diet, particularly during the breeding season. Young have been fed small green caterpillars, mayflies, and other winged insects. Prey delivered to nestlings tends to be larger than what is generally available. During the breeding season, adults consume mostly insects and spiders and rarely bud scales. It feeds heavily on spiders and caterpillars and accesses tent caterpillars by tearing a hole in the tent with its bill. In New Hampshire, 6 stomachs contained an average of 1.3 spruce budworms. It ate a low to moderate number of budworms compared with other species. In New Brunswick, it showed no response to increasing numbers of budworms. During a spruce budworm outbreak in Maine, stomachs contained 83% and 16% budworm larvae and pupae in 2

years. In another Maine location, it fed heavily on birch leafminer sawflies. Beetles constitute a large proportion of the winter diet, but they are not as prevalent in the breeding season diet. It also consumes moths, ants, wasps, bees, flies, locusts, scale insects, plant lice, lacewings, and mayflies. Four wintering birds in Florida had consumed mostly hymenopterans (ants, bees, and wasps) and spiders, and lesser amounts of caterpillars, maggots, beetles including weevils, scale insects, bugs, and grasshoppers (Bent 1953; Crawford and Jennings 1989; Graber and Graber 1951; Mitchell 1952; Moldenhauer and Regelski 2020; Morris et al. 1958; Morse 1967, 1971b; Mousley 1924).

The Northern Parula is an infrequent host of the Brown-headed Cowbird. The nest shape and side entrance may inhibit entrance by the cowbird and some nests may not be sturdy enough to support a cowbird. In Ontario, there is little overlap in the ranges and habitat preferences of this warbler and the cowbird. Parasitism has been reported in Florida, Kansas, Virginia, Missouri, Oklahoma, New Jersey, New York, Pennsylvania, Connecticut, Delaware, and Maryland. The Northern Parula may build over nests containing cowbird eggs, but has been observed feeding cowbird fledglings in Delaware, Oklahoma, and Maryland (Lemieux et al. in Gauthier and Aubry 1996; Moldenhauer and Regelski 2020).

Direct habitat loss does not currently appear to be a major concern in Ontario, but the Northern Parula has largely been eradicated due to habitat destruction in southern Michigan, southern Wisconsin, and the Mississippi River lowlands of Missouri. Draining of bogs and other moist wooded areas were implicated in its decline in southern Wisconsin (Moldenhauer and Regelski 2020).

Indirect effects due to decline or loss of beard lichen appear to be significant limiting factors in some regions. Lichens are sensitive to sulphur dioxide. Air pollution that affected lichen survival has largely extirpated or reduced the Northern Parula in several northeastern states including Massachusetts, Connecticut, New Jersey, New York, and Vermont. Old-growth balsam fir forests with high densities of beard lichen are very vulnerable to the spruce budworm, which also provides an excellent food source for the Northern Parula. To protect balsam fir forests from budworm outbreaks, foresters recommend that forests not be allowed to mature to this stage and, if an outbreak is imminent, that the timber be harvested immediately. The shorter rotations and pesticides are detrimental to the Northern Parula's habitat and prey (Lemieux et al. in Gauthier and Aubry 1996; Moldenhauer and Regelski 2020).

Forest management may be detrimental or beneficial to the Northern Parula, depending upon the prescription used. Clear-cutting temporarily eliminates habitat, but high densities may occur in clear-cuts as young as 6 years in northern Ontario. Short rotations that preclude development of beard lichen and minimize the presence of spruce budworms are detrimental (Lemieux et al. in Gauthier and Aubry 1996; Welsh and Fillman 1980). Vanderwel et al. (2009) studied the effects of partial tree harvest on the Northern Parula, with particular reference to the Boreal Forest Region of Ontario. There was no change in its abundance with removal of 30% of trees, but it declined when 50-70% of trees were removed. In the Canadian Shield of Ontario, there was no difference in its abundance in early successional and mid-successional clear-cuts and burns in the same seral stages. It was significantly less abundant in both early successional and mid-successional stands than in mature stands (Zimmerling et al. 2017). Haché et al. (2013) studied the effects of selection harvesting in northern hardwoods in New Brunswick. Forty percent of the BA was removed and canopy

coverage was reduced by 20%. The authors expected the parula to decline due to its preference for mature trees, but there was no measurable effect. The Northern Parula expanded its range into Tennessee, North Carolina, and Virginia only after the dense virgin spruce forests were cut (Moldenhauer and Regelski 2020). This may have created the edge habitat that it prefers when dominant competitors are present. In South Carolina bottomland forests, Harrison and Kilgo (2004) examined the response of the Northern Parula to clear-cutting and to clear-cutting where residual patches of trees and snags were retained. It completely disappeared from the clear-cut habitat. In the patch-retention clear-cuts, it declined the first year after harvest but recovered in the second year. In Illinois, Robinson and Robinson (1999) created openings of 0.02-0.4 ha in a 2,000-ha forest through selection thinning. It was significantly more abundant in selectively cut areas than in unharvested forest. Bowen et al. (2007) concluded that creation of small gaps in the forest through selection harvesting increased habitat diversity and usage by the Northern Parula, and that this was particularly beneficial in stands with a sparse understorey due to a dense canopy.

In North Carolina pine-oak forests, the Northern Parula responded positively to fire but occurred more frequently only after low-intensity fires (Rose and Simons 2016).

Declines in the Maritime Provinces prior to 1966 were attributed to the widespread use of DDT (Moldenhauer and Regelski 2020).

Heavy rains can result in nests being abandoned or failing. A newly completed nest was abandoned following 3 days of continuous rain. At least 2 Maine nests containing young collapsed as a result of extended rainstorms (Morse 1971b; Mousley 1928).

Blake et al. (1992) studied the effects of drought on the Northern Parula in Wisconsin. It exhibited no significant variation in relation to any moisture indices.

Price (2004) predicted that the breeding range of the Northern Parula might contract in southern Ontario if the average summer temperature increased by 2°C.

Status

Anecdotal information suggests that the Northern Parula may have been more common in the early 1900s than it is currently. At that time, it was a very common to abundant spring migrant (Fleming 1907; McIlwraith 1894) and was apparently more common as a breeder then in Parry Sound and Muskoka districts (Mills 1981). It was more abundant there and in many other areas of the province when extensive old-growth forests existed. By the 1960s, there were only 0-3 reports annually in Algonquin Provincial Park, but there was a major increase in numbers and distribution in the 20 years preceding Tozer's (2012) book. Baillie and Harrington (1937) reported that it occurred locally during the breeding season throughout most of the eastern half of the province from Lake Erie to northern Hastings County north to at least Lake Abitibi and probably to the western end of Lake Superior. The only breeding record for the province at that time was from Algonquin Park where adults were observed feeding young on 9 July 1934. During the first atlas, the breeding range was determined to extend from the Bruce Peninsula and Manitoulin Island along the southern edge of the Canadian Shield and throughout much of the Canadian Shield, with a more spotty distribution in the northwest portion of the Boreal Forest Region. Even in the heart of its range, it was found in only 33-50% of squares. There were only 4 scattered records in the Carolinian Forest Region,

suggesting a possible range retraction in this area since Baillie and Harrington's (1937) publication. Highest concentrations occurred in the Algonquin Highlands with other concentrations on the southern side of Manitoulin Island, near Sault Ste. Marie, and on the Bruce Peninsula (Helleiner in Cadman et al. 1987). James (1991) considered the Northern Parula a rare to uncommon breeder across the province north to Red Lake, Lake Nipigon, and Timmins, and south to Bruce and Peterborough counties. There are sight records north to Big Trout Lake and south to Chatham-Kent.

The second atlas demonstrated that the breeding distribution was essentially the same as during the first atlas. An exception was that the Northern Parula disappeared from the northern shoreline of Lake Erie except for a single record in Niagara Region. Its probability of observation increased significantly province-wide and in all regions except the Hudson Bay Lowland and Carolinian Forest Region, where it rarely occurs. Increases were most evident on Manitoulin Island, north of Lake Huron, and in the area surrounding Algonquin Park. Highest densities occurred in the Algonquin Highlands, east of Lake Superior, and in the region from Thunder Bay to Kenora (McLaren in Cadman et al. 2007).

Breeding Bird Survey (BBS) data for 1980-2007 indicate a more robust population of the Northern Parula than for most neotropical migrants. Significant increases were recorded during this period for Ontario, Maine, Illinois, Michigan, Missouri, and New Hampshire (Moldenhauer and Regelski 2020). These authors noted that these results should be interpreted with caution, but they are consistent with trends determined by the second atlas. BBS data for 1970-2021 indicate that it increased at annual rates of 3.2% in Canada and 5.32% in Ontario. Trends for 2011-21 were annual increases of 3.73% in Canada and 3.96% in Ontario. Results were highly reliable for the Canadian trends, of medium reliability for the long-term Ontario trend, and of low reliability for the short-term Ontario trend (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

After the young leave the nest, the female and fledglings move through the canopy at a lower level than the male, who continues to sing. Once the young fledge, there is a tendency for both adults and fledglings to move to early successional areas, such as small forest gaps created by selective thinning and clear-cuts 3-9 years old. During the postfledging period in South Carolina, all observed birds were in or at edges of forest gaps with none observed in forest interior. In Missouri, none were seen in oak-hickory forests during the postfledging period, although the Northern Parula nested within this habitat. Numbers declined from the breeding to postfledging seasons in mature riparian forests, although it continued to occur in this habitat. Numbers increased from the breeding to postfledging seasons in a 9-year-old clear-cut. It did not breed in 3-year-old clear-cuts, but was present during the postfledging period (Bowen et al. 2007; Moldenhauer and Regelski 2020; Pagen et al. 2000).

Porneluzi et al. (2014) netted during the postfledging period in a Missouri oak-pine-hickory forest 2-15 years after it was clear-cut. The Northern Parula was captured in low numbers each year and showed no significant trend over time.

MIGRATION

The Northern Parula is a nocturnal migrant that spends the day in mixed flocks with other warblers, chickadees, titmice, and other woodland birds (Harrison 1984; Moldenhauer and Regelski 2020).

Spring arrival may be correlated with increasing temperatures. The mean maximum temperature at arrival in Wisconsin and Michigan was 5°C. Males arrive on the breeding grounds before females to establish a territory, but the timing differential of the sexes has not been quantified. In southern and central Ontario, most migrants arrive in the first week of May and have passed through by the end of the month. Rarely, individuals may arrive in the last week of March or mid-April, and stragglers may persist until the first week of June (Black and Roy 2010; Curry 2006; Fleming 1907; LaForest 1993; Lancaster et al. 2004; Mills 1981; Moldenhauer and Regelski 2020; Tozer 2012; Weir 2008).

Autumn migration may be triggered by temperature with the mean temperature upon departure from Wisconsin being 7.2°C. Birds begin to leave the breeding grounds in August. Males cease singing in late July and birds become very inconspicuous, making it difficult to track departure times. In the southern Shield, most leave by the first week of September, but some remain until the end of September. In the south, migrants arrive in the last week of August or first week of September and may remain until mid-October (Black and Roy 2010; Curry 2006; Fleming 1907; LaForest 1993; Lancaster et al. 2004; Mills 1981; Moldenhauer and Regelski 2020; Tozer 2012; Weir 2008).

During migration, the Northern Parula is less discerning in its habitat selection than during the breeding season. During migration, it occurs predominantly in deciduous trees, but may use almost any species of tree or shrub. It prefers deciduous woodlands, but may occur in roadside and shade trees, in parks and residential yards, and in orchards and shrubby areas. In Illinois, most spring and autumn migrants were detected in bottomland forests, but it also occurred in forest edges and upland forests. In North Carolina, it was not observed in thickets during spring migration. It occurred in a variety of forest types including those dominated by pine, pine-hardwoods, oak-hickory, beech, and floodplain forests. It was seen most frequently in beech forests and this appeared to be preferred habitat. During spring migration in Ohio, it was significantly more abundant in riparian than upland forests. Riparian forests were dominated by sycamore, Manitoba maple, silver maple, sugar maple, white ash, cottonwood, hackberry, white elm, and honey locust. Upland forests were dominated by sugar maple, red and white oak, white ash, white elm, and hickory. Riparian stands had significantly lower percent shrub coverage (19% compared with 39%), higher percent canopy cover (83% compared with 74%), and fewer trees larger than 8 cm DBH than upland stands. The Northern Parula and Baltimore Oriole were the only migrants that were more abundant in riparian than upland stands. The Northern Parula appeared to actively select for riparian forest habitat during spring migration. In South Carolina bottomland forests, it was 5 times more abundant in and at edges of small gaps created by selective thinning than in unbroken forest. In autumn, all observations were in and at edges of forest gaps indicating a preference for small forest gaps. During migration, it tends to move high in the canopy and in the crowns of lower trees. During spring migration in North Carolina, 51.5% of observations were in the canopy, 45.6% were in low trees, 2.9% were in shrubs, and 0% were on the ground. In the canopy, 24.6% of all observations were at the top of the crown, 19.6% in the inner crown, 7.3% in the lower crown, and 0% on the bole. In low trees, 17.4% of observations were at the top of the crown, 21.7% in the inner crown, 6.5% in the lower crown, and 0% on the bole. In shrubs, 1.5% of observations were at the top of the crown, 0.7% in the inner crown, and 0.7% in dense thickets, with no observations in the lower crown, brush piles,

or grasses (Bent 1953; Bowen et al. 2007; Graber et al. 1983; Moldenhauer and Regelski 2020; Parnell 1969; Rodewald and Matthews 2005).

During autumn migration in New York, Lebbin et al. (2007) observed the Northern Parula searching for food at night in trees illuminated by lights from a football stadium. Many individuals and species of warblers foraged simultaneously within the same trees, interacting with each other as is typical in mixed-species flocks during the daytime.

The Northern Parula is commonly killed during migration by striking television towers and other tall objects (Bent 1953; Graber et al. 1983; Moldenhauer and Regelski 2020).

In New York, Zelt et al. (2017) compared spring arrival dates, autumn departure dates, and length of the breeding season for 1888-1939 and 1967-2012. There was little climate change during the first period but significant warming occurred during the second period. The Northern Parula arrived significantly earlier during the second period but there were no significant differences in its autumn departure dates or length of the breeding season.

James (1991) considered the Northern Parula a rare to uncommon migrant in Ontario. There are indications that numbers of migrants may be lower now than they were historically. Fleming (1907) considered it an abundant migrant and McIlwraith (1894) stated that it was a very common migrant. In Elgin County, it was an uncommon migrant in 1891 and 1954 but by 2000 it was a rare spring and very rare autumn migrant (Lancaster et al. 2004). In the Hamilton area, it was documented in larger numbers prior to the 1950s (Curry 2006).

Magnolia Warbler

Setophaga magnolia

BREEDING SEASON

Habitat Requirements

Ontario Magnolia Warbler nests were in open and dense woods. It preferred mixed woods (62.1% of nests) to coniferous (31.0%) and deciduous (6.9%) stands. It inhabited both mature and second-growth forests. Nests were usually at woodland edges or openings that had dense understories of small coniferous, and less frequently, deciduous trees and shrubs (Peck and James 1987). James (1984b) concluded that it occupied mostly mixed and coniferous forests. Occupied stands may range from very young to very mature but presence of young coniferous trees, usually with dense deciduous shrubs, is essential. In more mature forests, it prefers open woods, edges, or clearings.

In the Boreal Forest Region near Pickle Lake, the Magnolia Warbler occurred in disturbed edges of coniferous forests (James 1980). From Pickle Lake north to the Wetico Hills, it was most abundant in mixed scrub followed by deciduous scrub and mixed forest, deciduous forest, coniferous forest with an understorey, coniferous scrub, and coniferous forest without an understorey. It was absent in heath and tundra habitat (McLaren and McLaren 1981). Near Lake Nipigon, it was one of the dominant species in spruce–balsam fir forests, particularly in immature stands with frequent openings dominated by shrubs. It was also common in black spruce–white cedar–alder stands,

mixed spruce-fir-deciduous stands, and in clear-cuts (Kendeigh 1947; Sanders 1970). Near Manitouwadge, it occurred in all age classes of forests but was most abundant in stands 1-23 years old (Venier et al. 2009). Near White River, it was most frequent in stands 18-20 years old, but not significantly (Venier and Pearce 2005). Welsh (1993) considered it a species that occupied all age classes of forest and documented it in stands 3-220 years old. Near Quetico Park, Apfelbaum and Haney (1985) reported it in stands 1-370 years old. In the Clay Belt of Ontario, Welsh and Lougheed (1996) found the Magnolia Warbler in every stand they surveyed. It was most abundant in balsam fir–spruce stands followed by those dominated by jack pine, trembling aspen, and balsam poplar. It occurred in wet to dry sites, but less frequently in wet stands and was present in stands that covered the entire spectrum of nutrient levels. Near Hearst, it occurred in upland mixed and lowland coniferous stands. It occurred in clear-cuts as young as 3 years old and in all older clear-cuts and uncut forests. It reached very high densities and was the dominant species in 2 stands. In many other stands, it was second in abundance to the Tennessee Warbler which was extraordinarily abundant due to a spruce budworm outbreak. On the northeast shore of Lake Superior, Baillie and Hope (1943) found it mostly in mixed woods, particularly where there were small spruces present.

In the Great Lakes–St. Lawrence Forest Region in the Canadian Shield, the Magnolia Warbler tended to avoid pure jack pine stands near Gogama and preferred edges of mixed forests. It occasionally nested in jack pine stands 15-25 years old where there were openings with some small spruce growing. It was more common in 15-30-year-old mixed stands where small spruce or balsam fir were interspersed at edges or openings (James and Peck 1995a). Kirk et al. (2012) reported that it occurred in mature and old-growth stands of white pine, and was slightly more common in mature stands. It was the fifth-most abundant bird species in these communities and represented 4.7% of all bird sightings. In white pine stands in Algonquin Park, it was present in clear-cuts 2-9 and 10-16 years old and in stands with no recent history of harvesting (Kingsley and Nol 1999). In Algonquin Park, Martin (1960) reported the Magnolia Warbler in stands dominated by black spruce, black spruce–white cedar, white birch–poplar, hemlock, and balsam fir–spruce-hardwoods, and in plots at edges of forests. He considered it characteristic of boreal forest and did not record it in pure deciduous or immature white pine stands. In poplar-birch stands, it was active from the ground to the treetops but concentrated its activities at heights of 1.5-9 m, from the mid-level of shrubs to the mid-canopy. In black spruce–white cedar, territories ranged from the ground to 9 m, midway up the height of the cedars. In hemlock stands, it ranged from 1.5-6 m, entirely below the canopy. In balsam

fir–spruce-hardwood stands, it was second in abundance, but occurred at higher density in pure coniferous stands. In plots at edges of mixed forests, it was second in abundance to the Red-eyed Vireo. Tozer (2012) reported that it often nested in Algonquin Park in young coniferous growth such as balsam fir and white spruce. In Muskoka and Parry Sound districts, it preferred balsam fir and spruce forests (Mills 1981). In tolerant hardwood stands near Sault Ste. Marie, it was associated with the number of hardwood saplings (mostly sugar maple) and the percent coverage by hardwood seedlings less than 50 cm tall (Holmes and Pitt 2007).

No detailed information has been compiled on the Magnolia Warbler's habitat requirements in the Great Lakes–St. Lawrence Forest Region south of the Shield. In this area, it also prefers mixed and coniferous forests, especially where there are small conifers present. The structure of its habitat is similar to that of the Chestnut-sided Warbler. Both species require young, dense patches of shrubs or saplings, with the Chestnut-sided Warbler preferring deciduous species and the Magnolia Warbler preferring conifers. The Magnolia Warbler may also breed in coniferous plantations in this region (LaForest 1993; Weir 2008).

Sutherland (1986) described breeding habitat in the Carolinian Forest Region in Halton Region and Middlesex and Norfolk counties. Breeding habitat in Halton consisted of the interface between a regenerating wet meadow and a white cedar–tamarack stand. The meadow was almost completely covered with dense regeneration of white cedar and tamarack, with lesser numbers of trembling aspen, balsam poplar, and beaked willow. In Middlesex County, the Magnolia Warbler was found in an intermediate-aged coniferous plantation bordering the Dorchester Swamp. In Norfolk County, it has been encountered regularly in the extensive, mature coniferous plantations at St. Williams and Turkey Point. There are also breeding season records from Long Point in white pine and white cedar woodlands. In southwestern Ontario, it may occur in larger cedar swamps and older coniferous plantations. In the Hamilton area, it has been observed since the 1990s in coniferous plantations, but many of these are maturing to the point where they are no longer suitable habitat (Curry 2006). It is more the structure of plantations than their age that determines their suitability. The Hamilton plantations are intermediate in age and have not been thinned extensively; consequently they have few shrubs and saplings in the understorey. The Norfolk County plantations that are inhabited are mature and have been managed for timber harvest. Many of these have evolved into mixed forests with a well-developed understorey. In Elgin County, it nests in ravines dominated by hemlock (Lancaster et al. 2004).

Throughout its range, the Magnolia Warbler nests mostly in mixed and coniferous forests and, to a much lesser extent, deciduous forests. In deciduous forests, it typically seeks out patches of conifers but nests in pure deciduous forests in the southern portion of its range. It is characteristically associated with spruce and balsam fir stands, in either pure stands of these species, in stands where these species codominate, or in spruce-fir stands mixed with varying amounts of poplar and birch. South of the more boreal stands of spruce and fir, it is most common in hemlock stands, often in ravines. Other conifers that it may be associated with include white cedar, white pine, pitch pine, and junipers. It appears to be a habitat generalist at the forest community level, occurring in a wide range of vegetation communities on soils that range from dry to very wet. It also inhabits a range of stand ages from very young clear-cuts to old-growth forests. In some areas, it nests in coniferous

plantations, particularly those dominated by spruce. It occasionally inhabits shrubby fields (Back 1979; Beals 1960; Bent 1953; Brooks 1940, 1947b; Campbell et al. 2001; Capen 1979; Chapman 1907; Crawford and Titterington 1979; Cumming 2004; Dawson 1979; Dunn and Hall 2020; Erskine 1977; Freedman and Johnson 1999; Harrison 1984; Hedge et al. 1996; Hoffman 1989a; Kendeigh 1947; Kirk et al. 1996; Kotesovec 1994a; Lamoue and Morrier in Gauthier and Aubry 1996; Nice 1926; Parker et al. 1999; Sabo 1980; Schieck et al. 1995; Sinclair et al. 2003; Temple et al. 1979).

Forest structure is probably more important to the Magnolia Warbler than forest type. It is a warbler of dense shrubs and saplings, and presence of young conifers is the most predictable aspect of its habitat. Consequently, it is associated with young stands, including fields regenerating with conifers and clear-cuts, and forests with open canopies that allow coniferous regeneration. Territories may include both mature forests and clear-cuts. In New Jersey, it was the first warbler to colonize regenerating old fields. Densities in New Brunswick plantations were very low until tree-sized plants became established at about age 13 years. Once plantations form a closed canopy they become unsuitable until harvesting opens up the canopy and allows regeneration to occur. In northern hardwood stands, it is more abundant in disturbed and early successional habitats than in mature undisturbed areas; it is uncommon in this type of habitat. In Quebec black spruce stands, it was associated with younger development stages such as recent clear-cuts and burns, although it also occurred in lower densities in forests 120-200 years old. Over a 30-year period at a site in New York, it disappeared as a breeding species. This was attributed to natural succession, with the formerly open canopy becoming closed and shading out the shrub layer. In dense, young stands of spruce and balsam fir, it is often the dominant warbler or even dominant species, except for the spruce-budworm specialist warblers during an outbreak. Riparian areas dominated by alders or willow shrubs are another habitat that it readily occupies. Over 35 years of succession in New York, the Magnolia Warbler increased significantly in an open agricultural field that transitioned to a second-growth forest. Over 33 years, it remained stable in an undisturbed mixed forest. In a Christmas tree plantation where the trees were well spaced but grew taller over 25 years, it increased significantly (Bent 1953; Brooks and Bonter 2010; Campbell et al. 2001; Dunn and Hall 2020; Erskine 1977; Freedman and Johnson 1999; Imbeau et al. 1999; Lent and Capen 1995; Litwin and Smith 1992; Morgan and Freedman 1986; Morse 1989; Niemi and Pfannmuller 1979; Noon et al. 1979; Thompson et al. 1999).

In Ontario, the Magnolia Warbler inhabits all ages of forests from very young clear-cuts to mature stands. Studies in other areas often found that it preferred certain age classes of forest, but the preferences often differed in the same geographic region suggesting that the preferences are related more to stand structure and species composition than age. In the Prairie Provinces, Kirk et al. (1996) found no significant differences in its abundance in stands 0-9, 15-20, 40, or 80 years old, although it was more abundant in 15-20-year-old stands. Schieck et al. (1995) reported it only in aspen-dominated stands that were older than 120 years in Alberta. It was significantly more abundant in forests older than 140 years than in younger stands in Saskatchewan. The older stands had a higher proportion of conifers and higher percent coverage by shrubs (Cumming and Diamond 2002). The studies in the prairies were conducted in the Boreal Forest Region, where Erskine (1977) stated that it was more common in young than mature coniferous forests. The Prairie Boreal Forest Region is often dominated by poplars, with conifers occurring predominantly in more

mature stands which may explain differences in preferences for stand age. In mixed forests in the northeast, it was associated with late succession and mature stands (Temple et al. 1979). In Maine, Titterington et al. (1979) found it in all age classes of spruce–balsam fir stands, from clear-cuts dominated by slash and bare ground to dense forests with a closed canopy and open understorey. It was significantly more abundant in the mid-stage of succession which was characterized by deciduous regeneration taller than 2 m with a well-developed but slower growing coniferous regeneration layer. It was one of the dominant species in this stage of succession. In Pennsylvania, it occurred in 100% of old-growth hemlock–white pine–hardwood stands, 15.1% of woodlots statewide, and in 31.5% of woodlots in the Appalachian Plateau. Haney (1999) considered it to have old-growth affinities.

Collins (1983a) found no differences in the habitat preferences of the Magnolia Warbler in Maine and Minnesota. It was associated with more than average coverage by conifers and moderately sized trees that were mostly larger conifers. It was in a guild that inhabited forest and forest edge with a high percentage (70%) of ground cover and moderate canopy closure. In Wisconsin, the Magnolia Warbler was in a guild associated with yellow birch and all conifers (spruce, balsam fir, white cedar, and hemlock) except pine (Beals 1960).

Despite its usage of young and often very small stands, the Magnolia Warbler appears to prefer landscapes that are heavily forested. In Quebec, the mean forest cover within 500 m of territories was 56.5%. This value may be biased upwards because the entire study area was heavily forested (Bourque and Desrochers 2006; Dunn and Hall 2020).

Some studies examined the Magnolia Warbler's preference for riparian and nonriparian balsam fir stands in Newfoundland and Quebec, and in coniferous forests in British Columbia. In 1 Newfoundland study, there was no significant difference in its abundance in riparian areas, in forest interior, or at forest edges distant from riparian areas, although it was most abundant in the latter habitat. Another Newfoundland study found that it was significantly more abundant in 30-m-wide riparian buffer strips than in undisturbed strips 50 m wide. In Quebec, it was more abundant in riparian than nonriparian stands, but not significantly; riparian habitat consisted of meadow marsh and shrub thickets. During the breeding season in British Columbia, it was positively correlated with riparian willow and alder thickets, but not significantly (LaRue et al. 1995; Whitaker and Montevecchi 1997, 1999; Wiebe and Martin 1998).

Ralston et al. (2019) surveyed for the Magnolia Warbler in 20 plots in boreal forest habitat in New York, Vermont, Maine, Nova Scotia, and Newfoundland. It occurred at 14 of the sites indicating broad habitat preferences and an ability to use multiple boreal forest habitats. It was found throughout low- and high-elevation sites at low latitudes.

Some studies identified microhabitat preferences of the Magnolia Warbler. In Minnesota, average habitat characteristics were 51.1% ground cover, 76.1% shrub coverage, 61.1% canopy coverage, 16.9 m canopy height, 40.0% coniferous coverage, 4.6 tree species in the surrounding 0.04-ha circle, 18.0 trees 7.5-15 cm diameter at breast height (DBH), 12.4 trees 15.1-23 cm DBH, 8.9 trees 23.1-30 cm DBH, 3.8 trees 30.1-38 cm DBH, 2.1 trees 38.1-53 cm DBH, 0.6 tree 53.1-68 cm DBH, and 0.2 tree larger than 68 cm DBH. It occurred in a broad range of habitat, but always had some dense growth of spruce or balsam fir saplings within its territory. Presence of small conifers was the

most predictable component of its habitat. It appeared to be a habitat generalist but was restricted to a narrow species-specific subset of habitat resources (Collins et al. 1982). In Vermont, it occurred in habitats with dense vegetation less than 3 m tall and no overhead tree canopy. It was associated with a very dense understorey in clear-cuts and also in pole-sized stands. Mean habitat characteristics were 76.3% green ground cover, 6.7% ground cover by slash, 48.3% canopy closure, 11.2 m canopy height, 11.0 m^2 basal area (BA) deciduous cover, and 9.7 m^2 BA coniferous cover (Thompson and Capen 1988). In subalpine areas of New Hampshire, it occurred where there were wet depressions with means of 7.9 m canopy height, 59% canopy closure, 72% coniferous foliage volume, and 10 cm DBH for live trees (Sabo 1980). In subalpine areas of New Hampshire and Maine, abundance of the Magnolia Warbler was negatively correlated with total foliage volume of deciduous stems smaller than 2 cm DBH (DeGraaf et al. 1998). In the mid-Atlantic states, its presence was positively correlated with percent coverage by conifers, percent ground cover, and forest cover within 2 km. It was negatively correlated with the number of snags larger than 3 cm DBH and foliage density between 2 and 3 m (Robbins et al. 1989).

Without any documentation, Freemark and Collins (1992) designated the Magnolia Warbler a forest-interior species. This is not the case and, if anything, the opposite may be true in many areas. In Maine, Morse (1967) found it both at forest edges and in forest interior. In Newfoundland, Whitaker and Montevecchi (1999) considered it a species of forest edges and open areas rather than a forest generalist or forest-interior species. Bent (1953) stated that it avoided forest interior in favour of more open spaces.

Freemark and Collins (1992) stated that the Magnolia Warbler was classified as area-sensitive by some authors but not by others. No references to its being area sensitive were found. It was not identified as area-sensitive in Maryland or the mid-Atlantic states (Bushman and Therres 1988; Robbins 1979; Robbins et al. 1989). In Maine, it nested on islands as small as 1 ha (Morse 1989) and it was not restricted to larger islands in Wisconsin (Beals 1960).

Ontario nests were in living trees and shrubs with the exception of one in a dead tree. The Magnolia Warbler greatly preferred conifers (91.0% of nests in 7 species) over deciduous species (9.0% in 4 species). A more recent nest was found in common juniper to bring the total number of coniferous nest-tree species to 8. It greatly preferred nest-tree species shorter than 3 m (86.4% of nests) to those 3-6 m tall (4.5%) and larger trees (9.1%). The DBH of 3 nest trees ranged from 2.5 to 7.5 cm. The most common nest-species were spruce (59 nests), balsam fir (19), hemlock (5), white cedar (4), maple (3), and alder (3). Nests may be either distant from the trunk on a limb, usually within several branchlets or a crotch, or against the trunk. Ten nests were 0.6-2.4 m from the tree trunk. Four nests were on lateral branches between the trunks of 2 adjacent small trees. Nest heights were 0.25-6 m, with most 0.8-1.5 m from the ground (Peck and James 1987, 1998a). A nest near Campbellville was in a dense clump of white cedars 8-10 m tall. It was 2.25 m above ground near the end of an upturned lower bough of a small cedar (Sutherland 1986).

Nests elsewhere are typically elevated a short distance above the ground in a living tree, where they are usually well concealed. Most nests are in conifers, particularly balsam fir and various spruce species (black, white, red, and Norway). Further south, hemlock is a preferred nest-tree species; of 50 Pennsylvania nests, 49 were in hemlock. Other nest-species include meadowsweet, juniper,

blackberry, witch-hazel, pin cherry, sugar maple, willow, and birch. Nests were 0.15-10.7 m from the ground, but were seldom higher than 5 m and usually under 3 m. Of 33 Maine nests, 54.5% were less than 1.5 m from the ground, 39.4% were 1.5-3.0 m up, 6.1% were 3.0-4.6 m up, and 0% were higher than 4.6 m. These results are typical for the species. The nest is on a lateral branch or crotch at or distant from the trunk (Bent 1953; Campbell et al. 2001; Chapman 1907; Cruickshank 1956; Dunn and Hall 2020; Harrison 1984; Kotesovec 1994a; Mills 1981; Mousley 1916a, 1924, 1946; Nice 1926; Sinclair et al. 2003; Stanwood 1910a).

Males establish a territory immediately upon arrival and maintain them until the young fledge, but the intensity of defence wanes in the latter part of the nesting cycle. Most activities are conducted within the territory but females sometimes go well beyond the territorial boundaries during incubation. The function of this is unknown because this is past the period when females may seek extra-pair copulations. Near Quebec City, territories were significantly autocorrelated, or clumped, at scales of 250, 350, 450, and 550 m. Near Lake Nipigon, 7 territories averaged 0.57 ha (range 0.40-0.65 ha). Few observations were made of individual birds, so territories could have been larger. In Algonquin Park, average territory size was 0.30 ha (range 0.26-1.69 ha). In New York, 15 territories averaged 0.73 ha. The smallest (0.24 ha) was in a dense shrubby area. The largest (1.2-1.6 ha) included a pine-spruce plantation where the nest was located. In subalpine habitat in New Hampshire, territories averaged 0.7 ha. On 2 Maine Islands, average territory sizes over 6 years were 0.70-0.75 ha and 0.75-0.88 ha and 9 territories in spruce forest on the mainland averaged 0.72 ha (range 0.51-1.05 ha; Bourque and Desrochers 2006; Dunn and Hall 2020; Kendeigh 1945, 1947; Martin 1960; Morse 1976, 1977; Sabo 1980).

No information is available on natal philopatry, but it is probably low. No information is available on the proportion of adults that exhibit breeding season site fidelity. Nine birds banded in their probable breeding location were recovered at the original banding site in subsequent years indicating some level of site fidelity (Dunn and Hall 2020).

Limiting Factors

Peck and James (1987, 1998a) reported eggs in Ontario nests from the last week of May until the third week of July, with most present in the last 3 weeks of June. In Algonquin Park, nests are under construction from late May to late June, eggs are present from late May to mid-July, nestlings are present from early June to early August, and dependent fledglings have been seen from mid-June to late August (Tozer 2012).

It is uncertain if nest construction is initiated immediately after the female arrives or if some time elapses. Nests take approximately 6 days to construct. The first egg is laid 1-3 days after the nest is complete. Incubation may begin after the second egg is laid but typically not until the clutch is complete. The incubation period of Ontario nests was 11-13 days. Overall, incubation periods of 10-15 days have been reported but the Ontario range is more typical. Young may leave the nest when they are 8 days old when they are incapable of flight, but more frequently at age 9-10 days (Bent 1953; Dunn and Hall 2020; Morse 1989; Mousley 1924; Nice 1926; Peck and James 1998a; Stanwood 1910a).

A single brood is raised annually. There are indications of possible second broods in New York and Pennsylvania, but double brooding has not been conclusively documented. One New York

study reported that second broods were attempted regularly, but this may have been referring to replacement clutches. The Magnolia Warbler renests regularly if a clutch is lost and 1 or 2 replacement clutches may be laid in an attempt to raise a brood. Clutches of 2-5 eggs were reported in Ontario (average 3.78 eggs). Four-egg clutches were most abundant and constituted 64.8% of clutches. In other areas, clutches of 3-6 eggs have been reported, with only 1 author reporting a 6-egg clutch. Four eggs is the typical clutch size. An analysis of North American clutches revealed that 90% consisted of 4 eggs, 7% held 3 eggs, and 3% contained 5 eggs (Bent 1953; Campbell et al. 2001; Chapman 1907; Dunn and Hall 2020; Harrison 1984; Kendeigh 1945; Mousley 1916a, 1924; Peck and James 1987; Stanwood 1910a).

The mating system is monogamous and pairs remain intact throughout the breeding season. Both sexes are probably capable of breeding at age 1 and every year thereafter. Many populations contain a sizable population of nonbreeding floaters, suggesting that some first-year males may not be successful in attracting a mate (Dunn and Hall 2020; Nice 1926).

Mills (2007) studied the foraging strategies of the Magnolia Warbler during different seasons in Parry Sound District. During the breeding season and autumn, it was associated with conifers, hardwoods, and early successional habitats. It was associated more with early successional habitats in mid-summer (which may have included the postfledging period). Habitat selection during the breeding season and autumn allowed it access to a wider range of tree species. Foraging occurred at heights of 3.9-11.8 m during the breeding season and 3-11.9 m in autumn. Most authors concur that the Magnolia Warbler forages predominantly in the shrub and subcanopy levels rather than in the upper canopy, although a small proportion of foraging occurs there. Females may also forage in the herbaceous layer. In Saskatchewan, it used subcanopy trees more than any other species and had the lowest average foraging height. It mostly used young regenerating trees. Average foraging heights are consistent throughout its range: 7.3 m in Maine (range 0.0-13.7 m); 5.8 m in conifers and 6.9 m in deciduous species in Saskatchewan; 7.4 m in northern Ontario; 5.4 m in Mackenzie District; and 72.6% of observations 2-8 m from the ground in New Hampshire (Cumming 2004; Greenberg et al. 1999; Kotesovec 1994a; LaRue et al. 1995; Morse 1967; Sabo 1980). In Maine, there was considerable overlap in the foraging heights of the sexes, but males tended to forage higher than females. Males foraged lower than their song perches but still well above females. Male foraging height was associated more with the level of their singing perches than that of the nest; females foraged lower near the nest level. Feeding at the same level of the nest probably saves the female energy. Higher foraging by the male allows him to be conspicuous and facilitates territory defence (Morse 1968). The Magnolia Warbler may exhibit preferences for tree types and species and where it forages within trees. These preferences differ geographically, probably in response to which competitive species are present and to local prey availability. In Saskatchewan, it foraged more than expected in white birch based upon its availability and less than expected in trembling aspen. It used spruce and balsam fir in proportion to their availability. In northern Ontario, 47.0% of foraging occurred in conifers compared with only 28.0% in Mackenzie District; 72% of foraging occurred on conifers in subalpine New Hampshire. In Saskatchewan conifers, it was significantly more abundant in the middle of the tree with no usage of the extreme top or bottom. In deciduous trees, the inner parts of branches near the trunk were used significantly less than the 2 outer zones and there was no difference in usage among the vertical zones (Cumming 2004; Greenberg et al. 1999; Sabo 1980).

Most feeding occurs where the overhead foliage can be reached, predominantly from a small twig. About 58% of foraging occurs on the undersurface of leaves, 22% on the tops of leaves, and 20% on twigs. Gleaning is the preferred foraging technique but hovering, including some flycatching, is sometimes as common as gleaning (Dunn and Hall 2020; Kotesovec 1994a; Morse 1967, 1968; Sabo 1980).

Some studies compared the Magnolia Warbler's foraging strategies with those of other warblers and species. In Maine, Morse (1967) concluded that its foraging was not particularly similar to that of the Golden-crowned Kinglet, Northern Parula, Blackburnian Warbler, or Black-throated Green Warbler. In Saskatchewan, the Magnolia Warbler had a 95% overlap with the Boreal Chickadee and Yellow-rumped Warbler in conifers and an 88% overlap with the Tennessee Warbler in deciduous species. Two thirds of observations of the Boreal Chickadee and Magnolia Warbler were in subcanopy trees, but the Yellow-rumped Warbler was found significantly more in canopy trees than these 2 species. Two thirds of observations of Tennessee, Blackburnian, and Black-throated Green warblers were in canopy. Use of subcanopy trees by the Magnolia Warbler mostly segregated its habitat from potentially competitive warbler species (Cumming 2004). In New Hampshire, Sabo (1980) identified the Magnolia and Yellow-rumped warblers as a transition group from conifer and large substrate use to the more generalized species and distinct from the kinglets on fine substrates and the Red-breasted Nuthatch on the bole. The Black-throated Green Warbler aggressively displaced the Magnolia Warbler. Density of the Magnolia Warbler was higher in similar habitats where the Black-throated Green Warbler was absent. Both the Magnolia and Yellow-rumped warblers foraged low in trees but differed somewhat in habitat selection.

Nestlings are fed mostly caterpillars, but also grasshoppers, miscellaneous insects, and spiders. Adults eat mostly insects, predominantly caterpillars, and some spiders. There is 1 record of the Magnolia Warbler feeding on cultivated grapes. Adults have eaten aphids, leafhoppers, beetles (weevils, soldier beetles, and leaf beetles), flies, brown and green lacewings, caddisflies, beetle larvae, scale insects, sawfly larvae, ants, moths, and locusts. It eats later instars of the black-headed budworm and takes considerable numbers of spruce budworms when they are at epidemic levels. In New Hampshire and Maine, it was 1 of 4 species that ate the most budworms along with the Cape May, Bay-breasted, and Blackburnian warblers. Despite its high consumption of spruce budworms, the breeding density of the Magnolia Warbler often declines during budworm outbreaks. This has been documented in Ontario near Lake Nipigon and in New Brunswick and Maine. Near Manitouwadge, there was either no response or possibly some evidence for a positive response to budworm numbers. The inverse relationship with budworm populations has been attributed to competition with more common and aggressive species such as the Bay-breasted Warbler. Forty-nine stomachs collected in Maine during a spruce budworm outbreak contained 48% and 39% budworm larvae and pupae by volume in 2 years. The diet of 4 adults from the Lake Nipigon area consisted of 30.3% beetles (weevils, click beetles, and soldier beetles), 29.4% spiders and harvestmen, 12.9% lepidopterans, 11.3% aphids, 7.4% flies (house flies and march flies), 5.8% green and brown lacewings, and 2.9% leafhoppers (Bent 1953; Crawford and Jennings 1989; Dunn and Hall 2020; Gage et al. 1970; Kendeigh 1945, 1947; Kotesovec 1994a; Mitchell 1952; Morris et al. 1958; Mousley 1924; Nice 1926; Venier et al. 2009).

The Magnolia Warbler is an infrequent host of the Brown-headed Cowbird. It is unknown what effect parasitism has on its reproductive success. It may successfully fledge cowbirds. Although the current rate of parasitism is low, there are concerns that parasitism may be increasing. In Ontario, 12 of 122 nests (9.8%) were parasitized. The actual frequency of parasitism is probably lower because large areas of the Magnolia Warbler's range in Ontario have few or no cowbirds. In Quebec, 6 of 147 nests (4.1%) were parasitized; 3 of 15 nests (20.0%) in British Columbia were parasitized; 6 of 31 nests (19.4%) in Maine and Pennsylvania were parasitized; and 1 of 164 nests (0.6%) reported to the Western Foundation of Vertebrate Zoology was parasitized (Bent 1953; Campbell et al. 2001; Dunn and Hall 2020; Harrison 1984; Hedge et al. 1996; Mousley 1946; Peck and James 1998a).

Habitat loss and degradation do not appear to be significant issues for the Magnolia Warbler. It has been suggested that it is more common now than prior to European settlement because forest clearing created suitable habitat. This may not be the case in southern Ontario because the original forest cover should have been more favourable than the current agricultural landscape with scattered woodlots. Clear-cutting and other forest management practices in the Canadian Shield improve habitat, but it has declined in Algonquin Park and other areas as a result of fire suppression and forest maturation, which result in the loss of the shrub layer. In the south, coniferous and mixed plantations may provide suitable breeding habitat. Browsing by white-tailed deer may reduce or eliminate the shrub layer in forests. On Anticosti Island, the Magnolia Warbler was able to use the ground layer vegetation where deer densities were high. Nonetheless, it was recommended that deer density not exceed 7.5 per km^2 and large areas of southern Ontario support higher densities than that target (Cardinal et al. 2012; Dunn and Hall 2020; Lamoue and Morrier in Gauthier and Aubry 1996; Tozer 2012).

In Ontario, forest harvesting is beneficial for the Magnolia Warbler. In the Boreal Forest Region, Vanderwel et al. (2009) concluded that it increased when 30%, 50%, or 70% of the tree cover was removed. In Quebec black spruce stands, Imbeau et al. (1999) concluded that it would benefit from short logging rotations. Near Sault Ste. Marie, selection harvesting in northern tolerant hardwoods resulted in an increase in its abundance 2-3 years after harvesting. Postharvest numbers were inversely related to the amount of residual BA (Holmes and Pitt 2007). In the Canadian Shield of Ontario, it was significantly more abundant in early successional and mid-successional clear-cuts than in burns in the same seral stages. It was significantly less abundant in early successional and mid-successional stands than in mature stands (Zimmerling et al. 2017). In Minnesota, it was one of the most responsive species to harvesting, increasing in abundance in clear-cuts and partial cuts relative to control areas (Hanowski et al. 2005). Forest clearing may reduce populations if conifers are eliminated or if the habitat becomes permanently fragmented. In Saskatchewan aspen stands, it was most abundant in stands older than 140 years old because these contained higher proportions of coniferous cover. The rotation age was 80-90 years, and it was concluded that it could decline if stands older than rotation age were completely lost from the landscape (Cumming and Diamond 2002; Dunn and Hall 2020).

Abnormally cold or wet periods may depress populations. Extended periods of fog may also reduce breeding success (Dunn and Hall 2020; Morse 1968).

In Alberta, Bayne et al. (2008) observed no differences in occupancy rates at noisy compressor stations and quiet well pads. The Magnolia Warbler apparently exhibited no response to chronic noise.

In Alberta, the Magnolia Warbler was significantly less abundant at pipelines than in adjacent forest interior. There were no significant differences in its abundance at seismic lines or well pads than in forest interior adjacent to these features (Bayne et al. 2016).

Price (2004) predicted that the summer range of the Magnolia Warbler might exclude southern Ontario if the average summer temperature increased by 2°C. In southern Quebec, it was associated with cooler and wetter summers and was considered sensitive to climate change. In central Quebec and Labrador, it was associated with stands having the warmest summer temperatures and would probably benefit from climate change (DesGranges and LeBlanc 2012; DesGranges and Morneau 2010). The Quebec results underscore the difficulties in predicting effects of climate change on species over broad geographic areas.

Status

Presumably the Magnolia Warbler was always a common breeder in the province, although earlier ornithologists discussed its status as a migrant only. Baillie and Harrington (1937) considered it common in coniferous forests north from about latitude 44°N to the Albany River, where it was the most abundant warbler. It bred from southern Georgian Bay and Frontenac County west to Thunder Bay and probably to Lake of the Woods. They expected that it would breed in the south because it had nested in New York adjacent to the St. Lawrence River. James et al. (1976) reported it to be common from Guelph north to Big Trout Lake and Fort Albany. During the first atlas, the Magnolia Warbler had a continuous range throughout the Canadian Shield, Manitoulin Island, the Boreal Forest Region, and the southern portion of the Hudson Bay Lowland. It was also found in scattered locations south of the Shield, mostly in the Great Lakes–St. Lawrence Forest Region. A few breeding records were obtained in the Carolinian Forest Region near Long Point, near the Thames River, and on the Lake Huron shoreline (Welsh in Cadman et al. 1987). Sutherland (1986) concluded that it was a very rare breeder in southwestern Ontario, despite recent records from Halton Region and Middlesex and Norfolk counties. It may have been more common in the south previously, with records from Middlesex, Perth, Wellington, and York 1884-1944. It was previously much more abundant in Algonquin Park after extensive fires and heavy logging created suitable habitat (Tozer 2012). James (1991) considered the Magnolia Warbler a common summer resident from southern Georgian Bay and Ottawa north to Big Trout Lake and Fort Albany; occasional and rare north to Sutton Lake and Fort Severn; and occasional and rare south to Norfolk County.

The second atlas indicated no significant change in the breeding distribution of the Magnolia Warbler, although there were isolated records from the Tundra Region. Its probability of observation increased significantly province-wide and in all atlas regions except the Hudson Bay Lowland, where it experienced a nonsignificant increase. Large increases occurred south of the Shield, with it reported in many new squares. Increases were attributed to succession of retired farmland to young forests in the south and forest harvesting in the north. It was one of the most abundant species in the province. Highest densities occurred in the Boreal Forest Region south of latitude 51°N and the

western portion of the Great Lakes–St. Lawrence Forest Region in the Shield. This corresponds with the area where most clear-cutting operations take place (McLaren in Cadman et al. 2007).

Much of the Magnolia Warbler's range is not sampled by the Breeding Bird Survey (BBS). BBS results suggest that it is increasing, with a significant rangewide increase of 1.3% per year 1966-2007. There was a significant increase of 3.4% 1966-79 and a nonsignificant increase of 0.06% 1980-2007 (Dunn and Hall 2020). BBS data indicate that it increased at an annual rate of 9.49% in Canada and decreased at an annual rate of 0.169% in Ontario 1970-2021. The trends for 2011-21 were annual decreases of 1.57% in Canada and 3.87% in Ontario. The results were of medium reliability except that the short-term Canadian trend was highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Young leave the territory shortly after fledging, but may be attended by the adults until they are 25 days old. Once they are independent, juveniles often join other birds in loose flocks (Bent 1953; Dunn and Hall 2020). During the postfledging period in Pennsylvania, Stoleson (2013) found almost identical numbers of Magnolia Warblers in mature forests and adjacent clear-cuts. It could conceivably have bred in both habitats, so it was unknown whether there were any movements from breeding to postfledging habitats.

MIGRATION

Most migration by the Magnolia Warbler is nocturnal, but it may move during the day to correct for displacement by winds during the night. During the day, it occurs in mixed flocks of small passerines, particularly those centred around the Black-capped Chickadee. It may also occur in flocks as large as 50 comprised solely of Magnolia Warblers. Three birds banded at the Long Point Bird Observatory (LPBO) were recovered in Cuba, the Honduras, and Guatemala. Birds of both sexes tracked during spring migration that were captured at LPBO moved predominantly northward toward the southern tip of Georgian Bay. Some females moved northeastward to the shoreline of Lake Ontario between Toronto and Kingston (Brewer et al. 2018; Dunn and Hall 2020; Morbey et al. 2018).

Males arrive on the breeding grounds prior to females by as much as 7-10 days in New York and Ohio (median date of 19 May for males and 26 May for females) but the difference is not as pronounced in Ontario. At Prince Edward Point, mean arrival for males was 21.2 May compared with 24.1 May for females. In spring at LPBO, mean capture dates for males were 16.9 May for after-second-year birds, 20.4 May for second-year birds, and 18.9 May for those of undetermined age. Mean capture dates for females were 21.4 May for after-second-year birds, 23.9 May for second-year birds, and 23.0 May for those of undetermined age. For both sexes, after-second-year birds arrived significantly earlier than second-year birds. In Ohio, adult birds also arrived significantly earlier than yearlings. Mean capture dates were 13 May for adult males, 17 May for yearling males, 21 May for adult females, and 23 May for yearling females. At a Minnesota site, average stopover time was 4 days in both spring and autumn. At Long Point, the midpoint of spring migration was 21 May. In southern Ontario, the Magnolia Warbler typically arrives in the first or second week of May and is common until the end of May. A few may arrive in late April. The peak of migration is in the last half of May with most migrants gone by the end of May, but a few remain into early June. In the southern Shield, most arrive in the last half of May (Black and Roy 2010; Boone et al. 2010; Curry 2006; Dunn

and Hall 2020; Fleming 1907; Francis and Cooke 1986; Keast 1980; LaForest 1993; Lancaster et al. 2004; Mills 1981, 2005a; Stewart et al. 2002; Tozer 2012; Weir 2008).

Most birds leave the breeding grounds by mid-August and juveniles initiate autumn migration 1-2 weeks earlier than adults. At LPBO, juveniles preceded adults by an average of 16 days in 1 year and 5 days in another year. At Moosonee, single birds observed on 31 July and 7 September were considered migrants. In the southern Shield, migration peaks in early September with the latest records in late September or early October. In the south, autumn migrants are present from mid-August to early or mid-October, with rare records as late as mid-November. The midpoint of autumn migration at Long Point is 7 September (Black and Roy 2010; Curry 2006; Dunn and Hall 2020; Fleming 1907; LaForest 1993; Lancaster et al. 2004; Mills 1981, 2005a; Tozer 2012; Weir 2008; Wilson and McRae 1993; Woodrey and Chandler 1997).

Dunn and Hall (2020) stated that spring arrival dates of the Magnolia Warbler were 0-4 days earlier than they were historically. At Long Point, Mills (2005a) compared first spring arrival and last autumn departure dates 1974-2002. There was a tendency toward earlier spring arrival but this was not significant. There was also no significant difference in arrival times of the sexes. There were no differences in autumn departure dates.

Boone et al. (2010) used stable isotopes as an indicator of the wetness of wintering habitat used by spring migrants captured in Ohio. For some species, wetness of wintering habitat can affect migration timing. The Magnolia Warbler overwintered in both mesic and xeric habitats and there was no relationship between winter habitat moisture and migration timing, energetic condition at capture, or moult and breast-streaking conditions.

During migration, the Magnolia Warbler occurs in a variety of habitats including forests and forest edges, bottomland forests, riparian shrub thickets, shrubby pastures and fields, city parks, backyards, orchards, and farmyards. It tends to be associated more with shrubs and forest edge. In forests, it uses treefall gaps where there is more shrub cover than in the surrounding forest and tends to remain low in the canopy and in shrubs. During spring and autumn in Illinois, it was most abundant in forest edge habitat and shrubby areas. In spring, small numbers occurred in bottomland forests but higher usage of this habitat occurred in autumn. During both migration periods, but particularly autumn, some birds were detected in upland forests, orchards, marshes, and pastures. During spring migration in Ohio, it was significantly more abundant in mature upland than mature riparian forests. Upland forests had a more open canopy (74% compared with 83%) and more than twice as much shrub coverage (39% compared with 19%). It was positively correlated with riparian habitat during migration in British Columbia, particularly in autumn when this relationship was significant. Riparian habitat consisted of willow and alder shrubs; the nonriparian habitat was coniferous forest. In both Ohio and British Columbia, the Magnolia Warbler appeared to select areas with extensive shrub coverage. During autumn migration in Pennsylvania, it was significantly more abundant in forest edges, forest-agricultural edges, shrub-sapling-stage forests and suburban forests than in pole-stage forests and forest interior (Bent 1953; Campbell et al. 2001; Chapman 1907; Dunn and Hall 2020; Graber et al. 1983; Leighton et al. 2002; Rodewald and Brittingham 2002, 2004; Rodewald and Matthews 2005; Wiebe and Martin 1998).

Prey availability is important in determining whether Magnolia Warblers gain or lose weight during migratory stopovers, particularly in spring. At Long Point, the earliest spring migrants lost weight at the tip and midpoint of the peninsula, but gained mass at the base of the peninsula. By the peak of migration, birds experienced a net gain in weight at the midpoint. At the tip, birds continued to lose weight, but conditions improved as the season progressed. Due to the coldness of the lake, there is marked retardation of phenology at the tip of the peninsula. Although large numbers of birds occur there, it is not necessarily good habitat for refuelling. During the peak of autumn migration, it gained mass at all 3 sites at Long Point, probably because prey is not limiting at this time (Dunn 1998, 2000). Emerging midges along the Great Lakes shorelines can be an important source of prey in spring. Along the Lake Huron shoreline in Michigan, the coast was an important resource-rich area with more arthropods near than distant from the shoreline. Emerging midges appeared to be responsible for creating high-quality stopover habitat and spiders were also more abundant at the shore (Smith et al. 2009). On the southwestern shore of Lake Erie in Ohio, there was no difference in abundance in midge biomass inland and at the shoreline. As spring progressed, birds at both inland and shoreline sites consumed more aquatic insects and experienced greater refuelling performance later in the day. There was no association between midge biomass and refuelling performance, but the Magnolia Warbler opportunistically supplemented its diet with midges. The lack of relationship for this warbler may be because it has a later, narrow migratory window when terrestrial food resources are more abundant. Refuelling was influenced more by foraging opportunities later in the day than by midge availability (MacDade et al. 2011).

During migration, the Magnolia Warbler forages in low trees, the subcanopy, and shrubs. During autumn at Prince Edward Point, it foraged at heights of 1.5-9 m. During spring migration in South Carolina, 4.6% of foraging occurred in the canopy, 77.3% in low trees, 18.2% in shrubs, and 0% on the ground. In the canopy, 0% of foraging occurred in the upper crown, lower crown, or on the bole, and all 4.6% occurred in the middle of the crown. In low trees, 59.1% of foraging occurred in the inner crown, 18.2% in the lower crown, and 0% in the upper crown or on the bole. In shrubs, 13.6% of foraging occurred in the inner crown and 4.6% in the lower crown, and 0% in the upper crown, dense thickets, brush piles, and grasses. During autumn migration at Prince Edward Point, 43% of foraging occurred on outer leaves, 8% on twigs and inner leaves, 14% on outer branches, 20% on sapling foliage, 10% on sapling branches, 3% on small shrubs, and 0% in the air, on inner branches, the trunk, and the ground. In New York during autumn migration, it was suspected that it was foraging nocturnally in trees illuminated by artificial lights, but this could not be confirmed (Graber et al. 1983; Keast 1980; Lebbin et al. 2007; Parnell 1969).

During migration, the Magnolia Warbler's diet consists almost entirely of invertebrates. Five found dead near Prince Edward Point in autumn had eaten approximately 15 beetles each. In autumn in Ohio during cold, wet weather, it fed on honeysuckle fruit. A week later, the fruit had been depleted and 2 were seen creeping through the lawn, apparently plucking tiny arthropods off the undersides of grass blades and violet leaves (Keast 1980; Tramer and Tramer 1977).

The Magnolia Warbler is a common victim of strikes at buildings and other tall structures. At the Lennox generating station chimneys near Kingston, 2,485 were killed 1972-82, with 230 and 760

mortalities on 5 and 6 September 1981. In Wisconsin, 1,346 were collected at a television tower 18-30 September 1963. On Padre Island, Texas, 1,109 of 2,421 mortalities (45.7%) at lighted buildings and wires were Magnolia Warblers (Graber et al. 1983; Dunn and Hall 2020; Weir 2008).

The Magnolia Warbler is susceptible to blood parasites that are transmitted by black flies. Infection has the potential to cause a delay in spring arrival, increased probability of nest desertion, and decreased clutch size, hatching success, and fledgling success. Two Ohio studies examined the incidence of infection during spring migration, and 36.3-39.5% of birds were infected. The intensity and the probability of infection were not related to energetic condition, capture date, or sex. After-second-year birds were more likely to be infected than second-year birds (Boone et al. 2010; DeGroote and Rodewald 2010).

In Pennsylvania, an outbreak of the viburnum leaf beetle resulted in almost complete mortality of the southern arrowwood, which was formerly the third most abundant shrub species. Prior to the infestation, spring migrating Magnolia Warblers gained significant mass after sunrise, but no weight gains occurred after the infestation (Smith and Hatch 2017).

Strode (2003) studied the effects of climate change on the migration of the Magnolia Warbler in Illinois and North Dakota. Over 100 years, there was no significant spring temperature change in Illinois, but spring advanced an average of 8.6 days in North Dakota since 1961. Spring also advanced north of Illinois. The Magnolia Warbler exhibited no response to changing temperatures and now has as many as 20 fewer days to travel between southern Illinois and northern Minnesota. In New York, Zelt et al. (2017) compared spring arrival dates, autumn departure dates, and length of the breeding season 1888-1939 and 1967-2012. There was little climate change during the first period but significant warming occurred during the second period. The Magnolia Warbler arrived significantly earlier, departed significantly later, and had a significantly longer breeding season during the second period.

James (1991) considered the Magnolia Warbler an abundant migrant in Ontario. Hussell et al. (1992) reported a nonsignificant decline in migratory Magnolia Warblers of 1.4% per year at LPBO 1961-88. Trends by period were: 1961-70, −8.9%; 1970-79, +9.8%; and 1979-88, −2.0%. Variations in trends by decade may have been related to spruce budworm populations. More recent data from migration counts across Canada 1997-2006 indicate general stability or small increases at most sites (Dunn and Hall 2020).

Bay-breasted Warbler

Setophaga castanea

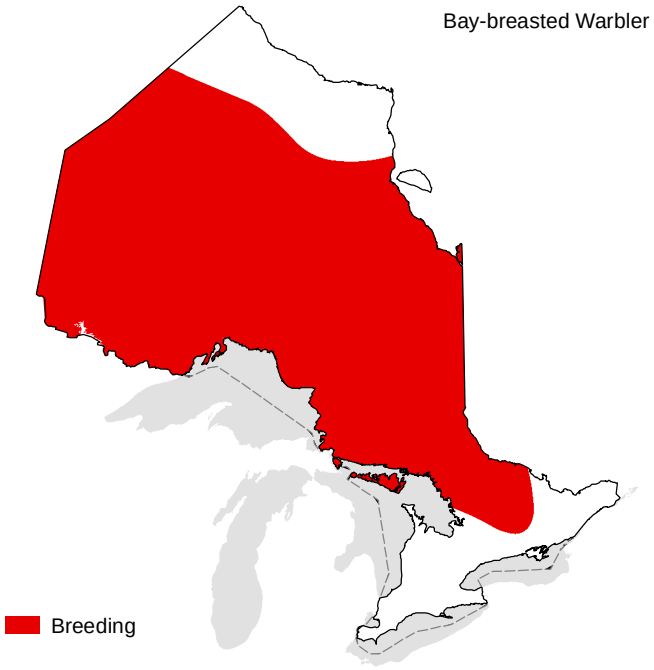
BREEDING SEASON

Habitat Requirements

Ontario Bay-breasted Warbler nests were in coniferous and mixed forests. This warbler showed a distinct preference for open coniferous stands with a dense deciduous understorey (66.7% of nests). Nests in denser mixed (20.0% of nests) and coniferous (13.3% of nests) forests were usually near water or clearings (Peck and James 1987). It requires tall, mature, and dense conifers with live branches in the shade of the forest canopy. Occupied stands usually have a dense understorey of deciduous or coniferous shrubs in the forest or at edges. Nesting may occur in lowland or upland forests (James 1984b).

In the Hudson Bay Lowland near Moosonee, the Bay-breasted Warbler nested in a lichen-rich spruce forest bordering a stream (Wilson and McRae 1993).

Most information on the Bay-breasted Warbler's habitat requirements in Ontario is from the Boreal Forest Region, which constitutes most of its range in the province. From Pickle Lake north to the Wetico Hills, it was most common in mixed forests followed by deciduous forests, coniferous forests without an understorey, and coniferous forests with an understorey. It was absent in scrub, heath, and tundra habitats (McLaren and McLaren 1981). James (1980) observed it regularly in small



numbers in mixed forests near Pickle Lake. It is associated with older, closed stands of mixed woods where there is little interspersion between young and old forests and higher amounts of intact older forests (Rempel 2007; Rempel et al. 2007). Near Lake Nipigon, it was strongly associated with white spruce and balsam fir. Black spruce was not favoured because it is not attractive to spruce budworms. Balsam fir supported the highest densities of budworms and this warbler (Kendeigh 1947). In the same area during a period when spruce budworms were scarce, it nested in low density in an overmature stand that was 30 m tall with a broken canopy dominated by 60-cm diameter at breast height (DBH) trembling aspen. This stand had a scattered understorey of white birch and white spruce and dense thickets of balsam fir regeneration and mountain maple (Sanders 1970). Near Hearst, it nested in mature upland mixed forests and clear-cuts in lowland coniferous and upland mixed stands. It occupied clear-cuts as young as 6 years were in upland stands. The youngest occupied lowland stand was 24 years old (Welsh and Fillman 1980). At Quetico Park, it was rare to uncommon in stands 1-23 years old but common in stands 67-73, 112-176, and 367-370 years old. In the 67-73-year-old communities, Bay-breasted and Blackburnian warblers were the dominant species. In the heavier white spruce and balsam fir cover in the 112-year-old stand, the Bay-breasted Warbler was the most abundant species and it and the Blackburnian Warbler were the most important species in the 175- and 176-year-old stands (Apfelbaum and Haney 1999). Welsh (1993) considered the Bay-breasted Warbler a late-succession species. Highest densities occurred in stands older than 50 years. Much lower densities were present in stands 20-30 years old, and it was absent or sparse in stands younger than 20 years. Near Manitouwadge, it occurred predominantly in mature stands, but occupied intermediate-aged and young stands when spruce budworms became abundant. It altered its habitat choices when food was extraordinarily abundant (Venier et al. 2009). In the Clay Belt, it was most abundant in white spruce stands, followed by those dominated by tamarack or white cedar, white spruce–balsam poplar, and black spruce. It was uncommon in jack pine stands. It occurred in stands that were poor to rich in nutrients and wet to dry, but was more common in damp, nutrient-rich stands (Welsh and Lougheed 1996).

In white pine stands in the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region, the Bay-breasted Warbler inhabited both mature and old-growth stands. It was slightly more abundant in mature than old-growth stands (Kirk et al. 2012). In white pine stands in Algonquin Park, it was uncommon in stands with no recent history of harvesting and in cuts 2-16 years old (Kingsley and Nol 1999). In Algonquin Park, Martin (1960) did not observe it in black spruce or black spruce–

white cedar stands, but recorded it in low density in hemlock stands. He considered it characteristic of hemlock stands. Near Gogama, it was common in jack pine forests 40 years and older, but only when the jack pine budworm was present in epidemic numbers. It was present every year in adjacent mixed forests that supported spruce trees, a habitat that it clearly preferred over jack pine (James and Peck 1995a).

The Bay-breasted Warbler nests predominantly in the Boreal Forest Region, so its habitat preferences elsewhere are similar to those in Ontario. It is consistently present in spruce forests only when spruce budworms are abundant but may be found in balsam fir stands even when budworms are absent. Regularly used forest types include those dominated by white or red spruce, balsam fir, a mix of spruce and balsam fir, and spruce–balsam fir mixed with trembling aspen, balsam poplar, and white birch. It has nested in spruce plantations in New Brunswick. Seldom-used stands include those dominated by white pine, hemlock, white cedar, tamarack, and northern hardwoods. In British Columbia, it nested in mature trembling aspen stands at edges of mature white spruce forests. Extralimital nesting occurred in southern Manitoba during a forest tent caterpillar outbreak. The habitat was uncharacteristic, consisting of a narrow ridge of pure deciduous species dominated by peach-leaved willow, Manitoba maple, cottonwood, and green ash. The shrub layer was dominated by sandbar willow, red elderberry, pin cherry, and red-osier dogwood (Back 1979; Bent 1953; Campbell et al. 2001; Dawson 1979; Erskine 1977; Freedman and Johnson 1999; Harrison 1984; Kirk et al. 1996; Mendall 1937; Noon et al. 1979; Sabo 1980; Sealy 1979; Sequin in Gauthier and Aubry 1996).

Several studies described the characteristics of forests inhabited by the Bay-breasted Warbler. In Quebec balsam fir–white cedar stands, it was associated with mature forests. It was equally abundant in nonriparian stands and riparian stands with a wetland band of alder and grasses (LaRue et al. 1995). Parker et al. (1999) found significantly higher densities near streams in New Brunswick, although it also occurred in nonriparian areas. In the taiga area of British Columbia, it inhabited mixed stands of white spruce and trembling aspen with a multilayered canopy, frequent openings, and a dense understorey of highbush cranberry and white birch. Breeding habitat includes mature and old-growth stands of white spruce, including those interspersed with trembling aspen, white birch, balsam poplar, willow, and alder, and with a poorly to moderately developed shrub layer. Typical habitat includes trees taller than 20 m with a DBH greater than 50 cm and a shrub layer of highbush cranberry, prickly rose, and alder. In more upland areas, it selects mature spruce or mixed stands with an understorey of highbush cranberry and white birch (Campbell et al. 2001). In the Yukon, the Bay-breasted Warbler nests in dense, tall, old-growth white spruce forests along rivers and also in old-growth spruce stands mixed with trembling aspen and balsam fir both in and distant from riparian areas. These forests are characterized by high structural complexity with a shrubby understorey, standing and fallen dead timber, and abundant woody debris (Sinclair et al. 2003). In the Prairie Provinces, Kirk et al. (1996) considered it an old-forest species associated with stands rich in nutrients growing on dry soils. In Saskatchewan, it was most abundant in stands older than 140 years (Cumming and Diamond 2002). In Newfoundland, it was associated with young stands (40 years old) that were nutrient poor (Thompson et al. 1999). On an island in Maine, it was common only where there were dense growths of lichen-covered lower branches of spruce in the shade of the forest canopy. This habitat does not appear until the forest becomes dense and contains large

trees. When this island became infested with spruce budworms, the Bay-breasted Warbler was the dominant species and also occupied dense young stands of conifers (MacArthur 1958). In Maine spruce–balsam fir stands, it was absent in early successional areas and first appeared in low density when hardwood regeneration was taller than 4.5 m and both deciduous and coniferous trees were 10-15 cm DBH. It was most abundant in stands with a dense canopy of spruce and balsam fir and an open forest floor (Titterington et al. 1979). Erskine (1977) concluded that it was characteristic of mature stands in the Boreal Forest Region and that it was scarce or lacking in young coniferous stands. When spruce budworms are abundant, it expands into young and intermediate-aged stands in response to the abundant food. It may inhabit mixed-wood stands as young as 8 years (Venier et al. 2020).

Near Quebec City, Drolet et al. (1999) did not find the Bay-breasted Warbler in any areas where there was less than 55% forest cover within the surrounding 100-ha landscape. They concluded that forest remnants as small as 5 ha embedded in a clear-cut dominated landscape may be inadequate to support it. In Saskatchewan, it was absent in a fragmented landscape but common in nearby contiguous forest (Venier et al. 2020). A 5-ha stand near Great Slave Lake supported the Bay-breasted Warbler (Erskine 1977).

Other studies described microhabitat preferences of the Bay-breasted Warbler. In subalpine forests in New Hampshire, it was a mid-slope species that preferred some wet depressions in its territory. Average habitat characteristics were 11.3 m tall canopy, 75% canopy coverage, 59% conifer foliage volume, 19% conifer foliage volume 0-2 m from the ground, 44% deciduous foliage volume above 5 m, and 13 cm DBH of live trees (Sabo 1980). In New Brunswick, it selected areas with high densities of large deciduous trees (Parker et al. 1999). In Maine spruce–balsam fir forests, it was significantly correlated with the number of hardwood and softwood stems 10-15 cm DBH and the number of coniferous stems larger than 20 cm DBH, the largest size category.

Ontario nests were in conifers: 60.0% in black spruce, 20.0% in white spruce, 13.3% in balsam fir, and 6.7% in jack pine. Nests were situated from the lowest branch of taller trees to near the tops of trees, with most in the lower third. Nests were on horizontal branches, usually among numerous branchlets. Nests were 0.3-2.4 m from the trunk with most 0.9-1.5 m distant; 4 nests were near or at the trunk. Nest height was 2.5-7 m with most 3.5-5.5 m up (Peck and James 1987). Mills (1981) reported a nest near Bala that was 1.2 m from the ground in a roadside maple.

Throughout its range, most Bay-breasted Warbler nests are in spruce and balsam fir trees, much less frequently in pines or hemlock. During extralimital nesting in deciduous habitat in Manitoba, 9 nests were in Manitoba maples and 1 was in green ash. Nests are typically on a horizontal limb 1.5-3 m from the trunk but occasionally at or near the trunk. Fifty-four Canadian nests averaged 4.9 m from the ground (range 1.2-9 m). Some nest trees were beside roads, in small clumps of trees in forest openings, and within 20 m of a building. Nests are not very well concealed and some are remarkably out in the open, but they blend in so well with their surroundings that they are difficult to find (Bent 1953; Campbell et al. 2001; Chapman 1907; Cruickshank 1956; Harrison 1984; Mendall 1937; Philipp and Bowdish 1917; Sealy 1979; Sequin in Gauthier and Aubry 1996; Sinclair et al. 2003; Venier et al. 2020).

Territories are established immediately upon arrival in spring. In New Brunswick, populations increased 5.7-fold during a spruce budworm outbreak but the mean territory size remained constant. Initially there had been unoccupied interstices between territories that became filled in as the population increased (MacArthur 1958). In Manitoba, 9 nests were clumped together and one was 510 m from the group. The non-random dense clumping occurred despite availability of other similar habitat (Sealy 1979). Near Lake Nipigon, 88 territories averaged 0.15 ha (range 0.04-0.49 ha), the smallest territory size of the warbler species present. Few measurements were taken so territories could have been larger than reported; territories could have been as large as 0.88 ha. Average territory sizes on 4 plots were 0.32, 0.17, 0.15, and 0.12 ha (Kendeigh 1947). Average territory size in subalpine forests in New Hampshire was 1.5 ha (Sabo 1980).

No information is available on natal philopatry. On the Gaspé Peninsula of Québec, 6 of 57 adults (10.5%) returned the following year. Spruce budworm larvae were abundant in each year. Results indicated that the Bay-breasted Warbler has low site fidelity even when spruce budworms are plentiful (Moisan Perrier et al. 2021). It is a good example of a fugitive species that is dependent upon periods of superabundant food supplies. It is often absent in large geographic areas for long periods of time until a budworm outbreak occurs. It may then become the most abundant breeding bird species, but leaves when the outbreak has run its course. The invasion of deciduous habitat in Manitoba during an outbreak of forest tent caterpillars suggests that it responds directly to prey abundance rather than to vegetation. The Manitoba forest tent caterpillar population remained high the year after the area was occupied by the Bay-breasted Warbler, but the warblers were present in only 1 year (MacArthur 1958; Morse 1989; Sealy 1979).

Limiting Factors

Nests with eggs have been reported in Ontario from the second week of June through the first week of July (Peck and James 1998a). In Algonquin Park, nestlings are present from late June until the second week of July and dependent fledglings have been observed from mid-June to mid-July (Tozer 2012).

It is unknown how much time elapses after the female arrives until nest building commences, and the time it takes to build a nest is unknown. Eggs are laid at the rate of 1 a day. It is uncertain when incubation starts but it appears to occur early in the laying period. The incubation period at 1 nest was slightly over 12 days and young hatched over a period of 2 days. Nestlings fledge when they are 10-12 days old. They may remain in the vicinity of the nest for 9 days (Harrison 1984; Mendall 1937; Venier et al. 2020).

A single brood is raised annually. It is unknown if replacement clutches are laid if the first is lost. Ontario nests contained clutches of 4-6 eggs (average 5.38 eggs). These included 6 each of 5- and 6-egg clutches and a single clutch of 4 eggs. Clutches of 3-8 eggs have been reported, with 5 and 6 eggs the most common clutch sizes with a typical range of 4-7 eggs. The mean size of 49 New Brunswick clutches was 5.43 eggs (range 4-7 eggs). During spruce budworm outbreaks, the Bay-breasted Warbler occasionally lays 6-8 eggs, more than any other warblers except the Tennessee and Cape May warblers, 2 other budworm specialists. The Bay-breasted Warbler lays more eggs during budworm outbreaks (average of 5.8 eggs) than when budworms are scarce (average of 5.1 eggs). In Manitoba, 2 unparasitized clutches contained only 3 eggs. The small clutches may have

been because the birds were nesting in atypical habitat and the cowbird parasitism rate was high (Bent 1953; MacArthur 1958; Mendall 1937; Morse 1989; Peck and James 1998a; Philipp and Bowdish 1917; Sealy 1979; Venier et al. 2020).

The age at first breeding is unknown, but is probably 1 year. The mating system is assumed to be monogamous. In atypical habitat in Manitoba, 1 male mated with a second female after the first disappeared. This male may have mated polygynously, but this was not confirmed. One female built a nest, abandoned it, and took over another unfinished nest and mated with a different male. Pair bonds were quickly established and may have been quite transitory (Sealy 1979; Venier et al. 2020). In Maine, Hensley and Cope (1951) removed breeding males and females from the population. There was an increase in population after removal, possibly due in part to increasing spruce budworm numbers. There appeared to be a large surplus floating population of Bay-breasted Warblers.

The Bay-breasted Warbler is a slow and methodical forager that spends 76% of its time creeping along branches smaller than 10 mm in diameter. It regularly works from the lichen-covered bases of branches well out to their tips, although the largest amount of time is spent in the interior of the tree. When spruce budworms are abundant, it frequently remains motionless on a branch and catches the caterpillars as they descend on their threads; this can be a highly effective foraging technique. Foraging movements within a tree are in a radial pattern and most foraging occurs mid-height in the tree. In conifers in Saskatchewan, only 0-4.9% of foraging time was spent in the top one fifth and bottom two fifths of the tree. In the 2 middle zones, more than 15% of the time was spent in the inner part of the tree with large branches mostly devoid of needles, more than 15% in the central layer of older needles and larger branches, and 5-9.9% of time in the outer layer with new growth, fresh needles, and small twigs. In deciduous trees, 0-4.9% of foraging time was spent in the top third of the tree, and more than 15% in the middle zone. In the lower third of the tree, 5-9.9% of time was spent in the inner zone and 10-14.9% of time was spent in the central and outer zone. It used all tree species in proportion to their availability but tended to favour white spruce and avoid white birch. It used small twigs at ends of branches and treetops significantly less than their abundance. Mean foraging height was 10.3 m in conifers and 11.8 m in deciduous trees. The Bay-breasted Warbler and Black-throated Green Warbler foraged significantly higher than the Blue-headed Vireo and Magnolia Warbler in conifers. The Bay-breasted Warbler tended to occur more frequently in canopy than subcanopy trees. The Bay-breasted Warbler and Blue-headed Vireo favoured foraging on large inner and middle branches that were seldom used by other species. Similar foraging techniques and uses of different parts of trees were used in Maine, where the Bay-breasted Warbler foraged more than expected in red spruce. In that state, there were no significant differences in the foraging movement patterns of Bay-breasted and Blackpoll warblers, but they were significantly different from other warbler species. Most warblers fed in different areas of trees in different manners. The Bay-breasted Warbler obtains most prey by gleaning from conifer needles or from the top and occasionally bottom of small deciduous leaves. Hawking and hovering are rare foraging techniques. In Maine, different warbler species behaved in a manner such that they were exposed to different foods by feeding in different positions in trees, indulging in hawking and hovering to different extents, moving in different directions through trees, and moving at differing rates. They also probably have the greatest need for food at different times due to differing nesting

chronologies (Cumming 2004; Greenberg et al. 1999; MacArthur 1958; Morse 1978; Sabo 1980; Venier et al. 2020).

Limited data suggest that young are fed mostly caterpillars and moths (Venier et al. 2020). McMartin et al. (2002) examined the diet and food-niche overlap among the Bay-breasted, Tennessee, and Cape May warblers near Longlac during a spruce budworm outbreak. They examined the diet during 2 periods: 7-11 June and 18-28 June. In the early period, the Bay-breasted Warbler's diet consisted of 75.7% beetle adults, 5.7% caterpillars, 8.6% flies, 2.9% spiders, and 7.1% other invertebrates (soft-winged bugs, hymenopteran larvae and adults, true bugs, beetle larvae, snails, odonates, caddisflies, and neuropterans). Diet during the late period consisted of 29.6% adult beetles, 57.7% caterpillars, 5.6% flies, 2.8% spiders, and 4.2% other invertebrates. The diet during the 2 periods was significantly different, being dominated by adult beetles early in the season and by caterpillars later. The food-niche breadth for the Bay-breasted Warbler doubled from early to mid-season but declined by two thirds for the other 2 warblers. In the early season, the 3 species differed in their consumption of adult beetles, caterpillars, and flies, with the Bay-breasted Warbler consuming the most beetles. Later, the only difference in diet among the 3 species was in the amount of adult beetles consumed, with the Bay-breasted Warbler again eating the most. The different diets were probably a reflection of the tendency of the species to forage in different locations within trees, and beetles are found mostly in the interior portions of trees. The limited consumption of caterpillars early in the season was because of their small size. Kendeigh (1947) summarized the diet of 6 Bay-breasted Warblers near Lake Nipigon during a spruce budworm outbreak. They had consumed 37.3% lepidopterans (including geometer moth larvae), 23.1% flies (including march and crane flies), 12.4% spiders, 12.4% mayflies, 7.8% soft-winged bugs (including aphids and planthoppers), 6.2% beetles (including click and scarab beetles), and 0.7% true bugs (including stink bugs). In Maine, Mitchell (1952) examined the contents of 135 stomachs during a spruce budworm outbreak. They contained 51% and 35% budworm larvae and pupae by volume in 2 years. In Manitoba, Bay-breasted Warblers were observed feeding on forest tent caterpillars that were less than 20 mm in length, and on flying insects that were probably midges. Two stomachs contained mostly midges, but also leaf beetles, ichneumonid wasps, plant bugs, chewing lice, and seeds (Sealy 1979). The Bay-breasted Warbler has also eaten house flies, gall flies, ants, lacewings, moth cocoons, cankerworms, geometer moth and other caterpillars, grasshoppers, locusts, and dragonflies (Bent 1953; Venier et al. 2020). In Maine, the Bay-breasted and Black-throated Green warblers tended to eat more caterpillars than Cape May, Yellow-rumped, and Blackburnian warblers. Otherwise, the diet of the Bay-breasted Warbler was most similar to that of the Blackburnian Warbler, and the feeding habits of these species are similar.

Food abundance is a limiting factor to the Bay-breasted Warbler and significantly affects its abundance and distribution. It is a spruce budworm specialist, colonizing areas or significantly increasing during budworm outbreaks and declining or disappearing when the outbreak is over. It may be absent to uncommon when budworms are scarce and be the most abundant species during outbreaks. It also responds to outbreaks of the black-headed budworm, jack pine budworm, and forest tent caterpillar. Near Lake Nipigon during a spruce budworm outbreak, it was the most abundant species, representing 28.8% of all birds present. Habitat appeared to be saturated for it. A later study in the same area when there were no budworms determined that it was almost absent.

Near Manitouwadge, it experienced an enormous increase in territory density from 1979 to 1983 as budworm populations increased. There was a 4.7-fold increase in its density in mature forest over 5 years and it became much more abundant in young and intermediate-aged stands where it was formerly uncommon. In 1 area of Maine, the response to budworm populations was direct, immediate, and strong, with the population increasing 12-fold. Another study in Maine and New Hampshire found no population increase in association with a budworm outbreak, but the study was conducted in only 1 or 2 years in the 2 study areas. The Bay-breasted Warbler was one of the species that consumed the most budworms, along with Blackburnian, Cape May, and Magnolia warblers. When budworm populations are high, food is superabundant and the entire bird population has little effect on it. In Maine and New Hampshire, all birds combined consumed 84% of budworms when the budworm population was low (100,000 per ha), but only 22% when populations were 550,000 per ha. Budworm abundance also affects social dominance among warbler species. When budworm populations are low, the Black-throated Green Warbler is dominant to the Bay-breasted Warbler. When budworms and the Bay-breasted Warbler are abundant, this warbler also inhabits younger coniferous stands, forcing the Black-throated Green Warbler to abandon spruce stands and occupy ridges dominated by mixed growths of hardwoods and hemlock. When it is abundant, the Bay-breasted Warbler is dominant to the Blackburnian Warbler and can depress populations of Blackburnian and Magnolia warblers and other species (Crawford and Jennings 1989; Gage et al. 1970; James and Peck 1995a; Kendeigh 1947; MacArthur 1958; Morris et al. 1958; Morse 1978, 1989; Sanders 1970; Sealy 1979; Venier et al. 2009).

The Bay-breasted Warbler is a rare host of the Brown-headed Cowbird because there is little overlap in the 2 species' distribution. In a Manitoba extralimital nesting effort in atypical deciduous forest habitat, 4 of 6 nests were parasitized. Prior to the Manitoba records, only 4 cases of parasitism were known: 2 in Quebec and 2 in Alberta. Of 65 nests reported to Canadian nest records schemes, only 1 (1.5%) was parasitized (Sealy 1979; Venier et al. 2020).

Most major threats to the Bay-breasted Warbler are related to forest management. Shorter rotation periods have been adopted in eastern Canada, thereby reducing the area of mature forest that it prefers. Younger stands are also less likely to support spruce budworm outbreaks. Planting of black spruce and jack pine, which are more resistant to the spruce budworm, diminishes breeding habitat quality. In Saskatchewan, the Bay-breasted Warbler was most abundant in stands older than 140 years, but rotation age is only 80-90 years. It may suffer some population density reduction if stands older than rotation age are completely lost from the landscape. Populations also appear to decline with partial harvest techniques, when as few as 30% of trees are removed. Eighty-two percent of the breeding population occurs in Canada's Boreal Forest Region and almost a third of this area is allocated to timber companies. A 1995 forest management plan for New Brunswick projected that mature spruce–balsam fir forest will decline from 46% of the landscape to 8% in 40 years. The Bay-breasted Warbler has been demonstrated to avoid riparian and upland leave strips (buffers) 32-132 m wide. Modelling determined that Bay-breasted Warbler populations would not be maintained in Ontario's Boreal Forest Region even if all harvesting guidelines for key species were followed (Cumming and Diamond 2002; Rempel et al. 2007; Vanderwel et al. 2009; Venier et al. 2020; Wells 2007). In the Canadian Shield of Ontario, it was significantly more abundant in early successional clear-cuts than in early successional burns, but was equally abundant in mid-

successional clear-cuts and burns. It was significantly less abundant in early successional than mature stands but equally abundant in mid-successional and mature stands (Zimmerling et al. 2017). Fire suppression may have a positive effect, allowing more stands to become mature and more vulnerable to spruce budworm predation (Sequin in Gauthier and Aubry 1996).

Spruce budworm populations have declined recently and this has resulted in a decline of the Bay-breasted Warbler. Declines have been evident on both the Breeding Bird Survey (BBS) and migration monitoring data. In the 1960s, no budworm outbreaks of any consequence occurred. A massive outbreak began to build in 1970 that peaked in the early 1980s. The budworm population has fallen since then with 2 resurgences in the mid-1980s and early 1990s. Budworm defoliation in Ontario peaked at 18,850,000 ha in 1980 and declined to 28,000 ha in 2004. Spraying for budworms was an annual event from 1952 until the early 1990s, but there is little evidence that it was effective in reducing outbreaks. Areas sprayed were only a small proportion of the infested area and probably had no effect on Bay-breasted Warbler populations. Its numbers may have stabilized somewhat because of budworm control programs and shorter harvest rotation periods that keep budworm populations at low to moderate levels over long periods of time instead of massive outbreaks followed by tree defoliation and death and a crash in the budworm population. During the first Quebec atlas, breeding evidence for the Bay-breasted Warbler was obtained most frequently in areas that were subjected to budworm outbreaks. Once outbreaks subsided, populations of both budworms and warblers appeared to be greater in balsam fir stands that had been treated with insecticides than in untreated stands (Anonymous 2013; McCracken 2004; Morse 1989; Sequin in Gauthier and Aubry 1996; Venier et al. 2009, 2020).

In 1989 in New Brunswick, birds collected 3 days after spraying with fenitrothion had an average brain acetylcholinesterase inhibition rate above the level that is considered life threatening. In the early 1990s, fenitrothion was replaced by Bt and is no longer used (Venier et al. 2020).

Expansion of the forest industry further into the Boreal Forest Region could have adverse effects on the Bay-breasted Warbler. Other potential threats include prospecting for minerals, oil, and natural gas and building hydroelectric facilities. Winter habitat is also being lost to agriculture (Anonymous 2013; Wells 2007).

In Alberta, the Bay-breasted Warbler was significantly more abundant at seismic lines than in adjacent forest interior. There was no difference in its abundance at pipelines and well pads than in forest interior adjacent to these features (Bayne et al. 2016).

Venier et al. (1999) compared the Ontario breeding distribution of the Bay-breasted Warbler with 24 climate variables. Results suggested a strong influence on its breeding distribution that was probably related to the effects of climate on vegetation distribution. It was negatively correlated with variation in monthly precipitation and the timing of the end of the growing season. Price (2004) concluded that the Bay-breasted Warbler might become extirpated as a breeding species in southern Ontario if the average summer temperature increased by 2°C. In Saskatchewan, Cumming et al. (2014) determined that the northern limits of Bay-breasted Warbler distribution appeared to be associated with a July minimum temperature isotherm. Subject to that constraint, higher abundance was associated with closed mixed forests and open coniferous forests. Within those vegetation communities, abundance was highest when the mean April temperature was higher

than –1.6°C, when the April leaf area index was less than 215 (an indicator of mixed forest), or when the standard deviation of the April minimum temperature was more than 2.0°C. In southern Quebec, the Bay-breasted Warbler was correlated with cooler and wetter summers. DesGranges and Morneau (2010) considered it very sensitive to climate change. In central Quebec and Labrador, it showed no strong relationship with climate variables, but occurred in stands with a moderate number of growing-degree days (DesGranges and LeBlanc 2012).

Status

Baillie and Harrington (1937) considered the Bay-breasted Warbler a fairly common breeder in certain localities between the northern portion of the Bruce Peninsula and the transcontinental railway. At that time, numerous summer records from Cochrane, Kenora, Temiskaming, Nipissing, Parry Sound, and Thunder Bay districts and Victoria County indicated that it was more common and widespread than formerly supposed. The most northerly records were from Moose Factory and latitude 53-54°N along the Manitoba border. The first atlas demonstrated that it ranged throughout the Canadian Shield and in the Hudson Bay Lowland to Attawapiskat in the northeast to the northwest corner of the province. Distribution was spotty in the Great Lakes–St. Lawrence Forest Region in the Shield and on Manitoulin Island. Budworm populations peaked in the province just prior to the first atlas and the range determined by it was considered maximal. Densities were probably more than 100 per km^2 throughout the Boreal Forest Region such that the Ontario breeding population was probably several million during the first atlas (Welsh in Cadman et al. 1987). James (1991) considered the Bay-breasted Warbler to be common across the north as far north as Sandy Lake and Fort Albany; uncommon in the Algonquin Highlands; occasional and rare north to near Fort Severn and Attawapiskat, and south to Muskoka District and Renfrew County.

The second atlas was conducted during a period of low budworm abundance. There was no significant change in the distribution of the Bay-breasted Warbler between atlases, but it was more spottily distributed at the northern and southern extremes of its range. There was no significant difference in its overall probability of observation between atlases. Significant declines in the Hudson Bay Lowland and the Shield portion of the Great Lakes–St. Lawrence Forest Region (consistent with the observed northern and southern range contractions) were offset by a significant increase in the Boreal Forest Region. It was most abundant in the Boreal Forest Region, particularly in a band from Little Sachigo and Sandy lakes east to the Clay Belt. Numbers outside the Boreal Forest Region were very low or 0 on point counts (Zimmerling and Nicoll in Cadman et al. 2007).

BBS data suggest that the Bay-breasted Warbler is declining. The United States reported nonsignificant annual declines of 1.9% 1966-2007 and 0.5% 1980-2007. Using different analytical techniques, Environment Canada reported significant declines of 3.0% and 5.2% for the same periods. Declines of the Bay-breasted Warbler are probably linked to declines of the spruce budworm (Venier et al. 2020). Populations also fluctuate in non-infested areas, so it is difficult to assess changes in status and how these are related to budworm populations (Harrison 1984). BBS results indicate that it increased at an annual rate of 0.155% in Canada and decreased at an annual rate of 0.419% in Ontario 1970-2021. Trends 2011-21 were an annual increase of 2.08% in Canada and an annual decrease of 2.39% in Ontario. The long-term Canadian trend was of medium reliability; the other trends were of low reliability (A.C. Smith et al. 2023).

MIGRATION

The Bay-breasted Warbler is a nocturnal migrant. During the day, particularly in autumn, it may forage in mixed-species flocks, especially those containing Blackpoll Warblers. Autumn migration is triggered by favourable conditions such as high pressure, clear skies, and strong north to northeast winds (Bent 1953; Brewer et al. 2018; Chapman 1907; Venier et al. 2020).

The Bay-breasted Warbler is a late spring migrant, possibly because of its northern breeding range. Spring migration is rapid with stopovers of short duration, often a single day or 2 at most. Males arrive a few days earlier than females. At Long Point, mean capture dates for males were 16.5 May for after-second-year birds, 20.0 May for second-year-birds, and 18.9 May for those of undetermined age; adults arrived significantly earlier than yearlings. Mean capture dates for females were 19.6 May for after-second-year birds, 20.1 May for second-year-birds, and 22.6 May for birds of undetermined age; there was no significant difference in timing of arrival of age classes. At Prince Edward Point, the mean date of capture was significantly earlier for males (23.3 May) than for females (24.7 May). In southwestern Ontario, spring migration spans all of May to mid-June. Spring migration in southeastern Ontario occurs over less than 2 weeks beginning in mid-May, with the peak in the third week of May when females arrive. In the southern Shield, most birds pass through in the third and fourth weeks of May. First arrival near Lake Nipigon was 25 May (Black and Roy 2010; Curry 2006; Francis and Cooke 1986; Keast 1980; Kendeigh 1947; LaForest 1993; Lancaster et al. 2004; Mills 1981; Stewart et al. 2002; Tozer 2012; Venier et al. 2020; Weir 2008).

Autumn migration is more protracted and birds may linger longer at stopover sites than in spring. In West Virginia, adults and juveniles migrated simultaneously. Autumn migration may begin in late July shortly after nesting is completed. In the southern Shield, autumn migrants are usually present from mid-August to mid-September, with some arriving in early August and others remaining until the first week of October. In southern Ontario, migration occurs from the end of July until the end of October with the peak in mid-August (Black and Roy 2010; Campbell et al. 2001; Curry 2006; Keast 1980; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Venier et al. 2020; Weir 2008).

In British Columbia, migration habitat is similar to breeding habitat. In most other areas, the Bay-breasted Warbler occupies a greater diversity of habitat during migration and is not restricted to using conifers (Campbell et al. 2001; Venier et al. 2020). During spring migration in Illinois, it preferred upland oak-hickory forests over bottomland forests and shrubby areas. It also occurred in forest edges in both spring and autumn. In autumn, it occupied all woody habitats, but was least common in shrub and pine habitats in southern Illinois. In central Illinois, it was most numerous in shrubs (Graber et al. 1983). During spring migration in Ohio, it was significantly more abundant in mature upland forests than in mature riparian forests. These habitats were structurally similar, except that upland forests had significantly less canopy cover (74% compared with 83%) and 39% shrub coverage compared with 19% (Rodewald and Matthews 2005). During autumn migration, it was not observed in pole-stage forest habitat. From most to least abundant, it occurred in forest edges, forest interior, shrub-sapling-stage forests, forest-agricultural edges, and suburban forests. There was no significant difference in its usage of habitats (Rodewald and Brittingham 2002). In addition to

forested and shrubby areas, the Bay-breasted Warbler may occur in urban parks and rural residential yards (Leighton et al. 2002).

Keast (1980) examined the foraging strategies of the Bay-breasted Warbler at Prince Edward Point during autumn migration. It fed at heights of 1.5-18 m, but mostly at 5-13 m with a peak at 10 m. It occasionally fed for part of the day at 17-18 m, then in the tops of saplings, subsequently descending for short periods into shrubs. Similar to the breeding season, it fed radially and slower than other warblers, approaching the foliage along branches. Foraging time was equally spent on outer leaves, on sapling foliage, and on sapling branches. Foraging was not observed on twigs, inner leaves, outer branches, inner branches, the trunk, low shrubs, or the ground. During autumn migration in New York, Lebbin et al. (2007) observed it foraging at night in an area illuminated by football-stadium lights. It made aerial sallies after insects and appeared to glean insects from foliage. One spring day in Illinois, several foraged on urban plantings of Norway spruce and Scotch pine, hovering at branch tips in the manner of parids (Graber et al. 1983).

The Bay-breasted Warbler is predominantly insectivorous during migration, but occasionally eats fruit during autumn migration. Mueller and Mueller (1976) observed several feeding on flowering dogwood berries in North Carolina. During cold, inclement weather in Ohio, Tramer and Tramer (1979) observed 4 Bay-breasted Warblers eating the fruit of yews. After the fruit was depleted, they foraged by creeping through the lawn, apparently gleaning tiny arthropods from the undersides of grass blades and violet leaves. It has also eaten Virginia creeper berries during autumn migration (Venier et al. 2020).

The Bay-breasted Warbler is one of the more common victims at television towers and other tall structures. It was the seventh most commonly killed species at the Long Point lighthouses 1961-2001. From 1972 to 1982, 2,408 were killed at the Lennox generating station chimneys with peak kills of 831 and 758 on 5 and 6 September 1981. The Bay-breasted Warbler represented 3.7-12.6% of warbler kills at towers in Michigan, Ontario, and Wisconsin; 3.1-6.9% in Maryland and Tennessee; and 1.6% in Georgia and Florida (Anonymous 2013; Venier et al. 2020; Weir 2008).

James (1991) considered the Bay-breasted Warbler a common migrant in Ontario. This is true for most of the province, but it appears to be uncommon during spring in Niagara Region and uncommon during both migration periods in Elgin County (Black and Roy 2010; Lancaster et al. 2004). In Hamilton, McIlwraith (1894) observed that it was abundant in some springs but rare or entirely absent in others. This may have been related to spruce budworm abundance or perhaps varying weather conditions. He rarely saw more than 3 or 4 together but observed a flock of 50 or more feeding in a clump of willows overhanging Hamilton Bay in spring 1885. In most areas, it is more abundant during autumn than spring migration. This is probably due to the addition of juveniles to the population but it may be partially because birds remain in stopover locations longer, allowing numbers to build up. In the Hamilton area on 21 May 1960, a fallout of this warbler occurred during wet, foggy weather. A single person observed an estimated 350, but there were probably thousands over the city. During migration in Ontario, typical daily maxima are 20-30 in spring and 50-300 in autumn (Black and Roy 2010; Curry 2006; LaForest 1993; Mills 1981; Tozer 2012; Weir 2008).

Similar to the BBS, migration monitoring data indicate a decrease in the Bay-breasted Warbler. Population indices at LPBO are closely related to the extent of spruce budworm outbreaks in

Ontario. Significant decreases have been observed since the outbreaks began to ebb. In the 15 years prior to 2004, autumn numbers at LPBO decreased by as much as 51%. Levels at that time were slightly below the pre-budworm 1960s. McCracken (2004) concluded that there was no need for alarm provided that budworm infestations continue to occur. Hussell et al. (1982) reported that it decreased at LPBO 1961-70 at a rate of 12.2% per year. It increased 19.8% annually 1970-79 and decreased 5.1% annually 1979-88. Overall, it experienced a nonsignificant decrease of 0.8% per year 1961-88. These population changes were related to budworm abundance. Budworm numbers have remained low with a resultant decrease in Bay-breasted Warbler numbers at LPBO. It decreased significantly 0.84% per year 1967-2004 and at a rate of 4.2% 1994-2004. The annual decrease between 1981-86 and 2001-06 was 3.4%. A significant decrease of 7.4% per year was experienced at the Thunder Cape migration monitoring site (Venier et al. 2009, 2020). The decrease is not restricted to Ontario, but is widespread. In Michigan, numbers banded in autumn peaked at 126 in 1981. Results in subsequent years were 23 in 1982, 14 in 1983, 1 in 1984, 5 in 1993, 0 in 1994, and 3 in 1995 (Venier et al. 2020).

Blackburnian Warbler

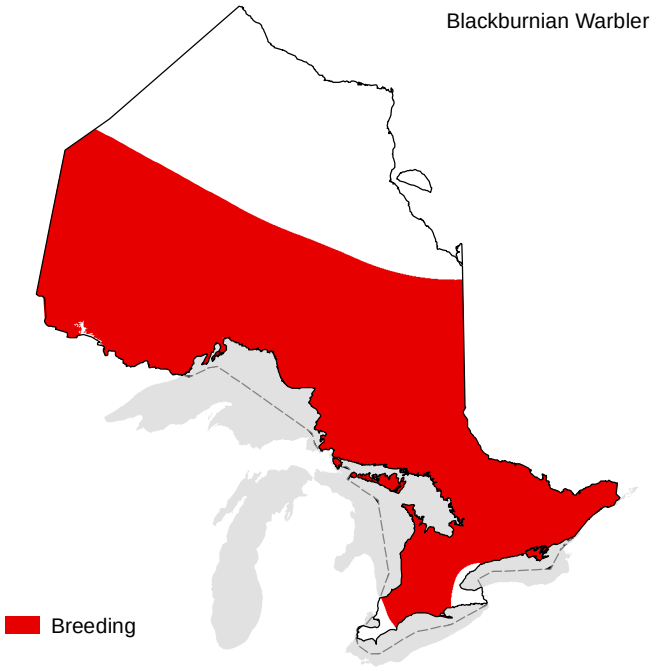
Setophaga fusca

BREEDING SEASON

Habitat Requirements

Ontario Blackburnian Warbler nests were in coniferous (60.0% of nests) and mixed (40%) forests. One was in a spruce bog and another was in a recent burn (Peck and James 1987). It prefers undisturbed coniferous and mixed forests and selects mature stands that are somewhat open with old to overmature large trees. It nests in both upland and lowland sites and prefers areas with balsam fir and hemlock (James 1984b).

In the Boreal Forest Region of Ontario, Blackburnian Warbler habitat consists of mature conifers in closed mixed-wood forests, with little interspersion between older and young forests and high amounts of forest older than 80 years. It was associated with high canopy closure, moderately tall stands, and high amounts of hardwoods (Rempel 2007; Rempel et al. 2007). In northwestern Ontario, it was widespread in most forest stand types except pure spruce and pure hardwood stands, but was abundant in only red pine and white pine stands. It also occurred in stands dominated by jack pine, trembling aspen–white birch, and white spruce–balsam fir (Welsh 1993). Near Lake Nipigon, it inhabited coniferous forests and stands dominated by white cedar, poplar-birch, and spruce (Kendeigh 1947). On the northeast shore of Lake Superior, it occurred only in large mature mixed



stands (Baillie and Hope 1943). Near Quetico Park, it occurred in all age classes of forest, but was least abundant in stands 1-23 years old. In stands 67-73 years old, it and the Bay-breasted Warbler were the dominant species. These were closed-canopy forests with a sparse, park-like understorey. These 2 warblers continued to be the most important in stands 112, 175, and 176 years old, and the Blackburnian Warbler was the most abundant species in stands 112 years old. The stands in which it dominated were comprised of jack pine and poplar. In jack pine stands near White River, it was most abundant in stands 40-100 years old, but not significantly. It was not a significant indicator for any age class. Its abundance was strongly negatively associated with coarse woody debris with 25-75% of the wood soft but with the shape still intact (Venier and Pearce 2005). Near Hearst, Welsh and Fillman (1980) reported it in uncut upland mixed woodlands and lowland conifers, where it was most abundant in upland stands. It also occurred in clear-cuts in upland stands 6-24 years old and in 24-year-old lowland cuts. In the Clay Belt, it was most abundant in balsam fir–white spruce–balsam poplar stands followed by those dominated by balsam poplar, balsam fir–spruce, tamarack or white cedar, and black spruce. It was most common in wet, nutrient-rich stands but also occurred in nutrient-poor stands (Welsh and Lougheed 1996).

The Blackburnian Warbler was common in mature and old-growth white pine stands in the Great Lakes–St. Lawrence Forest Region in the Canadian Shield. It was slightly more abundant in old-growth stands than mature stands, but not significantly. It was the third-most abundant species. It used both white pine and red pine stands extensively, preferring mature or old-growth stands. It was not observed in stands younger than 66 years. The density of supercanopy pine trees was the most important variable in determining its presence and abundance. It was correlated with basal area (BA) of conifers, total BA, stand age, and presence of medium-sized and large pines (Kirk et al. 2012). It also nests in younger pine stands. Kingsley and Nol (1999) observed it in 71.4-100% of uncut white pine stands in Algonquin Park compared with 70-81.8% of stands 10-16 years old and 7.5% of stands 2-9 years old. Near Gogama, James and Peck (1995a) considered the Blackburnian Warbler characteristic of jack pine forests as well as mixed forests where pines represented at least 40% of the tree cover. It did not colonized areas until pines were at least 10 m tall. It was never numerous until pines attained a height of 12 m. It was common in older pine forests, usually where trees were dense and uniform and there were few tall shrubs. In northern hardwood stands near Sault Ste. Marie, the Blackburnian Warbler was associated with short shrubs in the understorey. Near Pimisi Bay, Lawrence (1953b) found it predominantly in mature conifers, including white pine, white spruce, hemlock, and red pine in order of importance. These stands had some scattered poplars and

white birch within them. In other areas, she observed it in climax stands of conifers with sparse or no undergrowth and with deciduous trees and shrubs only around the edges of the stands. In Algonquin Park, it was most abundant in hemlock stands and characteristic of hemlock. In hemlock stands, it occurred at heights of 3-24 m, from 3 m below the bottom of the canopy to the top of the canopy. It was the most abundant species in hemlock stands. Other stand types it occurred in included black spruce–white cedar, balsam fir–spruce, white birch–poplar, white birch–poplar–balsam fir–spruce, and immature white pine. In mixed forests, it was not observed above 12.2 m, which represented the top of the coniferous forest cover, although the deciduous trees extended above this. In balsam fir–spruce stands, it occupied the central portion of the canopy. In black spruce–white cedar stands, it occurred at heights of 3-17.7 m. These heights represented the bottom of the canopy and top of the shrubs to above the white cedar layer but 3.5 m from the top of the spruce (Martin 1960). In Parry Sound District, it was associated predominantly with conifers during the summer but moved to areas of conifers and white birch later in the season (Mills 2007). In Haliburton County and Muskoka District, the Blackburnian Warbler occurred mainly in mature forests, especially coniferous stands where there was limited understorey. It was associated with intermediate levels of canopy volume and slightly less than the mean tree density. It was associated with tall canopies. It occurred mostly in undisturbed forests or on cottage lots in mature woods where the canopy layer had not been disturbed (Clark et al. 1983).

In the off-Shield portion of the Great Lakes–St. Lawrence Forest Region, Speirs and Orenstein (1975) found the Blackburnian Warbler in a mature white pine plantation that included a small relict of red maple–red oak forest. They considered it associated with pines. At Presqu'ile, it nested in a stand of planted and natural conifers (LaForest 1993).

In the Carolinian Forest Region, the Blackburnian Warbler nested for many years in hemlock in Milton Heights (Curry 2006). In Elgin County, breeding birds occur in mature woodlands, especially those containing pine. It also nests in pine plantations and ravines dominated by hemlock (Lancaster et al. 2004).

The Blackburnian Warbler nests in a wide diversity of habitats throughout its range. In the eastern Boreal Forest Region, it is characteristic of balsam fir and spruce stands, but is seldom found in pure spruce stands. It is characteristic of mature coniferous stands and is scarce or lacking in young stands. It inhabits the most fertile coniferous stands available whether they are hemlock, balsam fir, or spruce amidst poplar. It is one of the most regular and common species in white pine and red pine stands, and also pitch pine stands in Ontario (Erskine 1977). In the western Boreal Forest Region, it is also associated with coniferous species, but is characteristic of white spruce stands. It occurs in mature drier sites that are rich in nutrients (Kirk et al. 1996). In Quebec, its probability of observation is high in deciduous forests with conifers and in mixed forests, especially where balsam fir occurs. It becomes less common as the percentage of conifers increases and where pure coniferous stands are found, particularly those dominated by spruce (Lanoue and Dauphin in Gauthier and Aubry 1996). In Maine, it is common in almost pure coniferous forests dominated by white spruce and red spruce. It inhabits only stands with tall or supercanopy spruce and its density is directly related to the volume of tall conifers. It inhabits the highest strata of the treetops, especially where the socially dominant Black-throated Green Warbler is present. The Blackburnian Warbler avoided small islands

forested with spruce in Maine, but occurred on similarly sized islands in New York and Minnesota where the conifers were 4 m taller. In Maine, it avoided areas of blowdown and small groves of white birches among the spruce, although in other areas it may be common in conifers mixed with poplars and birch (Kendeigh 1945; Morse 1967, 1976, 2020). In Maine, Vermont, and other areas, it may occur in low densities in clear-cuts in deciduous and mixed forests (Lent and Capen 1995; Titterington et al. 1979). On islands in Wisconsin, it was most abundant in stands dominated by pines, including jack, white, and red pines. Densities were the same in stands dominated by white birch–yellow birch–white cedar and hemlock–yellow birch, with lesser numbers in red maple–yellow birch stands. It was highly associated with pines and its numbers increased with increasing importance of conifers (Beals 1960). In New York and many other areas, the Blackburnian Warbler prefers spruce draped with beard lichen (Morse 2020). In New Brunswick, it breeds in spruce plantations older than 20 years and in mixed forests of red spruce, red maple, balsam fir, trembling aspen, white pine, and white birch in decreasing order of abundance. It is one of the most abundant species there. It was associated with high densities of large coniferous trees. It selected, in order of preference, stands dominated by pine, a mix of tolerant and intolerant hardwoods with spruce, mixed spruce and intolerant hardwoods, and spruce–balsam fir. It avoided stands of mixed tolerant and intolerant hardwoods, intolerant hardwoods, and intolerant hardwoods mixed with spruce (Freedman and Johnson 1999; Parker et al. 1999). In Quebec, it occurs predominantly in mixed forests and particularly in mature balsam fir stands where it seeks tall trees towering over the canopy. It is common in balsam fir–white cedar stands and occurs in 6-15-year-old strip-cuts through both deciduous and coniferous forests. It is absent in final strip-cuts and clear-cuts (Falardeau et al. 1999; Lanoue and Dauphin in Gauthier and Aubry 1996; LaRue et al. 1995). Further south in its range, the Blackburnian Warbler prefers stands dominated by or containing hemlock. It attains its highest density within hemlock stands. In the extreme southern portion of its range, it nests in deciduous stands where conifers are completely lacking or scarce. These forests may be dominated by northern hardwoods such as sugar maple, beech, and yellow birch or more southern species such as oaks. Early in the period when the chestnut tree was being attacked by blight, it was common on dry ridges dominated by chestnut sprouts. Presence of large trees is less of a requirement in deciduous stands because there is less likely to be competition from the Black-throated Green Warbler, although the 2 species occasionally nest together in hardwoods. Even where conifers are present or even dominant, the Blackburnian Warbler may occasionally nest in low densities in deciduous stands dominated by northern hardwoods or poplar-birch. In Ohio, a female foraged predominantly in a walnut tree in the lawn of an urban park but nested in Norway spruce planted at the edge of the lawn. A Massachusetts nest was in an open growth of white cedar 36 m from a house, but the male usually sang from a mature pine and hemlock forest 137 m distant. A Minnesota nest was directly over the entrance to a cabin; it was in a cedar tree (Back 1979; Bent 1953; Brooks 1940, 1947b; Capen 1979; Chapman 1907; Erskine 1977; Harrison 1984; Holmes and Schultz 1988; Kotesovec 1993; Morse 2020; Nice 1932b).

Several studies examined microhabitat preferences of the Blackburnian Warbler. In New Brunswick, territory density was determined by the density of mature red spruce and yellow birch. It foraged and sang in both mature coniferous and deciduous species, but avoided immature conifers (Young 2004). In Michigan, 90% of Blackburnian Warblers were in coniferous stands,

predominantly in sawlog-sized stands, although some occurred in pole-sized stands. Stand types it nested in included hemlock, white spruce–balsam fir, white pine, white cedar, upland hardwoods, mixed coniferous swamp, and red pine. Occupied sites had dominant trees that were 60-167 years old with a high BA (10.6 m^2 for conifers and 3.2 m^2 for deciduous species), high canopy closure (80.1%), low understorey coverage (15.8%), and low herbaceous cover (38.5%). It inhabited older, medium to high density, mesic, conifer-dominated forests (Doepker et al. 1992). In Maine, it was associated with a coniferous overstorey and larger conifers. It was positively correlated with deciduous trees less than 10 cm diameter at breast height (DBH) and taller than 4.5 m, negatively associated with conifers the same size, and positively correlated with conifers larger than 20 cm DBH (Titterington et al. 1979). In northern Wisconsin mesic forests, it first appears when forests become sawtimber-sized (trees larger than 23 cm DBH). Occupied stands had a mix of deciduous and coniferous species with a predominantly closed canopy and an understorey of saplings (Hoffman 1989a). In New Hampshire and Maine, DeGraaf and Chadwick (1987) concluded that the Blackburnian Warbler was associated with sawtimber-size spruce–balsam fir forest. They considered it a size-class obligate species that preferred 1 size class but occurred in others. In subalpine areas of these 2 states, its abundance was negatively correlated with percent ground cover, the number of deciduous trees 2-10 cm DBH, and the number of woody stems per ha (DeGraaf et al. 1998). In northeastern mixed forests, Temple et al. (1979) considered it associated with mature forests and increasing amounts of pine. Niemi and Pfannmuller (1979) placed the Blackburnian Warbler in a guild that was common in mature upland coniferous stands, uncommon in mature lowland coniferous stands, and very uncommon in alder, mature deciduous upland forest, disturbed shrubby areas, young plantations, aspen regeneration, and recent clear-cuts. It was associated with increasing numbers of trees and saplings and moderate numbers of low shrubs. The average habitat characteristics of the Blackburnian Warbler in Minnesota were 56.7% ground cover, 41.0% shrub cover, 77.3% canopy cover, 16.1 m canopy height, 55.0% coniferous cover, 6.1 tree species per 0.04-ha circle, 16.1 trees 7.5-15 cm DBH per circle, 11.7 trees 15.1-23 cm DBH, 9.5 trees 23.1-30 cm DBH, 4.9 trees 30.1-38 cm DBH, 2.7 trees 38.1-53 cm DBH, 0.4 tree 53.1-68 cm DBH, and 0.2 tree larger than 68 cm DBH. It was associated with mature, mostly undisturbed forests containing coniferous cover and preferred moderate ground and shrub coverage with more than 75% canopy cover. Territories consistently contained more than 50% conifers, usually spruce or balsam fir, mostly in the large tree-size categories (Collins et al. 1982). Collins (1983a) compared the habitat usage of the Blackburnian Warbler in Maine and Minnesota and found that usage of areas with trees 7.5-15 cm DBH and 15.1-23 cm DBH differed significantly in the 2 areas. In Minnesota, it occupied habitats with tall canopies, moderate coniferous cover, few small trees, and more large trees. In Maine, it selected areas with high canopy closure, variable coniferous cover, and many trees in the smaller size class. Despite this, the Blackburnian Warbler was associated with large conifers in both states.

Most authors concluded that the Blackburnian Warbler requires mature stands, and 2 studies quantified this. In Saskatchewan, Cumming and Diamond (2002) demonstrated that it was most frequent in forests older than 100 years. Its probability of detection on point counts was 20-49% in 50-60- and 80-90-year-old forests, more than 100% in forests 100-110 years old, and 80-100% in forests 140 or more years old. In Pennsylvania, it occurred in 100% of old-growth hardwood-hemlock-pine forests compared with 18.6% of forests statewide and 35.0% of forests on the

Appalachian Plateau. Haney (1999) considered it to have old-growth affinities and it achieved particularly high densities in the oldest mixed forests.

It is possible that the Blackburnian Warbler is area sensitive in the west but not in the east. In Saskatchewan, it was more common than expected in mature white spruce stands that were large but isolated. The relationships between its abundance and forest type and the amount of forest within 5 km were significant, but the relationship with forest size was not (Hobson and Bayne 2000). In Maine, it was absent on islands smaller than 1 ha, but occurred on similarly sized islands in Minnesota and New York where there were tall white pines or spruce available. Avoidance of small islands in Maine was likely because the trees were too short rather than because the habitat patches were too small (Morse 2020). A Wisconsin study found that it was not confined to large islands (Beals 1960). In Minnesota, it nested on 0.5-1.1-ha islands, but was not documented on smaller islands (Howe 1979). There appear to be no studies that have conclusively demonstrated that the Blackburnian Warbler is area sensitive.

Freemark and Collins (1992), Hobson and Bayne (2000), and Morse (2020) all concluded that the Blackburnian Warbler was a forest-interior species, but provided no documentation, although Morse (1967) stated that it was typically an inhabitant of forest interior in Maine. In Quebec balsam fir–white cedar stands, it was significantly more abundant in nonriparian than riparian habitat. This may have been more a function of habitat suitability than edge avoidance. Riparian areas contained open wetland strips of alder–reed grass or sweet gale, habitat that is unsuitable (LaRue et al. 1995). In Maine, its abundance was correlated with distance from an interstate highway even after accounting for variation in habitat. This suggested that the highway was exerting a negative influence on this warbler (Ferris 1979). It was not determined if this was an edge-avoidance effect or due to noise, disturbance, predation, or other factors. During 1 breeding season, a male Blackburnian Warbler defended a territory at the edge of the St. Williams Forest, often singing from trees at the extreme edge (personal observation). Nests have been found at the very edge of stands and even in sparse tree cover near buildings but adjacent to coniferous or mixed habitat in Manitoba, Minnesota, and Massachusetts (Bent 1953; Nice 1932b). There appears to be no evidence that the Blackburnian Warbler is an obligate forest-interior species.

All Ontario nests were in living coniferous trees: 55.2% in pines, 20.7% in hemlock, 17.2% in spruces, 3.4% in balsam fir, and 3.4% in white cedar. Most nests were in the top portions of trees, although some were at mid-level and some were in lower branches. Usually they were on horizontal branches, often among smaller branchlets or at crotches; 17.6% were near or against the trunk. Nests were 0.9-5 m from the trunk with most 1.8-2.4 m from the trunk. Heights of nests from the ground were 2.4-17.4 m, with most 6-12 m up (Peck and James 1987, 1998a). Three nests in the Pimisi Bay area were 8.0-16.8 m from the ground, with 2 in white pine and 1 in white spruce. All were on a horizontal branch 2.4-3 m from the trunk. The bottom of 1 nest was not affixed to the limb, resting loosely upon it, half suspended and attached to 4 short, stiff twigs by spider silk. Another nest was in a crotch of 3-cm diameter branches (Lawrence 1953b).

Nests are almost invariably placed in conifers although there is 1 record of a nest in a chestnut tree. The Blackburnian Warbler occasionally nests in pure deciduous stands, so it is likely that nests in deciduous trees are more prevalent than the literature suggests. In Canada and New England,

most nests are in spruce, white pine, and balsam fir; hemlock is greatly preferred further south. Lesser numbers of nests have been reported in white cedar and tamarack. Red and white spruces are favoured nest trees. It may use black spruce in the north and planted Norway spruce in the south. In addition to white pine, it has nested in jack pine, and it is likely that it also uses red pine and pitch pine. Nests are almost always on a horizontal branch, occasionally near the trunk, but more frequently some distance from it and occasionally at the extreme outer tips of branches. In white cedar, nests may be at the very top of trees. Nests have been reported at heights of 1.5-25.6 m from the ground, with most above 9 m (Bent 1953; Chapman 1907; Cruickshank 1956; Kendeigh 1945; Kotesovec 1993; MacArthur 1958; Morse 2020; Nice 1932b).

Males establish territories are established as soon as they arrive and maintain them only until the young fledge. At Pimisi Bay, no territories were defended beyond late July. There is 1 report of the Blackburnian Warbler nesting in colonies but examination of the data reveals that birds were simply present in moderate to high density with no evidence of clustering of territories. At Pimisi Bay, these warblers did not nest close together. Near Quebec City, territories were significantly clumped at scales of 450 and 550 m. Its distribution there was probably related to the clustered distribution of ground cover and the percent coverage of deciduous trees, at least at the 250-m scale. Although the amount of available food does not affect territory size, there is a close relationship between foliage volume at high levels in trees and territory size. The Blackburnian Warbler concentrates its activities in treetops where there is only about 40% of the foliage volume per unit area than in the level frequented by the Black-throated Green Warbler. The density of the Blackburnian Warbler is typically almost 40% of that of the Black-throated Green Warbler. Near Lake Nipigon, 4 territories averaged 0.85 ha (range 0.81-0.89 ha), but few observations were made, so territories could have been larger. Average territory size in Algonquin Park was 0.18 ha (range 0.04-0.96 ha). At Mirabel, Quebec, territories averaged 1.0 ha (range 0.6-1.7 ha). Nine New York territories averaged 0.53 ha. In Maine, territories averaged 0.4-0.6 ha in white and red spruce forests and 1.1 ha in largely deciduous forests (Bent 1953; Bourque and Desrochers 2006; Kendeigh 1945, 1947; Lanoue and Dauphin in Gauthier and Aubry 1996; Lawrence 1953b; Martin 1960; Morse 1976, 1977, 1989, 2020).

No information is available on natal philopatry and little information is available on adult site fidelity. At Pimisi Bay, 3 territories were occupied in 3 consecutive years. These birds were not banded so it is unknown if the same individuals were present each year (Lawrence 1953b). In New Brunswick, Zitske et al. (2011) banded 205 males over 7 years and 54 (26.3%) were resighted at least once. Two males (7.7%) dispersed 65-650 m from where they were originally captured. It is possible that reproductively unsuccessful birds emigrated in search of better habitat quality.

Limiting Factors

Eggs have been reported in Ontario nests throughout June and in the first week of July (Peck and James 1987). Dependent fledglings are regularly observed in Algonquin Park from late June to mid-August, and occasionally until the end of August (Tozer 2012).

Two first nests at Pimisi Bay took 4 and 6 days to build and it took 3 days to build a replacement nest. The first egg was laid in one of these nests 2 days after it was completed. Presumably 1 egg is laid per day, although this has not been confirmed. Incubation probably starts with the laying of the

last egg. The incubation period at 1 Ontario nest was 12 days and possibly 13 days at another. There is no other information on the incubation period. It is unknown how old young are when they leave the nest (Bent 1953; Lawrence 1953b; Morse 2020; Peck and James 1987).

A single brood is raised annually, but renesting may occur if the first brood is unsuccessful. At Pimisi Bay, no third nesting attempts were made after 2 failures. In Ontario, clutches of 4 or 5 eggs have been reported (average 4.29 eggs, mode 4 eggs). Elsewhere, clutches of 3-5 eggs have been reported with 4 eggs most common. The mean size of 44 clutches from Maine and Vermont was 3.96 eggs. There is no evidence that clutch size varies with spruce budworm populations (Bent 1953; Chapman 1907; Lawrence 1953b; MacArthur 1958; Morse 2020; Peck and James 1987).

The age at first breeding is unknown, but is probably 1 year. Some populations contain vagrant nonbreeding individuals and these are most likely yearling males that were unsuccessful in defending a territory or attracting a mate. The mating system is monogamous. There is no evidence of extra-pair copulations, although this has not been studied in any detail. Silent second males have been observed on territories and it is possible that they were seeking extra-pair copulations. Pairs remain together until the young fledge. There is no evidence of pairs rejoining in subsequent years (Morse 1976, 2020).

Some studies determined where the Blackburnian Warbler forages in conifers in Maine, Vermont, and Saskatchewan. Conifers were divided into 5 vertical zones and 3 horizontal zones. The inner horizontal zone consisted of large-diameter branches that were largely devoid of needles, the central zone contained fairly large branches with old needles, and the outer zone had new growth of fresh needles and small twigs. In all areas, it consistently fed in the top 2 zones, mostly in the outer zone and also in the central portion of the zone second from the top. It made limited use of the central zone and used the 2 bottom zones less than expected with almost no usage of the lowest zone. Within conifers, it moved in a radial direction, similar to the Bay-breasted Warbler, but significantly different from the Cape May, Black-throated Green, and Yellow-rumped warblers in Maine and Vermont. In Saskatchewan, the Blackburnian Warbler exhibited one of the least diverse foraging patterns in trees along with the Blue-headed Vireo, but there was 0% overlap with the vireo with respect to other foraging techniques. The Blackburnian Warbler foraged significantly higher in conifers than all other warblers except Bay-breasted and Black-throated Green warblers. In Saskatchewan, there was an 85% overlap in foraging between Blackburnian and Bay-breasted warblers, significantly higher than for most other pairs of warblers. The Blackburnian Warbler was intermediate between the Bay-breasted and Black-throated Green warblers in its method of foraging, usually moving out from the base of branches to the tips in the manner of the Bay-breasted Warbler, occasionally hopping about rapidly on the foliage at the tips of branches looking for insects, and even hovering occasionally. It seldom hawked flying insects. Warblers in coniferous forests tended to feed in different places within trees and in different manners and were therefore probably exposed to different prey items, thus reducing competition. Competition is further reduced by differing times for peak food requirements, with the Blackburnian Warbler nesting considerably sooner than the Bay-breasted Warbler. The Blackburnian Warbler can only persist in large numbers when the forest is sufficiently old that the primary feeding zone of the dominant Black-throated Green Warbler stops well below the treetops where the Blackburnian Warbler prefers to feed

(Cumming 2004; MacArthur 1958). In Maine, Morse (1967) studied the foraging of the Blackburnian Warbler and other species in spruce. It foraged at an average height of 15.2 m (range 10.7 to more than 19.8 m). It usually foraged at greater heights than the Northern Parula, Magnolia Warbler, Yellow-rumped Warbler, and Golden-crowned Kinglet and, to a lesser extent, the Black-throated Green Warbler. The Blackburnian Warbler did not use the tips of foliage as frequently as the Northern Parula, yet foraged more similarly to the Northern Parula and Black-throated Green Warbler than to the Magnolia and Yellow-rumped warblers. Foraging by the Blackburnian Warbler was 19.8% at the tips of foliage (16.7% by gleaning and 3.1% by hovering), 48.9% on live twigs as large as 5 mm, 2.1% on dead twigs, 2.1% on dead branches, 4.2% on the distal portions of branches, 15.6% on the proximal portions of branches, and 3.1% by flycatching. Only 4.2% of foraging occurred on deciduous species. Studies were completed in Saskatchewan and New Hampshire on the foraging tactics of the Blackburnian Warbler in deciduous trees, where there may be a different suite of potential competitors. In Saskatchewan, the average foraging height in deciduous species was 15.7 m, the same as in conifers. Its foraging height was significantly higher than that of the Blue-headed Vireo and Magnolia Warbler, but not significantly different from Yellow-rumped and Tennessee warblers. The most overlap in foraging tactics in deciduous trees with the Blackburnian Warbler was with the Yellow-rumped Warbler. The Blackburnian Warbler spent 89.9% of its foraging time in the canopy, 10.1% in the subcanopy, and 0% in the shrub and herbaceous layer (Cumming 2004). In Minnesota, the Blackburnian Warbler foraged at heights of 1-15 m, but predominantly at 6-12 m. Eighteen percent of foraging occurred in red pine, 51% in white pine, 19% in deciduous trees, 2% in balsam fir, and 4% each in spruce and other species (Howe 1979). In New Hampshire, Robinson and Holmes (1982) considered the Blackburnian Warbler a near-surface searcher that predominantly gleaned small to medium-sized, often cryptic, insects. Others in this group included the Black-throated Green Warbler, which also gleans from leaves in the canopy, and Black-throated Blue Warbler, which forages similarly but exclusively in the understorey. The Blackburnian Warbler made 77.0% of its prey attacks on leaves and 14.4% on bark. It captured 1.8% of prey by hawking and 6.0% by flush-chasing. Holmes and Schultz (1988) compared the foraging strategies of 10 species in northern hardwood stands in New Hampshire, including their tree-species preferences. The 3 main tree species used by the Blackburnian Warbler for foraging were beech, sugar maple, and yellow birch. Forty-two percent of prey attacks were on upper leaf surfaces, 47% on lower leaf surfaces, 2% on leaf petioles, and 9% on twigs. The proportional use of these substrates varied among tree species. Prey was obtained predominantly by gleaning (70% of prey attacks) and 30% by hovering with little difference among tree species. Unlike in conifers, it did not concentrate its foraging in any particular strata. All 10 species differed significantly from each other in their use of foliage substrates, of tree species, and of petioles and small twigs combined. The Blackburnian Warbler did not change its use of attack manoeuvres significantly in different tree species. It foraged preferentially in yellow birch, which had the highest densities of caterpillars. In yellow birch, it and the Black-throated Blue Warbler and Rose-breasted Grosbeak overutilized upper leaf surfaces in proportion to their availability and underutilized lower leaf surfaces. In beech, the Blackburnian Warbler significantly overutilized upper leaf surfaces. It and the Black-throated Blue Warbler and Black-capped Chickadee differed from other species in directing proportionally more manoeuvres toward upper leaf surfaces. The Blackburnian and Black-throated Blue warblers consistently changed foraging patterns in the same manner among tree species. The Blackburnian Warbler, Black-capped Chickadee, Black-

throated Green Warbler, and Rose-breasted Grosbeak predominantly gleaned from foliage close to their perches. The only species that hovered to any extent were the Least Flycatcher and Blackburnian Warbler in beech and the Rose-breasted Grosbeak in yellow birch. In sugar maple, only the Blackburnian Warbler, Black-capped Chickadee, Scarlet Tanager, and Rose-breasted Grosbeak foraged in proportion to the distribution of available insects. In coniferous habitat in Maine, male Blackburnian Warblers foraged higher than females, lower than their song perches but higher than the nest. Females foraged closer to the nest height. Both sexes foraged predominantly at heights of 9.4-12.2 m, but males spent significantly more time in this level. Females foraged to a maximum height of 15.5-18.3 m; males foraged at heights in excess of 18.6 m. Males hawked significantly more than females and females hovered more than males. Females may not normally hover more than males because 65% of the hovering motions were conducted by 2 females seen in close proximity on a single day. When these 2 females were removed from the analysis, there was no significant difference in the amount of hovering by the sexes (Morse 1968). Holmes (1986) conducted a similar study in deciduous habitat in New Hampshire. There was no significant difference in the average foraging heights of the sexes: 15.1 m for males and 14.4 m for females. When G-tests were applied, females used a higher stratum proportionally more than males. Males foraged at heights of 6-26 m with a peak at 14 m; females foraged 2-26 m from the ground with a peak at 20 m. Similar to Maine, male foraging heights were correlated with song perch heights and female foraging heights were correlated with nest height. Both sexes were predominantly leaf gleaners that foraged with equal frequency in proximal and distal portions of canopy trees. The sexes differed significantly in their usage of tree species, with females exhibiting high selectivity for coniferous trees. Tree species usage by females was 8.5% for beech, 5.8% for sugar maple, 52.4% for yellow birch, 3.7% for white ash, and 29.6% for conifers. Male tree species usage was 14.0% for beech, 7.3% for sugar maple, 65.4% for yellow birch, 2.0% for white ash, 10.0% for conifers, and 1.3% for other maple species. Conifers represented only 1% of the available trees. In the Clay Belt of Ontario, 57.0% of foraging was in conifers at an average height of 13.6 m at 72% of tree height. Eighty-three percent of prey attacks were on foliage: 40.1% by aerial attacks, 4.8% by hanging, 22.0% by hovering, and 18.4% by reaching (Greenberg et al. 1999). In Parry Sound District, foraging height was 5-16 m during the breeding season and 4-13.5 m during autumn migration. Based upon foraging heights and general foraging strategies, the foraging manoeuvres of the Red-eyed Vireo and 6 warbler species were essentially indistinguishable (Mills 2007).

Nestlings near Pimisi Bay were fed green caterpillars and mayflies. Young at an Ohio nest were fed larvae, caterpillars, and winged insects. Two males near Lake Nipigon had consumed 196 prey items: 31.1% flies, including march flies; 28.6% beetles, including weevils and soldier beetles; 11.7% lepidopterans; 6.6% conifer sawflies; 6.6% ichneumonid wasps; 5.1% spiders; 4.6% brown lacewings; 3.6% short-horned grasshoppers; and 2.0% planthoppers. In New Hampshire, adults captured 75.0% caterpillars, 16.6% adult lepidopterans, 4.2% flies, 2.1% beetles, and 2.1% spiders. It was also likely that they preyed heavily on soft-winged bugs, particularly leafhoppers. Other prey the Blackburnian Warbler has eaten during the breeding season includes ants, wasps, crane flies, leaf beetles, spruce budworm caterpillars, and saddled prominent caterpillars. Birds offered gypsy moth larvae in an aviary experiment all refused to eat them (Bent 1953; Crawford and Jennings 1959; Holmes and

Schultz 1988; Holmes and Sturges 1975; Kendeigh 1947; Kotesovec 1993; Lawrence 1953b; Robinson and Holmes 1982; Whelan et al. 1989).

The Blackburnian Warbler may exhibit variable responses to spruce budworm outbreaks. It does not alter its clutch size when budworm numbers are high and its population may remain static, increase, or decrease during budworm outbreaks. Data from 2 areas in Ontario indicate that it was more abundant during outbreaks than when budworms were scarce or lacking. Near Lake Nipigon during an outbreak, density of the Blackburnian Warbler averaged 14.8 per km^2 (Kendeigh 1947). It was absent or rare in the same area when budworms were absent (Sanders 1970). Near Manitouwadge, density increased by 42% in mature stands during a budworm outbreak, but it continued to be absent in young and intermediate-aged stands (Venier et al. 2009). In New Brunswick, it exhibited a direct but weak response to increasing budworm numbers. It responded almost immediately to the outbreak, but to a lesser extent than the Bay-breasted Warbler. The Blackburnian Warbler apparently did not respond to an earlier outbreak in the same area (Morris et al. 1958). During a spruce budworm outbreak in New Hampshire and Maine, Blackburnian Warbler stomachs contained an average of 3.0 budworms, third highest of any species. It had densities almost twice as high as the Magnolia, Bay-breasted, and Cape May warblers and consequently consumed more budworms per ha than any other species. These populations of the Blackburnian Warbler did not increase with budworm populations, but the studies were done in outbreak years so densities could not be compared to periods when budworms were absent (Crawford and Jennings 1989). In Maine during a spruce budworm outbreak, 19 stomachs contained 20% and 26% budworm larvae and pupae by volume in 2 years (Mitchell 1952). Blackburnian Warblers may decline during budworm outbreaks if populations of Bay-breasted and/or Cape May warblers increase significantly. These 2 species are dominant to the Blackburnian Warbler (Morris et al. 1958; Morse 1989). The Blackburnian Warbler is most likely to be adversely affected by these 2 warblers during budworm outbreaks in areas lacking supercanopy trees. Where very tall trees are present, the Blackburnian Warbler may reduce competition by foraging above the preferred heights of the other warblers. In New Hampshire, Holmes and Sturges (1975) attributed an increase in Blackburnian Warblers to an outbreak of saddled prominent caterpillars.

The Blackburnian Warbler is an uncommon host of the Brown-headed Cowbird because this parasite avoids extensive mixed and coniferous forests, especially in more northern areas. The high nest height of the Blackburnian Warbler is not a deterrent to the cowbird. The highest nest reported (25.6 m) was parasitized. As of 1977, only 10 parasitized nests had been reported. Many parasitized nests are at edges of forests. The effects of parasitism on the reproductive success of the Blackburnian Warbler are unknown, but it has successfully fledged cowbirds. In Ontario, 4 of 12 nests (33.3%) were parasitized (Morse 2020; Peck and James 1998a). It is likely that parasitism rates are lower in the Boreal Forest Region.

Forest fragmentation at the landscape and local scales can affect Blackburnian Warbler abundance and survival rates. In New Brunswick, habitat loss was associated with a decrease in the number of individuals within a landscape. Annual survival rate increased with increasing amount of habitat within 100 m and there was some evidence for increased survival as habitat increased at the 2-km scale. Within-season survival was 12 times greater in landscapes with 85% habitat than those

with 10% habitat. The differential survival related to habitat abundance may be partly responsible for the lower probability of occurrence in landscapes with low amounts of habitat. There was little support for a relationship between area of mature forest and survival rates (Zitske et al. 2011).

Forest management practices that remove mature conifers are detrimental to the Blackburnian Warbler. In the Boreal Forest Region of Ontario, removal of 30% of trees within stands had no apparent effect but numbers decreased when 50% or 70% of trees were removed. By modelling current harvest prescriptions and natural disturbance regimes in the Boreal Forest Region of Ontario, it was predicted that the Blackburnian Warbler would experience a decrease over the next century. Two studies in Algonquin Park found no significant change in abundance as a result of single- and group-selection harvesting. In Michigan and New Brunswick, rotation periods in coniferous and mixed forests are typically 50 years or less. This is insufficient time for stands to mature to provide Blackburnian Warbler habitat. In addition, the high level of mechanization used to harvest pulpwood kills most of the advanced spruce–balsam fir regeneration. In Saskatchewan, rotation age is longer at 80-90 years, but this warbler is significantly more abundant in stands 100 or more years old. The older forests also contain a higher proportion of conifers than younger stands. In this area, the Blackburnian Warbler is likely to suffer some reduction in its population density if stands older than rotation age are lost from the landscape. Densities are low in retained riparian strips adjacent to clear-cuts (Cumming and Diamond 2002; Doepker et al. 1992; Jobes et al. 2004; Morse 2020; Rempel et al. 2007; Tozer et al. 2010; Vanderwel et al. 2009; Zitske et al. 2011). In the Ontario Canadian Shield, there was no difference in its abundance in early successional clear-cuts and burns, but it was significantly less abundant in mid-successional clear-cuts than in mid-successional burns. It was significantly less abundant in both early successional and mid-successional stands than in mature stands (Zimmerling et al. 2017). In northern hardwoods near Sault Ste. Marie, it had fairly high abundance in a stand where 42.0% of its total BA was removed, approximately 30% higher than the one third recommended in the silvicultural guidelines (Holmes and Pitt 2007). Webb et al. (1977) considered the Blackburnian Warbler a true species of undisturbed forest in New York northern hardwoods. It was most abundant in uncut stands and exhibited high and significant levels of decline at all intensities of logging. In Muskoka District and Haliburton County, it was negatively affected by even low levels of disturbance to forest structure (Clark et al. 1983).

Numbers of Blackburnian Warblers are thought to have declined during the periods of heavy use of persistent pesticides. Mortality was documented with application of DDT for control of Dutch elm disease. A decline and probable mortality was associated with use of fenithrothian for control of spruce budworms in New Brunswick (Morse 2020).

Weather factors such as late snow, cold, or extensive rain during the breeding season can depress populations. Under these circumstances, numbers may be reduced through scarcity of prey or mortality of nestlings due to exposure or starvation. A male continued to feed nestlings at a Pimisi Bay nest where the female had been killed. The young perished, most likely because the male failed to brood them (Lawrence 1953b; Morse 2020).

Factors outside Ontario may affect Blackburnian Warbler populations. Populations breeding in hemlock are at risk because of the woolly hemlock adelgid which attacks and kills hemlock (Morse 2004). In New Jersey and Pennsylvania over a 15-year period, hemlock declined from representing

56% of the total basal area to 46% as a result of the hemlock woolly adelgid; the amount of deciduous understorey increased. It was adversely affected by hemlock decline and decreased (Toenies et al. 2018). The hemlock woolly adelgid has recently colonized southern Ontario. Deforestation in the wintering grounds is serious and may affect populations (Morse 2020).

Venier et al. (1999) determined that climate had a strong influence on the breeding distribution of the Blackburnian Warbler in Ontario. Important factors determining its distribution included maximum diurnal, mean seasonal, and annual ranges in temperature; annual precipitation; range in precipitation; and total precipitation during the growing season. Price (2004) concluded that the Blackburnian Warbler might disappear as a breeding species from southern Ontario if the average summer temperature increased by 2°C.

Status

Baillie and Harrington (1937) considered the Blackburnian Warbler a fairly common summer resident throughout the province north from Lake Erie and Ottawa to Hudson Bay. The first atlas indicated a more constrained distribution. Although it still ranged from Lake Erie to Ottawa in the south, distribution south of the Canadian Shield was spotty. It was absent in Essex, Chatham-Kent, Lambton, and Middlesex and there were only 1 or 2 records each for Elgin County and Niagara Region. There were no records from the Hudson Bay Lowland during the first atlas, with the northern extent of breeding occurring roughly from Sandy Lake to south of Moosonee (Crins in Cadman et al. 1987). It is likely that the population south of the Shield declined between the time of Baillie and Harrington's (1937) publication and the first atlas due to deforestation. It is less likely that there was a change in the northern extent of its range. The range determined by the atlas was similar to that depicted by Godfrey (1986), who acknowledged that the northern limits of its range were uncertain. James (1991) considered the Blackburnian Warbler a common summer resident across the province north to Sandy Lake and Cochrane, but with sight records to Fort Severn. He considered it rare south of the Shield to Elgin County.

The second atlas revealed that there had been no significant changes in the breeding range of the Blackburnian Warbler since the first atlas. Its probability of observation increased significantly since the first atlas for the entire province, mainly because of a significant increase in the Boreal Forest Region and the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region. Although not significant, trends in all other regions were positive. There was considerable infilling of its range south of the Shield, particularly in the Great Lakes–St. Lawrence Forest Region, but also to some extent in the Carolinian Forest Region (Crins in Cadman et al. 2007). No explanation is evident for its increase. The increase in the Shield portion of the Great Lakes–St. Lawrence Forest Region may be because populations of the Bay-breasted and Cape May warblers declined significantly in this region. These species compete with the Blackburnian Warbler and are dominant to it. Their decline was likely related to decreases in spruce budworm populations, and Blackburnian Warbler populations may decline during budworm outbreaks due to competition from more dominant spruce-woods warblers. South of the Shield, numbers may have increased slightly due to maturation of mixed and coniferous forests. Highest densities occurred in the Shield portion of the Great Lakes–St. Lawrence Forest Region, with isolated areas of high density in the Boreal Forest

Region. Areas of high density coincided with the distribution of mixed forests with a strong coniferous component (Crins in Cadman et al. 2007).

The Blackburnian Warbler may experience annual fluctuations in its abundance. This has been documented in Maine, New Hampshire, and Wisconsin. Changes in abundance in Wisconsin were unrelated to drought and changes in annual precipitation (Blake et al. 1992; Holmes and Sherry 2001; Morse 1976). Changes in annual populations are most likely related to food supplies and competition from species that are dominant to it, especially the Bay-breasted, Cape May, and Black-throated Green warblers.

The overall population of the Blackburnian Warbler appears to be holding steady despite deforestation pressures in its wintering grounds and portions of the breeding grounds. Breeding Bird Survey (BBS) data for both 1966-2002 and 1993-2002 indicated no significant changes. It is probably underrepresented on the BBS because of its roadside count method and the fact that there are few roads in the core of its breeding range (Morse 2020). BBS results indicate an annual increase of 0.123% in Canada and an annual decrease of 0.459% in Ontario 1970-2021. Trends for 2011-21 were annual decreases of 0.547% in Canada and 1.02% in Ontario. Results were highly reliable except that the short-term Ontario trend was of medium reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

At Pimisi Bay, the onset of the postnuptial moult occurs in the third week of July. At this time, singing ceases abruptly and birds move out of their territories, often pursued by fledglings still begging for food. At this time, both young and old birds join flocks of warblers that are passing through (Lawrence 1953b). The male and female may each care for half the brood, moving independently of each other with no evidence of subsequent regrouping. Fledglings in Maine soon drift away from the natal area, often leaving spruce forests to seek nearby groves of white birch which often support large numbers of leafrollers and other caterpillars (Morse 2020). Central Ontario birds also moved to areas containing more white birch late in the season (Mills 2007). Fledglings from an Ohio nest remained in deciduous shrubbery shortly after leaving the nest (Kotesovec 1993). In Minnesota, Streby et al. (2011b) captured both juveniles and adults in 2-10-year-old regenerating deciduous clear-cuts during the postfledging period. No birds were captured in this habitat during the breeding season.

MIGRATION

The Blackburnian Warbler is a nocturnal migrant, but occasionally exhibits some daytime movement. During autumn migration, it is likely to join mixed flocks of other warblers as well as chickadees and other resident species (Morse 2020).

Males arrive in spring before females. At Long Point, the mean capture dates for males were 16.5 May for after-second-year birds, 20.0 May for second-year birds, and 18.4 May for males of undetermined age. For females, mean capture dates were 22.1 May for after-second-year birds, 26.4 May for second-year birds, and 25.4 May for females of undetermined age (Stewart et al. 2002). At Prince Edward Point, the mean date of arrival was 21.6 May for males and 27.0 May for females (Francis and Cooke 1986). Males are present there from 10 May to 7 June and females are present 15 May to 14 June; peak numbers occur 25-31 May (Keast 1980, 1990). In southern and central Ontario, the peak of migration occurs around mid-May, with average arrival in the first week of May.

Most have passed through by the end of May, but migrants may be present from the last week of April until mid-June (Black and Roy 2010; Curry 2006; Fleming 1907; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008). At Pimisi Bay, first arrivals occurred from 5 to 17 May (mean 12 May, median 13 May). Females arrived 3-23 days after males (median 9 days, average 11 days). The median of 9 days was considered more representative than the average (Lawrence 1953b). The Blackburnian Warbler was first observed on 20 May near Lake Nipigon (Kendeigh 1947).

During autumn migration in Virginia and West Virginia, juveniles passed through earlier than adults, although few adults were seen. Juveniles were observed from 3 September until 20 October; adults were observed 23-30 September (Stewart 1986). In the southern Shield, autumn migration is evident by mid-August and peaks in the first half of September with stragglers until mid-October (Lawrence 1953b; Mills 1981; Tozer 2012). Autumn migrants appear in the south by mid-August. The flight is heaviest in the first half of September but may extend into late September in the southeast. Migrants may arrive in mid- to late July and remain into early October, with rare stragglers remaining into November or even January (Black and Roy 2010; Curry 2006; Fleming 1907; Keast 1980, 1990; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008). Sheppard (1939) reported one in his garden in Niagara Falls 5-11 November.

During migration, the Blackburnian Warbler occurs in a variety of treed habitats, including deciduous, mixed, and coniferous forests. It has been stated that it prefers to forage in hemlock and pines, but it frequently occurs where there are no conifers. In Illinois, it showed no consistent preference for habitat, occupying woody areas such as bottomland and upland forests, forest edges, and shrubby areas equally in both spring and autumn. In addition to wooded and shrubby areas, the Blackburnian Warbler may be found in gardens and rural residential areas provided that some trees are present (Bent 1953; Graber et al. 1983; Morse 2020). During spring migration in Pennsylvania, it was most abundant in suburban forests followed by forest interior, forest-agricultural edges, and pole-stage forests. It was not detected in shrub-sapling-stage forests. It was significantly more abundant in suburban forests than in pole-stage forests (Rodewald and Brittingham 2007). During spring migration in Ohio, it was significantly more abundant in mature upland forests than mature riparian forests. Upland stands had significantly less canopy cover (74% compared with 83%) and more shrub coverage (39% compared with 19%; Rodewald and Matthews 2005). During autumn migration in Pennsylvania, there was no significant difference in its abundance in forest interior, forest-agricultural edges, suburban forests, shrub-sapling-stage forests, or pole-stage forests (Rodewald and Brittingham 2002, 2004). In early November in Niagara Falls, one appeared to roost overnight in a large weeping willow that was still almost in full leaf (Sheppard 1939).

The foraging habits during migration are similar to those used in the breeding season. Because the Blackburnian Warbler is not confined during migration to a territory where it may face competition from other warblers, it may forage at lower heights. During autumn migration at Prince Edward Point, it foraged at heights of 1.5-18 m, with a peak around 7 m. It sometimes fed part of the day at heights of 17-18 m, then in the tops of saplings, subsequently descending for short periods into shrubbery only 1.0-1.5 m tall. It occasionally showed some preference for feeding in conifers but commonly fed in deciduous species. Foraging locations were 5% in the air, 45% on outer leaves,

14% on twigs and inner leaves, 10% on outer branches, 2% on inner branches, 0% on the trunk, 19% on sapling foliage, 3% on sapling branches, 2% on low shrubs, and 0% on the ground. It was predominantly a crown and inner foliage feeder with some foraging conducted in outer branches and minor amounts in the canopy of saplings. During migration, it may modify its foraging behaviour to take advantage of unusual opportunities or to seek atypical prey when conventional prey items are scarce or lacking. During autumn migration in New York, Blackburnian Warblers searched at night for food among the foliage of trees illuminated by lights from a football stadium. It was observed eating insects on the ice of Lake Manitoba. Beetles, midges, other flies, and spiders were on the ice at that time. During a cold spell during spring migration in Massachusetts, it foraged in low shrubbery, grasses, and plowed fields, abandoning these areas later in the day when it warmed up (Bent 1953; Keast 1980; Lebbin et al. 2007; McNicholl and Goossen 1980; Morse 2020).

The Blackburnian Warbler continues to be largely insectivorous during migration, but may occasionally eat fruit when insects are scarce. An early spring migrant in Massachusetts ate ivy berries (Bent 1953; Morse 2020). Midges are abundant near the shorelines of the Great Lakes in spring and these areas provide an abundance of food for migrants. The midges attract large numbers of spiders and the warblers also prey upon them (R.J. Smith et al. 2007). Stomachs of Blackburnian Warblers killed at a hydro tower near Prince Edward Point contained small beetles and some plant material (Keast 1980). A very late autumn migrant at Niagara Falls appeared to be feeding on aphids and possibly aphid eggs on willow trees (Sheppard 1939).

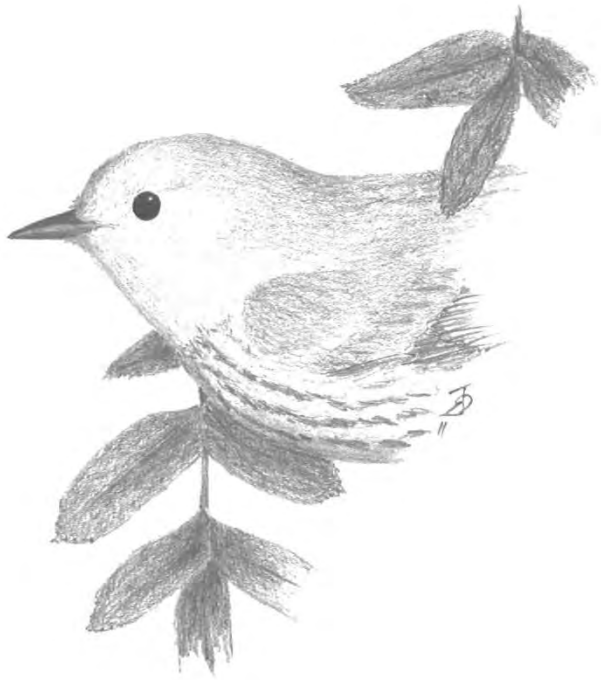
The Blackburnian Warbler is a common victim of collisions at tall structures. From 1972 to 1982, 1,491 were killed at the Lennox generating station chimneys near Kingston. Maximum kills of 136, 500, and 291 occurred on 2, 5, and 6 September 1981, respectively (Weir 2008).

James (1991) considered the Blackburnian Warbler a common migrant in Ontario, although Black and Roy (2010) considered it an uncommon spring migrant in Niagara Region.

Migration monitoring at Long Point indicated a nonsignificant decline in numbers of the Blackburnian Warbler 1961-88. Trends by period were: 1961-70, –8.1%; 1970-79, –14.7%; and 1979-88, –0.8%. Declines in the 1970s were attributed to decreases in the spruce budworm population, and its numbers corresponded closely with budworm numbers (Hussell et al. 1992).

Yellow Warbler

Setophaga petechia

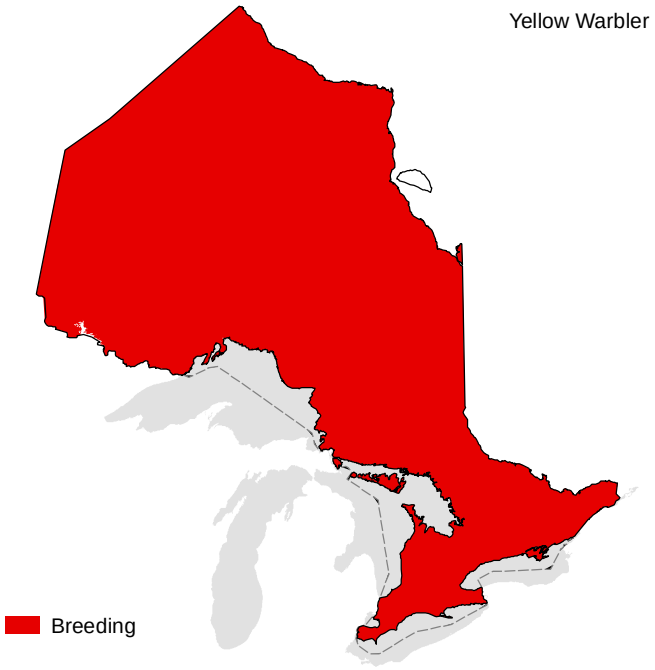


BREEDING SEASON

Habitat Requirements

The Yellow Warbler has one of the most extensive breeding ranges of any warbler, from above the treeline from the Atlantic to Pacific coasts south to Mexico and Venezuela. Forty-three subspecies are currently recognized within 3 main groups. It is likely in future that these 3 groups will be recognized as distinct species. Western populations appear to be genetically distinct from those in the east, so it is possible that they may also be split into individual species (Boulet et al. 2006; Lowther et al. 2020). The habitat preferences of the Yellow Warbler are remarkably similar throughout its range, except that the more southern subspecies nest in mangrove swamps, a habitat that is structurally similar to what is preferred range-wide (Salgado-Ortiz et al. 2008).

Ontario nests were predominantly in open shrubby habitat, most frequently (47.3% of nests) in overgrown fields and pastures. Other nesting habitats included floodplains and shorelines of rivers, lakes, and sloughs (18.8% of nests); in woodlots and at woodland edges (14.4%); in gardens and near cottages (10.6%); in hedges, fencerows, and old orchards (5.5%); in bogs and fens (2.1%); on railroad



and road rights-of-way (1.0%); and in boreal forest burns (0.3%). When the Yellow Warbler used forest cover, it appeared to prefer mixed woods to deciduous stands and only occasionally used coniferous forests. Occupied treed habitats were usually open and consisted primarily of short trees and shrubs. Both wet and dry sites were occupied. Nests were often near water, probably due to its preference for nesting in willow, alder, and dogwood. In tundra habitat, nests were in willow and alder thickets along sloughs and rivers (Peck and James 1987).

In the Tundra Region of Ontario, the Yellow Warbler was a common breeder in alder thickets along the Hudson Bay coast. It also nested in deciduous shrubs in swamps between the spruce forest and barren coastal regions (Manning 1952). At Cape Henrietta Maria, it nested in dense willows bordering tundra sloughs (Peck 1972).

In the Hudson Bay Lowland, the Yellow Warbler nested in alder and willow thickets along the James Bay coast. On islands near Moosonee, it nested in tall willow thickets near the river bank and at edges of barrens (Manning 1952). At North Point north of Moosonee, it nested primarily in wet thickets of willow and grey alder interspersed with common cattail. This habitat was immediately inland from extensive tidal marshes and formed a nearly continuous narrow band along the coast, broken only by scattered cattail marshes (Rimmer 1988).

In the Boreal Forest Region from Pickle Lake north to the Wetico Hills, the Yellow Warbler was most abundant in deciduous scrub, followed by deciduous forest, mixed scrub, mixed forest, and coniferous forest with an understorey. It was not detected in coniferous forest without an understorey, coniferous scrub, heath, or tundra (McLaren and McLaren 1981). In this forest region, it is confined mostly to areas of deciduous shrubs such as forest openings or along the margins of rivers, streams, and open wetlands. It does not usually inhabit clear-cuts, even when they are in the earliest stages of succession.

Habitat in the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region is similar to that used in the Boreal Forest Region. James and Peck (1995a) rarely encountered the Yellow Warbler in jack pine stands near Gogama where it occurred only in very young regeneration with a high component of deciduous growth. In Algonquin Park, it was only moderately common in partly open country and at edges of woods (MacLulich 1938). Tozer (2012) concurred, noting that it was limited by the scarcity of willows and the presence of heavily wooded areas. It nests in the park in willows and alders bordering lakes, ponds, and marshes; along an old railway right-of-way; along a hydro corridor; and in roadsides, fields, and clearings. In Parry Sound and Muskoka districts, it nests

in moist thickets of willow and other thickets, which are widely but not commonly distributed. It nests in old fields, small scrubby islands, and wet open areas such as pond margins (Mills 1981). Wilson (1985) reported that it was one of the most common breeding birds on sparsely vegetated bedrock islands in Georgian Bay. North of Kingston on the Frontenac Axis, it nested in a marshy area dominated by willows, cattails, alders, and meadowsweet; in open rocky pasture interspersed with sapling and mature maples, staghorn sumac, and dense clumps of raspberries; and in open areas along a path through mixed forest (Yezerinac et al. 1995).

In Durham Region in the off-Shield portion of the Great Lakes–St. Lawrence Forest Region, Speirs and Orenstein (1975) reported high densities of the Yellow Warbler in a very young pine plantation that was still dominated by willows and meadowsweet, and in an abandoned apple orchard with hawthorn growth and an understorey of grasses.

In the Carolinian Forest Region at Point Pelee, Dodds and Otis (2009) recorded the Yellow Warbler in high densities in mature deciduous forests dominated by hackberry, black walnut, and green ash. One plot was adjacent to a red cedar savannah swamp and a road. In Hamilton, nests were more frequently found in lilac bushes in gardens than in natural habitats (McIlwraith 1894). South of the Shield, it is common in a variety of open habitats. In addition to the alder and willow thickets that it inhabits throughout the province, it occurs in old shrubby fields, lightly grazed pastures, hawthorn meadows, overgrown roadsides, and utility rights-of-way. It is no longer common in residential yards or orchards because these areas tend to be highly manicured now. It is also less frequent in hedgerows than previously, because residual hedgerows tend to be narrow and pass through row crops that do not provide any suitable nesting habitat (personal observation).

Habitat used by the Yellow Warbler throughout its range is very similar to what has been reported in Ontario. It shows a strong affinity for willow thickets with alder and other shrub species also used to a lesser extent. Several studies demonstrated that it increases with shrub density, particularly willow. Above the treeline, it nests in thickets of willows (often tea-leaved willow and bog willow), dwarf birch, and alder. It is characteristic of tundra habitat at the ecotone between tundra and boreal forest, and also characteristic of prairie-forest ecotones. It seldom inhabits the tundra itself except for shrubby areas around tundra sloughs or along rivers and streams. In prairie habitat, it avoids grasslands and nests in shrub thickets and riparian vegetation around pothole wetlands. It avoids vegetation around potholes unless taller trees or shrubs are available as singing perches for the male. In the Boreal Forest Region and other densely forested areas, it avoids forest habitat and occurs in shrubby areas along margins of rivers, streams, and wetlands. Shrubby islands in rivers and lakes may provide ideal habitat and support high densities. It may be present in or near towns in forested areas where it inhabits shrubby areas where forest was cleared. In extensively forested areas, it may occur in deciduous and mixed forests provided that the canopy is open and deciduous shrubs are common in the understorey. In Quebec, it inhabits burns and clear-cuts in extensive forests but usage of these habitats has not been documented elsewhere. These types of habitats are typically used only where they are in floodplains of rivers or bordering lakes. It seldom inhabits forested areas distant. Stand types used most frequently are those dominated by trembling aspen, balsam poplar, cottonwood, green ash, and willow. Dune habitats at Delta Marsh in Manitoba supported the highest reported densities. Tree cover consisted of peach-leaved willow, green ash,

and Manitoba maple with an understorey of sandbar willow. In North Dakota, the Yellow Warbler reached its highest density in willow shrub communities followed by lowland forests of elm, Manitoba maple, cottonwood, black ash, and peach-leaved willow. It was common to abundant in all available habitats, including bur oak forests, trembling aspen forests, and juneberry thickets. On regenerating strip mines in Illinois, it always nested in dense stands of moderately tall black locusts. On Maine islands dominated by spruce, it nested successfully on islands that had sizeable areas not covered by coniferous growth. It nested in deciduous shrubs and saplings at edges of conifers or in large forest openings. On 1 island, it frequented growths of sumacs and small patches of birches. On small islands completely covered with coniferous growth, nesting was unsuccessful and males seldom acquired a mate. There are records of the Yellow Warbler nesting in coniferous forests in Maine. On the mainland, several nested in white spruce 6-9 m tall. On an island, more than 100 nested in white spruce and well into a dense forest of red spruce 18-21 m tall. The only other record of it nesting in conifers appears to be from California where it has nested among fir saplings (Arnold and Higgins 1986; Briskie 1995; Brooks 1940; Campbell et al. 2001; Celada 2004; Chapman 1907; Erskine 1977; Faanes and Andrew 1983; Finch 1989b, 1991a; Gauthier in Gauthier and Aubry 1996; Graber et al. 1983; Hebard 1961; Hobson and Sealy 1989a; Hoffman 1989b; Hutto 1981; Jehl 2004; Jehl and Smith 1970; Karr 1968; Keast 1980; Kirk et al. 1996; Knopf and Sedgwick 1992; Lowther et al. 2020; Manning and MacPherson 1952; Mossman 1988; Morse 1973, 1989; Olechnowski and Debinski 2008; Parnell 1969; Quinlan and Green 2012; Sammler et al. 2008; Sinclair et al. 2003; Taylor and Littlefield 1986; Taylor and Taylor 1979).

The Yellow Warbler is more widely distributed within fragmented landscapes where it frequents a wider variety of habitats than in tundra or forested landscapes. In fragmented landscapes, it still prefers moist to wet habitats rich in nutrients but it also nests in upland areas. Presence of shrubs is a key habitat component. Willows and alders are used universally throughout its range, but other species that form thickets may also be used: apple, hawthorn, raspberries, roses, dogwoods, elm saplings, blueberries, southern arrowwood, sweet gale, bayberry, leatherleaf, elderberries, chokecherry, meadowsweet, and multiflora rose. In addition to riparian areas and wetland borders, it nests in old fields as well as shrubby areas along utility corridors. In New Jersey, it was common in fields 10 and 20 years old but was absent in 40-year-old fields that had become densely overgrown with deciduous saplings and trees. In Minnesota, it was most abundant in shrub habitat along a transmission line corridor followed by tall shrubs in control areas. It was not detected in sedge fens, low shrub communities, or open or closed spruce forests. In Great Lakes coastal meadows in Michigan, it preferred wet meadows where it was associated with greater shrub species diversity and a higher frequency of willows than was generally available. The Yellow Warbler is urban adapted and will nest in shrubby areas in backyards, cemeteries, and urban parks as well as in farmyards, hedgerows, roadsides, and shelterbelts. It occasionally nests in deciduous forests, especially those dominated by early successional species such as poplar and birch. It avoids pole-sized stands dominated by these species because the trees are too dense to provide suitable habitat. In Alberta, it was significantly more abundant in old-growth than young or mature aspen stands and in South Dakota, it was more abundant in mature than immature green ash stands. In the old-growth aspen stands, trees were large and sparse with an open canopy and a moderate density of shrubs. The mature green ash stands had a higher density of chokecherries in the understorey than younger

stands. When it occurs in northern hardwood stands, which is infrequent, it is present only in disturbed or early successional habitats and is absent in mature undisturbed hardwoods. It may occasionally occur in pine stands, but only when they are very young and have a deciduous or shrub component. In Wisconsin, it nests in pine and oak barrens. In these habitats, it was common in shrub prairies, fairly common in pine-dominated barrens and cutovers, and uncommon in nearly forest, diverse barrens, and river terrace barrens. In South Dakota, it was significantly more abundant in contiguous riparian woodlands than small isolated woodlots. It is likely that the woodlots were surrounded by agriculture, providing minimal shrubby habitat (Back 1979; Bent 1953; Brewer 1955; Campbell et al. 2001; Capen 1979; Cilimburg et al. 2002; DellaSala 1985; Gauthier in Gauthier and Aubry 1996; Gentry et al. 2006; Graber et al. 1983; Harrison 1984; Hobson and Bayne 2000; Hoyt 1948; Kirk et al. 1996; Leighton et al. 2002; Mitra 1999; Morse 1989; Mossman et al. 1991; Mousley 1926; Niemi and Hanowski 1984b; Niemi and Pfannmuller 1979; Noon et al. 1979; Riffell et al. 2001; Rumble and Gobeille 1988; Samson 1979; Schieck et al. 1995; Schroeder 1982c; Suthers 1988).

In North Dakota 400-m landscapes with less than 30% tree cover, the Yellow Warbler increased with increasing tree cover within 100 m, attaining a maximum probability of occurrence at 70% tree cover. In landscapes with more than 30% tree cover, there was no response to increasing tree cover from 10% to 60%, with its probability of occurrence remaining stable around 5%. From 60 to 100% tree cover, its probability of occurrence increased to 22%. It may respond more to shrubs or woodland edges than the amount of tree cover. It preferred landscapes that were 42-75% forested; no areas were more than 75% forested (Cunningham and Johnson 2016, 2019).

Some studies examined which areas are settled first by arriving males or compared nest-site patches with random areas, thereby providing insights to microhabitat preferences. At Churchill, most nests were built in the largest shrubs near or at the centre of a willow patch. Nesting in the centre of willow patches helped to compensate against predators because shrubs were leafless and nests were obvious well into the incubation period (Briskie 1995). In Colorado, nests were in shrubs that were taller than random and in shrub patches that were also taller and of more uniform size than occurred in the overall shrub community. Nests occurred in shrubs with a larger radius in patches of greater willow density and more uniform shrub density than random. Nest shrubs were in clumps of closely spaced shrubs. Overall, nest shrubs tended to occur in clumps of uniformly sized shrubs. The Yellow Warbler selected nest sites were selected primarily on patterns of shrub distribution within a vegetation patch and not on factors associated with the shrub itself (Knopf and Sedgwick 1992). In British Columbia, 4 males settled first on territories with a higher percentage of riparian habitat cover, in areas with a greater diversity of shrubs, and in areas with less high canopy cover. Areas selected for nesting had taller and denser shrubs than random areas (Quinlan and Green 2012). In New York, habitat consisted of scattered tall trees but 1 area had little or no vegetation shorter than 6 m. Early in the season, none of the males in the area without shrubbery were successful in attracting a mate but 20% of males in areas with shrubs were mated (Ficken and Ficken 1966). Another New York male in a shrubby area without tall trees for displaying eventually lost his territory to neighbours that had conspicuous singing perches (Ficken and Ficken 1965). In Yellowstone Park, Yellow Warbler abundance increased significantly with willow height. It was 6 times more abundant in willows 225 cm tall than in those 37.5 cm tall. It was also more abundant where willows were structurally more diverse (Olechnowski and Debinski 2008). In Alberta, it

inhabited patches of willows and aspens among mixed grasslands. Willows were used for nesting and foraging; aspens were used for foraging only. Nests were surrounded by greater amounts of willows within 5 m than random points. Territory occupancy and consistency of patch occupancy were affected mainly by the shape and area of the willow patch within a territory, or by the main patch in territories containing multiple willow patches. Warblers also chose patches with ponds supporting Red-winged Blackbirds earlier than patches without blackbirds. Presence of Red-winged Blackbirds reduced the risks of nest predation and parasitism by the Brown-headed Cowbird (Celada 2004). The average habitat parameters of the Yellow Warbler in Michigan were 96.1% ground cover, 38.9% shrub cover, 10.6% canopy cover, 6.0 m canopy height, 2.9% coniferous cover, and 1.1 trees in a 0.04-ha circle around the observation. It inhabited open fields with shrubs and was most common in open marshland with few or no trees, numerous shrubs, and very high ground coverage. It occurred in structurally simple habitat containing patches of shrubs or scattered trees (Collins et al. 1982). In North Dakota, its abundance was negatively correlated with the number of trees 15.1-23 cm diameter at breast height (DBH; Grant and Berkey 1999). In Arizona, it nested in habitats that were intermediate in height and shrub density. It occurred in tall vegetation with more foliage volume above 3 m and fewer trees than average. It used habitat similar to that of the Willow Flycatcher and was considered a habitat generalist (Brown and Trosset 1989).

Collins (1983a) compared habitat usage by the Yellow Warbler in Maine and Minnesota. There were significant differences in canopy cover, canopy height, percent coniferous cover, number of tree species, and number of trees with a DBH of 7.5-15 cm between sites, suggesting that it is adaptable in its habitat selection. Overall, it was associated with high ground coverage, large conifers, very open habitat, and medium-sized deciduous trees.

In Minnesota, Collins (1981) compared vegetation at nest sites and song perches. There were significant differences, with greater numbers of trees at perch sites which increased values for canopy cover, average tree height, and percent coniferous canopy cover.

The Yellow Warbler is not an area-sensitive species. As would be expected in forested habitat, its abundance is either unaffected by patch size or it is more likely to occur in small groves than larger woodlots (Grant and Berkey 1999; Hobson and Bayne 2000; Johns 1993). It is also not area sensitive within its preferred shrubby habitats. In Great Lakes coastal marshes, its abundance was unrelated to patch size and in Wyoming it inhabited significantly smaller patch sizes than were randomly available (Finch 1989b; Riffell et al. 2001). The only potential indication of area sensitivity was provided by Celada (2004) in Alberta. In that study, it inhabited small willow patches. Occupancy and consistency of occupancy were associated with patch size and shape. In this case, some nest patches were smaller than the territories, so the birds were not truly area sensitive.

Schroeder (1982c) prepared a habitat suitability index for the Yellow Warbler. He considered wet shrubby areas to be optimal and upland shrub areas to be marginal, but this may not be the case. Optimum shrub density was considered 60-80%. Completely closed shrub canopies were considered moderate in suitability due to probable restriction of movements by the birds. More recent research indicates that it prefers denser shrub thickets. Shrub heights of 2 m and greater were considered optimal.

In southern Ontario, the Yellow Warbler was significantly more common on conventional than organic farms and was negatively affected by the use of herbicides. The negative relationship with organic farms was possibly because conventional farms had significantly more riparian woodland, a preferred habitat (Kirk et al. 2011).

Nests reported to the Ontario Nest Records Scheme were in shrubs, trees, and vines. Deciduous species were greatly preferred as nest sites to conifers. Twenty-nine deciduous species supported 88.3% of nests; the remainder were in 7 species of conifers. The most frequently used species for nesting were hawthorns (35.0% of nests), willows (23.3%), raspberries (9.9%), white cedar (9.4%), dogwoods (8.5%), honeysuckles (7.2%), and spirea (6.7%). One nest was on a fallen limb and 3 were attached to stems of common reed in dense stands of this species. Most nests were in upright crotches in the central portion of a tree or shrub. Some were on horizontal limbs and a few were suspended from limbs. Four nests were over water. Nests were 0.3-6 m from the ground, with most 0.9-1.5 m up (Peck and James 1987). Wilson (1985) reported 3 nests on an island in Georgian Bay: one each in chokecherry, meadowsweet, and a silver maple sapling. Dance (2008) reported 2 nests in black alder in Oxford County. McIlwraith (1894) reported that nests were frequently found in lilac bushes in residential yards in Hamilton. Most yards are now too manicured to provide any nesting habitat.

Nests throughout the Yellow Warbler's range are usually a short distance above ground in a deciduous tree, shrub, or vine, although 44% of British Columbia nests were in conifers. Willow is a preferred species for nesting throughout its range with all 211 nests reported in Alberta in willow. Willow was the dominant nest-species in British Columbia. At Delta Marsh, more than 50% of nests were in Manitoba maple, which was the second-most abundant tree species behind peach-leaved willow. In Iowa, most nests were in small patches of wolfberry. In addition to the species reported in Ontario, the Yellow Warbler has nested in fox grape, red raspberry, gray dogwood, common elderberry, Allegheny blackberry, tartarian and Japanese honeysuckle, flat-leaved willow, bog willow, hoary willow, limestone willow, dwarf birch, roses, blueberries, southern arrowwood, red maple, ashes, sweet gale, bayberry, poison ivy, apple, crabapple, wolfberry, Manitoba maple, cottonwood, gooseberry, currant, trembling aspen, snowberry, elms, holly, buttonbush, oaks, pear, Saskatoon, autumn olive, multiflora rose, and red-osier dogwood. It appears to select nest sites to minimize predation and parasitism, and branching structure of the nest tree or shrub may be important. In Illinois, there was no significant difference in nest survival rates in native and nonnative shrubs although survival was slightly higher in nonnative species. In Colorado, many birds nested in the same location as the previous year despite the fact that the shrubs had been killed by a fire: nests were obvious at distances of more than 20 m. Branches of willows and other shrubs often overlap within the canopy, so individual shrubs may be indistinguishable to the birds. At a Michigan site, the Yellow Warbler preferentially selected fox grape for nesting. Nests in grape vines were built at a greater height than those in dogwoods, and higher nests had a reduced rate of cowbird parasitism. Dogwoods provided a more stable substrate than vines, with failure in vines due mostly to wind and other events rather than predation and parasitism in dogwoods. Most nests are in crotches of shrubs or saplings. In mangroves in Florida, 35% of nests were on horizontal or diagonal branches and only one was against a trunk. One nest was in the crotch of a dead tree beside an apartment and another was 1.8 m from a door that was used daily. Nests have been reported at heights of 0.2-

18 m, but few are higher than 5 m and most are less than 3 m from the ground. Nest materials may be taken from old Yellow Warbler nests and 1 nest was built of material taken from an active American Redstart nest. Nests may be built in the same crotch as the previous year's nest or even on top of it, but there are no records of old nests being repaired and reused. When nests are parasitized, the Yellow Warbler adds additional layers to its nest to bury cowbird eggs. One 6-tier nest was reported from Illinois (Bent 1953; Bigglestone 1913; Brewer 1955; Briskie 1995; Campbell et al. 2001; Chapman 1907; DellaSala 1985; Enos et al. 2024; Ficken and Ficken 1966; Graber et al. 1983; Hebard 1961; Hoyt 1948; Knopf and Sedgwick 1992; Leighton et al. 2002; MacKenzie et al. 1982; Mitra 1999; Mousley 1926; Prather and Cruz 1995; Rowher 2012; Schrantz 1943; Sinclair et al. 2003).

Males establish territories immediately upon arrival and defend them at least until the young fledge. Territories may be quite small, allowing warblers to pack into small patches of suitable habitat at high densities. There may be some overlap in territories, and birds have been observed travelling as far as 490 m outside the territory to forage. A few males attempt to defend 2 territories that may be as far as 30 m to 1.2 km apart, and some are successful in securing a mate and a nest on both territories. Monogamous males tend to have territories smaller than 0.4 ha and more frequently around 0.2 ha. Average territory sizes at 2 sites in Rhode Island were 0.20 ha and 0.21 ha; averages of 0.15 ha and 0.16 ha have been reported; Utah territories averaged 0.14 ha (range 0.05-0.29 ha); 4 Illinois territories averaged 0.17 ha (range 0.06-0.38 ha); and Quebec territories were 0.2-1.2 ha. In Michigan, 3 polygynous males had territories that averaged 0.78 ha, significantly larger than the 0.21 ha for monogamous males. A polygynous male in Manitoba had a territory size of 0.0474 ha and the 2 females used exclusive areas within his territory that they defended aggressively. The polygynous male's territory was not significantly larger than the average territory size of 0.0429 ha held by monogamous males (Brewer 1955; DellaSala 1986; Ficken and Ficken 1965; Ford 1996; Gauthier in Gauthier and Aubry 1996; Hobson and Sealy 1989a; Lowther et al. 2020; Mitra 1999; Schroeder 1982c).

Limited data suggest that natal philopatry rates are low. In New Jersey old-field habitat, 0 of 55 young returned. In Rhode Island, 3 of 147 nestlings (2.0%) returned to nest. All were males and they were recaptured 250, 900, and 1,000 m from their natal area. Three additional banded birds were observed but not captured. If these were yearlings, the return rate could have been as high as 4.1%. In Quebec, 4.5% of nestlings returned to breed (Lozano and Lemon 1999; Mitra 1999; Suthers 1988).

Adult site fidelity appears to be high. On the James Bay coast of Ontario, 64% of males and 75% of females returned the following year (Rimmer 1988). Only 29.9% of males returned to a study area north of Kingston (Yezerinak et al. 1996). In Quebec, return rates over 3 years were 34.5% for males and 31.5% for females. It was uncertain if there was a relationship between the previous year's breeding success and return rates (Lozano and Lemon 1999). In Rhode Island, 56% of males and 42% of females returned, mostly in the following year but 2 males skipped a year before returning. Over 3 years, 7 of 43 males (16.3%) relocated 60-1,200 m from their former territories. Two had failed to fledge young the previous year on the territory that they abandoned; the breeding success of 1 male was unknown. One male had been successful the previous year. He returned to his original territory for 1 day then disappeared. Five additional males moved 200-1,200 m (average 460 m) within breeding seasons. Most returning females moved less than 200 m from their previous year's

nest. Three females moved longer distances of 0.6, 1, and 10 km (Mitra 1999). In Colorado, annual return rates were 60-62% for males and 32-44% for females (Knopf and Sedgwick 1992). In Montana, Cilimburg et al. (2002) established 7 study areas but searched for returning birds over a larger area that encompassed 85-90% of the available habitat. Overall, 46.3% of males and 29.5% of females returned in 1 or more subsequent years. In the first year of expanded searches, 17.0% of the resighted birds were found off the core study areas or in a different core area and that increased to 29.6% the following year. Only 4 of the birds found on extended searches were within 0.5 km of the original breeding sites. The distance that birds moved between subsequent years was 4-24,728 m, with a median of 86 m for males and 153 m for females. Seven percent of males and 12% of females dispersed further than 1.5 km. For males, the survival rate was estimated at 41.8% using core analyses and 49.5% using dispersal analyses. For females, these numbers were 35.0% and 41.3%. The authors concluded that emigration could have substantial effects on survival rate estimates for the Yellow Warbler.

Limiting Factors

Eggs have been reported in Ontario nests from mid-May until the third week of July, with most present in the first 3 weeks of June (Peck and James 1987). At North Point on the James Bay coast, clutch initiation averaged 21, 23, and 23 June over 3 years (range 15 June to 2 July). Fledging averaged 11, 12, and 12 July (range 5-27 July). Active nests were present from 6 June until 5 August (Rimmer 1988). In Algonquin Park, eggs were present from early June to late June, nestlings were present mid-June to mid-July, and dependent fledglings were observed from early July to early August (Tozer 2012).

Males have established territories by the time females arrive. Females may visit several territories before they finally select a territory and mate. It may be several days before pair bonds are stabilized. At Churchill, females began to build nests 1-2 days after arrival, but longer intervals may occur further south. Construction of first nests may take 4-10 days and averaged 6.2 days at Churchill. Replacement nests may be built in 1-3 days and a cowbird egg can be buried in 1 day. In Rhode Island, an average of 6.3 days (range 1-12 days) elapsed between nest construction and laying of the first egg. In more northern areas where the breeding season is shorter, it is likely that the interval between nest completion and egg laying is much less. In Iowa, egg laying began on the day after nest completion or even on the same day. In more northern areas, clutch initiation is much more synchronized than in southern locations. At Churchill, clutch initiation spanned 2 weeks, less than half the period at Delta Marsh. Nest initiation also occurred within a 2-week period at North Point. One egg is typically laid per day but occasionally a day may be skipped. In Manitoba, significantly more laying interruptions occurred between the first and second eggs compared with eggs 3 and 4 and eggs 4 and 5, and more interruptions occurred between the second and third eggs than between the fourth and fifth eggs. More than half of egg interruptions occurred during the week that coincided with the peak of clutch initiation and they were more likely to occur when May temperatures were warmer. Eggs not laid during interruptions were not replaced resulting in lower clutch sizes when laying was skipped. Partial or full incubation may occur with laying of the penultimate egg, but typically full incubation begins with laying of the final egg or even later. At North Point, the incubation period was invariably 11 days. The incubation period at other Ontario nests was 9-14 days, but mostly 11-13 days. Overall, incubation periods of 9-15 days have been

reported; most eggs hatch in 11 or 12 days. At Churchill, the average incubation period was 11.7 days, significantly longer than the average of 11.3 days at Delta Marsh. Northern birds compensated for the shorter breeding season and slightly longer incubation period by initiating nesting earlier than more southern birds, prior to leaf-out. Most eggs hatch within a day, with an average hatching spread of 1.3 days for 4-egg clutches and 1.2 days for 5-egg clutches at Churchill. Nestling periods of 8-15 days have been reported, with the time that young spend in the nest decreasing northward. In Mexico, the nestling period averaged 11 days (range 9-13 days); in Florida, the nestling period averaged 12 days (range 10-14 days); in Iowa, the nestling period was 9.5 days (range 8-11 days); and at Churchill, the nestling period was 8.5 days (range 8-10 days; Bent 1953; Bigglestone 1913; Briskie 1995; Campbell et al. 2001; Ficken and Ficken 1966; Goossen and Sealy 1982; Graber et al. 1983; Gullion 1988; Harrison 1984; Hébert and Sealy 1992; Jehl 2004; Lowther et al. 2020; McMaster et al. 1999; Mitra 1999; Mousley 1926; Peck and James 1998a; Prather and Cruz 1995; Rimmer 1988; Salgado-Ortiz et al. 2008; Schrantz 1943; Westphal and Sealy 2018).

The Yellow Warbler typically raises a single brood in a breeding season, but a few birds raise a second brood. Most studies found no evidence of double brooding but Sealy (2014) reported that 20 birds had double broods at Delta Marsh in 5 of 11 years. All pairs remained together through the second nesting attempt and both yearlings and adults raised second broods. Eighteen of the 20 double-brooded pairs initiated their first nest by 2 June. None of the first clutches of double-brooded pairs were parasitized but 4 of the 20 second clutches were parasitized. Eleven pairs used the same nest for both broods and 9 built new nests for the second brood; in 5 cases, the original nest had deteriorated. The mean time between the initiation of first and second clutches was 30.2 days. Double broods have also been reported from the Northwest Territories, British Columbia, Saskatchewan, Quebec, and Mexico. Although no double broods have been reported in Ontario, there is a good probability that a small percentage of pairs raise a second brood. Renesting occurs if a nest fails and as many as 5, but rarely more than 3, attempts may be made to raise a brood. In more northern areas such as Churchill and North Point, only 1 replacement clutch may be attempted. These may not be successful due to the shortness of the season. At North Point, only 3 pairs renested and only 1 replacement nest was successful. Clutches of 2-6 eggs have been reported in Ontario and there is a single record of an 8-egg clutch, with possibly more than 1 female contributing to this nest. Most clutches contained either 4 or 5 eggs; the average clutch size was 4.04 eggs. Clutch size increases with latitude, averaging 2.5-2.8 in the tropics and 3.8-5.1 in temperate areas, with largest clutch sizes reported in Alaska. Most Canadian clutches contain 4 or 5 eggs with averages of 4.65 at Churchill, 4.5 at Delta Marsh, and 4.24 for the Prairie Provinces. In Quebec, most nests started before 15 June had 5-egg clutches but later nests had mostly 4-egg clutches. The same occurred in Manitoba before and after 7 June. A similar decline in clutch size with season was documented in Rhode Island, with clutches decreasing at a rate of 1 egg per 36 days (Briskie 1995; Campbell et al. 2001; Chapman 1907; Goossen and Sealy 1982; Graber et al. 1983; Hobson and Sealy 1989b; Jehl 2004; Leighton et al. 2002; Lozano and Lemon 1995, 1999; Lowther et al. 2020; Peck and James 1987; Prather and Cruz 1995; Rimmer 1988; Salgado-Ortiz et al. 2008; Schrantz 1943; Sealy 2014; Sodhi 1995).

Both sexes are capable of breeding when they are 1 year old and breeding occurs every year thereafter. All Manitoba females that were captured had incubation patches suggesting that they

all nested. At North Point, the sex ratio was male biased and many of the nonbreeding males were yearlings. In this population, a high proportion of yearling males and possibly some older males did not breed. Presence of a floating population has been reported from other areas suggesting that some males are unsuccessful in defending a territory or attracting a mate. The mating system is typically monogamous, but a small proportion of males are bigamists. In British Columbia, 1 of 77 males (1.3%) was a bigamist. Polygynous males may either have larger than normal territories capable of supporting 2 females, or have 2 discrete territories. In Michigan, polygynists were first to settle on territories and they were selected first by females. A yearling male in Manitoba was polygynous and he had one of the lowest song rates and repertoires and fed nestlings at a much lower rate than other males. It appeared as though females were selecting the territory rather than the male. Females that nest on the same territory with a bigamous male are aggressive toward each other until the eggs hatch. The primary female is more aggressive suggesting that she is attempting to prevent polygyny in order to ensure the male's parental care. When females in a polygynous relationship nest asynchronously, the male provides more care to the first nest. When both members of a pair return the subsequent year, they may or may not reunite. Most studies have found no evidence of remating, but 3 of 14 returning pair members (21.4%) reunited in Rhode Island. In Massachusetts, most returning males and females nested on the same territory as the previous year and remated with a previous mate if available. Extra-pair copulations are an important component of the Yellow Warbler's mating system. Extra-pair paternity was found in 25% of 12 nests at Churchill and in 53.8% of 130 nests north of Kingston. At Churchill, 13% of 53 nestlings were extra-pair compared with 33.1% of 484 nestlings at Kingston. Lower incidence of extra-pair young at Churchill was probably related to the lower breeding density and the highly synchronous nesting. Broods comprised of only extra-pair young or completely lacking them were more abundant than expected. Broods with mixed paternity were under-represented. Most confirmed extra-pair sires were neighbours, but some males travelled considerable distances for extra-pair copulations: occasionally as far as 3 territories away and some extra-pair sires did not nest in the same field. Neighbours occasionally have extra-pair young in each other's nest. Intrusions into other territories were most frequent during the neighbouring female's prefertile and fertile periods and declined significantly during incubation. Males intruded into neighbouring territories before, during, and shortly after their own female's fertile period. In an attempt to avoid cuckoldry, males perch higher and remain closer to their female during her fertile period. Thus, populations with highly synchronized nesting have fewer opportunities for extra-pair copulations. Divorce of pairs has not been documented within a breeding season, even through several renesting attempts. Intraspecific parasitism has not been positively confirmed, but abnormally large clutches of 6, 7, and 8 eggs occur rarely. In 4 of 1,500 nests at Delta Marsh, more than 1 egg appeared per day, suggesting intraspecific parasitism. At Delta Marsh, Yellow Warbler eggs were added to other clutches by researchers. Of 17 eggs added to nests that were still unlined, 16 were buried and the other nest was abandoned. All 21 eggs added to lined nests were accepted. This suggested that egg burial resulted from continued building of an unfinished nest rather than a response to a parasitic egg (DellaSala 1986; Ford 1996; Goossen and Sealy 1982; Hobson and Sealy 1989a, 1989b; Lowther et al. 2020; Mitra 1999; Quinlan and Green 2012; Reid and Sealy 1986; Sealy et al. 1989; Rimmer 1988; Yezerinac et al. 1995, 1996, 1999).

Males forage at higher heights than females. Females tend to remain in shrubs near the nest level while males display and forage in taller trees. In Manitoba, the mean foraging height was 7.1 m for males and 4.4 m for females. Average foraging heights of females remained constant through the nestling period but males' foraging heights varied: 9.2 m from arrival until the first egg was laid, 6.1 m during egg laying and incubation, and 5.4 m during the nestling period. Both sexes increased their foraging height during the postfledging period: 8.0 m for males and 6.8 m for females. Overall, both sexes foraged from less than 3 m from the ground to 21 m. Foraging heights depend upon the available vegetation. In some areas, females may concentrate their foraging 0.5-1.5 m above ground. In Utah, Yellow Warblers foraged from 0.3 m to the top of the vegetation (16.8 m), but mostly at 6-8 m (mean 7.3 m). Mean foraging height in the Mackenzie District of the Northwest Territories was 5.1 m; in Wyoming and Mexico, mean foraging height was 2.6 m. In data combined from southern Ontario, Montana, and Colorado, Yellow Warblers foraged as high as 14.9 m at mean heights of 4.0-6.1 m at a proportional height of 71.8% of the canopy in areas of moderate foliage density (Busby and Sealy 1979; Greenberg et al. 1999; Hobson and Sealy 1989b; Hutto 1981; Lowther et al. 2020; Morse 1973; Weidenfeld 1992). During the breeding season in North Carolina, 92.9% of observations of the Yellow Warbler were in low trees and 7.1% were in shrubs. It was not observed in the canopy or on the ground. In low trees, 50.0% of foraging occurred at the top of the crown, 35.8% in the inner crown, 7.1% in the lower crown, and 0% on the bole. All observations in shrubs were in the inner crown. Singing males were observed at heights of 1.5-15 m, mostly at 3.7-6.1 m (average 4.9 m). Nonsinging birds were seen at heights of 0-15 m, mostly at 3-7.6 m (average 4.5 m; Parnell 1969). In Wyoming and Mexico, most foraging (39.2%) occurred in the top quartile of shrubs, 33.9% in the third quartile, 17.9% in the second quartile, and 8.9% in the bottom quartile. Most foraging occurred in lower vegetation densities: 37.5% in 0-15% vegetation density, 46.4% in 15-50%, 10.7% in 50-85%, and 5.4% in 85-100%. It foraged 71.4% of the time on outer vegetation, 12.5% in the middle of shrubs, and 16.1% in the interior. Foraging techniques included 68.2% gleaning, 25.8% sallying, and 5.9% hovering. Foraging substrates included 41.9% foliage, 30.1% bark, 25.8% air, and 2.2% ground. Once young fledged, the mean foraging height increased from 2.6 to 3.1 m (Hutto 1981). In Utah, 95.5% of prey was obtained by gleaning, 1.7% by sallying, and 2.8% by hovering (Lowther et al. 2020). In Ontario, Montana, and Colorado, the Yellow Warbler captured prey while standing on a perch (58-70% of the time) or by aerial actions such as hover-gleaning, outward-striking, and aerial hawking (29-43% of manoeuvres; Weidenfeld 1992). In Mackenzie District, 94.9% of foraging was in deciduous species, 80.0% in foliage, 46.4% by aerial attacks, 8.5% by hanging, 1.5% by hovering, and 5.1% by reaching (Greenberg et al. 1999). On small islands in Maine, it concentrated its foraging heavily upon small limbs. It used deciduous vegetation more frequently and dead limbs less frequently than the American Redstart (Morse 1973). In Manitoba, the sexes differed in the substrates they used for foraging. From arrival through egg laying, males foraged in the upper and outer sections of trees and shrubs. Females foraged in the lower and inner sections. Later in the season, there was more overlap in the portions of trees used, but the difference was still significant. In all periods, females gleaned less and hovered more than males. From arrival to initiation of egg laying, females foraged more in ashes and less in willows than males. Females foraged more in shrubs throughout the breeding season than males. Males frequently foraged in large willows with sparse foliage, thereby making them more conspicuous for displaying. Females preferred Manitoba.

maples, partially due to greater abundance of food, but possibly because they were less conspicuous among their leaves (Busby and Sealy 1979).

Near Kingston, more brightly coloured males provisioned less food to the young, but they held better territories and spent more time defending them such that the growth rate of nestlings and other reproductive parameters were not affected. In 1 experiment, weights were added to males that subsequently reduced their provisioning rates. Females did not compensate by delivering more food and nestlings of experimental birds had a lower growth rate. In another experiment, supplemental food was placed within 30 cm of the nest. This had no effect on the provisioning rates of males, but females with supplemental food spent more time brooding the young to age 6 days than control females but the reverse was true by age 8 days. It appears as though males and females provide for their brood independently of each other (Biermann and Sealy 1982; Bigglestone 1913; Briskie 1995; Graber et al. 1983; Hobson and Sealy 1989b; Lozano and Lemon 1995, 1996; Mousley 1926; Schrantz 1943; Studd and Robertson 1988, 1989). In Manitoba, young were fed midges, mosquitoes, geometer moth caterpillars, other larvae, other flies, and other insects. Females with 5 young provided more geometer moth caterpillars and fewer midges and mosquitoes than those with 4 young. Females feeding 4 or 5 young brought a larger proportion of midges and mosquitoes and a smaller proportion of geometer moth caterpillars to 8-day-old young than 2-day-old young, but proportions remained the same over time for broods of 3. Males with broods of 4 or 5 fed more midges and mosquitoes and fewer caterpillars to young than those with broods of 3, and the trends by age class were the same as for females. Overall, males brought more geometer moth caterpillars and females brought more midges and mosquitoes. Compared with availability, adults selected geometer moth caterpillars and avoided all other insects when feeding 2-day-old chicks. When feeding 8-day-olds, midges, mosquitoes, geometer moth caterpillars, and other larvae were selected and other flies were avoided. The main components of nestlings' diets were adult midges and mosquitoes and geometer moth caterpillars (Biermann and Sealy 1982). In Iowa, young were fed mostly insects and a few spiders. Insects provided to nestlings included flies, mayflies, moths, mosquitoes, grasshoppers, ants, beetle larvae and adults, damselflies, treehoppers, and bees. There are records of adults feeding nestlings green worms, but these probably refer to geometer moth caterpillars (Bigglestone 1913; Mousley 1926).

Busby and Sealy (1979) studied the feeding ecology of adult Yellow Warblers at Delta Marsh. Food consisted of midges, geometer moth caterpillars, mosquitoes, narrow-winged damselflies, long-horned caddisflies, other insects, and spiders. Adult midges were the dominant prey, comprising 58% and 56% of the diet over 2 years. The category of all other insects was second-most numerous in the diet, constituting about 30% of the diet. The diet of the sexes was almost identical, although females ate damselflies more frequently than males. Damselflies were the largest food items and mites were the smallest. Prey was taken in proportion to its availability, with the exception that lady beetles were avoided and mites and spiders were consistently taken less than their availability. In 1 year, midges were taken less than their availability and more than their availability in another. Geometer moth caterpillars were taken in proportion to their availability 1 year and were under-represented the other year. These apparent differences with respect to availability may have been due to sample sizes. Overall, 34 and 38 families of insects were included in the diet over 2 years and many groups were not identified to family. Other studies demonstrated that adult Yellow

Warblers eat mostly insects. They have been documented eating geometer moth caterpillars, adult moths, gypsy moth caterpillars, beetles (weevils, ground beetles, and soldier beetles), flies, aphids, grasshoppers, spiders, centipedes, locusts, true bugs, and hymenopterans. One bird in Saskatoon ate so many leafroller caterpillars that it was incapable of flight. It occasionally eats a few wild fruits such as raspberries. It does not respond numerically to infestations of forest tent caterpillars or other defoliating insects. In Maine, it avoided nesting on small islands where deciduous tree and shrub species had been defoliated by insects (Bent 1953; Goossen and Sealy 1982; Graber et al. 1983; Leighton et al. 2002; Lowther et al. 2020; McIlwraith 1894; Morse 1973).

The Yellow Warbler is a common host of the Brown-headed Cowbird. The warbler is capable of recognizing cowbird eggs by their larger size and artificial eggs with unusual colouration or patterns. Warblers may either accept or reject cowbird eggs. Cowbird eggs that are laid in nests containing 2 or more warbler eggs are usually accepted. By this point, warblers have a significant investment in their nest. Renesting at this stage may put the replacement nest out of synchronization with the rest of the population which may make it more vulnerable to predation. In addition, the peak abundance of insects may have passed by the time young hatch. Cowbirds begin laying approximately 3 weeks before Yellow Warblers and may lay eggs in incomplete nests. Most of these eggs are rejected and a high proportion of nests containing a single warbler egg and some containing 2 warbler eggs have the cowbird egg rejected. The percentage of nests near Kingston where cowbird eggs were rejected was 100% when there were 0 warbler eggs in the nest, 75% when there was 1 warbler egg, 33.3% when there were 2 warbler eggs, 50% when there were 3 warbler eggs, 20% when there were 4 warbler eggs, and 0% when there were 5 warbler eggs. The warbler's bill is too small to allow it to eject eggs and it does not pierce-eject eggs. The Yellow Warbler uses 2 strategies to reject cowbird eggs: by building another layer of the nest over them or by deserting the nest. At Delta Marsh, 66.7% of cowbird eggs were rejected by burial and 33.3% by desertion. In London, most cowbird eggs laid in empty nests were rejected through desertion. Occasionally only the cowbird egg is buried, but more frequently any warbler eggs that are present are also buried. When only the cowbird egg is buried, there is no interruption in the laying schedule of the female warbler. If a warbler egg is buried, the mean time from burial to the laying of the next warbler egg was 3.1 days near Kingston, with an additional 1-day delay for each additional egg that was buried. Kingston nests with buried cowbird eggs had a success rate of 78%, not significantly different from the 80% for unparasitized nests. The desertion rate was 41.7% of parasitized nests compared with 3.1% of unparasitized nests. During the laying but not the incubation period, the female cowbird may remove a warbler egg from the nest. In Manitoba, the number of warbler eggs in parasitized nests was 0.32 less than in unparasitized nests, suggesting that an egg was removed from about a third of nests. Near Kingston, mean clutch size of parasitized nests was 3.6 eggs compared with 4.1 eggs for unparasitized nests, suggesting that a warbler egg was removed from half of nests. At least 80% of egg removals occurred on day 1 or 2 of the warbler's laying cycle. All clutches reduced to a single cowbird egg were deserted, 31% of clutches reduced to 1 cowbird and 1 warbler egg were deserted and 0% of nests with 2 cowbird eggs were deserted. At Mer Bleue, 31% of nests were parasitized and 12% were depredated. Parasitism of replacement clutches was significantly higher in nests in new locations than in old re-lined nests in which the original clutch was buried. Of total egg losses, 41% were due to cowbird activity and 35% to predation. Of egg losses due to parasitism, 61% were

due to burial of the original clutch, 28% due to nest abandonment, and 11% due to warbler egg removal by cowbirds. At Delta Marsh, researchers artificially parasitized nests with real cowbird eggs and removed a single warbler egg from some nests. Hatching success of warblers varied significantly among treatments: 95% in control nests, 83% with 1 cowbird egg added and 1 warbler egg removed, and 73% with 1 cowbird egg added and no removal of warbler eggs. Results suggested that the ability of the warblers to incubate all eggs effectively was compromised by large clutches. Removal of warbler eggs by the female cowbird increases hatching success of cowbirds in some years and may increase the hatching rate of the remaining warbler eggs. The timing of hatching of the cowbird is a key determinant of warbler hatching success and survival. In 3 of 5 nests near Kingston where the cowbird hatched before the warblers, only a single warbler fledged. In 2 nests where the species hatched synchronously, 3 and 4 warblers fledged. In Michigan, parasitism had more significant effects on Yellow Warbler nesting success, with only 5.9% of parasitized nests fledging warblers compared with 55% of unparasitized nests. Clutch size was significantly lower in parasitized nests (2.16 compared with 3.53 eggs) and parasitized nests had smaller warbler broods (0.32 compared with 2.00 nestlings). Warblers nested at high density there and this may have facilitated parasitism. Light intensity at the nest was a good predictor of parasitism because well-concealed nests were less likely to be parasitized. Cowbirds did not fare well at this site either, with only 12.9% of eggs producing fledglings. All successful cowbird eggs were laid in synchrony with warbler eggs and were in nests containing a single cowbird egg. At Delta Marsh, 52% of parasitized nests failed, significantly more than the 37% of unparasitized nests. If nests are found by cowbirds, they may be more visible or have other attributes that make them more vulnerable to predators. Both predation and parasitism rates decrease with increasing nest height. Parasitism rates are highly variable and are related to the openness of the habitat and local abundance of the cowbird. Of 1,464 nests reported to the Ontario Nest Records Scheme (ONRS), 422 (28.8%) were parasitized. Of 256 nests reported to the ONRS south of the French River, Lake Nipissing, and Mattawa River, 110 (43.0%) were parasitized. Twenty-three percent of parasitized nests were deserted compared with 1% of unparasitized nests, significant at the 0.001 level. Clutches were buried in 50% of parasitized nests but egg burial was not recorded in 146 unparasitized nests. Considering both desertion and egg burial, cowbird eggs were rejected by the Yellow Warbler in 73% of parasitized nests. At London, 68% of nests were parasitized and 45 of 109 nests (41.2%) were parasitized north of Kingston. Parasitism rates are 0% in the Hudson Bay Lowland and probably close to 0% in most of the Boreal Forest Region. In Illinois, parasitism rates increased over time in response to continued deforestation and increases in the cowbird population. Prior to 1900, 6% of nests were parasitized compared with 40.5% after 1900. In 1 population, 87% of nests were parasitized. At Delta Marsh, the parasitism rate was 21%; in 3 Michigan study areas, 54%, 50%, and 0% of nests were parasitized; 1 of 94 nests (1.1%) was parasitized in Rhode Island, but Common Yellowthroat, Swamp Sparrow, Song Sparrow, and Red-winged Blackbird were commonly parasitized; 12 of 41 nests (29.3%) were parasitized in Iowa; 6 of 96 nests (6.25%) in New York were parasitized; 1 of 18 Minnesota nests (5.6%) was parasitized; 59 of 393 British Columbia nests (15.0%) were parasitized; and 29% of British Columbia nests were parasitized at 1 study area. In another British Columbia study area, 18% of nests were parasitized and females rejected 24% of these, mainly by deserting the nest. Parasitism reduced warbler clutch size by 0.8 egg and 1.3 fewer warblers fledged from parasitized nests. There was some evidence that parasitism reduced the productivity of older females less than it did for yearlings (Briskie et al. 1990;

Burgham and Picman 1989; Campbell et al. 2001; Clark and Robertson 1981; DellaSala 1985; Goossen and Sealy 1982; Graber et al. 1983; Graham 1988; Guigueno and Sealy 2010; Guigueno et al. 2014; Hahn and Hatfield 1995; Hanski et al. 1996; Hobson and Sealy 1989b; McLaren and Sealy 2000; McMaster and Sealy 1997; Mitra 1999; Peck and James 1998a; Quinlan and Green 2012; Rock et al. 2013; Rothstein 1975; Schrantz 1943; Scott and Lemon 1996; Sealy 1992; Sealy et al. 1987).

Habitat for the Yellow Warbler is probably declining south of the Canadian Shield. It formerly nested in residential yards and orchards, but these are now too manicured to provide suitable habitat. Many hedgerows between fields and along roads and ditches have either been removed or consist of narrow strips surrounded by unsuitable habitat. There are also fewer pastures than previously and most that persist are heavily grazed and support no shrubs. The shrubby fields it prefers are often considered suitable for development or a return to agricultural land and, if left undisturbed, develop into forest patches that are unsuitable nesting habitat. In Algonquin Park, forest maturation and succession in open areas have reduced the amount of suitable habitat (Tozer 2012).

In many areas, grazing by ungulates, particularly moose and elk, has affected the density and height of willows. In most of these sites, densities of the Yellow Warbler were significantly lower in ungrazed areas. Where cattle grazing has decreased or terminated, Yellow Warbler populations increased significantly (Anderson 2007; Celada 2004; Earnst et al. 2012; Knopf and Sedgwick 1992; Olechnowski and Debinski 2008; Taylor and Littlefield 1986). In southern Ontario, high densities of white-tailed deer may affect shrub density and consequently Yellow Warbler abundance. On the tundra near Churchill, heavy grazing by geese did not affect the abundance of the willow-nesting guild, which includes the Yellow Warbler (Sammler et al. 2008).

In northern populations, cold, windy, or wet weather can be a significant limiting factor. At North Point, the greatest cause of nest failure was exposure of eggs and nestlings due to severe northeast storms blowing in from James Bay (Rimmer 1988). At Churchill during a late spring, clutch initiation did not occur until 30 days after males arrived and most birds did not attempt to breed. Only 4 nesting attempts were observed that year, and 2 were abandoned before clutch initiation. In some years with late springs, birds may forego breeding altogether (Briskie 1995).

Leighton et al. (2002) concluded that domestic cats took a heavy toll of young in Saskatoon. This is probably true in the fragmented landscape of Ontario south of the Shield.

Presence of certain other warbler species may potentially inhibit usage by the Yellow Warbler. The Yellow Warbler uses earlier successional habitat than the Chestnut-sided Warbler. When the 2 species are present, there is frequently a rough zonation between the 2 species around edges of abandoned beaver ponds, forest edges, and other areas where succession is well underway. The songs of the 2 species are similar and they countersing at each other when they have adjacent territories. When the Chestnut-sided Warbler is absent, the Yellow Warbler may occupy more mature deciduous growth, although this is not preferred habitat (Morse 1989). In Maine, islands smaller than 1 ha supported either the Yellow Warbler or the American Redstart, but not both species. It is uncertain if this was because of interspecific competition or because the habitat on individual islands was much more suitable for one of the species (Morse 1973). In Illinois, upland shrubby areas that support Prairie Warblers support few, if any, Yellow Warblers (Graber et al. 1983).

In British Columbia, van Oort et al. (2015) examined the effects of fluctuating water levels at a reservoir. Typical of many Ontario reservoirs, water was stored in the spring and released later in the year. Yellow Warblers nested in shrubs around the margin of the reservoir at an average height of 2.2 m. Twenty-eight percent of warbler nests failed due to submergence. At that reservoir, peak water levels occurred in early July. Flooding of nests in riparian habitat at Ontario reservoirs is less likely to occur because reservoirs are typically full by the time it initiates nesting. Storms that occur after drawdown has been initiated have the potential to flood nests.

In New Jersey and Pennsylvania over a 15-year period, hemlock declined from representing 56% of the total basal area to 46% due to the hemlock woolly adelgid; the amount of deciduous understorey increased. The Yellow Warbler responded favourably to hemlock decline and increased, probably due to the increased prevalence of a deciduous understorey (Toenies et al. 2018).

Drake et al. (2013) studied the effects of winter habitat on breeding British Columbia Yellow Warblers. Winter habitat had a carry-over effect only on the productivity of yearling females. Birds originating in mesic winter habitat within a dry to seasonal climate region produced 0.8 more fledglings than those from wetter climate regions.

Chronic noise does not appear to affect the Yellow Warbler adversely during the breeding season. In Alberta, it was equally abundant near noisy compressor stations and quiet well pads. Near roads in Edmonton, it was not affected by road noise or any other variable tested (Bayne et al. 2008; Proppe et al. 2013).

In Alberta, the Yellow Warbler was equally abundant along seismic lines and pipelines as it was in adjacent forest interior, but was significantly more abundant near well pads than in adjacent forest (Bayne et al. 2016).

Price (2004) concluded that the Yellow Warbler might decline as a breeding species in southern Ontario if the average summer temperature increased by 2°C.

Status

The Yellow Warbler has always been common in Ontario and undoubtedly benefitted from forest clearing by European settlers. Baillie and Harrington (1937) stated that it nested from the southern boundaries of the province north to Hudson Bay and west to Lake of the Woods: essentially the entire province. They concluded that it was much more common in the south. The first atlas confirmed that its range included the entire province. It was found in almost every square south of the Canadian Shield but was absent from many squares in the Algonquin Highlands where there is almost continuous tree cover. It was most abundant in the agricultural south (Carpentier in Cadman et al. 1987). James (1991) considered the Yellow Warbler locally common throughout the province. Wilson and McRae (1993) stated that it was the most common and well-distributed warbler along the Hudson and James bay coasts.

The second atlas revealed no changes in the distribution of the Yellow Warbler, and it was found in every square south of the Shield. There was no difference in its probability of observation province-wide or in most regions, but a significant increase was documented in the Hudson Bay Lowland. The reasons for this increase, if it was real, were uncertain. It was most abundant south of the Shield and along the James Bay coast and portions of the Hudson Bay coast. In the south, it was

most abundant in a broad band south of the Shield from Lake Simcoe to the eastern boundary of the province, and in Niagara Region in a broad band westward along Lake Erie to Rondeau. Lowest densities occurred in heavily forested portions of the Shield, both in the Great Lakes–St. Lawrence and Boreal forest regions (McLaren in Cadman et al. 2007).

Breeding Bird Survey (BBS) data suggest that Yellow Warbler populations are stable or increasing. The data showed no significant trends for Canada and the United States for 1966-96, but there was a significant increase of 2.5% per year in southern Ontario (Lowther et al. 2020). Morse (1989) concluded that it appears to have increased throughout its range, perhaps due to the presence of hedgerows and suburban habitats. Results of the Marsh Monitoring Program indicate that the Yellow Warbler increased significantly in southern Ontario at a rate of 1.6% per year 1995-2004 (Timmermans et al. 2006). Gauthier (in Gauthier and Aubry 1996) concluded that it had probably increased over the past 20 years in the southern portion of Quebec, where it is most abundant. This was attributed to a decrease in cowbird populations and farmland abandonment. BBS data indicate that it decreased at annual rates of 0.296% in Canada and 1.03% in Ontario 1970-2021. Trends 2011-21 were annual decreases of 1.44% in Canada and 2.52% in Ontario. All results were highly reliable except that the long-term trend for Canada was of medium reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

In Iowa, adults fed fledglings in the immediate vicinity of the nest for approximately 3 days. They became more dispersed after that, but could still be found in the general vicinity for 7-10 days (Schrantz 1943). On the James Bay coast north of Moosonee, both sexes cared for the brood, either by splitting the brood or by keeping it together and sharing duties. One male tended all 4 fledglings, frequently flying between his territory and areas as far as 100 m from the fledglings. At North Point, fledglings reached independence 2-3 weeks after leaving the nest (Rimmer 1988).

North of Moosonee, almost all adults initiated moult during the period of fledgling care. One female started her moult immediately after loss of a replacement brood. The moult occurred between early July and early September and was initiated from early July to early August. Moulting takes 35-42 days. Males initiate the moult before females and second-year birds are the first to moult. Moulting birds were incapable of sustained flight but those nearing completion of the moult were probably capable of flight (Rimmer 1988). In Alberta, moulting began while caring for fledglings. The moult was completed away from the breeding area (Flockhart 2010).

After the young reached independence at North Point, 7 males remained on or within 100 m of their territories and 4 migrated directly from their territories. Two males were on their territories late in the moult cycle, but may have temporarily moved off their territories following nesting. Two males were found considerable distances from their territories during the moult. Postbreeding females exhibited very little site attachment. Most dispersed from the study area while tending fledglings or after terminating parental duties. There was no evidence of pair mates associating after breeding. In addition to the departure of breeding females, there was a considerable influx of unbanded females in early and middle phases of the moult. These may have bred further north and some of these remained through all or most of their moult. It seemed unlikely that females initiated migration before or during the peak moult period (Rimmer 1988).

In British Columbia, Hepp et al. (2018) studied the effects of territory inundation by a reservoir on fledgling survival rates for 21 days following fledging. Water levels generally began to rise after Yellow Warblers had initiated nesting. Fledglings in areas that were flooded had significantly lower survival rates than those in territories that were not inundated. Reservoirs with fluctuating water levels have the potential to lower survival rates of fledglings.

MIGRATION

The Yellow Warbler is predominantly a nocturnal migrant but it may move diurnally to a greater extent than other warblers, particularly in autumn (Lowther et al. 2020). One juvenile travelled from Long Point to Georgia in 16 days, averaging 72 km per day. A second-year bird banded near Moosonee was recovered 3 months later in Milwaukee, 1,086 km from the banding location (Brewer et al. 2018).

Males arrive on the breeding grounds before females and adults arrive before yearlings. There may be a trend for the interval between arrivals of the sexes to be less in more northern areas, but results are variable. It is likely that the interval varies annually at each given location depending upon weather conditions. Males are likely to arrive earlier during favourable springs with a resultant longer interval between arrival dates of the sexes. At Prince Edward Point, the mean date of arrival was 1.7 days earlier for males than females. Although this was the shortest interval between the sexes of all the species that Francis and Cooke (1986) studied, the differences were still significant. At Churchill, females were first seen on the same day as males or within 2 days (Briskie 1995). At Lesser Slave Lake in Alberta, males arrived about 3 days earlier than females (Flockhart 2010). In Rhode Island, first arrival dates for males were 18-29 April compared with 25 April to 2 May for females (Mitra 1999). In Massachusetts, females arrived as early as males in 1 of 5 years. Elsewhere, intervals between the arrival of males and females has been reported as 10 days in Michigan, 9-10 days at James Bay, and 4-5 days in central Alberta (Lowther et al. 2020). In British Columbia, older males established territories an average of 8.1 days before yearling males. Older females initiated nests an average of 5.3 days before yearling females (Drake et al. 2013).

In southern Ontario, the Yellow Warbler arrives in late April or the first week of May. The main influx is during a 3-week period in May. In the southern Shield, average arrival is mid-May and the earliest records are in the first week of May. At North Point, birds arrive in late May with the main influx in the first 10 days of June. Birds at northern latitudes arrive earlier in relation to spring phenology than more southern birds. Southern birds arrive during or shortly before leaf-out but northern birds arrive to snow-covered ground long before leaves are out (Black and Roy 2010; Briskie 1995; Curry 2006; LaForest 1993; Keast 1990; Lancaster et al. 2004; Lowther et al. 2020; Mills 1981, 2005a; Tozer 2012; Weir 2008).

The Yellow Warbler is one of the earlier passerines to initiate autumn migration. Migration may begin in early to mid-July as soon as the juveniles are independent. Migrants have been observed in Florida as early as 20 July and in South Carolina on 4 July. Southern populations appear to leave earlier than northern birds, probably due to earlier completion of breeding and the prebasic moult. In Ontario, juveniles move south before females but at more southern latitudes there may be no difference in the timing of migration by the age classes. At Lesser Slave Lake in Alberta, there was no differential timing in migration of the sexes. At North Point, migration of juveniles peaked during

mid-August and adult numbers peaked in late August and early September. Latest dates were mid-September for juveniles and late September for adults. In the southern Shield, most autumn migrants are seen in August. Some probably leave in late July, most have left by early September, and the latest records are in late September. In the south, autumn migrants are moving through by mid-July with heavy flights later that month. Peak numbers occur in the first half of August and most are gone by the end of August. Some remain into the first or second week of September with rare records into November and December. At Prince Edward Point, local breeders leave their territories in the first 2 weeks of July and most have passed through by the end of August. Juveniles are present at the banding station from mid-July until the end of August with the peak near the end of July and early August. Adults are much less abundant and are present from mid-July to early August. The midpoint of autumn migration at Long Point is 7 August (Bent 1953; Black and Roy 2010; Campbell et al. 2001; Chapman 1907; Curry 2006; Flockhart 2010; Keast 1980, 1990; LaForest 1993; Lancaster et al. 2004; Lozano and Lemon 1999; Lowther et al. 2020; Mills 1981, 2005a; Rimmer 1988; Tozer 2012; Weir 2008).

Habitat used by the Yellow Warbler during migration is very similar to its breeding habitat. It occurs predominantly in deciduous shrub areas and woodland edges. It continues to favour areas of willow shrubs in wetlands and riparian areas. To a lesser extent, it may occur in second-growth forests that are either open or have considerable edge habitat. It frequents suburban and rural residential areas more often during migration than during the breeding season. During spring migration in North Carolina, the numbers of birds seen per hour were 3.54 in wet thickets, 0.07 in floodplain thickets, and 0 in pine forests, pine-hardwood forests, oak-hickory forests, dry thickets, and beech forests. During spring migration in Pennsylvania, detections per 100-m transect were 0.002 in forest and 0.370 in shrubs; captures per 1,000 net-hours were 0 in forest and 6.0 in shrubs. In Ohio during spring migration, it was equally abundant in mature upland and mature riparian forests. The Yellow Warbler was the least abundant of species for which data were presented, indicating that these habitats are marginal. In Minnesota and Michigan, it showed a nonsignificant affinity for floodplain forests rather than upland forests, but numbers in both forest types were low (Campbell et al. 2001; Graber et al. 1983; Kelly et al. 2000; Kirsch et al. 2013; LaForest 1993; Lowther et al. 2020; Parnell 1969; Rodewald and Matthews 2005; Smith and Hatch 2008; Tozer 2012).

During autumn migration at Prince Edward Point, the Yellow Warbler fed mostly at middle heights. Two percent of foraging occurred in the air, 53% on outer leaves, 7% on twigs and inner leaves, 2% on outer leaves, 27% on sapling foliage, 4% on sapling branches, and 5% in low shrubs. Foraging was not observed on inner branches, trunks, or the ground. Of 17 grounded at Point Pelee 28-30 April, 20% of foraging occurred on sapling twigs, 5% on sapling trunks, and 75% in low shrubs; aerial foraging occurred but was rare. No foraging was observed on outer foliage, bare twigs, branches, trunks, the ground, or in marshes. Foraging heights were 75% at 0.6-1.8 m, 15% at 3 m, 10% at 5 m, and 0% on the ground or above 5 m (Keast 1980). During spring migration in North Carolina, 10.5% of foraging occurred in the canopy, 77.3% in low trees, 13.1% in shrubs, and 0% on the ground. In the canopy, 7.9% of foraging occurred at the top of the crown, 2.6% in the inner crown, and 0% in the lower crown and on the bole. In low trees, 59.1% of foraging occurred in the inner crown, 18.2% in the lower crown, and 0% at the top of the crown and on the bole. In shrubs, 2.6% of foraging occurred at the top of the crown, 10.5% in the inner crown, and 0% in the lower

crown, dense thickets, brush piles, or grasses (Parnell 1969). During unusually inclement spring weather in Manitoba, Yellow Warblers were observed foraging on the ice of Lake Manitoba. Beetles, midges, other flies, and spiders were on the ice at that time (McNicholl and Goossen 1980). During autumn migration in New York, Yellow Warblers sallied for insects at night from the top of a conifer illuminated by lights from a football field (Lebbin et al. 2007).

During migration, the Yellow Warbler occasionally collides with television towers and other tall structures. Relatively few are killed, especially when the abundance of the species is taken into account. Ninety were killed at the Lennox generating station chimneys over a decade (Graber et al. 1983; Leighton et al. 2002; Lowther et al. 2020; Raveling and Warner 1978; Weir 2008).

DeGroote and Rodewald (2010) examined Ohio spring migrants for blood parasites and 12.7% of warblers were infected. They concluded that this was unlikely to have a negative effect on migration timing or energetic condition during spring migration.

During autumn migration in Idaho, McClure et al. (2013b) constructed a phantom road by broadcasting road traffic noise within a woodland. The Yellow Warbler was negatively affected by noise with an average of 4.5 birds present under quiet conditions and 0-0.25 at noise levels of 55-57 db(A). The results of this study contrast with those undertaken during the breeding season that found noise to have no effects on Yellow Warblers.

The effects that climate change have had and may have in future on migration of the Yellow Warbler are uncertain. Mills (2005a) examined spring arrival and autumn departure dates at Long Point 1976-2000. In spring, it could be considered as arriving earlier when the first arrival date is considered. Vanguard individuals may be responding disproportionately to climate change. When spring quartiles of the migration period were compared, there was no difference in arrival times over the study period. Instead of leaving later in autumn as would be predicted, warblers left earlier by 3.7 days per decade. It is possible that birds are completing breeding and their moult earlier than they did historically. Near Boston, it arrived significantly earlier 1988-2007 than in 1851-1973. All species of birds arrived in that area approximately 0.77 days earlier per 1°C increase in temperature (Ellwood et al. 2010). Boulet et al. (2006) identified other potential effects of climate change. It is anticipated that the frequency and severity of tropical storms and hurricanes will increase in the Gulf of Mexico. When weather conditions are unfavourable (strong rain, adverse wind directions, or storms), some birds barely make it to the first available land or oil rig and many probably die en route or at stopover sites.

James (1991) considered the Yellow Warbler a common migrant in the province. Hussell et al. (1992) reported a nonsignificant increase of migrant Yellow Warblers of 1.2% at Long Point 1961-88. Trends by periods were: 1961-70, –3.6%; 1970-79, +9.1%; and 1979-88, –6.3%. At the Port Weller piers in Niagara Region, counts of the Yellow Warbler 1993-2017 indicated a significant increase in numbers (Black 2017).

Chestnut-sided Warbler

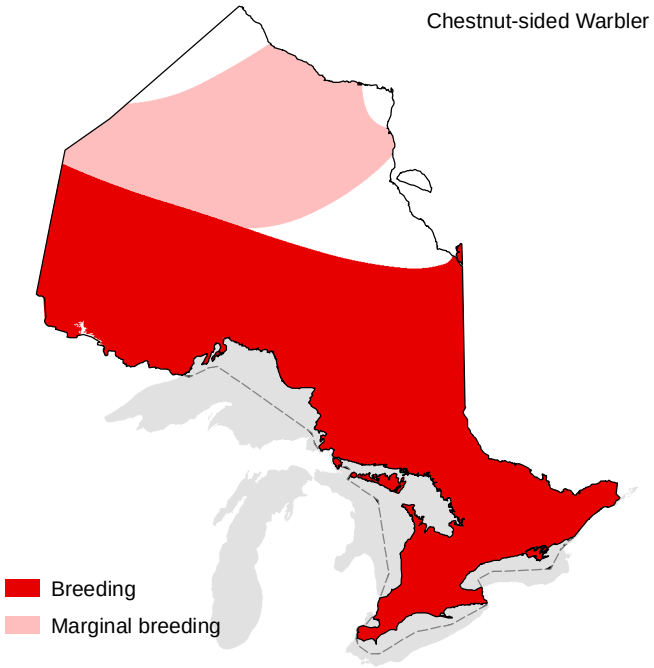
Setophaga pensylvanica

BREEDING SEASON

Habitat Requirements

Ontario Chestnut-sided Warbler nests were most often in the understorey and at edges of deciduous and mixed woods, occasionally in coniferous woods; in semi-open and logged woodlands; in overgrown fields; in brushy woodland borders; in swampy areas and beaver meadows; along shrubby hydro corridors; and in sphagnum bogs. Nests were commonly near roads and water, indicating its preferences for open and edge areas (Peck and James 1987).

In the Boreal Forest Region, the Chestnut-sided Warbler was associated with younger, more open deciduous forests that were highly disturbed. It was also associated with high levels of edge between young and old forests (Rempel 2007; Rempel et al. 2007). Welsh (1993) considered the Chestnut-sided Warbler an early successional species. It occurred only in stands 21 years old and younger. Near Pickle Lake, McLaren and McLaren (1981) observed it in low density in deciduous scrub and mixed forest. Also near Pickle Lake, James (1980) observed it in scrub vegetation near towns and in the Lysander Lake area. Near Lake Nipigon, it nested in low densities in trembling



aspen and spruce–balsam fir stands (Sanders 1970). At Quetico Park, it was most abundant in stands 1-23 years old, uncommon in stands 112-176 years old, and absent in stands 67-73 and 367-370 years old (Apfelbaum and Haney 1985). Near Hearst, it nested in upland and lower-slope clear-cuts in mixed forests 3-24 years old and in lowland coniferous clear-cuts 5-9 years old. It did not occur in unharvested upland mixed or lowland coniferous stands. It was often the dominant species in upland clear-cuts 3-11 years old (Welsh and Fillman 1980). Near Manitouwadge, it was common in stands 1-21 years old, uncommon in 24-36-year-old stands, and rare in stands 60-223 years old (Venier et al. 2009). On the northeast shore of Lake Superior, it inhabited older thickets and small second growth (Baillie and Hope 1943). In the Clay Belt, it was most abundant in stands dominated by balsam poplar and trembling aspen followed by those dominated by white spruce–white birch. It was associated with wet, nutrient-rich sites (Welsh and Lougheed 1996).

In the Great Lakes–St. Lawrence Forest Region in the Canadian Shield, the Chestnut-sided Warbler occurred in both mature and old-growth white pine stands where it was more common in mature stands (Kirk et al. 2012). In jack pine stands near Gogama, it was associated with deciduous shrubs in mixed regeneration. It first appeared when growth was approximately 3 m tall, became abundant in growth 6-7 m tall with numerous small shrubs, and persisted in diminishing numbers until tree crowns formed a canopy. Few remained once trees reached a height of 10 m in these dense pine plantations (James and Peck 1995a). At Pimisi Bay, a nest was at the edge of an opening in the woods in an area that became overgrown with bracken fern later in the season. The opening was surrounded by mature second growth and supported deciduous saplings and beaked hazel (Lawrence 1948). In Algonquin Park, it was most abundant in plots at edges of forests. In one of these plots, it was the second-most abundant species. It was also common in poplar–white birch stands where it was fourth in abundance. It was common in balsam fir–spruce stands and these types of stands mixed with hardwoods, and uncommon in black spruce–white cedar stands. It was not recorded in bogs, immature white pine stands, pure hardwoods, or hemlock stands. In poplar-birch stands, it ranged 1.8-8.8 m from the ground which corresponded to the middle of the shrub layer to 2 m below the top of the canopy. In balsam fir–spruce stands, it occupied the central canopy. Martin (1960) considered it characteristic of pioneer deciduous forest. MacLulich (1938) considered it fairly common in Algonquin Park in logged forests and thickets; it appeared to favour white birch trees. In white pine stands in Algonquin Park, it was significantly less abundant in stands with no recent history of harvesting than it was in more recently cut stands. It occurred in 26.7-28.6% of

stands with no recent cutting, 72.7-90.0% of stands cut 10-16 years previously, and 83.3% of stands cut 2-9 years previously. Density was highest in the most recent cuts (Kingsley and Nol 1999). In Parry Sound District, the Chestnut-sided Warbler was absent in pure jack pine stands but occurred in open jack pine stands mixed with a variety of deciduous species (James 1979a). It nested in all sorts of semi-open areas in Parry Sound and Muskoka districts, including open woods, margins of ponds and streams, hydro corridors, and roadsides (Mills 1981).

In Durham Region in the off-Shield portion of the Great Lakes–St. Lawrence Forest Region, Speirs and Orenstein (1975) reported the Chestnut-sided Warbler in a pure pine plantation with no understorey. Included in their plot was a small relict of sugar maple–oak forest with an understorey of hophornbeam. Given its requirement for shrubs, it is most likely that it nested in the deciduous forest.

In the Carolinian Forest Region, the Chestnut-sided Warbler benefitted from forest thinning in Elgin County. It nests there in dense tangles of raspberry shrubs that grow up on logging trails throughout woodlots (Lancaster et al. 2004). McIlwraith (1894) commented that it was very partial to raspberry patches in the Hamilton area. In southern Ontario, its abundance was positively correlated with the amount of forest cover within 2 km and negatively correlated with the amount of forest cover more than 100 m from edge, woodlot size, and the amount of regional forest cover. These relationships were not significant (Austen et al. 2001).

Throughout its range, the Chestnut-sided Warbler is associated with early successional deciduous growth. This may include shrubby meadows and pastures, regenerating clear-cuts and burns, utility rights-of-way, forest edges, and open-canopied forests of almost any type that have deciduous undergrowth. It nests in both wet and dry areas, but has a tendency to inhabit drier areas than the Yellow Warbler. It responds favourably to small openings in mature forests such as anthropogenic clearings, those resulting from windthrow, beaver ponds, hydro or pipeline corridors, roads, and strip-cuts as narrow as 20 m. It typically avoids the immediately adjacent mature forest along rights-of-way and strip-cuts. Where there are only small gaps, it may forage in forested habitat but nests within the gaps. Less frequently used habitats include coniferous plantations with a deciduous understorey, black spruce stands, and bogs and fens. In young clear-cuts and shrubby rights-of-way through forested habitat, the Chestnut-sided Warbler is often one of the most common species. In forested areas, it shows a preference for areas dominated by white birch or poplars. In forested landscapes, it may be a fugitive species that must be constantly moving in response to the shifting mosaic of open habitat patches embedded within extensive woodlands (Back 1979; Beals 1960; Bent 1953; Bielefeldt and Rosenfield 1994; Brooks 1940, 1947b; Byers et al. 2004, 2020; Chapman 1907; Dawson 1979; DeGraaf et al. 1998; Dessecker and Yahner 1987; Erskine 1977; Faanes and Andrew 1983; Falardeau et al. 1999; Ferris 1979; Freedman and Johnson 1999; Freedman et al. 1981; Graber et al. 1983; Hanski et al. 1996; Hobson and Bayne 2000; Kendeigh 1945; King and DeGraaf 2004; Kirk et al. 1996; Klaus et al. 2010; Lemieux and Choinière in Gauthier and Aubry 1996; Lent and Capen 1995; Litwin and Smith 1992; Moorman et al. 2012; Morgan and Freedman 1986; Mossman and Hoffman 1989; Mossman et al. 1991; Mousley 1916a; Niemi and Hanowski 1984b; Noon et al. 1979; Pitts 1990; Schill and Yahner 2009; Siebenheller and Siebenheller

1990; Sodhi and Paszkowski 1995; Streby et al. 2011b; Suthers 1988; Taylor and Taylor 1979; Titterington et al. 1979; Yahner 1993, 2003; Yahner et al. 2002).

Chestnut-sided Warbler abundance may be related to the amount of forest cover in the landscape, but results are contradictory. In southern Ontario, Austen et al. (2001) found that it had a tendency to be more common where there were greater amounts of forest within 2 km, although this relationship was not significant. Byers et al. (2020) noted that it was largely absent in intensive agricultural areas of Ontario and Wisconsin. This may be a result of the paucity of shrublands in these areas rather than an influence related to the amount of forest cover. In Saskatchewan, its abundance was significantly correlated with the amount of forest cover within 5 km, although it occurred in both forested and fragmented landscapes (Hobson and Bayne 2000). In the mid-Atlantic states, it was positively correlated with the amount of forest within 2 km (Robbins et al. 1989). More forest equates to more forest edge which may potentially provide suitable habitat. Near Quebec City, the Chestnut-sided Warbler was the species least likely to be found in forest habitat of all species studied by Bourque and Desrochers (2006). This area is heavily forested, usually with 50-60% or more forest cover; consequently, much of this area was unsuitable habitat. It is likely that increasing forest cover is beneficial in fragmented landscapes, particularly those that are agricultural or urban in nature, but detrimental in areas that are heavily forested. In North Dakota, it was positively correlated with elevation at the 200-m scale. This indicated that it was capable of occupying high-elevation landscapes that have experienced limited disturbances, where there are only small gaps in forest cover (Gilbert and Ferguson 2019).

Numerous studies examined the age or tree-size classes of forests that the Chestnut-sided Warbler inhabits. These almost unanimously concluded that it prefers young stands and those dominated by smaller trees. It occurs sparingly in more mature stands where it is associated with deciduous shrubs and saplings in the understorey. In Maine spruce–balsam fir stands, it was absent in both mature forests and recent clear-cuts characterized by much bare soil and dense slash. It reached its greatest abundance in clear-cuts with dense coverage by raspberry bushes and regenerating hardwoods less than 2 m tall. It was one of the dominant species in this stage of succession. It continued to be common in the next stage of succession when hardwood regeneration was taller than 2 m and there was a well developed but slower growing coniferous stratum. It declined considerably once hardwood regeneration was taller than 4.5 m with trees 10-15 cm diameter at breast height (DBH; Titterington et al. 1979). In Vermont, it was associated with low successional age, few conifers, more snags, moderate amounts of poplar and white pine, more red maple, and limited amounts of hophornbeam, red oak, beech, and sugar maple (Lent and Capen 1995). In Pennsylvania, it occurred in 9.1% of old-growth forests, 40.7% of forests statewide, and 68.6% of forests on the Appalachian Plateau. Its abundance was significantly negatively correlated with old-growth forest (Haney 1999). In northern mesic forests in Wisconsin, it was associated with young and often dense forests and sapling deciduous forests (Hoffman 1989a). In Alberta and Saskatchewan, it was situated at the younger end of the forest-age scale (Kirk et al. 1996). In northeastern mixed forests, Temple et al. (1979) considered it a mid-seral stage species associated with increasing density of yellow birch, sugar maple, and pine. In New Jersey, the Chestnut-sided Warbler nested in old fields that were 10 and 20 years old, but not in a 40-year-old field. The older field was too overgrown with dense shrubs and trees to provide suitable habitat (Suthers 1988). In

New Hampshire and Maine, it demonstrated a significant preference for tree-size classes within forests. It was most abundant in the sapling stage (trees 2-12.5 cm DBH), approximately equally abundant in pole-sized (12.5-22.5 cm DBH) and sawtimber-sized trees (larger than 22.5 cm DBH), and least abundant in trees larger than 60 cm DBH. It was 1 of 4 species exhibiting the strongest association with sapling-sized stands (DeGraaf et al. 1998). In Wisconsin, it tended to increase where the trees were small or the total basal area (BA) was low (Beals 1960). In northern hardwoods in Nova Scotia, the Chestnut-sided Warbler is the most characteristic and abundant species of young stands (Morgan and Freedman 1986).

Microhabitat preferences of the Chestnut-sided Warbler were described in several studies. Its average habitat characteristics in Minnesota were 92.8% ground cover, 66.9% shrub cover, 46.3% canopy cover, 13.1 m canopy height, 9.1% coniferous cover, 3.4 tree species per 0.04-ha circle, 7.1 trees 7.5-15 cm DBH, 6.7 trees 15.1-23 cm DBH, 3.2 trees 23.1-30 cm DBH, 1.1 tree 30.1-38 cm DBH, 0.3 tree 38.1-53 cm DBH, 0.4 tree 53.1-68 cm DBH, and 0.2 tree larger than 68 cm DBH. Its habitat was most similar to that of the Golden-winged and Mourning warblers and also the Common Yellowthroat and Yellow Warbler. These 5 species prefer open habitats with dense ground cover and moderate shrub cover. The habitat of this guild ranged from open marshland with few or no trees (Common Yellowthroat and Yellow Warbler) to areas of dense aspen coppice (Mourning Warbler) and deciduous edge vegetation (Chestnut-sided and Golden-winged warblers). The Chestnut-sided Warbler was associated with more ground cover and more medium-sized trees and was found in deciduous second growth (Collins et al. 1982). In Maine, it was significantly associated with raspberry bushes and the number of deciduous woody stems smaller than 10 cm DBH, 2.1-4.5 m tall (Titterington et al. 1979). In Vermont, mean habitat characteristics were 84.0% green ground cover, 7.9% ground slash, 35.8% canopy closure, 9.5 m canopy height, 6.1 m canopy depth, 3.6 m^2 per ha BA deciduous plants, 0.5 m^2 per ha BA conifers, mean DBH 5.5 cm for deciduous species, and 4.6 cm DBH for conifers. It was associated with dense understorey, open habitats, and deciduous cover (Thompson and Capen 1988). In the Prairie Provinces, the Chestnut-sided Warbler was on the midpoint of the scales for moisture and nutrient richness (Kirk et al. 1996). In the mid-Atlantic states, its abundance was negatively correlated with BA and snags larger than 3 cm DBH (Robbins et al. 1989). In North Carolina, its abundance was significantly negatively correlated with canopy coverage (Lumpkin and Pearson 2012). In Minnesota clear-cuts, it was positively correlated with increasing foliage complexity: BA of dead trees, shrub density, shrub BA, and shrub height (Niemi and Hanowski 1984a). In New Hampshire and Maine, it was significantly correlated with the number of coniferous and deciduous trees larger than 10 cm DBH and the number of woody stems per ha. It was negatively correlated with foliage volume of both deciduous and coniferous trees larger than 10 cm DBH and the foliage volume of deciduous trees smaller than 2 cm DBH (DeGraaf et al. 1998).

Collins (1983a) compared the habitat characteristics of the Chestnut-sided Warbler in Minnesota and Maine. The percent ground cover and number of trees 7.5-15 cm DBH in territories differed significantly between the 2 states. In Minnesota, it was associated with moderate ground cover and intermediate numbers of medium-sized deciduous trees. In Maine, it inhabited areas with slightly more ground cover and more medium-sized trees.

Territories in shrubby areas typically have some taller shrubs, saplings, or trees that function as song perches. Collins (1981) compared the vegetation at nest sites and song perches and found that they were significantly different. Perch sites had a greater number of trees than nest sites, which increased the values for percent canopy cover, average tree height, and percent conifers.

Freemark and Collins (1992) considered the Chestnut-sided Warbler an area-sensitive species but noted that various studies classified it differently. In addition, many studies were examining forested habitat when determining its area sensitivity but few studies examined area sensitivity in the shrubby habitats that it prefers. In forested habitat, Byers et al. (2020) concluded that patch size did not affect any breeding parameters. It was not area sensitive in Saskatchewan (Hobson and Bayne 2000). In Wisconsin, Mossman and Hoffman (1989) stated that it preferred large tracts of upland forests but provided no additional information. In Rhode Island, it was not observed in swamps smaller than 5 ha and occurred in low density in swamps 6-20 ha. Larger swamps had longer and often more irregular perimeters with a greater diversity of upland habitats along the edge. All edge species increased with increasing swamp edge (Golet et al. 2001), and this was likely also true for upland forests. King and DeGraaf (2004) examined Chestnut-sided Warbler usage of clear-cut patches 0.15-0.69 ha (average 0.39 ha) imbedded in extensive upland deciduous forests in New Hampshire. Every patch was occupied by 1-3 territorial males indicating that it was not exhibiting area sensitivity. Density was highest in small patches and decreased with increasing patch size. Despite the fact that it was more abundant in smaller patches, larger patches appeared to be of higher quality. Larger patches were occupied first, nests were initiated earlier in large patches, and large patches were occupied by birds with larger and brighter patches of colour in their plumage. Younger birds may be relegated to inferior habitat (smaller patches) where they are confined to smaller territories. Birds in this area appeared to nest away from edges of habitat patches, although the authors acknowledged that patches might be entirely edge. There was no relationship between patch size and shape and rate of predation. Roberts and King (2019) conducted similar studies in Massachusetts in forest canopy openings created by group-selection harvesting. The chestnut-coloured flank appeared to function as a status badge signalling older and larger birds. Probability of occurrence did not reach 90% until patch size was 0.48 ha in 1 year and 0.72 ha in another, suggesting that larger openings conferred advantages with respect to nesting success. Birds in larger openings nested earlier, giving them time to renest in the event of a failure. Birds with larger badges were negatively correlated with the presence of forbs, ferns, and grasses, confirming that these represent inferior habitat. Larger-patched birds were positively correlated with irregularly shaped openings.

The habitat requirements of Chestnut-sided and Yellow warblers are similar and the 2 species occasionally nest in the same area. The 2 species countersing when they have adjoining territories. The Chestnut-sided Warbler prefers drier areas with slightly more advanced succession than the Yellow Warbler. The Chestnut-sided Warbler is much less likely to be found in the willow and alder thickets that the Yellow Warbler prefers. The Yellow Warbler seldom occurs in sapling-stage forests that are suitable habitat for the Chestnut-sided Warbler. In successional gradients around beaver ponds, the Yellow Warbler nests in the inner edge that is wetter and supports few trees. The Chestnut-sided Warbler inhabits the outer drier band with more deciduous shrubs and saplings. The

Yellow Warbler may nest in suburban areas but the Chestnut-sided Warbler avoids these areas (Byers et al. 2020; Chapman 1907; Lemieux and Choinière in Gauthier and Aubry 1996; Morse 1989).

Ontario nests were elevated over ground or occasionally over water (1.3% of nests). They were most often in shrubs or small trees but sometimes in ferns and herbaceous plants. Deciduous trees and shrubs (18 species, 91.4% of nests) were greatly preferred to conifers (5 species, 8.6% of nests). The most commonly selected species were hazel, raspberries, maples, and alder. Most nests were in crotches of trees or shrubs but some were at the junction of 2 adjacent plants. Occasionally nests were saddled on 1 or 2 branches. Nest positions varied from the outer periphery of a shrub to against the main trunk of a small tree. Nests were 0.2-1.8 m from the ground, with most 0.5-0.9 m up (Peck and James 1987). Lawrence (1948) reported a nest near Pimisi Bay 45 cm from the ground in a raspberry bush. In Algonquin Park, nests are typically in deciduous shrubs, particularly beaked hazel, 1-2 m from the ground (Tozer 2012). A nest in Elgin County was 1.3 m up in a red elderberry in a woodlot that had been logged 5 years previously (Lancaster et al. 2004).

In Pennsylvania, nest sites had a higher woody stem density than randomly selected sites. Schill and Yahner (2009) concluded that abundance of the Chestnut-sided Warbler may be limited by availability of suitable nest sites represented by sites with high foliage density. Throughout its range, it nests predominantly in deciduous shrubs and saplings close to the ground. Beaked and American hazel are highly preferred for nesting where they occur. Other species it has nested in include raspberries and blackberries, huckleberry, mountain laurel, barberry, viburnums, spiraeas, alder, red-osier and gray dogwood, and bracken fern. In Massachusetts, it nested in equal numbers in native and nonnative shrubs such as multiflora rose and Russian olive. It may nest in saplings of oak, maple, birch, beech, and hophornbeam. Nests may be 0.2-2.0 m from the ground, but most are 0.5-0.8 m up; in New Hampshire, 2% of 217 nests were on the ground. Most nests are well concealed but a few are exposed. In dense shrubs, nests may be attached to as many as 4 stems but most are in a fork in a single shrub or sapling (Bent 1953; Byers et al. 2020; Chapman 1907; Graber et al. 1983; Harrison 1984; Kendeigh 1945; King et al. 2001; Mousley 1916a, 1924; Pitts 1990).

The Chestnut-sided Warbler is territorial and males may chase each other when their territories are close to each other. It may also chase male Yellow Warblers and the 2 species commonly countersing when they have neighbouring territories. Near Quebec City, territories were significantly clumped at scales of 250 and 350 m, but not at 450 or 550 m. A similar study found no evidence of autocorrelation of territories at any scale. Near Pimisi Bay, 1 territory was 0.30 ha with the nest near its centre. In Algonquin Park, territories averaged 0.15 ha (range 0.04-0.51 ha). In New York, 4 territories averaged 0.64 ha (range 0.49-1.02 ha). During the incubation period, males greatly increased the area that they used, wandering 60-215 m outside the territory and covering an area of 0.8-4.9 ha or more. These additional areas, which may be considered the home range, always extended into unoccupied areas and in no cases did the home ranges of 2 males overlap. In small forest gaps in New Hampshire, birds frequently foraged in adjacent mature forest. It was not determined if these foraging areas were defended as part of the territory or if foraging home ranges overlapped. Gap sizes were 0.15-0.69 ha and all were occupied, suggesting that some territories were as small as 0.15 ha provided that adjacent forest was not part of the territory. Elsewhere,

territories as large as 0.405-1.10 ha have been reported (Bourque and Desrochers 2006; Byers et al. 2020; Kendeigh 1945; King and DeGraaf 2004; Lawrence 1948; Martin 1960).

No information is available on natal philopatry, but it is probably very low. The only information on adult site fidelity is from old-field habitat in New Jersey where 9 of 46 adults (19.6%) returned in a subsequent year (Byers et al. 2020; Suthers 1988). Because suitable habitat is transitory due to natural succession, adult return rates for adult Chestnut-sided Warblers may be lower than for many other species.

Limiting Factors

Eggs have been reported in Ontario nests from the last week of May until the end of July, with most present in the second and third weeks of June (Peck and James 1987). In Algonquin Park, nests are under construction late May to late June, eggs are present late May to late July, nestlings are present mid-June to late July, and dependent fledglings have been observed from late June to mid-August (Tozer 2012).

The female occasionally selects a nest site outside the territory so that territorial boundaries must be adjusted. Limited information is available on how long it takes to build the nest; 2 took 4 and 5 days to complete. In 1 nest at Pimisi Bay, the first egg was laid 4 days after the nest was complete. In Michigan, the first egg was laid 1-6 days after the nest was completed, but typically 3 days after completion. In Massachusetts, males are present and defending territories for several weeks before any females lay eggs. This is unlikely to be the case in Ontario and other more northerly areas. One egg is laid per day. Incubation begins with the laying of the last egg or in the afternoon the day before the last egg is laid. The incubation period of 26 Ontario clutches was 10-13 days with most eggs hatching in 10 or 11 days. Other studies confirmed the same range of incubation periods. Eggs often hatch asynchronously, with the last chick to hatch frequently a day younger than its siblings. Young may fledge when they are 8 days old, but usually only if they are disturbed. They are capable of flight at age 9 days but may remain in the nest 10-11 days if undisturbed (Bent 1953; Byers et al. 2004, 2020; Harrison 1984; Kendeigh 1945; Lawrence 1948; Mousley 1924; Peck and James 1998a).

There are anecdotal records of the Chestnut-sided Warbler raising 2 broods, but this does not appear to have been confirmed with banded birds. McIlwraith (1894) stated that it raised 2 broods in Ontario and Andrle and Carroll (1988) concluded that it occasionally raised 2 broods in New York. In Massachusetts, Kroodsma et al. (1989) concluded that it raised 2 broods and noted that there was a resurgence in singing after the first brood fledged that may have been associated with initiation of a second brood. Renesting commonly occurs if the first nest is lost. A new nest is built for the replacement clutch. Clutches of 1-5 eggs have been reported in Ontario. A fledgling was successfully reared from the nest in which a single egg was laid. The most frequent clutch size was 4 eggs (61.8% of clutches); clutches of 1, 2, and 5 eggs were rare. The average clutch size for Ontario nests was 3.49 eggs. Elsewhere, the clutch size was reported as 3-5 eggs. Four-egg clutches are typical; those containing 3 eggs are occasional and 5-egg clutches are rare (Bent 1953; Byers et al. 2020; Chapman 1907; Kendeigh 1945; Lawrence 1948; Mousley 1916a; Peck and James 1998a).

Both sexes are capable of breeding at age 1, although the proportion of birds that do so is unknown. Some populations contain floating unmated males or males that are successful in

defending a territory but unsuccessful in attracting a mate. The mating system is social monogamy, although 2 cases of bigamy have been reported. In Quebec, a female was killed after working on a nest for 2 days and the male continued to sing for several days before deserting it. He later moved about 75 m and was successful in securing another mate. Members of a pair that return in subsequent years are not known to remate, but sample sizes are very low (Byers et al. 2004, 2020; Mousley 1924). Only 1 study, in Massachusetts, has been undertaken on extra-pair paternity in the Chestnut-sided Warbler. Both sexes made regular forays into neighbouring territories. Twenty of 33 nests (60.6%) contained 1 or more extra-pair young and 47.4% of all young were extra-pair. For all brood sizes, the number of nests with 0 or many extra-pair young was greater than expected. Most extra-pair young were fathered by a nearby resident male (28% by a neighbour and 62% by males 2 or 3 territories distant). A few extra-pair young were sired by males 10 territories away, but territories averaged only 45 m in width such that the most distant extra-pair male resided within 400 m. Single nestlings in 2 nearby nests were fathered by a male that was not a resident within the study area. He may have been a nonterritorial floater or a more distant resident. Fifty-six percent of extra-pair males had nests that contained extra-pair young. A male's success at ensuring paternity in his own nest was not closely related to his success in obtaining extra-pair fertilizations. In 77% of extra-pair fertilizations, the first egg in the nest containing a male's extra-pair young was laid within 4 days before (54%) or after (23%) the first egg was laid in the male's own nest. The remainder were secured either later during the incubation period of his social mate (15%) or after his young had fledged (8%). All males but one were paired when they sired extra-pair young. Most extra-pair fertilizations were obtained during their own mate's fertile period, thus making them vulnerable to cuckoldry (Byers et al. 2004).

The Chestnut-sided Warbler tends to forage at low levels in shrubs and saplings or in the lower canopy, but may forage from the ground (rarely) to the canopy. It makes extensive use of shrubby patches when foraging, especially those dominated by raspberries. In Parry Sound District, foraging during early and midsummer was associated with early successional deciduous species such as willow, trembling aspen, alder, elm, black cherry, chokecherry, silver maple, and black ash. In autumn, it used areas with a higher component of white birch. Foraging height was 2-11 m during the breeding season and 2-10 m in autumn. In Wisconsin, it foraged in young disturbed forests with high light penetration and a well developed layer of shrubs and herbaceous species. Males foraged 55% of the time in hardwoods, 28% in aspen, 10% in conifers, and 7% in shrubs. Females foraged 36% of the time in aspen, 34% in hardwoods, 22% in shrubs, and 8% in conifers. Mean heights of activities were 5.47 m for males and 4.06 m for females. In the Clay Belt of Ontario, 96% of foraging occurred in deciduous species at an average height of 8.4 m. Seventy percent of foraging occurred in foliage and was 47.1% by aerial attacks, 2.8% by hanging, 15.8% by hovering, and 17.1% by reaching. This warbler relies heavily on searching the undersides of leaves for prey: 70% of searching occurs on the undersides of leaves, 11% on the upper surfaces of leaves, and 13% on twigs. Foraging techniques were 62% by gleaning, 17% by hovering, and 10% by leaping in 1 study. In Vermont, 70% of prey was captured in foliage, 18% in the air, 5% each on branches and twigs, and 2% on trunks. Forty-two percent of prey was captured by gleaning, 5.6% by aerial manoeuvres, and 2% by hanging. In Wisconsin, foraging substrates of males consisted of 54% branches, 25% twigs and leaves, 17% air, and 4% limbs and trunks. Female foraging substrates consisted of 55% branches,

24% twigs and leaves, 20% air, and 1% limbs and trunks. Males foraged 51% of the time by gleaning, 20% by hovering, 15% by sallying, and 14% by pouncing. Females foraged 42% of the time by gleaning, 33% by hovering, 20% by pouncing, and 5% by sallying (Bent 1953; Byers et al. 2020; Greenberg et al. 1999; Lent and Capen 1995; Mills 2007; Sodhi and Paszkowski 1995).

Nestlings are fed mosquitoes, small moths, and small flying insects when they are young and caterpillars, crane flies, small grasshoppers, large moths, dragonflies, and a variety of flying insects when they are older. During the breeding season, adult Chestnut-sided Warblers are almost entirely insectivorous, although they also eat spiders. It was the only old-field species that showed no evidence of eating plant food in New Jersey. In Illinois, 2 had eaten 77% caterpillars, 11% beetles, and 5% aphids. One bird had consumed 17 locusts and 21 other insects. Its primary prey includes caterpillars, fly larvae and some adults, and beetles. It consumes small tent caterpillars but not larger ones, spiders, metallic wood-boring beetles, ants, aphids, and leafhoppers. Near Manitouwadge, it increased in response to increasing spruce budworm populations, but not significantly. One stomach collected in Maine when spruce budworm populations were low contained 65% budworm larvae and pupae by volume (Bent 1953; Byers et al. 2020; Graber et al. 1983; Kendeigh 1945; Lawrence 1953; Mitchell 1952; Mousley 1924; Pitts 1990; Suthers 1988; Venier et al. 2009).

The Chestnut-sided Warbler is a common host of the Brown-headed Cowbird. The warbler rarely buries the cowbird egg in the nest. This most likely occurs only when the cowbird lays an egg in a nest that is still incomplete. In Ontario, 51 of 235 nests (21.7%) were parasitized and 29% of Quebec nests were parasitized. In Pennsylvania, 0 of 12 nests were parasitized but a high proportion of Hooded Warbler nests were parasitized. In Illinois, 5 of 7 nests (71.4%) were parasitized and 3 of 16 Minnesota nests (18.8%) were parasitized. Of 194 clutches reported in the late 19th and early 20th centuries, 18 (9.3%) were parasitized, suggesting that parasitism rates have increased (Bent 1953; Byers et al. 2020; Graber et al. 1983; Hanski et al. 1996; Lemieux and Choinière in Gauthier and Aubry 1996; Peck and James 1998a).

Habitat for the Chestnut-sided Warbler is probably declining south of the Canadian Shield. Shrubby and other early successional habitats are being lost to agricultural and urban land uses or to natural succession. Further north, early successional habitat continues to be provided regularly by forest management.

The Chestnut-sided Warbler responds favourably to forest harvesting and increases at all levels of harvesting intensity from single-tree selection to strip-cutting and clear-cutting. It increases with increased intensity of harvest. In the Boreal Forest Region of Ontario, models indicated that it would increase with forest management in comparison with natural disturbance regimes for all silvicultural options. A study in Algonquin Park determined that it was significantly more abundant in stands harvested within 1-5 years than in reference stands or in stands harvested 15-20 years previously. The logged stands were selectively cut with approximately 25% of BA removed. It was positively correlated with the percent coverage by slash and amount of shrubs 0.5 m or less tall. Another study in Algonquin Park confirmed that it responded positively to typical and intensive group selection, increasing 1 or 2 years postharvest. In northern hardwoods near Sault Ste. Marie, the Chestnut-sided Warbler increased in all areas where selection harvesting occurred. It increased 2-3 years postharvest. Its population in unharvested stands decreased during the same time period. It was

positively correlated with grass and sedge cover and the density of tall shrubs. In the Carolinian Forest Region of Ontario, it was a significant indicator of heavy or diameter-limit cuts. It was negatively correlated with the amount of retained BA. Similar positive responses to forest thinning or clearing have been documented throughout its range. In New York, it increased with increasing intensity of harvest. Populations peaked 1-6 years after harvest, declined to about 70% of the peak by year 7, declined to 50% in years 8 and 9, and were 40% of the peak 10 years postharvest. In Pennsylvania, it was absent in uncut aspen and oak stands but became abundant once these stands were cut. In the same state, it was more abundant where snags had been retained when stand improvements were made. Snag retention resulted in more woody plant growth as tall as 1.5 m. In New Brunswick, the Chestnut-sided Warbler exhibited a significant positive response to selection harvesting. It was absent prior to cutting, first appeared 1 year after harvesting and increased each year until 5 years postharvest when the study was terminated. In New York, it increased 10-fold 2-6 years postharvest, attaining its peak population 6 years after harvest and declining thereafter and becoming absent by 24 years postharvest. In 3 Minnesota areas, it responded positively to clear-cutting and to any amount of tree removal. In partially harvested areas, it was either the species that responded most favourably or was second in intensity of response to the White-throated Sparrow. In Nova Scotia clear-cuts, the Chestnut-sided Warbler was present in cuts 1-18 years old. Numbers increased to a peak 6-10 years after cutting and declined rapidly thereafter with few documented in stands 13 years or older. Timber harvesting in extensively forested landscapes provides habitat for it where it would typically be rare or absent (Byers et al. 2020; Haché et al. 2013; Hanowski et al. 2003; Holmes and Pitt 2007; Holmes et al. 2004; Jobes et al. 2004; Keller et al. 2003; Morgan and Freedman 1986; Niemi and Hanowski 1984a; Rempel et al. 2007; Stribling et al. 1990; Tozer et al. 2010; Webb et al. 1977; Yahner 2003). In the Canadian Shield of Ontario, there was no difference in its abundance in early successional and mid-successional clear-cuts and burns in the same seral stage. It was equally abundant in early successional and mature stands, but significantly less abundant in mid-successional than mature stands (Zimmerling et al. 2017).

In Minnesota, Hanski et al. (1996) studied the effects of clear-cuts on nest survival. The Chestnut-sided Warbler had the second-highest nest success rate (59%) of all species in trembling aspen–white birch stands interspersed with clear-cuts. In trembling aspen–jack pine stands, it had the lowest nest success rate (46%). Predation rates of all nests were lowest in open areas and regenerating clear-cuts and highest in forests. In New Hampshire, nest survival rates did not differ between clear-cuts and group-selection cuts or between cut edges and cut interiors. Survival was not lower in small patches (King et al. 2001).

In Michigan, Valentine et al. (2019) compared predation rates on artificial Chestnut-sided Warbler nests placed near forest openings and in forest interior. Openings were less than 100 m^2 and were cut as drilling pads for oil and gas extraction. Nests near edges were depredated more quickly and at higher rates. Birds appeared to be the primary predators and nests in shrubs may be more vulnerable to them than those on the ground.

Byers et al. (2020) documented some potential adverse effects of certain forest management practices. Control of caterpillars with pesticides or Bt may cause decreased productivity or abandonment of areas. The early successional areas inhabited by the Chestnut-sided Warbler are

less likely to be infested with caterpillars and treated, however. In 1 area, it continued to feed after spraying with fenithrothion but returned in smaller numbers in subsequent years.

The Chestnut-sided Warbler responds well to forest fires and prescribed burns. Forest fires create large areas of early successional habitat similar to clear-cuts. Regeneration may be more retarded on burns than cuts because the litter area is removed in burns and organic soils may be damaged or burned. In Georgia, it responded favourably to severe-intensity prescribed burns which resulted in significantly less canopy coverage than control areas. Warbler densities were low in severe burns for the first 1-2 years and increased significantly 3-6 years postburn; shrub density was significantly lower 1-2 years after fire. It was positively correlated with shrub density and negatively correlated with canopy cover and BA (Klaus et al. 2010). Effects of prescribed burns are likely to vary considerably depending upon soil types and species of trees and shrubs present. Fires that eliminate or significantly reduce shrub coverage for extended periods of time could be detrimental.

Mahoney et al. (1997) studied the effects of acid rain on the Chestnut-sided Warbler. Their study areas were near North Bay, which is downwind of Sudbury and subjected to acid rain, and Loring, which is unaffected by air pollution. They predicted that it was less likely to be affected than a forest-dwelling species (Black-capped Chickadee), and this was correct. At the area of declining forest (North Bay), there were significantly lower calcium levels in geometer moth caterpillars, lower magnesium levels in beetles, and higher aluminum and magnesium concentrations in geometer moth caterpillars. There was no significant difference in Chestnut-sided Warbler clutch or brood size and hatching success at the 2 sites. It appeared to obtain sufficient calcium for eggshell formation despite a scarcity of snails at both sites.

In Pennsylvania, daily nest survival rates increased with woody stem density but decreased with the amount of coverage by Allegheny blackberry. Better concealed nests had lower survival rates (Schill and Yahner 2009).

Blake et al. (1992) determined that abundance of the Chestnut-sided Warbler was significantly negatively correlated with drought and moisture anomaly indices in Michigan but not in Wisconsin. During the study period, drought was more severe in Wisconsin than it was in Michigan. It is uncertain if drought has a significant effect on the Chestnut-sided Warbler.

In the Appalachian Mountains in North Carolina, abundance of the Chestnut-sided Warbler was significantly negatively correlated with the number of houses and other buildings within 200 m. It appears to avoid houses even if there is suitable habitat around them (Lumpkin and Pearson 2012).

Price (2004) predicted that the breeding range of the Chestnut-sided Warbler might contract in southern Ontario if the average summer temperature increased by 2°C. In North Carolina, its abundance was negatively correlated with temperature, suggesting that it may be vulnerable to climate change there (Lumpkin and Pearson 2012).

Status

The Chestnut-sided Warbler is one of the species that benefitted most from deforestation by European settlers. In the mid-19th century, it was extremely rare and Audubon saw it on only 1 occasion, although he saw 5 at the same time. Its highly specialized requirements for early successional habitat probably confined it mostly to shrubby riparian areas, successional growth

around beaver ponds, areas cleared or burned for agricultural purposes by First Nations, and areas regenerating after forest fires. By 1900-20, it had become one of the most common species in areas disturbed by settlers (Bent 1953; Byers et al. 2020; Chapman 1907; Lemieux and Choinière in Gauthier and Aubry 1996; Morse 1989).

McIlwraith (1894) considered the Chestnut-sided Warbler a common breeder in the Hamilton area but Fleming (1907) considered it a rare summer resident that probably bred in the Toronto area. In 1859 in the Kingston area, it was a rare spring migrant. Its status began to change there around the end of the 19th century and the first nest was found in 1896. It became common and remained so in the late 20th and early 21st centuries (Weir 2008). Its status followed a different path in Elgin County where it was a common breeder in 1891, rare breeder in 1954, and an uncommon and local breeder in 2000 (Lancaster et al. 2004). Baillie and Harrington (1937) considered it a common summer resident north to latitude 55°N on the Ontario-Manitoba border east to northern Algoma District and Lake Abitibi. The first atlas refined the breeding range of the Chestnut-sided Warbler. The northern extent of its range in the west was approximately latitude 51°N eastward to the Moosonee area, with 1 extralimital record from the Fawn River in the northern portion of the Hudson Bay Lowland. It was most common in the Shield portion of the Great Lakes–St. Lawrence Forest Region. Its distribution south of the Shield was somewhat spotty from east of Toronto and Lake Simcoe through the extreme southwest. There were few records from Essex County or Niagara Region (Martin in Cadman et al. 1987). James (1991) considered the Chestnut-sided Warbler a common summer resident in the Canadian Shield north to Kenora and Kapuskasing; occasional and rare north to Ney Lake and Moosonee; and rare to absent in southern agricultural areas.

The second atlas indicated that only minor changes in the breeding distribution of the Chestnut-sided Warbler had occurred since the first atlas. It was observed in scattered locations further north in the Hudson Bay Lowland and even the Tundra Region. Nonetheless, it is likely absent or very thinly distributed in these ecoregions due to the scarcity of preferred habitat. It was observed in almost every square in the Shield portion of the Great Lakes–St. Lawrence Forest Region. Considerable infilling occurred in its range south of the Shield, including in Essex County and Niagara Region, but losses were experienced in Lambton County. Its probability of observation was unchanged province-wide, although the trend was positive. Significant increases occurred in the Hudson Bay Lowland and the Great Lakes–St. Lawrence Forest Region south of the Shield. Trends in all other areas were positive but nonsignificant. It was most abundant in the Shield portion of the Great Lakes–St. Lawrence Forest Region. Moderate density occurred in the southern portion of the Boreal Forest Region with low density further north and south of the Shield (McLaren in Cadman et al. 2007). Numbers declined in Algonquin Park due to a greater prevalence of more mature forest than previously (Tozer 2012).

Byers et al. (2020) stated that the Chestnut-sided Warbler had been declining slowly since the 1960s, but that the population still remained healthy and that management did not appear to be warranted. Breeding Bird Survey data indicate that it decreased at annual rates of 0.57% in Canada and 1.36% in Ontario 1970-2021 and increased at annual rates of 0.996% in Canada and 0.584% in Ontario 2011-21. All results were highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

At 1 Ontario nest, brood division occurred once the young left the nest. Fledglings remain in dense shrubbery after leaving the nest. In Ontario, a fledgling accompanied by a female was last seen 91 m from the nest 28 days after fledging. One fledgling was observed begging for food 28 days after leaving the nest suggesting that young may be still partially dependent upon the adults 4 weeks after fledging. Young males may form small groups that wander widely during the period between independence and autumn migration (Byers et al. 2020; Lawrence 1948; Pitts 1990; Siebenheller and Siebenheller 1990).

During the postfledging period, the Chestnut-sided Warbler may be very common in young clear-cuts and is occasionally the most abundant early successional species in this habitat. Family groups may occur in other shrubby habitats such as power line rights-of-way. It seldom uses forested habitats during this period. In Pennsylvania, 126 adults and 78 juveniles were captured in clear-cuts compared with 1 adult and 0 juvenile in adjacent mature forest. Forests had greater canopy closure but there was no difference in shrub density in clear-cuts and forests. Shrub composition varied with raspberry canes and cherry saplings predominating in clear-cuts and beech and red maple saplings predominating in forests. In Michigan forested habitat, capture rates per 100 net-hours were 0.3 in upland habitat and 3.3 in riparian habitat. Upland habitat consisted of 100-year-old trembling and large-toothed aspens. Riparian areas had a mixture of alder, honeysuckle, and trembling aspen; 73% of juveniles were captured in riparian habitat. In this study area, it selected habitats with higher shrub coverage (Akresh et al. 2009; Major and Desrochers 2012; Marshall et al. 2003; McDermott and Wood 2010; Stoleson 2013; Streby et al. 2011b; Vitz and Rodewald 2006; Yahner et al. 2002).

In 4-7-year-old clear-cuts in West Virginia, adult Chestnut-sided Warbler abundance was positively associated with total arthropod biomass, BA, and understorey stem density and negatively correlated with caterpillar biomass and vertical vegetation complexity. Adults had higher capture rates at nets with more understorey stems which could serve as protective areas (McDermott and Wood 2010).

MIGRATION

The Chestnut-sided Warbler is a nocturnal migrant but some dispersal from the landing site may occur after dawn. During migration, it may join flocks and forage with other species, particularly the Black-capped Chickadee (Byers et al. 2020). One bird banded at Long Point was recovered in Cuba in autumn (Brewer et al. 2018).

In spring, after-second-year birds arrive before second-year birds, and males arrive before females. At Long Point, the mean capture dates for males were 16.0 May for after-second-year birds, 20.1 May for second-year birds, and 16.4 for males of undetermined age. Mean capture dates for females were 20.4 May for after-second-year birds, 22.8 May for second-year birds, and 20.7 May for females of undetermined age (Stewart et al. 2002). At Prince Edward Point, the mean date of arrival of males was 5.1 days earlier than for females: 20.3 May for males and 25.4 May for females. The average date of arrival was 10 May (peak 19-31 May; Francis and Cooke 1986; Keast 1980). In New York, males arrived 8 days earlier than females; males were 7 days earlier than females in Massachusetts (Kendeigh 1945; Kroodsma et al. 1989).

In southern Ontario, average arrival is in early May and migrants are common throughout May. Migrants may arrive in mid- to late April and remain into early June (Black and Roy 2010; Curry 2010; Fleming 1907; LaForest 1993; Lancaster et al. 2004; Weir 2008). Average arrival in the southern Shield is mid-May with the earliest records at the beginning of May (Mills 1981; Tozer 2012).

In the southern Shield, flocks of autumn migrant warblers contain good numbers of Chestnut-sided Warblers from mid-July through early September, and most are gone by the end of September (Mills 1981; Tozer 2012). In the Kingston area, approximately 30% have passed through by 31 August and 75% are gone by 15 September (Weir 2008). In the south, average arrival is mid-August and average departure is late September or early October. Migrants may be present from late July to early November (Black and Roy 2010; Curry 2006; Keast 1980; LaForest 1993; Lancaster et al. 2004).

During migration, the Chestnut-sided Warbler may be associated with shrubby and treed vegetation of almost any type. It may occur in areas seldom used for breeding, such as forest interior or pine woods, but these habitats are still used much less than typical breeding habitat (Byers et al. 2020; Campbell et al. 2001; Chapman 1907; Graber et al. 1983). During spring migration in Pennsylvania, it was significantly more abundant in shrubby areas than forests. Detections per 100 m of transect were 0.190 in shrubs and 0.007 in forests. Captures per 1,000 net-hours were 8.6 in shrubs and 0.6 in forests; 131 were captured in shrubs compared with 6 in forests (Smith and Hatch 2008). In Ohio during spring migration, it was more abundant in mature upland forests than mature riparian forests. The 2 forest types differed significantly for 2 vegetation parameters. Upland forests had less canopy cover (74% compared with 83%) and more shrub coverage (39% compared with 19%; Rodewald and Matthews 2005). In Pennsylvania, it occurred in all habitat types studied during autumn migration. It was significantly more abundant in forest edge and shrub-sapling-stage forest than in pole-stage forest. In 1 of 2 years, it was also significantly more abundant in these habitats than in forest interior. Intermediate usage was made of suburban forests and forest-agricultural edges (Rodewald and Brittingham 2002, 2005).

At Prince Edward Point during autumn migration, the Chestnut-sided Warbler foraged at heights of 1.5-12 m, but mostly at 5-10 m. Sixty-seven percent of foraging occurred on outer leaves, 6% on twigs and inner leaves, 6% on outer branches, 17% on sapling foliage, 3% on sapling branches, and 3% in low shrubs. No foraging occurred in the air, on inner branches, trunks, or the ground (Keast 1980). Graber et al. (1983) noted that it often foraged within 3 m of the ground during migration. During adverse weather conditions, the Chestnut-sided Warbler may alter its foraging techniques and consume atypical food items. During a spring grounding at Point Pelee during inclement weather, aerial foraging was the predominant foraging technique. Foraging on other substrates consisted of 20% on branches, 20% on sapling trunks, 10% on low shrubs, 10% on the ground in thickets, and 40% on bare ground. No foraging occurred on outer foliage or bare twigs or in marsh habitat. The proportion of foraging done at different heights was 50% on the ground, 10% 0.6-1.8 m from the ground, 10% at 3 m, 10% at 5 m, 10% at 7 m, 10% at 10 m, and 0% at 13 m and 17 m or higher (Keast 1980). Five birds collected by Audubon during a light snow in May had eaten nothing but grass seeds and spiders (Byers et al. 2020). During inclement weather during autumn migration in Ohio, 2 juveniles investigated yews and honeysuckles, but were not observed eating any berries (Tramer and Tramer 1977). During autumn migration, Lebbin et al. (2007) suspected that

it was foraging at night in trees illuminated by lights from a stadium, but could not positively confirm this behaviour.

The Chestnut-sided Warbler occasionally collides with tall structures during migration. A total of 349 were killed at the Lennox generating station chimneys. Of 2,552 birds killed in a single autumn night in Georgia, 320 (12.5%) were Chestnut-sided Warblers. Kills have also occurred in mid-May at television towers in Illinois (Byers et al. 2020; Graber et al. 1983; Weir 2008).

James (1991) considered the Chestnut-sided Warbler a common migrant in Ontario. At Long Point, the numbers banded decreased at a rate of 0.8% per year 1961-88. Trends by periods were all nonsignificant: 1961-70, –6.3%; 1970-79, +5.1%; and 1979-88, +3.0% (Hussell et al. 1992).

Blackpoll Warbler

Setophaga striata

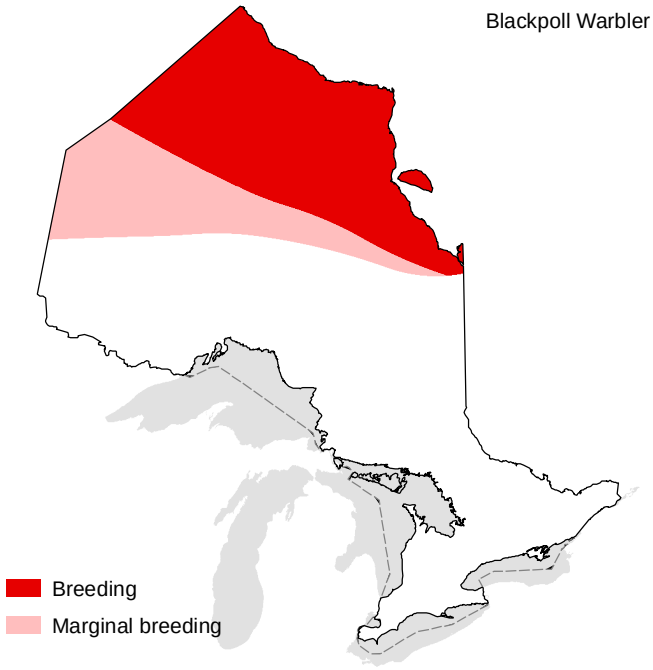
BREEDING SEASON

Habitat Requirements

Blackpoll Warbler nests in Ontario were in wet spruce-tamarack muskeg; a cutover spruce stand on mossy ground with growths of willow, poplar, and Labrador tea; and a willow-poplar stand on a high river bank. All nests were found in the 3 northernmost ecoregions in the province: the Tundra Region, the Hudson Bay Lowland, and the most northerly portion of the Boreal Forest Region (Peck and James 1987).

Little has been written about the Blackpoll Warbler's habitat preferences in Ontario and most data were collected in the Boreal Forest Region. Sutherland (in Cadman et al. 2007) identified its preferred nesting habitat as open spruce-lichen woodlands in wet spruce-tamarack taiga and burns. These habitats are dominated by black spruce with a variable low understorey of spruce saplings, alder, willow, birch, and Labrador tea. It also occurs in isolated groves of stunted spruce in open tundra, around small lakes and ponds, and along drainage courses in tundra. Less commonly, it occupies willow-aspen riparian woodlands. From Pickle Lake northward to the Manitoba border, it was most common in coniferous scrub followed by deciduous scrub, mixed scrub, coniferous forests

with an understorey, heath and tundra habitats, coniferous forests without an understorey, and mixed forests. It was absent in deciduous forests (McLaren and McLaren 1981). Near Hearst at the extreme southern limits of its range, it occurred in unharvested upland mixed forest dominated by white spruce. The site was moderately wet and slightly above average on the nutrient richness scale (Welsh and Fillman 1980; Welsh and Lougheed 1996).



The Blackpoll Warbler nests in 4 general habitats throughout its range. It has the most northern breeding range of the North American warblers. North of the treeline, it nests in deciduous shrub thickets dominated by alders or willows. These habitats are often at margins of wetlands, ponds, lakes, and watercourses. Usage of these habitats is widespread in Alaska, the Yukon, the Northwest Territories, Manitoba, and Quebec (DeLuca et al. 2020; Jehl 2004; Nadeau in Gauthier and Aubry 1996; Porsild 1943; Sinclair et al. 2003). It has not been documented breeding in willow or alder thickets in Ontario's Tundra Region (Sutherland in Cadman et al. 2007), although it has nested among willows and aspens in the Hudson Bay Lowland (Schueler et al. 1974).

Most of the Blackpoll Warbler population breeds in the northern portion of the Boreal Forest Region, from Alaska and the Yukon eastward to Newfoundland and Labrador. It is associated with spruce forests in this region and is most abundant in the taiga interface between the denser spruce forests to the south and the northern tundra. It prefers areas of young or stunted spruce and semiopen stands. It may nest in regenerating clear-cuts and where the canopy has been opened due to wind damage or spruce beetles. In most cases, it is associated with moist, nutrient-poor sites. Typical sites consist of open spruce woodlands, often with beard lichen growing on the trees, and a ground cover of sphagnum moss. It may occur in scattered locations far south of its normal breeding range. In these cases, it is confined to black spruce bogs and spruce swamps at high elevations. It is rare to uncommon in white cedar and tamarack stands (Dawson 1979; DeLuca et al. 2020; Erskine 1977; Gross in Bent 1953; Imbeau et al. 1999; Jehl 2004; Jehl and Smith 1970; Kirk et al. 1996; Matsuoka et al. 2001; Nadeau in Gauthier and Aubry 1996; Walley 1989a).

The third habitat type used by the Blackpoll Warbler is subalpine spruce forests. These high-elevation habitats allow it to nest south of the Boreal Forest Region in southern Alberta, southern Quebec, New York, New Hampshire, and Maine. Although it is found predominantly in spruce habitats in subalpine areas, it may also inhabit balsam fir stands. It may occur in mixed forests that include yellow and white birch and pin cherry. It inhabits forests that are 3-12 m in height with 60% canopy closure or less. It increases with elevation and is usually the dominant species in the upper

treed levels among dwarf spruce. In a high-elevation, 10-year-old clear-cut in New Hampshire occupied by the Blackpoll Warbler, the dominant trees were white birch, pin cherry, red maple, mountain maple, and balsam fir. Most trees were less than 7 cm diameter at breast height (DBH) and less than 4 m tall. Densities of stems per 10 m^2 were 5.8 for those 3 cm DBH and larger and 23.6 for those smaller than 3 cm (Campbell et al. 2001; DeLuca et al. 2020; Morse 1979; Nadeau in Gauthier and Aubry 1996; Sabo 1980).

The fourth habitat used by the Blackpoll Warbler consists of coniferous and mixed forests along the Pacific and Atlantic coasts. These forests may have a mix of spruce species and balsam fir as the dominant species. On an island in New Brunswick, tree-species composition in territories averaged 62.9% balsam fir, 28.3% red spruce, and 8.8% white spruce. It occurred in 2 distinct habitats based on the density per 100 m^2 of trees taller than 2 m and with a minimum DBH of 8 cm: areas dominated by white spruce with a modal density of 11-20 large trees; and areas dominated by balsam fir and red spruce with a modal density of 51-60 large trees. In British Columbia, it breeds at edges of spruce forests, often near water where deciduous shrubs such as willow are abundant. It also nests in forests dominated by fir (Campbell et al. 2001; DeLuca et al. 2020; Eliason 1986).

Near Quebec City, abundance of the Blackpoll Warbler was positively correlated with the amount of forest cover, edge, and core area combined within the landscape. Although it was associated with these landscape measures combined it did not appear to respond to these parameters individually (Drolet et al. 1999). Three landscape-type studies were completed in Newfoundland. Whitaker et al. (2008) captured 52% of birds in clear-cut landscapes and 48% in natural landscapes. In natural landscapes, forest openings consisted of peatlands and water bodies. Clear-cuts were the dominant openings in the modified landscape, which also contained natural openings. These authors were unable to identify a suitable habitat model for the Blackpoll Warbler. Taylor and Krawchuk (2006) observed no difference in its abundance in cut or uncut landscapes, with the landscape scale defined as a radius of 1,250 m around a territory. Its overall rate of occurrence was 50%: 49% in cut landscapes and 51% in uncut landscapes. At the neighbourhood scale of 150 m and the local scale of 12.5 m, it was associated with the amount of forest cover. Despite the almost equal occurrence rates in the 2 landscape types, more individuals were detected in natural landscapes. This suggested that it is less able to use regenerating clear-cuts despite its preference for partially forested landscapes. Competition with other early successional forest specialists would potentially contribute to this response. In natural landscapes, its probability of occurrence was 80% with 10-60% forest cover, 60% at 80% forest cover, and 30% at 100% forest cover. In cut landscapes, its probability of occurrence was 50% at 10% forest cover and 60% at 50% forest cover, declining to 20% at 100% forest cover. Leonard et al. (2008) completed a similar study in Newfoundland and obtained different results. They used the same landscape scale but their neighbourhood scale was 115 m. They captured fewer Blackpoll Warblers in naturally patchy neighbourhoods than in harvested neighbourhoods. The number of birds detected at the neighbourhood scale was 10 when 0% of the land was harvested, 0 when 10-90% of the area was harvested, and 17 when 100% was harvested. At the landscape scale, 0 were seen when 0% of the land was harvested, 3 when 10% was harvested, 2 when 20% or 30% was harvested, 8 when 40% was harvested, 4 when 50% was harvested, 5 when 60% was harvested, 1 when 70% was harvested, 2 when 80% was harvested, and 0 when 90-100% was harvested. Of 17 pairs that settled in

neighbourhoods where gaps in forests were created only by harvesting, only 2 occupied territories that were completely harvested. The remainder settled where all woodland gaps in the neighbourhood were created by harvesting, but where some woodland cover was available. Most Blackpoll Warblers occupied territories in harvested landscapes. Nesting also occurred in 5-6-year-old regenerating clear-cuts, and these birds were successful in fledging young. The authors concluded that clear-cuts created habitat for the Blackpoll Warbler, possibly by providing a richer food resource and an abundance of potential extra-pair mates in a more densely populated landscape.

Ralston et al. (2019) surveyed for the Blackpoll Warbler in 20 plots in boreal forest habitat in New York, Vermont, Maine, Nova Scotia, and Newfoundland. It occurred at 15 of the sites, but was restricted to colder sites at higher elevations or latitudes. This suggested that it might be adversely affected by warming due to climate change.

In the western portion of its range, the Blackpoll Warbler is predominantly a forest edge species. It nests in deciduous shrubs and scattered deciduous trees at edges of spruce forests. Suitable edge habitat is provided by river valleys, lakeshores, beaver ponds, avalanche tracks, sloughs, slow-moving streams, and patches of black spruce muskeg, a particularly favoured breeding habitat. In Alaskan spruce forests, it occurred only where heavy mortality of white spruce had occurred. This opened the canopy and promoted growth of alder and crowberry in the understorey. In Newfoundland, it was equally abundant in riparian stands, forest interior, and forest edges bordering on clear-cuts or non-forested openings. In the east, presence of deciduous shrubs is less important and young conifers are more important for nesting. It is less reliant on forest edge in the east, but prefers stands with a semiopen canopy. In Newfoundland, it nests in scrub and edge habitat as well as wooded and open areas (Campbell et al. 2001; Dalley et al. 2009; Matsuoka et al. 2001; Sinclair et al. 2003; Thompson et al. 1999; Whitaker and Montevecchi 1997, 1999).

Several studies examined microhabitat preferences of the Blackpoll Warbler. In deciduous shrub habitat in Alaska, the average height of shrubs in occupied plots was 2.6 m with 69% of occurrence in shrubs 1.3-2.8 m tall. It preferred nest sites with dense coverage below 1 m (DeLuca et al. 2020). Near Quebec City, it occurred only in sapling-stage and young forests and was not detected in forests 120 and 200 years old (Imbeau et al. 1999). In Vermont, nest sites had significantly more red spruce and leaf litter within 5 m and less green ground cover than unused random sites (DeLuca et al. 2020). In subalpine areas of New Hampshire, territories contained no surface water, mean canopy height was 6.4 m, canopy coverage averaged 57%, there was 69% coniferous foliage volume, 39% coniferous foliage volume 0-2 m from the ground, 25% deciduous foliage volume above 5 m, and live trees had an average DBH of 9 cm. It occupied mid- and upper slopes. In Maine, it was in a guild of forest and edge species occupying habitats with a high percentage of ground cover (70%) and moderate canopy cover. The Blackpoll Warbler was associated with high percent conifer cover (the highest of all warblers) and large trees (Collins 1983a). In Newfoundland, there was more coarse woody debris, more stems 1-2 m tall and taller than 2 m, and less high ground cover within 1 m of the nest compared with unused sites. Nest sites had more stems 1-2 m tall within 5 m than unused sites. Nest sites averaged 11% coverage by high vegetation compared with 13% for random sites, 0.5 stems 1-2 m tall within 1 m compared with 0 at random sites, 0 stems taller than 2 m at the nest

compared with 9 at random sites, and 5 stems 1-2 m tall at the nest site compared with 3 at random sites. Canopy cover was not an important variable differentiating nest sites from random sites. Variables within 1 m were more important than those within 5 m, and these were indicative of habitat that is both open (more coarse woody debris and less vegetation taller than 10 cm) and forested, with more stems 1-2 m and taller than 2 m. Structural objects, such as small and large downed wood and coarse woody debris, were more common at nest sites than random sites. Tall vegetation was denser at random than nest sites. Tall vegetation was found within the territory and was characteristic of the nest site at a larger scale but was not specifically selected for at the nest microsite (Dalley et al. 2008).

Four of the 5 nests reported in Ontario were on the ground at the base of willows, tamarack, and black spruce in lichens. The other nest was 15 cm from the ground in a 60-cm-tall spruce (Peck and James 1987).

Most nests reported elsewhere were in shrubs, saplings, or trees with lesser numbers on the ground. Nests have been reported 0-10.1 m from the ground, but most are 1 m or less from the ground. Mean nest heights included 0.4 m in Newfoundland (96.9% 1 m or less from the ground), 0.5 m in New Hampshire (range 0.3-0.8 m), 62% below 0.6 m and 42% below 0.3 m in Alaska, 3-3.5 m in British Columbia, 1.5 m on Grand Manon Island (range 0.3-3 m), 1.2 m in the Magdalen Islands, and 0.6-2.1 m on Kent Island in New Brunswick. In New Brunswick, second nests were higher than first nests, averaging 3.4 m from the ground (range 1.3-5.3 m) compared with an average of 2.5 m (range 0.6-5.3 m). Ground nests are frequently at the base of a tree and one was in a clump of grasses underneath a small fallen spruce. In the west, both deciduous and coniferous species are used for nesting, with alder, willow, and spruce favoured. Conifers are highly selected for nesting in the east. In Newfoundland, 43.6% of nests were in balsam fir, 30.8% in black spruce, 10.3% in moss, 5.1% in bare areas, 5.1% in snags, and 5.1% in unspecified locations. In New Brunswick, 32% of nests were in white spruce but it comprised only 9% of the available trees; 28% were in red spruce, and 40% were in balsam fir. In Vermont, 85% of 213 nests were in balsam fir and 15% were in red spruce. In New Hampshire, 86% of 50 nests were in balsam fir, 10% were in dead trees (predominantly balsam fir), and 4% were in red spruce. All nests on Kent Island were in white spruce as were nests on Grand Manan Island. Most nests are against the tree trunk but they are occasionally on a horizontal limb distant from the trunk, sandwiched between 2 trunks, or supported by live or dead branches away from the trunk. In New Brunswick, 50% of nests were oriented south to west relative to the trunk, but only 7.5% were oriented west to north. Southwest-facing nests offered maximum protection from occasional intense storms from the southeast and south-facing nests received maximum sunlight which may be important in damp, cool climates. Nests are not reused and a new nest is built for replacement or second clutches (Campbell et al. 2001; Chapman 1907; Dalley et al. 2008; DeLuca et al. 2020; Gross in Bent 1953; Harrison 1984; Porsild 1943; Sinclair et al. 2003).

The Blackpoll Warbler is territorial, but makes frequent forays off the territory. The maximum distance travelled from the centre of a territory in Newfoundland was 1,250 m. Despite the long-distance movements off territories, no evidence of polyterritoriality has been documented. In subalpine areas in New Hampshire, mean territory size was 1.5 ha. It preferred high-elevation communities and territory size decreased with elevation and density increased. Larger territories at

lower levels were not a result of decreased food abundance or increased competition, supporting the hypothesis that it is more adapted bioenergetically to cold, wet climate than other warbler species. Another New Hampshire study reported an average territory size of 0.89 ha (range 0.41-1.26 ha). In New Brunswick, territory sizes were 0.2-1.85 ha. In Newfoundland, territory sizes of males averaged 0.8 ha at the 50% isopleth (range 0.1-2.7 ha). At the 70% isopleth, the average was 1.5 ha (range 0.3-4.4 ha), and at the 90% isopleth, the average was 2.0 ha (range 0.5-7.9 ha). Home ranges averaged 1.3 ha at the 50% isopleth (range 0.3-8.1 ha). At the 70% isopleth, the average was 2.2 ha (range 0.6-15.7 ha), and at the 90% isopleth, the average was 4.3 ha (range 1.2-33.2 ha). Territory size was not affected by the amount of habitat that had been clear-cut, but home range size increased with the proportion of natural area at neighbourhood (115 m) and landscape (1,250 m) scales. Home range sizes were more variable in harvested than unharvested areas. Birds in landscapes that were naturally heterogeneous had increased space requirements, possibly because they were limited to foraging in trees and scrub along shorelines or edges of peatlands (Dalley et al. 2009; DeLuca et al. 2020; Leonard et al. 2008).

The rate of natal philopatry has been determined at only 2 locations, and in both cases sample sizes were small. In New Hampshire, 1 of 12 nestlings (8.3%) returned to breed and 14 of 20 (70.0%) returned in New Brunswick. The latter site was an island, and this may have influenced the extremely high return rate (DeLuca et al. 2020).

Variable return rates have been reported for adults, and the proportion of adults returning to a given area may vary considerably annually. In New Brunswick, 27-75% of adult males returned (average 48%), and 33-58% of females returned (average 49%). In 1 year, all 12 returning males defended a territory that included part of the previous year's territory; 11 of 12 females settled on a territory that included portions of their former territory. These data were collected on an 80-ha island where almost no predation occurred. In New Hampshire, 40-70% of adult males returned. Only 1 of 16 returning males moved the location of his territory. Reproductive success the previous year did not influence site fidelity. Another New Hampshire study reported return rates of 47-61% for adult males. They returned to within 200 m of their previous territories but the new territories did not necessarily overlap with the old ones. Lower return rates occurred in Newfoundland: 28.4% of males and 26.2% of females. One banded as an adult in a clear-cut was recaptured on territory in a natural forest opening 820 m distant the following year. The return rates were too low to be explained by mortality alone and suggested that there were landscape-scale movements of adults that may have included breeding dispersal, transience, and extra-territorial forays. The results are consistent with other observations that most boreal songbirds use home ranges far larger than their defended territories and that individuals may respond to landscape-scale habitat. There was no difference in return rates in natural and harvested landscapes. Site fidelity may be lower in the Boreal Forest Region due to regular large-scale disturbances and the shifting mosaic of stands (DeLuca et al. 2020; Eliason 1986; Whitaker et al. 2008).

Limiting Factors

Peck and James (1987) concluded that eggs were most likely to be present in Ontario nests in the last half of June and first week of July. Several days may elapse between nest-site selection and the initiation of nest building. In New Brunswick, 1-3 weeks elapsed between when the female was first

seen on the territory and when the first egg was laid. Nests take 3-4 days to build. One female started building a new nest 2 days after the first clutch was lost and the first replacement egg was laid 6 days after the loss. The first egg is laid 8-10 days after the initiation of nest building for first nests, but as soon as 4 days for later and second nests. When second broods are raised, there is an average of 9.1 days between fledging of the first brood and initiation of the second clutch (range 3-13 days). Eggs are laid at the rate of 1 a day. The incubation period is 11-12 days. The hatching period suggests that incubation begins before the clutch is complete. Hatching usually occurs over a 24-hour period but may occasionally take 2 days. Young fledge when they are 8-10 days old, mostly at age 9-10 days (Dalley et al. 2008; DeLuca et al. 2020; Gross in Bent 1953).

On Kent Island, 13 of 19 females (68.4%) raised 2 broods. Those that raised second broods initiated egg laying an average of 5.1 days earlier than those that raised a single brood. No female that initiated her clutch more than 10 days after the first egg of the season was laid had a second brood. Two females that switched mates after the first brood and mated with a previously unmated male had second broods. The previously unmated males were not present when the females initiated their first broods. The second broods on Kent Island appear to be unique, possibly because of extremely low rates of predation that allowed most birds to complete their first brood early enough to start a second brood. Of more than 300 pairs observed in Vermont and New Hampshire, none attempted a second brood. This may have been due to low success rates of initial nests compared with Kent Island. At more northern latitudes, it is unlikely that the Blackpoll Warbler has time to raise 2 broods due to the shortness of the season. If the first clutch is lost, a replacement clutch may be laid. Of 4 Ontario nests, 3 contained 4 eggs and 1 contained 5 eggs. Clutches of 2-5 eggs have been reported throughout its range with 3-5 eggs typical and 4 eggs most frequent. The mean clutch size in Newfoundland was 3.85 eggs and 67% of clutches had 4 eggs. On Kent Island, clutch size was 3-5 eggs with 5-egg clutches most frequent. The average clutch size for first clutches was 4.8 eggs (range 3-5 eggs) and second clutches averaged 3.4 eggs (range 3-4 eggs). Females older than 2 years laid significantly more eggs in a season (average 7.9, range 4-9) than yearlings (average 5.8, range 3-8). Mean clutch size in Vermont was 4.1 eggs and clutches averaged 4.0 eggs in New Hampshire with a range of 2-5 eggs at both sites (Chapman 1907; Dalley et al. 2009; DeLuca et al. 2020; Eliason 1986; Gross in Bent 1953; Peck and James 1987).

Both sexes are capable of breeding in their first year, but some yearling males may not breed. In New Brunswick, 4 of 12 yearling males (33.3%) bred but some additional ones may have bred outside the study area. Usually all females are mated regardless of their age and almost all birds 2 years old or older nest every year. Nonetheless, some after-second-year males may not obtain a mate. In Newfoundland, 1 study determined that 47.9-50.2% of captured birds were unmarked transients. The researchers concluded that these were most likely birds making forays from nearby territories rather than nonterritorial floaters. A radiotelemetry study in the same area determined that only 1 of 35 males (2.9%) was a nonterritorial floater but all birds made regular extra-territorial forays as far as 1 km from their territory centre. The Blackpoll Warbler is typically monogamous but polygyny was observed on Kent Island. At this site, bigamy occurred every year at rates of 8-40% of males. Bigamy occurred in first broods only and all second broods were by monogamous pairs. Polygyny was attributed to the high site fidelity of returning birds. Females tended to breed near their former territories; 91.7% of returning females nested in a territory that included a portion of the previous

year's territory. In 1 year, 6 females returned to an area where they had nested the previous year. Only 3 males returned and this resulted in 3 bigamous matings. In 1 case, a female returned to her territory but her previous mate was already mated with a yearling female. The older female also mated with the male and initiated her nest earlier than the yearling, thus becoming the primary female. In most cases, bigamy occurred when no unmated males were available near former nest sites of females. Territories of bigamous males supported significantly more large coniferous trees than those of monogamous or unmated males. This population was unusual in that it was confined to an island where adult return rates were exceptionally high. Polygyny rates are likely to be much lower in other areas, although this requires further study. Pair bonds of monogamous birds are maintained throughout the breeding season even when a second brood is initiated. On Kent Island, females that mated with a polygynous male for the first brood mated with a previously unmated male to raise their second brood. Several pairs reunited in subsequent years but this is less likely to occur in other portions of its range where adult return rates are much lower. Extra-pair copulations have not been observed and no studies have been undertaken on paternity of nestlings. Both mated and unmated birds enter territories of other males and approach the females, suggesting that extra-pair copulations are part of the mating system (DeLuca et al. 2020; Eliason 1986; Leonard et al. 2008; Whitaker et al. 2008).

On Kent Island, 90% of foraging observations of the Blackpoll Warbler were in conifers where it fed in the midcanopy in trees as tall as 10 m, often probing in closed buds at the tips of branches. It rarely used conifers shorter than 2 m and less than 8 cm DBH for foraging. In Newfoundland, it frequently foraged on regenerating balsam fir in remnant patches of timber within clear-cuts (DeLuca et al. 2020; Leonard et al. 2008). Morse (1979) characterized its foraging techniques in subalpine areas of New Hampshire. It foraged at medium heights in conifers, using the inner parts of limbs most frequently. It foraged at heights of 3-15 m, but mostly at 6-9 m, which did not differ significantly from the profile of the forest. Forty-four percent of foraging occurred on inner limbs, 24% on outer limbs, 18% on dead branches, 9% on deciduous species, 2% at tips of branches, and 1% each on the ground and trunks. In white birch, it exhibited a stronger tendency to forage on small outer parts of limbs than it did in firs. In white birch, 61% of foraging was on outer parts of limbs, 32% on inner parts of limbs, 4% on the tips of foliage, and 3% on dead limbs. Almost all foraging was by gleaning although a few prey attacks were by hawking and hovering. Sabo (1980) conducted similar studies in the same general area. Above elevation 1,200 m, average canopy height was 7.6 m compared with 13.1 m below 900 m. Average foraging heights at these elevations were 3.3 and 5.6 m, respectively. This is consistent with other observations that the Blackpoll Warbler forages at midheight of trees. The percent conifer volume declined from 95% to 64% going down the mountain and its usage of conifers declined from 69% to 35% accordingly. Foraging techniques were 44.6% leaf gleaning, 30.0% twig gleaning, 10.9% leaf hawking, 8.0% twig hawking and hovering, 4.3% leaf hovering, 0.9% branch gleaning, 0.3% bole pecking, 0.2% bole gleaning, 0.1% litter pecking, and 0% branch pecking, litter gleaning, and fallen log manoeuvres. Foraging occurred at similar rates distant from (56.4%) and near (43.6%) the trunk.

Nestlings are fed caterpillars, spiders, and flies. At first, young are fed small green caterpillars and aphids, but spiders and large adult insects are delivered by the time they are 6 days old. Little information is available about the adult diet during the breeding season. The Blackpoll Warbler is

predominantly insectivorous but presumably eats spiders as well. It has been confirmed eating mosquitoes and balsam woolly adelgids and fed on locusts during an outbreak in New Brunswick. It does not appear to respond to spruce budworm outbreaks, although limited research has been done on this (DeLuca et al. 2020; Eliason 1986; Gross in Bent 1953; Morris et al. 1958; Porsild 1943).

The Blackpoll Warbler is rarely parasitized by the Brown-headed Cowbird, with only 2 cases of parasitism reported in North America. There is limited overlap in the ranges of the 2 species and the cowbird rarely occurs in the habitats preferred by the Blackpoll Warbler. In the southern portion of this warbler's range, 0 of 41 New Brunswick nests, 0 of 50 New Hampshire nests, and 0 of 213 Vermont nests were parasitized. No parasitism has been documented in Ontario or British Columbia (Campbell et al. 2001; DeLuca et al. 2020; Peck and James 1987).

Habitat loss is not a significant factor in Ontario because of the northern range of the Blackpoll Warbler, although mining activities may have localized effects. Clear-cutting temporarily removes habitat, but these areas tend to be recolonized about 10 years after harvesting. In Newfoundland, low levels of forest harvest appeared to have limited influence on nest-site use and nest success. Fledging success was higher in areas with more clear-cut habitat within 20 m of the nest in some years but there was no relationship in other years. Areas that were clear-cut were more productive than unharvested areas and potentially supported a higher biomass of arthropods. Researchers in Newfoundland concluded that moderate levels of clear-cutting did not adversely affect the Blackpoll Warbler and it appeared to be beneficial in certain areas or years. Only 5.9% of this landscape was subjected to clear-cutting, so their results may not be broadly applicable (Dalley et al. 2008, 2009; DeLuca et al. 2020; Leonard et al. 2008; Whitaker et al. 2008).

On Anticosti Island, the Blackpoll Warbler was negatively affected by high deer densities in mature forests. Deer heavily browsed white birch and balsam fir and reduced shrub and sapling coverage (Cardinal et al. 2012). In Ontario, the Blackpoll Warbler nests north of the range of the white-tailed deer. Moose and caribou occur within its Ontario range, but densities of these 2 ungulates are not high enough to alter habitat structure.

Dalley et al. (2008) examined habitat characteristics relative to nest success in Newfoundland. The only consistent parameter that affected nest success was that successful nests had more large downed wood within 5 m of the nest than unsuccessful nests. Successful nests tended to have more open areas created by clear-cuts within 20 m than unsuccessful nests, but this relationship was not significant in every year.

The Blackpoll and Bay-breasted warblers are morphologically very similar and both forage mostly at midheight in the interior portions of conifers. Thus, they may be in direct competition with each other for food resources. Although the ranges of these 2 warblers greatly overlap, they rarely occur in the same locations. In New England, the Blackpoll Warbler is associated with high elevations. The Bay-breasted Warbler is associated with lower levels and spruce budworm outbreaks. The Blackpoll Warbler nests further north into the taiga and tundra than the Bay-breasted Warbler. Adaptations of the Blackpoll Warbler to colder weather include a relatively large body mass and probably a lower critical temperature and heat transfer coefficient. It has insulation with the most thickly developed semiplumes and down plumules among the warblers, a typical adaptation

to cold-climate thermoregulation. Most areas of coexistence of the Blackpoll and Bay-breasted warblers are at sites with abundant budworms (Morse 1979, 1989; Sabo 1980).

Degradation of subalpine spruce–balsam fir forests as a result of acid precipitation may harm populations in southeastern Canada and the northeastern United States, but this is unlikely to be an issue in Ontario. In the northeastern United States, the ecotone between hardwoods and montane spruce–balsam fir forests has shifted approximately 100 m upslope in the past 40 years. The lower levels of montane spruce–balsam fir forests appear to be sinks for the Blackpoll Warbler. It has been estimated that a 1°C increase in average temperature would eliminate more than half of the montane spruce–fir forest and that a 3°C increase would almost eliminate it entirely (DeLuca et al. 2020).

Status

It is likely that the historical range and abundance of the Blackpoll Warbler was similar to present conditions, but early ornithologists were uncertain of its breeding range and status. The first nest for the province was found on 2 July 1940 at Fort Severn on the Hudson Bay coast. Young were also observed near the Shagamu River and Lake Attawapiskat (Baillie 1960). The first atlas established the range of the Blackpoll Warbler as including the entire Tundra Region, most of the Hudson Bay Lowland, the extreme northwest corner of the Boreal Forest Region, and scattered areas south of Moosonee. From North Caribou Lake north to the Manitoba border, it was the most abundant species in spruce scrub (Welsh in Cadman et al. 1987). Welsh and Fillman (1980) reported it in low density near Hearst in the southern Boreal Forest Region. James (1991) considered it a common summer resident in the northern Hudson Bay Lowland south to Big Trout Lake and Moosonee, and rare south to Kesagami Lake. Wilson and McRae (1993) found it most consistently at Shagamu, but did not find it breeding in the tundra at Brant or at Moosonee.

The second atlas indicated a similar breeding range for the Blackpoll Warbler, although it nested further south in the western portion of the Boreal Forest Region than during the first atlas. The southern extent of continuous breeding range appeared to be in the vicinity of latitude 51°N, from Woodland Caribou Provincial Park to Moosonee. Breeding evidence was obtained in the Moosonee area southward 100 km to Kesagami Lake. Its probability of observation increased significantly province-wide and in the Hudson Bay Lowland since the first atlas. It was most abundant in the northeastern Hudson Bay Lowland inland from the coast in an area bounded by the Winisk and Attawapiskat rivers. It was more common in the Hudson Bay Lowland than in the Boreal Forest Region (Sutherland in Cadman et al. 2007).

Breeding Bird Survey (BBS) data for 1966-2009 indicated that the Blackpoll Warbler declined at a nonsignificant rate of 5.8% per year. This suggested that it was experiencing a widespread decline. The BBS data are unreliable for this species. Most routes are at the southern extremity of its range outside its core range. Populations at the periphery of the range are more likely to fluctuate than those in the core. At present, the Blackpoll Warbler is not well covered by any surveys (Anonymous 2009c; DeLuca et al. 2020; Nadeau in Gauthier and Aubry 1996). BBS results indicate that it decreased at annual rates of 3.456% in Canada and 4.0% in Ontario 1970-2021. Trends for 2011-21 were annual decreases of 5.39% in Canada and 2.78% in Ontario. All results were of low reliability except that the long-term trend for Ontario was of medium reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Young cannot fly strongly when they leave the nest but are adept at flying 9 days after leaving the nest. They begin to wander off the territory 20-25 days after fledging and are independent 25 days after leaving the nest. Both parents were observed feeding the same fledglings in 3 broods so brood division apparently does not take place (DeLuca et al. 2020).

In the Yukon, fledglings remained in low willows while the adults foraged in spruce, in open spruce with abundant willow and Labrador tea, in small spruce and willow along a creek, and in a trembling aspen stand (Sinclair et al. 2003). In Quebec, Major and Desrochers (2012) netted birds during the postfledging period in 5-12-year-old clear-cuts in balsam fir forest containing some black spruce, white spruce, and white birch. In the first year, they captured 14 Blackpoll Warblers but only 4 the following year.

Mitchell et al. (2010a) radiotracked juveniles in Newfoundland during the postfledging period. At the finest scale, they were associated with dense understorey woody stems and dense foliage above breast height. They were more likely to be observed at locations with coarse woody debris. Juveniles were very sensitive to the amount of clear-cut habitat at both the 115-m and 1,250-m scales. At 115 m, they were positively associated with high amounts of clear-cut land cover. The relationship was curvilinear at the 1,250-m scale. Individuals were positively associated with clear-cuts when 5% or less of the landscape was clear-cut but negatively correlated with clear-cuts above this value. Young appeared to seek dense cover that offered protection from predators and locations with high prey availability. At 16% of sites, birds were observed on the ground or in understorey vegetation. Birds may select locations with higher amounts of coarse woody debris to mitigate potential costs associated with exposure to wind.

Mitchell et al. (2009) studied the effects of clear-cuts on the movement of newly independent fledgling Blackpoll Warblers in boreal forests in Newfoundland. Medium movement rate was 303 m per day (range 4-7,380 m). Movement rate increased and residency time decreased as the proportion of clear-cut land increased, but if there was a high proportion of clear-cut land along the movement path to exit the neighbourhood, connectivity was impaired and movement rate was reduced. Clear-cuts may be low-quality habitat during the postfledging period.

Brown and Taylor (2015) determined that both adult and juvenile Blackpoll Warblers in Atlantic Canada moved distances more than 200 km prior to initiating autumn migration. Birds left Nova Scotia between 20 August and 14 September and departed across the Atlantic Ocean for their long-distance flight between 28 September and 13 October. Adults were detected as far as 484 km from the breeding area and juveniles were detected 200 km from their natal areas. Sixty-six percent of adults and 30% of juveniles moved west across the Gulf of Maine; 66% of adults were detected as far south as Cape Cod but no juveniles were detected that far south. Adults moved longitudinally slightly westward. Juveniles tended to move slightly eastward of their starting location.

MIGRATION

Most migration is nocturnal, but long-distance flights may continue into the daylight hours. At high latitudes, some movement may occur during the day because of the short nights. Autumn premigratory movements in a southward direction have been observed during day in the Churchill area. While making short-distance flights or while foraging during migration, the Blackpoll Warbler

may occur individually, in mixed flocks with other warblers, or in small single-species flocks. During the long-distance autumn flight, it travels in large flocks consisting solely of Blackpoll Warblers. It has the longest migration route of any passerine, breeding further north than any other warblers and wintering further south. Those breeding in the northwest travel about 8,000 km to reach the wintering grounds and none travel less than 4,000 km. It is the only warbler, and possibly the only passerine, to make an extensive transoceanic flight during migration (Badzinski 2002; DeLuca et al. 2020; Gross in Bent 1953; Jehl 2004; McNair and Nisbet 2011; Mitchell et al. 2010a, 2011; Morse 1989; Murray 1989; Nisbet et al. 1995).

The autumn migration route is complicated and has been the subject of considerable debate in the scientific literature. It is now agreed that migrants concentrate along the Atlantic coast from Virginia to Nova Scotia prior to making a transoceanic flight to northern South America. Birds from northwestern Canada and Alaska migrate in a southeastward direction to the Atlantic coast, travelling through southern Ontario and the states just south of the Great Lakes. At Churchill, birds appear to travel southward first prior to turning southeastward. Birds coalesce first into small flocks and then into larger flocks as they stream toward the northeastern deciduous forest. Birds breeding in northwestern Newfoundland initially move southeastward. Debate ensued on whether these birds were moving in a direction that was consistent with the transoceanic flight. It appears as though this is not the case because birds continuing in this direction would have to reorient their flight to the south while en route. Some Newfoundland birds may initially migrate southwest to Nova Scotia, New Brunswick, or New England before undertaking the transoceanic flight. In addition to the transoceanic flight theory, it has been hypothesized that the migration route was through the southeastern United States. It is generally agreed now that this is not the case. The Blackpoll Warbler is abundant in northern North Carolina during autumn migration but rare in South Carolina and areas further south. Sightings of large numbers in Florida coincide with extreme weather conditions whereby birds may have been grounded due to adverse weather. Transoceanic flight has been confirmed by radar and the fact that flocks occasionally appear on ships in the Atlantic Ocean. Birds remain at staging areas along the coast for 2-3 weeks prior to taking the transoceanic flight, building up fat reserves and waiting for a favourable wind. Birds initiate their flight when there are northwestern tail winds following passage of a cold front. The flight across the Atlantic Ocean is nonstop for a distance of about 3,000 km and requires the birds to travel continuously for 88 hours. They travel in large flocks at high altitudes averaging 3,000 m but are as high as 6,500 m at Antigua. The southern flight is predominantly passive, with birds gliding with the prevailing winds (Badzinski 2002; DeLuca et al. 2020; Jehl 2004; McNair and Nisbet 2011; Mitchell et al. 2010a, 2011; Morse 1989; Murray 1989; Nisbet et al. 1995).

Smetzer et al. (2017) and Smetzer and King (2018) used stable isotopes and the Motus Wildlife Tracking System to study the autumn migration of the Blackpoll Warbler in the vicinity of the Gulf of Maine. The range of isotopes indicated that they captured birds from a wide geographic area from the Maritime Provinces and New England to regions further west. The average stopover period was 3.5 days; 63% of birds were females and 74% were juveniles. Stopover flights of less than 50 km were directed mostly northward to inland sites, but 10% of flights were oriented offshore. All these latter flights were nocturnal suggesting that they were abandoned migratory flights. Of 6 migratory flights, 3 were directed offshore, 2 along the coast, and 1 inland. Three birds moved northward to

the Maritime Provinces and were last detected departing south over water from southeastern Nova Scotia. More stopover than migratory flights were made suggesting that it required high energy inputs to complete migratory flights. It appeared to actively select coastal or overwater routes for migratory flights. There may be greater hazards associated with coastal routes such as wind farms and communication towers. The average stopover period was 14.4 days and 59% of warblers made at least 1 stop in the Gulf of Maine that exceeded 7 days. Four birds stayed at the capture site for a mean duration of 12 days and a maximum of 22 days. Eight-three percent of birds stopped at 1 or more sites before continuing migration for a range of 1-25 days (mean 5.3 days) at individual stopover sites. Birds averaged 2.84 stops (range 1-6) and spent an average of 15.1 days on stopover throughout the study area. Those from more southern breeding areas made significantly more stopover bouts and spent significantly more total time in stopover than birds originating from more northern areas. Movement rate averaged only 0.69 km per day, with birds travelling via multiple short flights rather than in single sustained movements. The median distance of sustained flights was 42.73 km. The sample consisted almost entirely of hatch-year birds, but it is unlikely that age was the cause of the prolonged stopovers. They may be an adaptation for accumulating large fat stores to fuel long migratory flights. Brown and Taylor (2017) also used the Motus system and stable isotopes to monitor autumn migration of the Blackpoll Warbler in the Gulf of Maine area. Ninety-one percent of flights were nocturnal and 80% occurred between sunset and midnight. Only 13 of 75 movements (13.3%) were considered migratory with the remainder being local movements. One made a 200-km flight inland within New England. Many made flights that were not toward their migratory goal. The probability of making a properly oriented flight increased later in the season. Those that moved in indirect patterns were last detected at the same latitude or further north than their capture location. Adults tended to make more flights and moved in more tortuous patterns than juveniles. Adults and individuals from more western natal origins were more likely to move southwest over time. Results suggested that flights are not as costly to migratory birds as commonly assumed.

Males arrive before females in spring and adults arrive before yearlings. At Long Point, the mean capture dates for males were 22.8 May for adults, 24.7 May for yearlings, and 24.5 May for birds of undetermined age. For females, mean capture dates were 30.5 May for adults, 28.2 May for yearlings, and 30 May for birds of undetermined age. The Blackpoll Warbler was the only species studied for which female yearlings arrived before adults, but none of the results were significant (Stewart et al. 2002). At Prince Edward Point, the median date of arrival was 11.9 days earlier for males (16.9 May) than for females (28.8 May). Results were not significant due to the small sample size (Francis and Cooke 1986). On Kent Island, adult males arrived 6 days before adult females, who arrived 4 days before yearling males. Females arrived over a longer period with some old females arriving before any young males. Depending upon where early adult males settled, some females returned to areas where there were no unmated males present. This contributed to bigamy but the later arriving males were available to mate with polygynously mated females for their second brood (Eliason 1986). In New Brunswick, 1 male arrived 17 days earlier in his second year than when he was a yearling. In Vermont and New Hampshire, the first females are typically seen 2-3 days after the males arrive (DeLuca et al. 2020).

The Blackpoll Warbler is one of the last warblers to arrive in spring. Average arrival in southern Ontario is mid-May and the peak flight occurs in the last 2 weeks of May. Migrants may be present from early May to mid-June (Black and Roy 2010; Curry 2006; Fleming 1907; Keast 1980; LaForest 1993; Lancaster et al. 2004; Weir 2008). In the southern Shield, migration extends from mid-May to mid-June (Mills 1981; Tozer 2012). Wilson and McRae (1993) reported migrants at Ekwan on 2, 14, 15, and 19 June.

Morris et al. (2016) determined that younger birds moved through western sites in autumn before adults but the reverse was true in the east. Younger birds were in poorer condition and migrated slower due to shorter flights and/or longer stops. Adults and yearlings initiated their autumn migration through Virginia during the same 5-day period (Stewart 1986). In the southern Shield, average arrival is mid-August, average departure is mid-September, and migrants may be present from mid-July to early October (Mills 1981; Tozer 2012). Peak migration in southern Ontario is from mid-August to mid-September, with most gone by mid-October. Migrants may be present from late July to mid-November (Black and Roy 2010; Curry 2006; Fleming 1907; Keast 1980; LaForest 1993; Lancaster et al. 2004; Weir 2008). The midpoint of autumn migration at Long Point is 12 September (Mills 2005a).

During migration, the Blackpoll Warbler uses a much wider variety of habitats than during the breeding season. Where conifers such as spruce and tamarack are available, it may use them preferentially, although it is uncommon in spruce forests in Maine during spring migration. In the Yukon and British Columbia, it is frequently found in deciduous cover. Conifers are scarce or absent in the southern portions of its migration routes. In the Yukon, it is found in shrubby mixed forests adjacent to wetlands and in drier upland sites. Migration habitat in British Columbia includes a variety of forested habitats such as lakeside stands of trembling aspen and willow, riparian stands of cottonwood and willow, and groves of white birch; muskegs, including those dominated by black spruce, dwarf birch, and willow; dense stands of old-growth pine and white spruce; and mixed forests bordering marshes, fields, roadsides, and other openings. In riparian coniferous stands in British Columbia, it was negatively correlated with dense deciduous vegetation along streamsides and was most common in coniferous forests away from streams. In Illinois, forest edges and bottomland forests were the primary habitats it used during spring in the south. In central portions of the state, it occurred in high densities in all woody habitats, but was most abundant in upland forests where oaks predominated. In spring in Maryland, it occurred in large numbers in mature deciduous forests. During spring in North Carolina, the number of observations per hour were 1.31 in wet thickets, 1.13 in oak-hickory forests, 0.47 in floodplain forests, 0.16 in pine forests, and 0.07 in pine-hardwood stands. It was not observed in dry thickets or beech forests. During migration, the Blackpoll Warbler may occur in gardens, backyards, urban parks and shade trees, and orchards (Campbell et al. 2001; Chapman 1907; DeLuca et al. 2020; Graber et al. 1983; Gross in Bent 1953; Morse 1979; Parnell 1969; Sinclair et al. 2003; Wiebe and Martin 1998). Suomala et al. (2010) compared numbers of migrating Blackpoll Warblers during both migration periods on 2 islands in Maine. One was predominantly forest; the other was dominated by shrubs and saplings. There was no significant difference in numbers in spring or autumn over 2 years, but the trend was that it was more abundant on the shrubby island. During spring migration in Ohio, it was significantly more abundant in mature upland forests than in mature riparian forests. Upland forests had significantly

less canopy cover (74% compared with 83%) and more shrub coverage (39% compared with 19%; Rodewald and Matthews 2005). In 2 different years, Rodewald and Brittingham (2002, 2004) examined the habitat preferences of autumn migrants in Pennsylvania. In 1 year, the Blackpoll Warbler was equally abundant in all the habitats they studied. In the other year, it was significantly more abundant in forest-agricultural edges, in suburban forests, in pole-stage forests, and in forest-interior than it was in shrub-sapling stage forests.

Several studies summarized the Blackpoll Warbler's foraging techniques during migration. In Illinois, it searched from tree to tree in the central part of the state where prey was scarce, and from branch to branch in the south where prey was abundant. It foraged throughout the morning and at an increased rate between 1100 and 1200 hours, and also fed in the evening after 1500 hours until 1700 hours. It strongly selected for oaks and honey locust and used most other plants less than their availability. Oaks supported 64-82% of all leafroller moth caterpillars and this may be why they were favoured (Graber and Graber 1983). During spring migration in North Carolina, 27.1% of foraging by the Blackpoll Warbler occurred in the canopy, 68.8% in low trees, 3.3% in shrubs, and 0.8% on the ground. In the canopy, 17.4% of foraging occurred in the top of the crown, 11.5% in the inner crown, 8.2% in the lower crown, and 0% on the bole. In low trees, 8.2% of foraging occurred at the top of the crown, 46.7% in the inner crown, 13.9% in the lower crown, and 0% on the bole. In shrubs, 0.8% of foraging was at the top of the crown, 2.5% in the inner crown, and 0% in the lower crown and in dense thickets, brush piles, and grasses. On the ground, 0.8% of foraging occurred in the open, and 0% in dense thickets, grasses, and at water's edge. Singing birds were seen 1.8 m to more than 17 m from the ground (average 8 m). Nonsinging birds occurred within the same range of heights (average 6 m; Parnell 1969). During migration in Maine, all foraging in deciduous species took place in the canopy. Foraging occurred at heights of 0-24 m but mostly at 6-21 m which was not significantly different from tree height distribution. Seventy percent of foraging occurred on outer limbs, 16% at tips of branches, 12% on inner limbs, 1% on dead limbs, and 0% on the ground and tree trunks. It foraged significantly more at the periphery of trees during migration in Maryland than during the breeding season in New Hampshire. This was probably related to differences in the location of foliage in deciduous and coniferous trees. In Maryland deciduous trees, inner parts of branches consisted of limbs 3 cm or larger that did not support leaves, bark, or lichens that would be likely to provide hiding spaces for insects. In Maryland, almost all foraging was by gleaning, with some prey captured by hovering at vegetation or retrieving fallen food. On islands forested with spruce in Maine, spring migrants made heavy use of the inner parts of limbs (64% of foraging) and only occasional use of the tips of vegetation (4%) and dead limbs (4%). Seventy-nine percent of foraging occurred 6-9 m from the ground, slightly higher than in New Hampshire but that was likely a function of tree size. Migrants in spruce forests in Maine foraged in a similar manner to breeding birds in spruce forests in New Hampshire (Morse 1979). During autumn migration in New York, Lebbin et al. (2007) suspected that Blackpoll Warblers were foraging at night in areas illuminated by stadium lights, but could not confirm this.

More information is available on the Blackpoll Warbler's diet during migration than the breeding season. In spring in Illinois, most available prey consisted of caterpillars, particularly those of the linden looper and leafroller moths. The largest caterpillar eaten by any warbler was a 40-mm geometer moth larva consumed by a Blackpoll Warbler. Overall, the migration diet consists mostly

of larval and adult insects and other arthropods, although it may eat some seeds and fruit in autumn. Small fruits are available near Churchill in July and August but were apparently not eaten. Of 18 fecal samples analyzed in autumn in Rhode Island, 72.2% contained fruit and 100% contained insects. Fruit comprised 41% of identifiable food and included pokeweed, southern arrowwood, chokecherry, and bayberry. One was observed eating a yew berry during autumn migration in Ohio. The diet of 4 autumn migrants in Illinois consisted of 67% cankerworms. Most remaining prey consisted of beetles, especially currant-tip borers, plus 4% ants, 4% gnats, traces of true bugs and mites, and some undetermined seeds. Four killed at a tower near Prince Edward Point in autumn had eaten an average of 20 beetles 5-7 mm long. An autumn flock completely eradicated aphids on some poplar trees. During spring migration in Maryland, it fed on mayflies, pine sawflies, ants, weevils, wasps, and bees. It also eats winged termites, mosquitoes, and scale insects (DeLuca et al. 2020; Graber and Graber 1983; Graber et al. 1983; Gross in Bent 1953; Jehl 2004; Keast 1980; Tramer and Tramer 1977).

Migration is particularly hazardous for the Blackpoll Warbler because of its long-distance transoceanic flight in autumn. If headwinds are encountered during the 88-hour flight, it is unlikely that it can remain aloft long enough to complete the crossing. Forty-four were found dead or dying on a ship 70 km from the Massachusetts mainland, but it is probable that a high proportion of birds that encounter unfavourable winds drop into the ocean and perish. Adults are more at risk of mortality during autumn migration than juveniles. Adults undergo a moult prior to migration but juveniles do not. Adults have the physiological burden of reproduction and of preparing their offspring for migratory flight, which are a cost to the adults and a benefit to the young (Morse 1989; Stewart 1986).

The Blackpoll Warbler occasionally collides with towers, lighthouses, buildings, and other tall structures during migration and such collisions are sometimes a major source of mortality. Fifty-eight were killed at the Lennox generating station chimneys 1972-82. In September 1929, 31 were killed at the Long Point Lighthouse on 7 September, 6 on 9 September, and 199 from 22 to 29 September. At a Wisconsin television tower, it was the eighth most commonly killed migrant in spring and ninth in autumn. Kill rates are typically low on average, but very high kills may occur at lighted structures on evenings when there is abnormally low cloud cover. High winds and adverse weather conditions that cause individuals to deviate from their normal offshore route have caused large kills in Florida where typically few strike tall structures. Single-night mortalities have exceeded 50 in West Virginia and 600 in Florida at individual structures during adverse weather conditions (DeLuca et al. 2020; Graber et al. 1983; Gross in Bent 1953; Roberts and Tamborski 1993; Weir 2008).

Mills (2005a) examined autumn migration periods for the Blackpoll Warbler at Long Point 1975-2000 to determine if climate change had altered its migration timing. It exhibited a significant autumn delaying trend, but only for juvenile birds. Juveniles migrated 1.9 days per decade later during the period that was examined. Smith and Paton (2011) found similar results in Rhode Island. Blackpoll Warblers significantly delayed autumn migration 1960-2007; temperatures increased by 0.03°C per decade over this period. On average, long-distance migrants migrated 3.3 days per decade later. Morris et al. (2016) summarized its autumn migration across the continent 1967-2013.

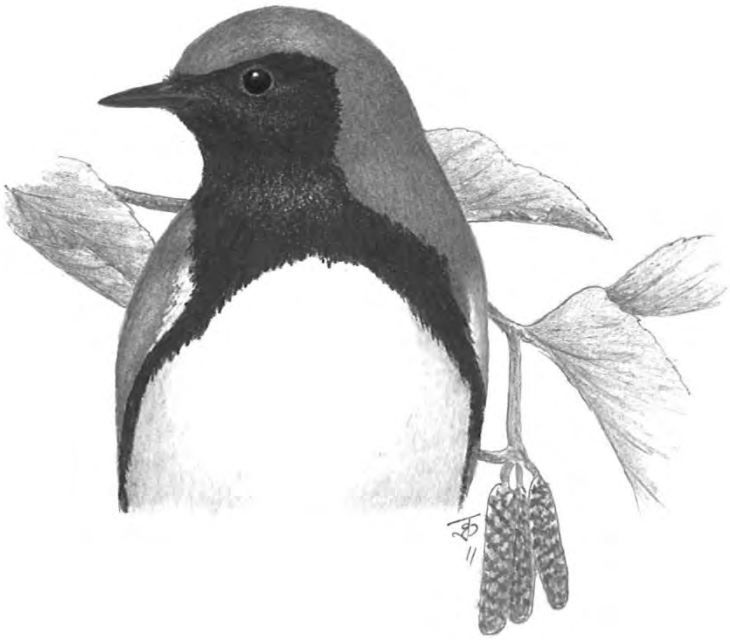
Autumn migration occurred about 1 day later per decade. Spring migration advanced at a rate of 0.5 day per decade continent-wide over a 30-year period (Covino et al. 2020b).

James (1991) considered the Blackpoll Warbler a common migrant in Ontario, although it tends to be uncommon in Elgin County, Niagara Region, Muskoka and Parry Sound districts, and Algonquin Provincial Park (Black and Roy 2010; Lancaster et al. 2004; Mills 1981; Tozer 2012).

Hussell et al. (1992) determined that there had been a nonsignificant increase in the number of migrant Blackpoll Warblers at Long Point of 0.7% 1961-88. Trends by period were: –1.7% 1961-70; +4.8% 1970-79; and +6.0% 1979-88. Its pattern of abundance on the BBS was similar to those of the Tennessee, Cape May, and Bay-breasted warblers suggesting that the Blackpoll Warbler might also respond to the abundance of spruce budworms. Badzinski (2002) analyzed banding station data across Canada. It declined at all stations except Long Point. Declines were most pronounced at Delta Marsh and Thunder Cape. Black (2017) reported a significant increase in May sightings at Port Weller 1993-2017.

Black-throated Blue Warbler

Setophaga caerulescens

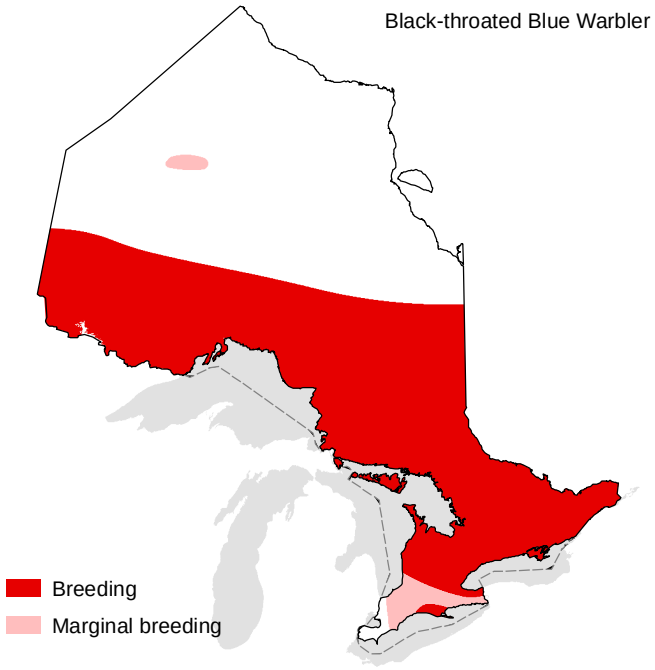


BREEDING SEASON

Habitat Requirements

Ontario Black-throated Blue Warbler nests were in mixed (66.7% of nests) and deciduous woods, all with a dense understorey. It selects deciduous understorey most frequently, but it also nests in woodlands with a coniferous understorey. Most nests were near open areas such as road edges, shorelines, and clearings (Peck and James 1987). It occurs mostly in deciduous or mixed forests in older second-growth or mature stands. It requires a fairly closed canopy and areas where there is some shrubby growth. In mixed forests, hemlock is the preferred coniferous species (James 1984b).

In the Boreal Forest Region near Manitouwadge, Venier et al. (2009) did not record the Black-throated Blue Warbler in forests 1-21 years old. It occurred at very low densities in forests 24-36 years old. It was 3 times as abundant in forests 60-223 years old, but still uncommon. At Quetico Park, Apfelbaum and Haney (1985) found it in very low densities in forests 112-176 years old. It was absent in forests 1-23, 67-73, or 367-370 years old. Near Hearst, it nested in clear-cuts 11-24 years old in upland mixed stands. It was second in abundance in a 19-year-old stand. It was absent in lowland coniferous stands of all ages (Welsh and Fillman 1980). In the Clay Belt, it occurred in 1 stand each



of trembling aspen, jack pine, tamarack–white cedar, balsam poplar, white spruce, and white birch. It was absent in black spruce. It occurred mostly in nutrient-rich sites in very wet to very dry sites (Welsh and Lougheed 1996). Smith (1957) reported it in mature white spruce forests in the Clay Belt west of Hearst and in black spruce stands in the Quebec portion of the Clay Belt.

Erskine (1977) concluded that the Black-throated Blue Warbler was not a regular inhabitant of spruce and balsam fir stands in the Boreal Forest Region, but it appeared in hemlock and mixed stands with hemlock in the transition area between that forest region and the Great Lakes–St. Lawrence Forest Region. It was common in sugar maple–beech and poplar-birch stands and occasional in pine stands.

In the Great Lakes–St. Lawrence Forest Region in the Canadian Shield, Kirk et al. (2012) documented the Black-throated Blue Warbler in both mature and old-growth white pine stands. It was slightly more common in old-growth stands, but not significantly. Near Gogama in areas dominated by jack pine, it was common only in deciduous forests taller than 16 m where there was 50-75% coverage by tall shrubs. Jack pine was usually rare to absent in these stands, but occasionally constituted as much as 60% of the tree cover. It was not observed in pure jack pine stands. Highest densities occurred in a 40-42-year-old mixed jack pine–deciduous forest (James and Peck 1995a). In Algonquin Park, it was common in old pine forests with much beaked hazel in the understorey, and in sugar maple forests (MacLulich 1938). Kingsley and Nol (1999) reported it in all age classes of white pine forests in Algonquin Park. It occurred in 75% of plots in 2-9-year-old cuts, 70-81.8% of plots in 10-16-year-old cuts, and 71.4-73.3% of plots with no recent history of logging. Also in Algonquin Park, Martin (1960) reported it in pioneer poplar–white birch stands, in mixed hardwood-spruce–balsam fir stands, in pure balsam fir–spruce stands, and in hemlock. It also occurred in shrubby plots at forest edges. Within deciduous stands, it confined its activities from about 0.5 m above ground to the lower tree branches in the canopy. Algonquin Park nest sites were characterized by low canopy cover and a large amount of regeneration, particularly of hemlock (Creasey 2013). Mills (1981) considered the Black-throated Blue Warbler an abundant breeder in Parry Sound and Muskoka districts in rich deciduous and mixed forests where there was a thick understorey of shrubs and saplings. During the breeding season and in mid-summer, it was associated with deciduous hardwood forests. In autumn, it switched its habitat preferences and was associated more with white birch stands (Mills 2007). In Muskoka District and Haliburton County, it occurred in mixed and deciduous forests with moderate canopy volume and tree density, indicative of selective tree removal in mature woods or of immature woods. Singing posts were in areas of very high tree

density and the highest amounts of understorey. It required a higher density of understorey than any of the other species studied (Clark et al. 1983).

In Elgin County in the Carolinian Forest Region, 2 of 3 breeding season records were in hemlock-dominated ravines (Lancaster et al. 2004).

Throughout its range, the Black-throated Blue Warbler nests predominantly in deciduous and mixed forests. In the Maritime Provinces, New England, and Minnesota, it nests mostly in northern hardwoods dominated by sugar maple, beech, and yellow birch. These may contain either no or varying numbers of conifers, especially hemlock and balsam fir, but also pines, spruces, and white cedar. In Quebec, it is more abundant in the deciduous and mixed forests of the Great Lakes–St. Lawrence Forest Region than in the more northern coniferous forests or in the urbanized and agricultural areas in the south. In the Maritime Provinces and Ontario, it is common in intolerant hardwood stands dominated by species such as trembling aspen, balsam poplar, and white birch. It is much less common in coniferous stands and, in conifers, is most frequent in stands of hemlock and less frequent in spruce, balsam fir, and pine stands. In New Brunswick, it nests in spruce plantations as young as 6 years old; it is rare in Wisconsin coniferous plantations. In New Brunswick, forest types that it selected, in order of preference, included intolerant hardwoods, spruce, mixed intolerant and tolerant hardwoods, and intolerant hardwoods mixed with spruce. Stand types used less than their availability, in order of decreasing avoidance, included pine, spruce and balsam fir, spruce, and spruce with some intolerant hardwoods. Other forest types that it may inhabit include oak-hickory, red pine plantations, and hemlock–yellow birch. In mountainous areas of South Carolina, it breeds most frequently in heavily wooded ravines, along streams, near seepages, and in riverine forests where there is dense undergrowth. In addition to forests, the Black-throated Blue Warbler nests in clear-cuts and strip-cuts in deciduous, mixed, and coniferous forests. It may inhabit clear-cuts when they are as young as 6 years old. In Vermont, some territories were entirely within undisturbed forest, others were completely within clear-cuts, and some contained both habitats. In Pennsylvania, it nests in shrubby areas of hydro transmission line corridors where they pass through deciduous forest (Beals 1960; Bielefeldt and Rosenfield 1994; Brooks 1940, 1947b; Crawford and Titterington 1979; Darveau in Gauthier and Aubry 1996; Falardeau et al. 1999; Freedman and Johnson 1999; Gates and Giffen 1991; Harrison 1984; Holmes et al. 2020; Holway 1991; King et al. 1997; Lent and Capen 1995; Lind 1999; Morgan and Freedman 1986; Parker et al. 1999; Pitts 1993; Steffes 1999; Temple et al. 1979; Yahner et al. 2002).

Presence of a shrubby understorey appears to be the most important habitat component for the Black-throated Blue Warbler. Shrubs appear to provide superior habitat than saplings. In northern hardwoods near Sault Ste. Marie, its abundance was positively correlated with small deciduous shrubs rather than hardwood saplings. In many areas, it appears to prefer 1 species of shrub over others, but the species that it uses vary geographically. Important species in Ontario are beaked hazel and American yew and it uses these more than their availability wherever they occur. Small balsam fir and spruce are often important features of habitat and they are particularly critical where heavy browsing by white-tailed deer has reduced the density of deciduous woody plants. In New Hampshire, areas with dense coverage of hobblebush are highly selected. In other areas, mountain maple, striped maple, and mountain laurel are important understorey shrubs in occupied

habitats. Saplings of sugar maple and beech may also provide habitat but are less frequently used than shrubs or spruce and fir saplings. The shrub layer is extremely important to the Black-throated Blue Warbler because it nests almost exclusively in it. It rarely occurs in habitats with poorly developed understories. Selection of dense shrubby areas seems most closely related to its nesting requirements and not to foraging needs or other factors. Dense shrubs provide a suitable nest substrate, shelter from the elements, and concealment from predators and parasites. In Vermont, the importance of shrubs depended upon the landscape context. In forested landscapes, occupancy rates remained nearly unchanged as shrub cover decreased but in fragmented landscapes, a decrease in shrub cover resulted in lower occupancy. Sites with high shrub coverage had a 40% probability of occupancy regardless of landscape-level patterns. In sites with low shrub coverage, occupancy declined from 30% in contiguous landscapes to 10% in fragmented landscapes. In sites within the most fragmented landscapes and with the lowest shrub coverage, there was a 16% probability that it would become locally extirpated. In the same landscapes, this probability declined to 13% when shrub cover was maximized. In New Hampshire, sites that were consistently occupied in 3 consecutive years were characterized by more deciduous vegetation than sites occupied less frequently (80% for 3 years of occupancy, 78% for 2 years of occupancy, and 68% for 1 year of occupancy) and hobblebush density was consistently higher (70 stems per 25 m^2 for 3 years of occupancy compared with 56 for 2 years and 48 for 1 year). At consistently occupied sites, its abundance was higher, males arrived earlier, and 55% of all fledglings were produced from territories that overlapped high-occupancy areas. All sites occupied in 3 years were occupied in the fourth year. Seventy percent of Black-throated Blue Warblers occurred on the high-quality sites which represented less than 50% of the occupied locations. Most reproductive output occurred from few locations that all had dense deciduous shrubs. Other New Hampshire studies demonstrated the importance of deciduous shrubs, particularly hobblebush. The percent cover was significantly greater at nest sites than random areas (94% compared with 26% within a 0.15-m radius and 87% compared with 28% within 0.30 m). Shrub density was significantly greater at nest sites than random areas at all scales examined: 1 m, 1-2 m, 2-5 m, and 5-10 m. Hobblebush density was also significantly greater at nest sites. This shrub accounted for most of the shrub density at nest sites but not at random sites. The Black-throated Blue Warbler selected areas with denser hobblebush coverage below 1.5 m and more open areas between 1.5 and 3 m than at random spots. It also selected patches of hobblebush that were larger than random, with 52.5% of nests occurring in shrub patches with a radius of at least 10 m. Nests tended to be distant from edges of hobblebush patches. Its density tended to be low until shrub density reached 40 stems per 40 m^2 and increased significantly with increasing shrub density. It was consistently and significantly more abundant in areas of high shrub density than in low shrub density. In high-density areas, 68% of males and 71% of females were 2 years old or older. Only 35% of males and 36% of females were older in areas of low shrub density. More unpaired males occurred in low shrub-density areas and warblers in high shrub-density areas produced more fledglings, mainly through double brooding. All these factors indicate that areas of high shrub density are preferred and superior habitat. A positive correlation between warbler and shrub density was also noted in northeastern mixed forests and in deciduous forests in the mid-Atlantic states. In West Virginia, it was most likely to occur in areas of high shrub density. Shrubs were removed from a plot in New Hampshire. Prior to treatment, the plot supported 3 entire and 4 partial territories. In the first year after treatment, 1 male

retained his territory but failed to attract a mate and 1 pair had a territory that was mostly in the defoliated area but nested 50 m into the adjacent forest. There was 1 nest the second year and 0 the following year. There was a 61% decline in warbler density on the treated plot. In Michigan sugar maple stands that were subjected to high grazing pressure by deer, the Black-throated Warbler was positively correlated with the amount of balsam fir in the understorey. It was negatively correlated with deciduous understorey and was absent in areas with minimal understorey. Presence of balsam fir allows it to persist in hardwood communities that are heavily browsed (Beals 1960; Bent 1953; Chapman 1907; Cornell and Donovan 2010; Dimmig et al. 2020; Doran and Holmes 2005; Holmes and Pitt 2007; Holmes et al. 1996, 2020; Holway 1991; Kearns et al. 2006; Lind 1999; Robbins et al. 1989; Steele 1992, 1993; Temple et al. 1979).

The Black-throated Blue Warbler is usually found in older stands, but may occur in those as young as 6 years. Holmes et al. (2020) stated that it did not occur in young clear-cuts or second growth but becomes common once the canopy is well developed and the shrub layer is dense, usually more than 50 years after cutting. Although that may be the case in New Hampshire, it is not universally true. In Maine spruce–balsam fir stands, it occurred in clear-cuts with dense raspberries and regenerating hardwoods less than 2 m tall and in all later stages of succession, but was least abundant in closed forest, possibly because of limited shrub coverage. It was positively correlated with the number of hardwoods larger than 20 cm diameter at breast height (DBH) and negatively correlated with the amount of slash within 1 m of the ground, the number of dead trees larger than 10 cm DBH, and the number of conifers larger than 20 cm DBH. It was one of the more common species in dense hardwoods taller than 4.5 m with a DBH of 10-15 cm (Titterington et al. 1979). In Vermont, it was associated predominantly with deciduous forests with a dense understorey, usually in pole-sized timber with a mean DBH of 8-15 cm. Plots with these characteristics included a large stand that had been clear-cut 20 years previously and stands where recent selective logging opened the canopy and allowed a dense understorey to develop (Thompson and Capen 1979). In Pennsylvania, Haney (1999) identified the Black-throated Blue Warbler as having significant negative old-growth affinity. It most commonly inhabited deciduous habitats typical of younger regenerating forests. In Wisconsin northern hardwoods, it first appears at the pole-timber stage when trees reach a minimum of 22.5 cm DBH, with the trees well spaced and a developing shrub layer and understorey of saplings (Hoffman 1989a). In northeastern northern hardwoods, Noon et al. (1979) reported it in 15% of plots in mature undisturbed forests and 40% of plots in disturbed and successional forests. Temple et al. (1979) considered it a mature forest species in northeastern mixed forests. In New Hampshire and Maine, it was most abundant in sawtimber-sized forests followed by pole-timber and large sawtimber. It was least abundant in sapling-sized forest. It was one of the species most strongly associated with mature forest (DeGraaf et al. 1998; DeGraaf and Chadwick 1987). It is likely that its distribution is influenced predominantly by the density of shrubs rather than the age of forests.

Several studies examined microhabitat preferences of the Black-throated Blue Warbler. In New Hampshire and Maine, it was positively correlated with the number of both coniferous and deciduous trees larger than 10 cm DBH, the number of conifers 2-10 cm DBH, the number of snags larger than 10 cm DBH and more than 5 m tall, total foliage volume of conifers larger than 10 cm DBH, and total foliage volume of deciduous species smaller than 2 cm DBH. It was negatively

correlated with canopy closure, the number of deciduous trees 2-10 cm DBH, the number of woody stems per ha, and the total foliage volume of conifers 2-10 cm DBH (DeGraaf et al. 1998). In Vermont, it was associated with high numbers of dead trees, increasing successional age, and higher numbers of conifers than average. It was negatively associated with numbers of aspen and white pine and coverage by hophornbeam, red oak, sugar maple, and beech; it was associated with moderate amounts of red maple (Lent and Capen 1995). Also in Vermont, average habitat characteristics included 13.7% green ground cover, 13.6% ground coverage by slash, 88.4% canopy closure, 22.1 m canopy height, 12.5 m canopy depth, 13.3 m^2 basal area deciduous species, 13.8 m^2 basal area coniferous species, 12.7 cm DBH for deciduous trees, and 17.0 cm DBH for conifers (Thompson and Capen 1988). In the mid-Atlantic states, it was significantly associated with foliage density between 0.3 and 1 m (Robbins et al. 1989). In Maine, it was associated with medium-sized to large trees in predominantly deciduous forests (Collins 1983a). In North Carolina, it was positively correlated with canopy closure and was the only species that increased with canopy cover (Lumpkin and Pearson 2013).

Freemark and Collins (1992), Holmes et al. (2020), and Lumpkin and Pearson (2013) identified the Black-throated Blue Warbler as a forest-interior species without providing any supporting documentation. Harris and Reed (2001) noted that there were several cases of it clustering territories near clear-cut edges. It is not a forest-interior species in Ontario. Peck and James (1987) reported that many Ontario nests were found at edges and Martin (1960) documented highest densities in edge plots in Algonquin Park. Three studies specifically studied the Black-throated Blue Warbler in relation to edge. In New Hampshire, King et al. (1997) established plots adjacent to clear-cuts 6 years old and younger. It was significantly more abundant in edge areas than forest interior and regularly defended territories within clear-cuts. Gates and Giffen (1991) examined edge effects along a forest-stream ecotone. It was significantly correlated with the bottomland hemlock–yellow birch–red maple forest along the stream and negatively correlated with the adjacent mature upland deciduous forest. The creek was bordered by a dense thicket of rhododendrons that probably attracted the warblers. Pitts (1993) reported a nest in South Carolina that was 8 m from a power-line right-of-way clearing. Harris and Reed (2002) studied the distribution and ecology of the Black-throated Blue Warbler in relation to forest-clear-cut edges in Maine. They surveyed 5 edge sites and 56 sites a minimum of 300 m from any clear-cut edges or roads. Clear-cuts abutting sites were 1-15 years old and were either completely devoid of trees or contained only a few dead trees and live saplings. Interior sites were dominated by trees at least 60 years old. There was a significantly higher proportion of yearling males (50.9%) at edges than in the interior (21.1%). Significantly more males were paired at edges (77.2%) than in the interior (55.4%) and in both areas, more yearlings were unmated than older birds. Of paired males, 34.1% of those at edge sites were observed with fledglings, significantly less than the 61.3% of males with fledglings in the interior. When all males were considered (paired and unpaired), there was no significant difference in the proportion of males with fledglings at edges (26.3%) or in the interior (39.9%). Fledging success was significantly correlated with male age, but only at edge sites where proportionately fewer yearlings fledged young. Males in the interior spent a greater amount of time in the understorey than males at edges even though the overall understorey density was lower in the interior. Males at edges spent most of their time in the canopy. There were several differences between edge and interior that had the

potential to affect reproduction and survival. These included differences in understorey vegetation density, prey abundance, predator densities, encounters with potential avian competitors, as well as age structure and pairing success of the warblers. These patterns did not consistently favour individuals nesting in interior over edge. There was no apparent net difference in the probability that a male establishing a territory at an edge or in the interior would produce fledglings. Male-age distributions and fledging-success patterns were consistent with the hypothesis that edge sites were inferior habitat and that yearling males may be prevented from settling in the interior by older males. Despite this, there was higher pairing success at edges, significantly higher understorey density, greater invertebrate density, and lower predator density that might indicate potential benefits of edge over interior. The results indicated that females did not avoid edges. Females' attraction to edge may be maladaptive, resulting in a lower probability of producing fledglings while males in interior sites remain unmated. It is most likely that the Black-throated Blue Warbler selects territories based on factors such as shrub density, food abundance, and predator density rather than distance from edge.

Based upon a literature review, Freemark and Collins (1992) concluded that the Black-throated Blue Warbler was area sensitive. Harris and Reed (2001) noted that it has been found in high densities in small fragments, but provided no information on the size of woodlots it inhabited. In the mid-Atlantic states, Robbins et al. (1989) determined that its abundance was positively correlated with forest size and that it rarely occurred in woodlands smaller than 100 ha. Its probability of occurrence was maximum (at approximately 20%) in woodlands larger than 3,000 ha and the probability was reduced to 50% of maximum at 1,000 ha. The 3 smallest forests in which it was seen a minimum of 2 times were 1,500, 1,500, and 1,120 ha. It was rare in this area and the conclusions were based on only 19 sightings. The results may not be representative of conditions in the core of its range. Beals (1960) studied the avifauna of islands ranging from a few hectares to more than 52 km^2 in Wisconsin. The Black-throated Blue Warbler was not confined to larger islands. Its distribution in southern Ontario according to the second atlas (Joos in Cadman et al. 2007) suggests that it may be area sensitive. It appears to be restricted to heavily forested landscapes such as the Bruce Peninsula, the Niagara Escarpment, the Oak Ridges Moraine, southeastern Ontario, the Norfolk Sand Plain, and the eastern shoreline of Lake Huron. No information is available on the size of forests it requires in southern Ontario, and this probably varies geographically depending upon the amount of forest within the landscape. Coleman et al. (2000) concluded that it probably requires a minimum of 100 ha of forest in locations off the Shield.

Ontario nests were in small trees and saplings. Conifers were slightly preferred, supporting 57.1% of nests in 5 species; 3 deciduous species were used. The most frequently used nest species were balsam fir (9 nests), maples (5 nests), hazel (4 nests), spruce (3 nests), and American yew (3 nests). Nests were between 2 or more upright trunks or branches or in crotches and were 0.2-1.7 m from the ground, with most 0.3-0.4 m up (Peck and James 1987). Baillie and Hope (1947) reported a nest 30 cm from the ground in a small balsam fir in Sudbury District. In Parry Sound and Muskoka districts, most nests were about 30 cm from the ground in small conifers (Mills 1981).

Throughout its range, the Black-throated Blue Warbler nests near the ground in a small shrub or sapling. In the Maritime Provinces, most nests are in small spruce or balsam fir and Quebec nests are

frequently in American yew. At 1 New Hampshire site, most nests were in hobblebush. All nests were in mountain laurel in another New Hampshire area. Other species that it nests in include blackberry, purple-flowered raspberry, sugar maple saplings, beech saplings, red oak saplings, small hemlocks, American fly honeysuckle, striped maple, mountain maple, grey alder, elderberry, and bracken fern. Most nests are in the crotch of a shrub or sapling and some are in clumps of dead leaves. Many have a dead branch or twig that forms part of the crotch and adds additional support for the nest. Almost all nests have a nearly complete canopy of vegetation over them, thereby concealing the nest, shading it, and protecting it from rain. The nest species is probably not important, with shrubs most likely to be selected based on their density, size of the patch, and the overhead cover they provide. No nests have been reported on the ground, but most are within 1 m of the ground and almost all are 1.5 m or less from the ground. In North Carolina, 95% of 563 nests were 0.95-1.30 m from the ground. One New Hampshire nest was 11.5 m from the ground in a yellow birch and another was 17 m from the ground in a hemlock. Nest heights typically average about 0.5 m from the ground or even lower. In North Carolina, early nests averaged 0.44 m from the ground; late nests averaged 1.81 m. One unusual nest was in the top of an overturned spruce. This was in an open woodlot so there may have been few typical nest sites available. Another was in a fallen tree amidst small twigs and last year's dead leaves. Nests are not known to be reused, but 1 nest was built on the platform of an old nest. It may incorporate material from old nests into a new one, including those of its own and other species (Bent 1953; Chapman 1907; Harding 1931; Harrison 1984; Holway 1991; Holmes 1986; Holmes et al. 1979, 1992, 2020; Kendeigh 1945; Lind 1999; Mousley 1924; Nice 1930a; Smith et al. 2018; Steele 1993; Stodola et al. 2010b).

When males first arrive, they range over large areas (5-10 ha) of the forest prior to settling in 1 location. In New York, males were frequently observed 150-180 m from their singing posts, and sang as they gradually worked their way back. Males in this population did not appear to be aggressive toward each other and frequently sang in the same or adjacent trees. It was doubtful if all the area that was used was defended, so it might better be defined as a home range. One polygynous New Hampshire male had nests 300 m apart. Ford (1996) interpreted this male as being polyterritorial, but there were no intervening males defending territories so it could also be interpreted as being a very large territory. Most New Hampshire studies concluded that territories are 1-4 ha, larger than reported elsewhere. Smallest territories occur where the shrub layer is dense and heterogeneous. In Quebec, territories are smaller than 2 ha. In Minnesota, territory sizes averaged 0.46 ha (range 0.21-0.77 ha), but the researcher acknowledged that the size of some territories may have been underestimated. In Algonquin Park, territories averaged 0.68 ha (range 0.10-1.55 ha; Darveau in Gauthier and Aubry 1996; Holmes et al. 2020; Kendeigh 1995; Lind 1999; Martin 1960; Nagy and Holmes 2005; Petit et al. 1988a). Near Quebec City, Black-throated Blue Warbler territories were not aggregated. Bourque and Desrochers (2006) concluded that it was strongly associated with habitat features and this may define its occupation pattern. Betts et al. (2008b) stated that there is evidence that it aggregates, suggesting that it may use the presence of other birds to cue in on suitable habitat. Holmes et al. (1979) stated that its distribution was patchy, coinciding with areas of high-density foliage.

Natal philopatry appears to be low. In New Hampshire, 22 of more than 5,000 nestlings (0.4%) returned. The closest returning bird was 300 m from its natal site but most were more than 500 m

away. One returning female bred 2.5 km from its natal site. The low apparent return rates may have been partially due to all studies being conducted on small plots (10-15 ha) in contiguous forest. Stable isotope analyses indicate that juveniles dispense over broad areas (Harding 1931; Holmes et al. 1992, 2020; Nagy and Holmes 2005).

Adult site fidelity is fairly high and once an adult has bred at a site, it is likely to return to breed. In New Hampshire, the annual survival rate of females was 40-45%. Within the same area, 37.4% of 99 adults returned in the first year after banding. Return rates were similar for the sexes (39% for males and 36% for females). Survival rates were estimated at 51% for males and 40% for females, and this difference was significant. Yearling males returned more frequently (42%) than older males (35%), but not significantly. The average distance between territory centres in subsequent years was 94 m for males and 153 m for females. Yearling males dispersed a median distance of 156 m compared with 83 m for older males. There were no significant differences in the distances dispersed by the sexes or age classes. Reproductive success the previous year did not affect return rates. Another New Hampshire study reported differing results. The overall mean dispersal distance was 193 m and females dispersed significantly greater distances (245 m) than males (163 m). Sixty-six percent of males and 46% of females returned to within 150 m of the previous year's territory. One percent of each sex dispersed longer distances (1,201-1,350 m for males and more than 1,350 m for females). Dispersal distances were shorter for older than younger males and also for males in higher-quality habitats than those in medium-quality habitats. Habitat quality was the most important predictor of female dispersal distance. Reproductive success was also important, with females that fledged more young dispersing shorter distances. In heavily browsed deciduous forests in Michigan, annual return rates for adults were 26% where the understorey was dominated by balsam fir and 11% in deciduous-dominated understories. These differences were not significant (Cline et al. 2013; Holmes and Sherry 1992; Kearns et al. 2006; Nagy and Holmes 2005; Sillett and Holmes 2002). Some males (probably yearlings) arrive later than average and establish territories in suboptimal habitat. As the breeding season progresses, many move to higher quality vacant habitat (Betts et al. 2008b).

Limiting Factors

Eggs have been reported in Ontario nests from the last week of May until the end of July, with most present in the last half of June (Peck and James 1987). In Algonquin Park, nests are under construction from mid-May to early July, eggs are present from late May to late July, nestlings are present from early June to early August, and dependent fledglings have been seen from late June to early August (Tozer 2012).

Pair formation usually occurs within a few hours of arrival but occasionally takes a few days. Nest building begins 3-7 days after arrival in favourable weather, but may be delayed as long as 14 days if it is cold or wet. Nests take 3-5 days to build and the first egg may be laid the day after the nest is complete. Eggs are laid at the rate of 1 per day. Incubation is usually initiated with the laying of the penultimate egg. The incubation period at 3 Ontario nests was 12 days. Elsewhere, incubation periods of 11-13 days have been reported, typically 12-13 days. Eggs tend to hatch on the same day and a 4-egg clutch hatched within a period of 1.5 hours; clutches occasionally hatch asynchronously. The nestling period is 8-12 days, mostly 11-12 days. The average nestling period in New Hampshire was 8.6 days compared with 11.4 days in North Carolina (Harding 1931; Holmes et al. 1979, 1992,

2020; Kendeigh 1945; Mousley 1924; Nagy and Holmes 2005; Nice 1930a; Peck and James 1998a; Pitts 1993; Stodola et al. 2010b).

Double broods probably occur in Ontario, but this has not been confirmed. Double brooding has been confirmed in Minnesota, North Carolina, and New Hampshire. Over a 20-year period in New Hampshire with a sample size of more than 2,000 nests, 3 attempts at third broods were documented. None of the third broods fledged young. In New Hampshire, the proportion of females that raised a second brood after successfully rearing a first brood ranged from 0% to 87% annually. On average, 53% of successful females initiated a second brood. In Michigan, 26-45% of birds raised 2 broods over 6 years. Females that raised a double brood nested on territories with greater food availability and produced heavier fledglings in their first brood compared with single-brooded females. The date of nest initiation and the age of females were not good predictors of whether a female would attempt a second brood. Females were more likely to be double brooded in years when food was abundant or when they were mated with an older male. Females raising more young in the first brood were less likely to double-brood. Despite the large number of females raising 2 broods in this population, some females failed to fledge any young. Replacement nests are common if a nest is lost due to predation or other factors. Females in New Hampshire made 1-4 nesting attempts (average 1.7, median and mode 2). These included replacement nests and multiple broods. There were few second broods in years when wet weather in late May and early June delayed nesting. In North Carolina, time until a new nest was started averaged 6.5 days following nest loss and 10.5 days after a successful nest (Holmes et al. 1992, 2020; Lind 1999; Nagy and Holmes 2005; Stodola et al. 2009). Clutches of 2-4 eggs have been reported in Ontario with 79.2% containing 4 eggs (average 3.71 eggs; Peck and James 1998a). Throughout the Black-throated Blue Warbler's range, clutches of 2-5 eggs have been reported. Four is the most frequent clutch size and 94.2% of New Hampshire clutches contained 4 eggs; 5-egg clutches are rare. The average clutch size in New Hampshire was 3.8 eggs. First clutches averaged 3.9 eggs, second clutches averaged 3.7 eggs, and third clutches averaged 3.6 eggs. Early clutches averaged 4.0 eggs and late clutches averaged 3.7 eggs. In North Carolina, average brood size was 3.39 for first nests and 3.23 for second nests (Bent 1953; Chapman 1907; Holmes et al. 1992; Nagy and Holmes 2005; Rodenhouse and Holmes 1992).

Both sexes are capable of breeding in their first year and all females of all age classes breed every year. In New Hampshire, the proportion of unmated males varied annually from 0% to 21.9%. Unmated males are mostly yearlings and birds in marginal habitat. Unmated males are most common in years when density is highest. Male removal studies in New Hampshire demonstrated that missing males were replaced primarily by neighbours, with little evidence of a floater population (Holmes et al. 1992, 2020). The mating system is typically monogamous, but some males are bigamists. In New Hampshire, polygyny rates ranged from 0% to 15% annually. Seven of 8 bigamous males were after-second-year birds and some females successfully raised 2 broods with a bigamous male. In the case of the yearling bigamous male, both his females raised 2 broods. Bigamous males raised significantly more fledglings (average 7.2, range 3-12) than monogamous males (average 4.4, range 0-8). Most pair bonds are retained through the entire breeding season, including replacement nests and multiple broods; divorce occasionally occurs. When both members of a pair return in a subsequent year a high proportion reunite. Of 20 cases when both

pair members returned, 16 (80%) reunited (Cline et al. 2013; Holmes et al. 1992, 2020; Petit et al. 1988a).

Extra-pair fertilizations are an important component of the Black-throated Blue Warbler's mating strategy, but intraspecific brood parasitism appears to be rare. In New Hampshire, 44.7% of 17 broods contained extra-pair young. Another study at the same site determined that 43% of 900 nestlings were extra-pair and 56% of 152 broods contained extra-pair young. In Vermont, 33.2% of nestlings were extra-pair and 52.9% of broods contained extra-pair young. In North Carolina, 32% of nestlings were extra-pair and 57% of broods contained extra-pair young. Females that had more than 2 neighbouring females with overlapping fertile periods were most likely to have extra-pair young. Synchrony of nesting in adjacent territories was an important factor regulating extra-pair fertilizations. Males that guarded their females closely during the incubation period were less likely to have extra-pair young in their nests. Extra-pair sires had a significantly higher annual return rate (67%) than those who were cuckolded (42%). This suggests that females may select high-quality males as extra-pair mates. In the same study area, 68.0% of extra-pair sires occupied a territory adjacent to the one supporting its extra-pair young and in most cases the sire was less than 2 territories away. There were 4 cases in which the male was separated from his extra-pair young by 2 or more territories. In addition, 70.2% of young whose sires were not identified were at the edge of the study plot where some neighbouring males had not been sampled. The probability of a male obtaining extra-pair copulations decreases with increasing distance to females and breeding density. Frequency of extra-pair copulations increases with breeding synchrony. Older males are more likely to sire extra-pair young than young males, which is probably associated with territory quality (Chuang et al. 1999; Holmes et al. 2020; Webster et al. 2001).

The Black-throated Blue Warbler forages mostly in the shrub and subcanopy layer of deciduous and mixed forests and is ecologically separated from the canopy-dwelling warblers. In New Hampshire, it actively selected layers 3-6 m and 6-9 m from the ground for foraging. Heights of 0-1 m, 1-3 m, and over 9 m were underutilized. Males did not use the shrub stratum for foraging and significantly overused the sparse foliage in the sapling and subcanopy strata. Females and males feeding fledglings foraged differently, overusing tall shrub foliage 1-3 m from the ground. Females significantly overused tall shrub foliage and underused subcanopy foliage. Horizontally, foraging males selected areas with a high density of shrub or sapling foliage and overused these areas. Other density classes were used in proportion to their availability. Foraging females underutilized areas with high densities of shrub or sapling foliage and areas with high numbers of shrubs. All other areas were used in proportion to their availability. Males foraged higher than females, often over areas of dense shrub foliage. Females foraged low but did not show any clear selection for dense shrub patches. In New Hampshire, males foraged at significantly greater heights (average 5.9 m, range 2-16 m) than females (average 3.3 m, range 0-16 m). Male song perch heights averaged 8.1 m. Of all species studied, the Black-throated Blue Warbler exhibited the lowest overlap in usage of strata by the sexes at 62.7%. Females foraged significantly more on hobblebush, herbaceous species, and ferns than males. In Parry Sound District, it foraged at heights of 2-13 m during the breeding season and at 3-12.5 m in autumn (Holmes 1986; Holmes et al. 1979, 2020; Mills 2007; Robinson and Holmes 1984; Steele 1993). The Black-throated Warbler foraged mostly by hovering (about 65% of attacks) and 35% by gleaning in New Hampshire. In Vermont, gleaning was the primary foraging technique

(77% of attacks compared with 23% for hovering). Density of the warblers may determine which foraging technique is dominant. In 1 study, its density was decreased and those in areas of low density gleaned more than those in high-density areas. Males in high-density areas had less time available for foraging due to territorial defence requirements and compensated by using more aerial attack manoeuvres. Approximately 75% of prey attacks are directed to leaves with limited amounts of foraging on twigs, branches, tree trunks, and in the air. Most prey attacks are directed to lower leaf surfaces. In a laboratory study, the Black-throated Blue Warbler learned to locate prey more efficiently when it was distributed on lower leaf surfaces, and capture rates were higher on lower than upper leaf surfaces (Dobbs et al. 2007; Holmes 1986; Lent and Capen 1995; Robinson and Holmes 1982, 1984; Whelan 1989). In New Hampshire, there was no significant difference in the tree species that the sexes foraged on. Females tended to forage in herbaceous species and ferns more than males. Prey attacks in beech, sugar maple, and yellow birch were directed mostly to lower leaf surfaces. Prey items in beech and yellow birch were attacked in proportion to their availability on leaf, petiole, and twig surfaces. In sugar maple, it used the lower surface of leaves and the caterpillars there significantly more than expected. In all trees combined, 82% of attacks were directed toward lower leaf surfaces, 10% to upper leaf surfaces, 8% to twigs, and 0% to petioles (Holmes 1986; Holmes and Schultz 1988).

Nestlings are fed predominantly insects, particularly caterpillars. On their first day, New Hampshire young were fed small insects, white grubs, and large numbers of 1-cm long smooth green caterpillars. On days 2-8, the diet consisted chiefly of these caterpillars, insects, grubs, other types of caterpillars, and occasionally mayflies. On days 9 and 10, dragonflies and mayflies were the staples of the diet, but caterpillars and grubs were still consumed. Other food items eaten by nestlings included slugs, winged ants, cabbage white butterflies, and moths. Other studies confirmed that green caterpillars and, to a lesser extent, grubs are important in the diet of nestlings. Quantitative sampling of nestlings' diets indicated that 58-87% of food consists of caterpillars. They have also been fed crane flies, other flies, some hymenopterans, and occasional beetles (Goodbred and Holmes 1996; Harding 1931; Mousley 1924; Nice 1930a; Rodenhouse and Holmes 1992).

During the breeding season, adults are predominantly insectivorous, although they eat some spiders. In New Hampshire, stomach samples consisted of 50.5% beetles, 27.6% caterpillars, 12.0% flies, 5.2% soft-winged bugs (mostly leafhoppers), and 5.2% hymenopterans. Other food items include spiders and harvestmen, dobsonflies, stink bugs, caddisflies, stoneflies, lacewings, damselflies, snails, crickets, and sawflies (Holmes et al. 2020; Robinson and Holmes 1982; Rodenhouse and Holmes 1992). Near Manitouwadge, the Black-throated Blue Warbler responded positively to a spruce budworm outbreak in mature forest, but not significantly (Venier et al. 2009). In a laboratory, Whelan et al. (1989) offered gypsy moth larvae to this warbler. One of 5 birds offered second-instar larvae accepted it and 1 of 3 offered third to sixth instar larvae accepted. In another trial, warblers were simultaneously offered 4 types of potential prey items. Zero of 12 birds chose gypsy moth larvae, 1 of 9 consumed a tussock moth larva, 12 birds each selected a cabbage looper, and 7 of 8 accepted mealworms. Smooth prey was selected over hairy prey. The authors concluded that it was unlikely to eat gypsy moth caterpillars if alternate prey was available. In New Hampshire, Rodenhouse and Holmes (1992) experimentally reduced prey abundance by spraying plots with Bt, which kills caterpillars. There were significant differences in nestling growth rates among years and

plots, but this could not be related to food abundance. Growth rates were influenced more by weather conditions, particularly precipitation. Rainfall probably increases food requirements but reduces foraging time and the availability of some insects. When food was abundant, all pairs attempted first broods, all pairs renested after nest failure, 75% of birds with successful first nests attempted a second brood, and 4 young fledged from each nesting attempt. When food was limited, fewer pairs made multiple nesting attempts such that productivity was reduced below replacement level. In times of low caterpillar biomass, even a brief period of adverse weather can create food scarcity. In contrast, insect irruptions can increase productivity.

The Black-throated Blue Warbler is an infrequent host of the Brown-headed Cowbird and it appears to accept cowbird eggs. In most cases, a single cowbird egg results in complete reproductive failure. Only about 20% of parasitized nests in Vermont fledged a single warbler. In Ontario, 4 of 26 nests (15.4%) were parasitized; in Quebec, 2 of 21 nests (9.5%) were parasitized. Parasitism rates are much lower in forested landscapes than in smaller forest patches. Zero of more than 5,300 nests in New Hampshire were parasitized, although 1 female was observed feeding a cowbird fledgling. In unfragmented forest in Michigan, 1 of 160 nests (0.6%) was parasitized. In small forest fragments in Vermont, 25 of 203 nests (12.3%) were parasitized (Darveau in Gauthier and Aubry 1996; Holmes et al. 2020; Peck and James 1998a).

Habitat loss and degradation do not appear to be significant limiting factors in Ontario. Forest cover has increased south of the Shield in the past half century, which may improve habitat suitability for the Black-throated Blue Warbler. There is a possibility that this trend will reverse itself because of the high value of agricultural land. Invasive species such as garlic mustard may inhibit shrub and sapling establishment and reduce habitat quality. In North Carolina, its abundance was negatively correlated with the number of buildings within 200 m (Lumpkin and Pearson 2013). Establishing a single house within a woodlot may reduce its suitability for the Black-throated Blue Warbler. In Quebec, Bélisle et al. (2000) translocated territorial males during the breeding season. Birds took more time and were less likely to return to their territories as the percent coverage by forest decreased. Fragmentation may disrupt habitat selection processes, reduce colonization of isolated patches, and ultimately alter population structure and dynamics.

The Black-throated Blue Warbler is not significantly affected by forest management provided that the shrub layer is maintained or enhanced (Holmes et al. 2020). Several studies examined the effects of selective logging on it in Algonquin Park. Jobes et al. (2010) found that it was significantly more abundant in recently logged sites 1-5 years old and in uncut stands than in stands logged 15-20 years previously. Old logged stands had a reduced shrub layer and reduced canopy cover, reducing their suitability for edge and shrub-associated species. Uncut stands contained high shrub densities, probably a result of natural gap disturbances, and this created suitable habitat. A significant increase in shrub density occurred shortly after harvesting, providing better habitat. Tozer et al. (2010) found no significant difference in its abundance in control plots and those where single- and group-selection harvest occurred. Abundance of the shrub-nesting guild showed no response in the first year postharvest but increased the next year in response to typical and group-selection harvest. Creasey (2010, 2013) found that single-tree selection in Algonquin Park created significant habitat changes but had no effect on this warbler's reproductive success. Holmes and Pitt (2007)

examined the effect of selection harvesting in northern hardwoods near Sault Ste. Marie. In 1 plot, it increased in abundance within 1-2 years after harvesting. In the other plot, it declined initially but increased 3-8 years after cutting. The initial decline was attributed to the change in abundance of American yew which declined from 21.1% coverage prior to cutting to 1.2-2.0% coverage 1 and 2 years after cutting. Density of this shrub recovered in the third year after harvesting. In the Canadian Shield in Ontario, there was no difference in its abundance in early successional stands after clear-cutting and fires, but it was significantly less abundant in mid-successional clear-cuts than in similarly aged stands after fire. It was significantly less abundant in early successional stands than in mature stands, but there was no difference in its abundance in mid-successional and mature stands (Zimmerling et al. 2017). Very similar results to the Ontario studies have been documented elsewhere. Densities in new cuts and control areas are often similar, but sometimes densities are much higher in new cuts than uncut areas, depending upon shrub densities in the unharvested areas. Density starts to decline 14-18 years postharvest as the canopy fills in and shrubs are replaced by saplings and pole-sized trees. In New Brunswick, it reached highest densities in selection cuts and 61% of fledglings were produced in the harvested areas. In another New Brunswick study, shrub density declined by 13.7% in the first year postharvest due to skidder damage, returned to original levels in the second year, and then increased steadily. An increase in the Black-throated Blue Warbler was evident in the fourth year postharvest (Bourque and Villard 2000; Haché et al. 2013; Keller et al. 2003). In New York, Webb et al. (1977) found no evidence of effects on the Black-throated Blue Warbler when 25%, 50%, 75%, or 100% of merchantable timber was removed from forest stands. In Maine, Harris and Reed (2001) examined the effects on this warbler of 0.45-1.67-ha clear-cuts 1 to more than 15 years old in extensive northern hardwood woodlands. Broadcast calls and mounted birds were used to elicit territorial responses. Birds moved an average of 40 m in clear-cuts in response to these and readily crossed roads that constituted 10-30-m gaps. Three of 38 birds (7.9%) moved across clear-cuts. Males moved furthest into clear-cuts older than 15 years indicating that vegetation structure influenced movement into open areas. Small-scale habitat fragmentation by forestry may not disrupt territorial movement by the Black-throated Blue Warbler.

In New Hampshire, the Black-throated Blue Warbler population is regulated by food availability, nest predation, and local population density. These 3 factors explained 91% of the variation in the number of young fledged each year (Holmes et al. 2020).

Two studies in Quebec (Darveau et al. 1992; DesGranges et al. 1987) investigated the effects of sugar maple decline on the Black-throated Blue Warbler. In 1 study area, trees lost about 20% of their crown foliage and no effects were observed on the warbler. The other study found that it was significantly more abundant in stands that had suffered die-back due to the sugar maple borer than in healthy stands. It is likely that die-back of the canopy favoured shrub growth and improved warbler habitat.

High density of deer results in overbrowsing which can reduce habitat suitability for the Black-throated Blue Warbler. In a heavily browsed area in Michigan, it avoided areas with deciduous species in the understorey and selected sites with regenerating balsam fir, a species seldom browsed by deer (Gates and Giffen 1991; Kearns et al. 2006).

Taliaferro et al. (2001) examined the effects of soil calcium concentrations on the Black-throated Blue Warbler in New Hampshire (a calcium-poor habitat) and Vermont (a calcium-rich habitat). There were no significant differences in eggshell mass or thickness or in the concentration of calcium in the eggs. A diet of predominantly caterpillars did not provide a sufficient source of calcium. Ingestion of 8 average-sized (60 mg dry mass) snails during the egg-laying period would provide enough calcium for eggshell formation for a 4-egg clutch. Acid precipitation could become a limiting factor for snails which could lead to eggshell-formation issues for this warbler.

Graves (1997) examined the proportions of yearlings and adult males in breeding populations over much of the Black-throated Blue Warbler's range. The proportion of yearling males increased as relative abundance decreased toward the margins of the breeding range. The ratios of yearlings to adult males in 2 Ontario populations in the southern Canadian Shield were 0.67:1.0 and 1.0:1.0. The ratio was 0.17-0.80 and generally much lower than in Ontario in the core of the range in the southern Appalachian Mountains. Populations with high proportions of yearlings may be sink populations because fewer second broods are produced by yearlings.

In New Hampshire, Biasiolli (2009) documented introduced species of slugs actively feeding on nestlings. In most cases, adults successfully repel slugs and they may function as nest predators only under atypical conditions. In 1 case of slug predation, the young had fallen out of the nest and were on the ground. In the other case, the male had abandoned the nest and left its defence solely to the female. Only 2 cases of slug predation were observed at this site in more than 2,900 nests.

Venier et al. (1999) used breeding bird atlas data for Ontario and macroclimate information to model the distribution of the Black-throated Blue Warbler in the province. The final model included the maximum diurnal temperature range, the mean seasonal range in temperature, the annual range in temperature, the annual precipitation, the range in precipitation amount, and the total precipitation during the growing season. Price (2004) predicted that its breeding range in southern Ontario might contract if the average summer temperature increased by 2°C. Holmes et al. (2020) reported the results of climate modelling in New Hampshire. A projected increase in summer rainfall of 20% could reduce breeding productivity by as much as 26%. Alternatively, increasing temperatures might enhance productivity by increasing the food supply and lengthening the breeding season.

Status

It is likely that extensive deforestation by European settlers significantly decreased habitat for the Black-throated Blue Warbler and reduced its abundance (Curry 2006; Peck and James 1987).

McIlwraith (1894) concluded that it was likely that a few pairs of Black-throated Blue Warblers bred in the southern portion of the province and reported a nest from Listowel. In 1901, it was an abundant summer resident in Muskoka and Parry Sound districts (Mills 1981). Baillie and Harrington (1937) stated that it occurred sparingly in deciduous woods north to Lake of the Woods, southern Thunder Bay District, and the Kapuskasing area. The first atlas demonstrated that its breeding distribution was confined almost entirely to the Great Lakes–St. Lawrence Forest Region, although it occurred in the extreme southern portion of the Boreal Forest Region. It was widespread in the Canadian Shield with a noticeable absence around the Sudbury area which was still largely deforested at that time. It occurred sparingly south of the Shield, most frequently on Manitoulin

Island, the Bruce Peninsula, and the Niagara Escarpment. There were no records in the Carolinian Forest Region or in the southwest south of a line approximately from Goderich to Orangeville. Highest densities were reported from Algonquin Park, the districts of Muskoka and Parry Sound, and Haliburton County (Fraser in Cadman et al. 1987). James (1991) considered the Black-throated Blue Warbler common north to Wawa and Timmins and south to southern Georgian Bay and Ottawa and becoming rare north to Kenora, Red Lake, and Cochrane, and south to York Region and Kingston.

The second atlas revealed that the Black-throated Blue Warbler had extended its range southward since the first atlas. It was much more widespread in the Great Lakes–St. Lawrence Forest Region south of the Shield. It was also present in the Carolinian Forest Region, predominantly in the heavily forested area near Long Point with scattered records at Rondeau, in Hamilton and Niagara Region, and in a few other locations. Its range also extended further north, occurring regularly to latitude 50°N, from about Ear Falls to the Kesagami Lake area in the east. The most northerly record was at latitude 53°N near Weagamow Lake. Its probability of observation increased significantly province-wide and in all 4 regions where it occurred. It was abundant in Algonquin Park, Muskoka and Parry Sound districts, Haliburton County, the Algoma Highlands, and the Temagami–Lake Timiskaming area (Joos in Cadman et al. 2007). Tozer (2012) noted the high density in Algonquin Park where it is one of the most common warblers.

Breeding habitat for the Black-throated Blue Warbler is probably more extensive now in southern Ontario and throughout its range than it was 100-150 years ago. Results of the Breeding Bird Survey (BBS) suggest that it is stable or increasing over most of its range, with the largest increases in eastern Canada in Quebec and New Brunswick (Holmes et al. 2020). BBS results indicate that it increased at an annual rate of 1.06% in Canada and decreased at an annual rate of 0.165% in Ontario 1970-2021. The trends 2011-21 were annual decreases of 2.2% in Canada and 3.35% in Ontario. The long-term trends were highly reliable; the short-term trends were of medium reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Upon fledging, the young remain low in the understorey for 1-2 weeks, usually in the territory but sometimes moving as far as 200-300 m in the first 2 weeks. By 10-14 days after fledging, the young are flying well and actively foraging. Brood division may occur with 1 or 2 young going with each parent. When a second clutch is initiated, the male becomes the main and perhaps sole care provider for the fledglings of the first brood while the female initiates the second clutch. Adults may continue to feed fledglings 33 days after they leave the nest, but the normal period of dependency is 2-3 weeks after fledging. Family groups remain in breeding habitat in July and August, and occasionally into September (Holmes et al. 2020). These observations were made in a large contiguous woodland in New Hampshire. Postfledging habitat use may potentially differ in fragmented landscapes or where there are clear-cuts within forested landscapes.

In Pennsylvania, Stoleson (2013) captured 11 adults and 44 juveniles in clear-cuts during the postfledging period compared with 6 adults and 4 juveniles in adjacent mature forests. Coverage by shrubs was very similar in clear-cuts and forests but clear-cuts were dominated by raspberries and cherry seedlings whereas forests were dominated by beech and red maple seedlings. A significantly higher proportion of juveniles occurred in cuts than forests. In Michigan, it occurs in

dense patches of regenerating aspens, spruce, and red pine plantations with a dense deciduous sapling understorey during the postfledging period (Holmes et al. 2020).

Betts et al. (2008a) broadcast calls and songs during the postfledging period in areas in New Hampshire that did not support breeding Black-throated Blue Warblers. Warblers were seen more frequently at these sites than at control sites that were silent. In the subsequent breeding season, males were 4.1 times more likely to settle in treatment areas than in controls. Late in the season, singing was 5.1 times more likely to occur in territories that successfully fledged young than those that did not. Postbreeding song may be a cue for settling in an area the following year. During the breeding season in Vermont, Cornell and Donovan (2010) found that birds used habitat characteristics rather than conspecifics' songs as cues to settle in territories.

MIGRATION

The Black-throated Blue Warbler is a nocturnal migrant. One bird banded in Sault Ste. Marie was recovered in Cuba (Brewer et al. 2018; Holmes et al. 2020).

Males arrive in spring before females and adult males arrive before juveniles. The mean capture date for males at Prince Edward Point was 17.2 May compared with 22.9 May for females (Francis and Cooke 1986). At Long Point, the mean capture dates for males were: 11.1 May for adults, 14.6 May for juveniles, and 14.6 May for those of undetermined age. There were insufficient data to detect any timing differences in female age classes (Stewart et al. 2002). Elsewhere, males usually arrive 1-3 days before females, but often appear a week earlier (Holmes et al. 1992). The median stopover time for 48 Black-throated Blue Warblers at Long Point was 3.5 days (range 1-18 days). Post-departure flight paths were similar for the sexes and were mostly northward toward Georgian Bay, with some movement into Niagara Region and toward Lake Simcoe (Morbey et al. 2018). In southern and central Ontario, most migrants appear in early to mid-May. Some may arrive in late April and females are seen into early or mid-June (Black and Roy 2010; Curry 2006; Fleming 1907; Keast 1980; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012).

In autumn, no differential timing of migration by the sexes was apparent in Virginia. Migration of juveniles started earlier at the coast than for adults, and migration of all age classes began earlier inland and was well past its peak when numbers peaked at the coast. This suggested that distinct populations migrated through the 2 areas. Juveniles also pass through earlier than adults in Florida (Holmes et al. 2020; Stewart 1986). Most migrants pass through the southern Shield in September, with some arriving in late August; others remain until early October (Mills 1981; Tozer 2012). In the south, most birds arrive in mid- to late August and depart in early October, with some remaining into November or December (Black and Roy 2010; Curry 2006; Fleming 1907; Keast 1980; LaForest 1993; Lancaster et al. 2004).

Covino et al. (2020a) analyzed timing of Black-throated Blue Warbler migration for 1966-2015 from all United States banding stations. During spring, males consistently migrated earlier than females and adults migrated earlier than yearlings. In autumn, there was no difference in timing of migration by the sexes, but juveniles migrated earlier than adults. Early spring migrants passed through 1.1 days earlier per decade and the peak of migration also occurred earlier. In autumn, the peak of migration remained constant but became more protracted.

During migration, the Black-throated Blue Warbler remains mostly in shrubby or forested habitats where it shows a preference for low shrubs in various types of woodlands. Nonetheless, it may be seen almost everywhere that there is suitable shrub or tree cover, including in parks, gardens, orchards, and around human dwellings (Bent 1953; Graber et al. 1983; Holmes et al. 2020; McIlwraith 1894). During spring migration in North Carolina, numbers seen per hour were 0.54 in floodplain forests, 0.27 in beech forests, 0.08 in wet thickets, 0.07 in pine–hardwood forests, 0.03 in oak-hickory forests, and 0 in dry thickets and pine forests (Parnell 1969). In South Carolina, Bowen et al. (2007) examined usage of forest gaps, edges, and forest interior by migrating Black-throated Blue Warblers. Gaps were 0.013, 0.26, and 0.50 ha in area. Gaps were densely vegetated and contained early successional fruiting species such as sumac, blackberry, poison ivy, and hawthorns. In spring, 60% of captures were in gaps, 40% were in edges, and 0% were in forest. The differences in usage of the 3 habitat types were all significant. In autumn, 52% of captures were in gaps, 42% were in edges, and 6% were in forest. There was no significant difference in usage of gaps and edges, but these 2 habitats were used significantly more than forest. On 2 islands in the Gulf of Maine during both migration periods, more Black-throated Blue Warblers were captured on the island with greater tree density, canopy cover, and density of shrubs taller than 3 m (Suomala et al. 2010). During spring migration in Ohio, it was significantly more abundant in mature upland forests than mature riparian forests. Upland forests had significantly lower canopy cover (74% compared with 83%) and significantly more shrub cover (39% compared with 19%; Rodewald and Matthews 2005). During autumn migration, it was equally abundant in all habitats that Rodewald and Brittingham (2002, 2004) studied: shrub-sapling-stage forest, forest interior, pole-stage forest, suburban forest, forest-agricultural edge, and forest edge.

Parnell (1969) studied the foraging behaviour of Black-throated Blue Warblers during spring migration in North Carolina. Foraging occurred 18.7% of the time in the canopy, 72.9% in low trees, 8.5% in low shrubs, and 0% on the ground. In the canopy, 10.2% of foraging occurred in the inner crown and 8.5% in the lower crown; no foraging occurred at the top of the canopy or on the bole. In low trees, 3.4% of foraging occurred at the top of the crown, 32.2% in the inner crown, 37.3% in the lower crown, and 0% on the bole. In shrubs, 1.7% of foraging occurred at the top of the crown, 6.8% in the inner crown, and 0% in the lower crown, dense thickets, brush piles, or grasses. Singing males occurred at heights of 1.5 m to more than 15 m (average 6.7 m). Nonsinging birds occurred at heights of 0-12.8 m (average 5.5 m). Keast (1980) reported atypical foraging behaviour during a grounding at Point Pelee 28-30 April. These birds foraged 25% of the time on tree boles, 25% on exposed ground, 20% on branches, 20% on sapling trunks, 10% on low shrubs, and 0% on outer foliage, bare twigs, sapling twigs and foliage, on the ground in thickets, and in marshes. Foraging occurrence at different heights was 25% on the ground, 10% at 0.6-1.8 m, 0% at 3 m, 30% at 5 m, 20% at 7 m, 15% at 10 m, and 0% at 13 m and higher. During adverse autumn weather in Ohio after most fruit on trees and shrubs had been consumed, a female was observed creeping on a lawn, apparently gleaning tiny arthropods from the undersides of grass leaves and violet leaves (Tramer and Tramer 1977). During autumn migration in New York, Lebbin et al. (2007) observed the Black-throated Blue Warbler foraging at night in trees illuminated by stadium lights. It made aerial sallies after insects and appeared to glean insects from foliage. In Florida, Brooks (1986) reported a migrant plucking insects from spider webs.

During migration, the Black-throated Blue Warbler is still predominantly insectivorous, but consumes some fruit in autumn. During spring migration in Wisconsin, a male drank sugar water from a hummingbird feeder. During autumn migration in Quebec, a female hovered while she drank beech sap from old sapsucker holes. It is also possible that she was consuming insects attracted to the sap. A late November migrant in Michigan fed on suet and peanut butter at a feeder (Brooks 1986; Harrison 1984; Mousley 1917; Niemuth 1997).

The Black-throated Blue Warbler is highly vulnerable to striking buildings, communication towers, and other tall structures during migration. Loss et al. (2014) analyzed bird-building collisions in the United States and determined that it was 45.5 times more likely to strike a building of any type than on average for birds. It was 86.4 times more likely to strike low-rises and 78.5 times more likely to strike high-rises than average. It was not among the top 20 most vulnerable species for striking residences 1-3 stories tall. Weir (2008) reported that 567 were killed at the Lennox generating station chimneys near Kingston. At a Florida lighthouse, Black-throated Blue Warblers struck it more than any other bird species (Bent 1953).

Strode (2003) studied the effects of climate change on the migration of the Black-throated Blue Warbler in Illinois and North Dakota. Over 100 years, there was no significant change in spring temperature in Illinois but spring had advanced an average of 8.6 days in North Dakota since 1961. Spring also advanced north of Illinois. The Black-throated Blue Warbler exhibited no response to changing temperature patterns and now has as many as 20 fewer days to travel between southern Illinois and northern Minnesota. In New York, Zelt et al. (2017) compared spring arrival dates, autumn departure dates, and length of the breeding season during 1888-1939 and 1967-2012. There was little climate change during the first period but significant warming occurred during the second period. The spring arrival date was significantly earlier, the autumn departure date was significantly later, and the breeding season was significantly longer during the second period.

James (1991) considered the Black-throated Blue Warbler a common migrant in Ontario. It declined at a nonsignificant rate of 0.2% per year at Long Point Bird Observatory 1961-88. Trends during other periods were: 1961-70, −1.6%; 1970-79, +4.3%; and 1978-88, −1.1%. Its population trends were similar to those for the budworm specialists, suggesting that it might respond to some degree to changes in budworm numbers (Hussell et al. 1992).

Palm Warbler

Setophaga palmarum

BREEDING SEASON

Habitat Requirements

There are 2 easily recognized subspecies of the Palm Warbler (Pittaway 1995), both of which breed in Ontario. The Western Palm Warbler breeds from northeastern British Columbia east to Moosonee and Kapuskasing. The Yellow Palm Warbler breeds from Mer Bleue and the Alfred Bog in southeastern Ontario east to Newfoundland (Godfrey 1986; Rand 1944). There appear to be no differences in the breeding habitat or behaviour of the subspecies.

Ontario nest were typically in wet areas, particularly spruce or spruce-tamarack bogs, with lesser numbers in spruce swamps and treeless muskeg (Peck and James 1987).

Wilson and McRae (1993) concluded that the Palm Warbler bred throughout the Hudson Bay Lowland, but avoided the coastal strip. In the extensive tamarack fen inland from Moosonee, it was the second-most common breeding warbler. Manning (1952) also reported it near the edge of the Moosonee town clearing.

In the Boreal Forest Region from Pickle Lake north to the Manitoba boundary, the Palm Warbler was most abundant in coniferous scrub, followed by mixed scrub, deciduous scrub, coniferous forest with an understorey, and in heaths. It was absent in deciduous and mixed forest, coniferous

forest without an understorey, and tundra (McLaren and McLaren 1981). Near Pickle Lake, it was uncommon at edges of spruce forests surrounding large bogs as well as in tamarack bogs (James 1980). In the Clay Belt, Welsh and Lougheed (1996) found it only in black spruce forests. These were nutrient-poor wet stands. Also in the Clay Belt, Smith (1957) confirmed it breeding in a tamarack-alder bog. Erskine (1977) considered it characteristic of more open spruce bogs and observed that it was one of few species that was nearly confined to boreal coniferous forests during the breeding season. It occurred predominantly in bogs and fens and other sites with young or low spruce. It rarely occurred in mature spruce stands. North of Upsala, Harris (1990) found evidence of the Palm Warbler nesting in upland cutovers regenerating with jack pine. The area was on fine sandy soil and had been cut 9 years previously. The clear-cuts often exceeded 100 ha and were interspersed within stands of 60-80-year-old jack pines. Trees within territories averaged 3 m in height (range 2-5 m) and were mostly spaced such that one could walk between them without touching the branches. The ground cover consisted of red-stemmed feather moss, haircup mosses, and reindeer lichen with frequent patches of bare sandy soil. Logging slash was present at most occupied sites. The most abundant non-woody plants included bunchberry, bristly sarsaparilla, and Canada bluejoint. The shrub layer was predominantly ericaceous, being comprised of Labrador tea, velvetleaf blueberry, and lowbush blueberry, but beaked willow, pin cherry, and prickly rose were also present. In northwestern Ontario, this warbler appears to select nesting habitat on the basis of vegetation structure rather than species composition. Young jack pine stands were structurally similar in many respects to open bogs since both habitats consist of small conifers with open areas of ericaceous shrub cover. It probably traditionally nested in young jack pines that regenerated after fire in northwestern Ontario.

Near Gogama in the Great Lakes–St. Lawrence Forest Region in the Canadian Shield, the Palm Warbler was detected once during the breeding season in a 20-year-old jack pine stand (James and Peck 1995a). South of the Shield in this forest region, it is confined to large bogs and fens. Mer Bleue is approximately 3,500 ha in area and supports 10-20 pairs and the Alfred Bog is approximately 4,200 ha and supports more than 100 pairs (Leckie 2011).

Both subspecies of the Palm Warbler nest in 3 distinct habitats, although the structure of these habitats may be similar. It most frequently nests in bogs, fens, and peatlands with scattered trees and a dense shrub layer of predominantly ericaceous shrubs. Much less frequently, it nests in young jack pine stands with well-spaced trees and patches of bare soil intermingled among ericaceous shrubs. It rarely nests in coniferous plantations.

In bogs, fens, and other peatlands, the Palm Warbler appears to be restricted to large patches of suitable habitat. Although not all authors reported the size of the habitat patches they found it in, the smallest reported occupied area was 146 ha. This bog was part of a larger wetland complex that totalled 344 ha. Its distribution outside the Hudson Bay Lowland and Boreal Forest Region is dictated by the distribution of large bogs and fens (Ibarzabal and Morrier in Gauthier and Aubry 1996; Peterson 1984; Wilson 2020).

In bogs and fens, the Palm Warbler is predominantly an edge species, nesting near the interface between the surrounding coniferous forest and the bog or fen. It tends to avoid areas with no or dense trees. Areas with scattered conifers in sphagnum moss provide ideal habitat. It appears to require the presence of shrubs, particularly those in the heath family. Shrub species that are frequently within territories include Labrador tea, leatherleaf, swamp laurel, bog laurel, sheep laurel, bog rosemary, rhododendrons, bog cranberry, and blueberries. Other shrubs that may be present in lower densities include wild raisin, swamp birch, and alders. Preferred areas have dense coverage of shrubs 1-2 m tall. Sphagnum moss or occasionally other moss species are typical ground cover in these types of habitat. Other common ground species may include pitcher plant, cottongrass, common juniper, bogbean, orchids, and a variety of sedge species. Highest densities in Maine peatlands occurred in areas with a ground cover of sphagnum moss, a well-developed ericaceous shrub layer, and 25-50% forest cover by black spruce, tamarack, and white pine. In most areas, black spruce or tamarack are the dominant tree species, but it also inhabits fens with white cedar. Territories require trees of varying heights. Males sing from treetops about 6 m high from the beginning of the breeding season until nestlings are present, when low shrubs are used as singing perches. In Nova Scotia bog habitat, tamarack was the preferred perch tree, possibly because they were the tallest trees available and did not have any foliage early in the season so that singing males were more conspicuous. Presence of small seedlings is important because almost all nests in peatlands are hidden under seedlings. In addition to bogs and fens, the Palm Warbler nests in coniferous forests and burned peatlands. Suitable coniferous forests are open stands of black spruce or tamarack with a ground cover of sphagnum or other mosses, dense shrub coverage, and occasionally reindeer lichen. It prefers open areas with scattered trees or isolated clumps of dwarf trees. These stands include creeping ericaceous shrubs and occasionally loose growths of alder, dwarf willow, or birch. Trailing arbutus and sweet fern may be common shrubs. In British Columbia, spruce snags and spruce with dead tops were frequent features in nesting habitat. In extensively forested areas, it nested along road rights-of-way and oil exploration cut-lines that created open habitat. In Minnesota, the Palm Warbler was significantly more abundant in closed than open spruce stands. In closed stands, overall vegetation height was significantly higher (6.6 m compared with 5.5 m), and tree density per 0.1 ha was significantly higher (45 compared with 23). In Quebec, it occasionally nests in intolerant hardwood stands. Forest stands used for nesting are typically wet and nutrient poor (Bent 1953; Campbell et al. 2001; Collins 1981; Dawson 1979; Desrochers et al. 1998; Harrison 1984; Ibarzabal and Morrier in Gauthier and Aubry 1996; Jehl 2004; Kirk et al. 1996; Knight 1904; Niemi and Hanowski 1984b; Peterson 1984; Rand 1944; Tyler in Bent 1953; Walkinshaw and Wolf 1957; Welsh 1971; Wilson 2020). In Minnesota, the Palm Warbler was positively associated with non-productive black spruce–tamarack stands (Zlonis et al. 2017).

The second habitat used for nesting by the Palm Warbler consists of young pine stands on nutrient-poor sandy soils. In this habitat in Michigan, it is found in the same areas inhabited by the Kirtland's Warbler. Walkinshaw and Wolf (1957) described the occupied habitat as low-statured jack pines with alternating clearings and dense stands. The ground cover consisted of grasses and shrub coverage by bearberry, blueberries, wintergreen, trailing arbutus, and sweet fern. All nests were in semiopen areas where jack pines or spruces were not very dense. In New Brunswick, the Palm Warbler nested on dry sandy ridges vegetated by groves of small pines and scattered spruce seedlings (Philipp and Bowdish 1917). Rand (1944) reported that it nested in young open spruce stands. Wilson (2020) considered a report of this warbler nesting in sandy plains on the north shore of the Gulf of St. Lawrence to be exceptional. In Maine, Knight (1904) reported it nesting in shrubby pastures, but this is the only report of this habitat being used. The dry sandy habitats used by the Palm Warbler in Michigan, New Brunswick, and Quebec are very similar to the habitat described in northwestern Ontario by Harris (1990).

Coniferous plantations are the final habitat used by breeding Palm Warblers. Mossman et al. (1991) stated that it was a rare breeder in Wisconsin coniferous plantations. In New Brunswick, Freedman and Johnson (1999) reported it breeding in high density in spruce plantations 7-21 years old, with peak populations in 13-15-year-old plantations. No other details were provided in these studies. It is possible that the plantations that were used were on sandy soil and had a similar structure to the other dry habitats that it has been documented breeding in. It is also possible that some of the jack pine stands used in Michigan were plantations.

Most Ontario nests were on the ground, predominantly in hummocks of sphagnum moss (63.6% of nests). Single nests of a total of 11 were in sedge hummocks, in lichens, in the shelf of a root of a fallen tree, and elevated 0.9 m from the ground. Nests were frequently near or at bases of small trees or shrubs; 1 was under a fallen branch (Peck and James 1987, 1998a).

Birds nesting in bogs, fens, and open swamps usually sink their nest into the moss. Most are at the base of a small spruce seedling or other small woody vegetation and are well concealed from above. Occasionally nests are in hummocks of moss with no overhead cover. In a Nova Scotia bog, 6 of 7 nests were less than 30 cm from the ground on outside edges of hummocks of common juniper. The other was 30 cm from the ground in a clump of ferns. In dry habitats, nests may either be on the ground or as high as 35 cm from the ground in small conifers or occasionally in low hanging branches of a larger tree. There is 1 report of a nest 1.2 m from the ground (Knight 1904; Peterson 1984; Philipp and Bowdish 1917; Tyler in Bent 1953; Walkinshaw and Wolf 1957; Welsh 1971; Wilson 2020).

Although some authors stated that the Palm Warbler occurs in loosely aggregated colonies, most territories are widely scattered. There is no evidence of true colonial nesting. Males establish territories as soon as they arrive and maintain them until the nestlings fledge. All activities appear to be conducted within the territory. In Nova Scotia, territorial boundaries were established along natural edges such as rows of well-developed trees or a forest edge. In all areas, the territory could have been expanded into unoccupied areas, so territory size was determined by individual males. All territories of successful males contained a significant portion of open bog, but no completely open areas were selected for a territory. Of 3 males that did not breed, 2 had territories in almost

completely wooded areas and a significant proportion of the other territory was wooded. This suggested that wooded areas were inferior habitat. Territories in a Nova Scotia bog averaged 2.50 ha (range 1.02-3.26 ha). The largest territory was held by a bigamist male and it was different from other territories in that it had no neighbours and contained a swamp and a pond. Some unmated males held territories. Territory sizes of monogamously mated males were 1.12-2.62 ha. Some Nova Scotia territories had extensions in spring as large as 1.17 ha that were not always defended. Maine territories averaged 4.0 ha; territories in 1 Quebec area averaged 3.8 ha (range 0.7-13.7 ha). Territories in peatlands with scattered black spruce in the Lac-St.-Jean region were 1.3, 3.4, 3.6, and 13.2 ha (average 5.38 ha; Harrison 1984; Ibarzabal and Morrier in Gauthier and Aubry 1996; Knight 1908; Walkinshaw and Wolf 1957; Welsh 1971; Wilson 2020).

No information is available on natal philopatry. The only information on adult site fidelity is that 1 of 2 males in Maine returned the following year to the same territory. It did not maintain the territory (Wilson 2020).

Limiting Factors

Eggs have been reported in Ontario nests from the last week of May until the first week of July, with most present during the last 3 weeks of June (Peck and James 1998a).

It is unknown how long nest building takes. One apparently complete nest had an egg in it 2 days later. The incubation period is 11 days and the nestling period is 9-12 days, mostly 10 days (Bent 1953; Knight 1904; Peterson 1984; Welsh 1971; Wilson 2020).

Although some studies concluded that the Palm Warbler raises only a single brood, double brooding has been confirmed in Quebec and there is anecdotal information that suggests second broods may be fairly common. Most birds in a Nova Scotia bog had single clutches. Two cases of attempted second broods occurred, but both failed due to predation. Egg dates in Maine are suggestive of second clutches, with nests being constructed in early May and again in mid-June. One researcher had reason to believe that it frequently, if not regularly, raised 2 broods in Nova Scotia. Renesting may occur if the first clutch is lost. All Ontario nests contained either 4 or 5 eggs, mostly 4 (average 4.38 eggs). The clutch size is almost always 4 or 5 eggs. Of 61 Nova Scotia nests, 59% contained 5 eggs and 41% contained 4 eggs for an average of 4.59 eggs (Bent 1953; Harrison 1984; Ibarzabal and Morrier in Gauthier and Aubry 1996; Peck and James 1998a; Tyler in Bent 1953; Welsh 1971; Wilson 2020).

The age at first breeding is unknown, but is probably 1 year. In Nova Scotia, 3 of 10 males did not appear to breed and their territories were in inferior habitat. It is possible that these were nonbreeding yearlings. The Palm Warbler is typically monogamous but 2 cases of bigamy have been reported (Welsh 1971; Wilson 2020).

The Palm Warbler is the most terrestrial member of its genus, feeding on the ground, from scattered trees and shrubs in the territory, and in the air with flycatching sallies either from the ground or a low perch. It mostly gleans prey from leaves and cones but captures some prey on the ground and some by hawking. In a black spruce bog in Minnesota, it fed at an average height of 4.1 m; average tree height was 6.2 m. It also opportunistically captures arthropods feeding on carrion (Knight 1908; Wilson 2020).

The Palm Warbler is largely insectivorous, with the most important prey items including mayflies, beetles, lepidopterans, flies, soft-winged bugs, and hymenopterans. It also eats gnats, mosquitoes, ants, aphids, and grasshoppers. In late summer and autumn, it may eat small amounts of vegetable matter such as small seeds and raspberries. It may also consume plant nectar (Bent 1953; Knight 1908; Tyler in Bent 1953; Welsh 1971; Wilson 2020).

The Palm Warbler is rarely parasitized by the Brown-headed Cowbird. No instances of parasitism have been documented in Ontario. Knight (1908) reported a Maine nest containing 2 warblers and 2 cowbirds but the fate of the young warblers was not determined. Wilson (2020) reported that there were only 4 known cases of parasitism: 2 in Maine and 2 in Alberta. Harrison (1984) stated that 7 cases of parasitism were known, but provided no further details.

Habitat loss is a concern south of the Canadian Shield. The Palm Warbler is restricted to large bogs and fens in this region. These are often converted to agricultural uses or mined for peat. These habitats are very sensitive to changes in the quality and quantity of water that they receive. Minor changes in these parameters can greatly affect bogs and fens. They may become either flooded and marsh-like, or increased nutrient inputs may result in the habitat being converted to thicket swamp, habitat that is unsuitable for the Palm Warbler. Approximately two thirds of the Alfred Bog has already been drained and converted into farmlands (Leckie 2011). Degradation of peatlands due to peat mining has been identified as a significant concern for the Palm Warbler in southern Quebec (Ibarzabal and Morrier in Gauthier and Aubry 1996). Desrochers et al. (1998) compared vegetation and density of warblers in natural peatlands and those where peat had been harvested using 2 different methods. Block-cuts consist of alternating 2-m-wide ridges and trenches 6-15 m wide. Vacuum sites are split into 30-m-wide fields separated by drainage ditches. Most abandoned sites had a 2-3-m-deep layer of peat left unmined. There were significant differences between harvested and natural sites and differences in ericaceous shrubs and sphagnum moss persisted at least 20 years postharvest. Post–block-cuts had very little sphagnum and much bare ground compared with natural sites, but were otherwise similar. Post-vacuum sites had significantly less cover in all strata except for herbaceous vegetation. The Palm Warbler showed a significant response to peat harvesting, with numbers detected per point count of 0.61 in undisturbed peatland, 0.11 in post–block-cut, and 0 in post-vacuum. Block-mining is no longer used and the industry has turned to vacuum harvesting. An artificial nesting study in southern Quebec determined that nest predation rates were 12% in undisturbed peatlands and 78% in natural peatlands adjacent to areas where peat was being harvested. Calmé et al. (1998) concluded that it was important to conserve large patches of peatlands to maintain habitat for the Palm Warbler in southern Quebec.

In Alberta, the Palm Warbler was significantly less abundant at seismic lines and pipelines than in forest interior adjacent to these features. There was no difference in its abundance at well pads and in adjacent forest interior (Bayne et al. 2016).

In Maine, the Palm Warbler decreased 50-67% on sites where paper mill sludge was spread. The sludge contained low concentrations of dioxin derivatives (Wilson 2020).

Forest management has the potential to provide short-term benefits for the Palm Warbler. Suitable habitat may be created where none previously existed if forests are clear-cut. To provide any potential habitat, clear-cuts must be large (100 ha minimum), have regeneration by jack pine,

and be situated on dry, nutrient-poor sandy soils. In Ontario in the Canadian Shield, there was no difference in its abundance in early and mid-successional clear-cuts and stands of the same age after fire. It was significantly more abundant in early and mid-successional stands than in mature forests (Zimmerling et al. 2017).

Status

The first Ontario Palm Warbler nest was found in Mer Bleue in 1901. Baillie and Harrington (1937) had only 1 additional breeding record from an island in Lake of the Woods. During summer at that time, it had also been observed at the southern end of James Bay, in Algoma District, and near Sault Ste. Marie. They concluded that it might be a rare breeder in various areas of northern Ontario. The first atlas confirmed that the Palm Warbler nested throughout the Boreal Forest Region and Hudson Bay Lowland, although its distribution was spotty. It was likely overlooked in some areas due to difficulty in accessing its habitat. There were very few records in the Great Lakes–St. Lawrence Forest Region and the Canadian Shield and only 2 south of the Shield, reflecting the rarity of suitable habitat in these areas (Welsh in Cadman et al. 1987). James (1991) considered the Palm Warbler an uncommon summer resident in the Hudson Bay Lowland; becoming rare south to northern Lake Superior; and occasional and rare south of Wawa and Timmins south to the Bruce Peninsula and Ottawa.

The second atlas showed the same general distribution for the Palm Warbler, but it was found in many new squares and blocks in the north with the distribution appearing less spotty. Some of the apparent infilling of the distribution map may be attributed to greater atlasser effort to survey open peatlands distant from roads and densely treed river corridors. Its probability of observation increased significantly between the atlases province-wide and in the Boreal Forest Region and Hudson Bay Lowland. In the Great Lakes–St. Lawrence Forest Region, it occurred only in the area from Thunder Bay west to Lake of the Woods and in the Ottawa area. Its probability of observation was 75.5% in the Hudson Bay Lowland where it is one of the more common species. Its probability of observation was 40% in the Boreal Forest Region, reflecting the lower amount of peatlands in this region. It was estimated that Mer Bleue supported 10-20 pairs and that more than 100 pairs bred in the Alfred Bog (Sutherland in Cadman et al. 2007).

Breeding Bird Survey data indicate that the Palm Warbler decreased at an annual rate of 1.01% in Canada and increased at an annual rate of 2.82% in Ontario 1970-2021. Trends for 2011-21 were annual increases of 0.213% in Canada and 3.32% in Ontario. All results were of medium reliability except that the short-term trend for Ontario was of low reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

In Michigan, brood division appeared to occur, with each adult caring for 2 fledglings exclusively. The first morning after young left the nest, they ranged 1.9-47.5 m from the nest, all separated but in the same general area. Three fledglings hid among leatherleaf and dead grasses; the fourth perched on a jack pine branch 30 cm from the ground (Walkinshaw and Wolf 1957). In Nova Scotia, fledglings from 1 nest strayed from the territory and the male followed to feed them, not defending his territory again (Welsh 1971). Adults have been reported feeding young as late as the end of August, but these may have been from a replacement or second brood.

Manning (1952) collected some juveniles at the edge of willow thickets on Ship Sands Island near Moosonee in early September. This suggests that juveniles may flock together prior to autumn migration. It is possible that these birds were migrants but southward movement was not noted until 9 days later.

Bent (1953) reported that families roosted every night in conifers near the nest for weeks after the young were able to fly.

MIGRATION

The Palm Warbler is a medium-distance nocturnal migrant. Because of the routes that the subspecies follow, the Western Palm Warbler is the subspecies that is typically observed in Ontario and few Yellow Palm Warblers are encountered. At the end of the 19th century in Hamilton, opposite trends were noted. There were no records of the Western Palm Warbler and the Yellow Palm Warbler was an occasional migrant that was apparently absent some years. In Hamilton, the Western Palm Warbler is now a common migrant; the Yellow Palm Warbler is rare. During the day while migrating, the Palm Warbler often occurs in small flocks, typically 10 or fewer but occasionally as many as 200 have been documented together. It is an early spring migrant, so it commonly flocks with other early migrants and resident species such as chickadees, Yellow-rumped Warblers, Golden-crowned and Ruby-crowned kinglets, juncos, and various sparrow species. In autumn, it flocks mostly with chickadees and other warblers (Bent 1953; Campbell et al. 2001; Curry 2006; Knight 1904; Leckie 2011; Leighton et al. 2002; McIlwraith 1894; Pittaway 1995; Tyler in Bent 1953; Wilson 2020; Wilson and Watts 1997).

The Yellow Palm Warbler initiates spring migration before the Western Palm Warbler (Wilson and Watts 1997). It is probable that males migrate before females, but this has not been confirmed. In southern Ontario, the Palm Warbler typically arrives in early May or late April and has departed by the third week of May. Migrants may be present from mid-April until early June (Black and Roy 2010; Curry 2006; Fleming 1907; LaForest 1993; Lancaster et al. 2004; Weir 2012). In the southern Shield, average arrival is early May, average departure is mid-May, and migrants may occur from late April to early June (Mills 1981; Tozer 2012). Kendeigh (1947) first observed this warbler north of Lake Nipigon on 26 May.

The western subspecies initiates autumn migration prior to the yellow subspecies, possibly because of its more southern wintering areas. In Virginia, the median date of autumn migration was 10.5 days earlier for the western subspecies than the yellow subspecies. All age classes moved south at the same time for both subspecies (Wilson and Watts 1997). In autumn, the length of stay at sites is weather dependent, with birds moving south rapidly before a severe or sudden cold wave (Wilson 2020). At a reclaimed landfill in New Jersey, the mean length of autumn stopover was 4.8 days, with a maximum of 14 days (Seewagen and Newhouse 2018). Manning (1952) noted a significant southward migration at Moosonee on 18 September. In the southern Shield, average autumn arrival is late August or early September and the average departure is early to mid-October (Mills 1981; Tozer 2012). In the south, most birds arrive in early to mid-September and leave in mid- to late October, with stragglers remaining into December (Black and Roy 2010; Curry 2006; Fleming 1907; LaForest 1993; Lancaster et al. 2004; Weir 2008).

During migration, the Palm Warbler is usually found in low vegetation and even on the ground. In spring, it is often in the company of the Yellow-rumped Warbler, but is less inclined to use upland forests. In the Kingston area, the Palm Warbler is especially common at shoreline sites and on islands. In Algonquin Park during spring migration, it is usually found low in brushy clearings, bogs, and forest edges. It has a broad tolerance in its habitat use during migration, but favours alder and willow thickets in riparian areas and early successional shrubby areas or those dominated by early successional trees such as birches. It may occur in shrubby roadsides and pastures and even in cultivated fields at significant densities. In British Columbia, vegetated spits, causeways, dykes, parks, golf courses, and beaches are typical habitat. It also occurs in suburban gardens and rural residential lots. Because it is an early migrant, the ground may still be frozen when it reaches the breeding grounds. During a brief but heavy spring snowstorm, hundreds congregated on a narrow strip of bare pebbly beach at the water's edge. During spring migration in Ohio, the Palm Warbler was significantly more abundant in mature upland forests than in mature riparian forest. Upland forests had significantly less canopy cover (74% compared with 83%) and significantly more shrub cover (39% compared with 19%; Bent 1953; Campbell et al. 2001; Chapman 1907; Faanes and Andrew 1983; Graber et al. 1983; Knight 1904; Leighton et al. 2002; Rodewald and Matthews 2005; Tozer 2012; Tyler in Bent 1953; Weir 2008; Wilson 2020).

During autumn migration at Prince Edward Point, the Palm Warbler foraged at heights of 3-10 m. Thirty-three percent of foraging time was spent on outer leaves, 33% on sapling foliage, and 34% on sapling branches. No foraging occurred on twigs and inner leaves, outer or inner branches, trunks, low shrubs, or the ground (Keast 1980). During spring migration in North Carolina, 36% of foraging occurred in the canopy, 18.2% in low trees, 0% in shrubs, and 45.5% on the ground. In the canopy, 9.1% of foraging occurred in the top of the crown, 9.1% in the inner crown, 18.2% in the lower crown, and 0% on the bole. In low trees, 13.7% of foraging occurred in the top of the crown, 32.3% in the lower crown, and 0% in the middle crown and on the bole. On the ground, 9.1% of foraging occurred in grasses, 16.9% in the open, and 0% in dense thickets and at water's edge (Parnell 1969). During spring migration, it forages in the most likely locations for the early development of insects such as sunny sheltered shores of ponds and streams, old orchards on hillsides, and near water. In Pennsylvania, it fed exclusively on the ground during early spring migration, but fed exclusively in trees in May after trees began to bud and flower. During spring migration in Quebec, it captured larvae from fresh buds of tamarack and on snags (Wilson 2020). During exceptionally inclement spring weather, Palm Warblers fed in scattered groups with other species of warblers on the ice of Lake Manitoba. Beetles, midges, other flies, and spiders were on the ice at that time (McNicholl and Goossen 1980). During autumn migration in New York, Lebbin et al. (2011) observed Palm Warblers searching for food at night among the foliage of trees illuminated by lights from a football stadium. Graber and Graber (1983) studied the foraging behaviour of the Palm Warbler during spring migration in Illinois. It fed preferentially on shingle oaks and hickories and used other trees less than their availability. The amount of food obtained from various tree species included 45.2% from shingle oak, 5.1% from other oaks, 44.7% from hickories (predominantly pignut hickory), 5.0% from sassafras, and 0.6% from black cherry. Shingle oak accounted for 13.9% of available trees compared with 7.0% for other oaks, 3.1% for hickories, 27.5% for sassafras, 5.9% for black cherry, and 1.8% for flowering dogwood. The percent time spent in each tree species was

29.3% for shingle oak, 10.7% for other oaks, 31.0% for hickories, 26.7% for sassafras, 0.7% for black cherry, and 1.7% for flowering dogwood. Several available tree and shrub species were not used for foraging, including honey locust, hackberry, elm, white ash, redbud, maples, sumac, multiflora rose, grape, sycamore, red cedar, hophornbeam, black gum, and Japanese honeysuckle. Where food was abundant, it foraged branch-to-branch. Where food was scarce, it foraged tree-to-tree. Where food was abundant, it tended to forage leisurely all day and remain in the area for approximately 3 days. Where food was scarce, it foraged only in the morning until 1000 hours and after 1600 hours and apparently migrated that night. Caterpillars were the dominant prey available and all caterpillars that it consumed were hairless. It selected either smaller-sized larvae (less than 15 mm) or small species (especially leafrollers) out of proportion to their availability. Leafroller moths constituted 19% of available prey but comprised 57% of prey taken by all warbler species. Linden looper moths constituted 49% of available prey and 42% of the diet of warblers in the same genus as the Palm Warbler. Geometer moth caterpillars constituted 65% of available prey and 62% of the diet of warblers in this group.

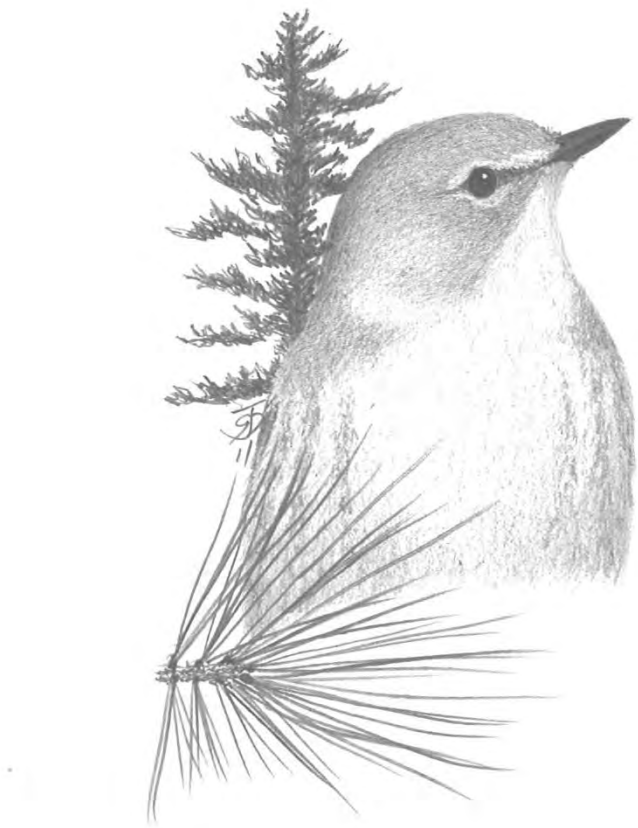
The Palm Warbler is often killed at television towers and other tall structures during migration. At 1 tower in Florida over a 25-year period, 1,827 were killed in autumn and 478 in spring, which represented 5.4% of all birds. It represented 6.6% of all birds killed at another Florida tower, 9% at a Florida power plant, 0.27% at Cape Canaveral, 9.1% at a tower in Illinois, and 1.4% at 9 other towers in Illinois (Graber et al. 1983; Leighton et al. 2002; Wilson 2020).

Strode (2003) studied the effects of climate change on the migration of the Palm Warbler in Illinois and North Dakota. Over 100 years, there was no significant spring temperature change in Illinois but spring had advanced by an average of 8.6 days in North Dakota since 1961. Spring also advanced north of Illinois. The Palm Warbler exhibited no response to changing temperature patterns and now has as many as 20 fewer days to travel between southern Illinois and northern Minnesota.

James (1991) considered the Palm Warbler a common migrant in Ontario. Most regional assessments concur with this, although Lancaster et al. (2004) considered it an uncommon migrant in Elgin County. It decreased at Long Point Bird Observatory at a nonsignificant rate of 1.5% per year 1961-88. Trends by period were: 1961-70, −6.6%; 1970-79, −1.0%; and 1979-88, +8.4%. The trends observed did not mirror those of the spruce budworm specialists (Hussell et al. 1992). At the Manomet Bird Observatory in Massachusetts, a significant decrease of 76% occurred in autumn for the Western Palm Warbler 1970-2001, but there was a significant increase of 26% in spring for the Yellow Palm Warbler (Wilson 2020).

Pine Warbler

Setophaga pinus

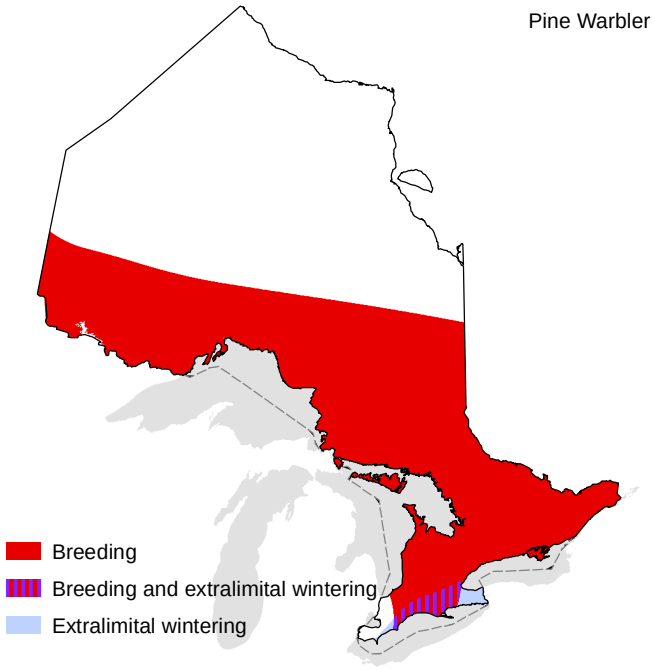


BREEDING SEASON

Habitat Requirements

Ontario Pine Warbler nests were usually in or at edges of open coniferous woods (8 of 14 nests, 57.1%) and 3 nests were in unspecified types of woodlands. Single nests were reported in each of an island with a few large pines, a mixed stand, and a lone tree in a village garden (Peck and James 1987). In Wellington County, 10 nests were in a mature coniferous woodland that was predominantly pine with some spruce (Peck and James 1998a). James (1984b) concluded that it occurred only in mature white pine or red pine forests and that these were typically somewhat open. It also nests in pitch pine stands in Ontario (Erskine 1977). Baillie and Harrington (1937) had a record of it nesting in a park in Simcoe.

In the Great Lakes–St. Lawrence Forest Region in the Canadian Shield, the Pine Warbler is associated predominantly with red pine and white pine stands. It has nested in jack pine stands elsewhere, but was not reported in these types of stands near Gogama or Parry Sound (James 1979a;



James and Peck 1995a). In Algonquin Park, it was mainly associated with white pine stands 80-100 years old and 25-30 m tall. It also occurred in stands that had been cut 2-9 or 10-16 years previously (Kingsley and Nol 1999). Tozer (2012) concluded that it was a common breeder in the park wherever there was adequate cover with large pines present. Kirk et al. (2012) reported that it occurred in mature and old-growth white pine stands in central Ontario. It was more abundant in old-growth stands, but not significantly. Presence of medium-sized to large pines with a diameter at breast height (DBH) of more than 40 cm was a significant predictor of its presence. The density of supercanopy white pine was the most important variable in predicting its abundance, and stand age according to Forest Resource Inventory maps was equally important. It was locally distributed in white pine and red pine stands in Parry Sound and Muskoka districts (Mills 1981).

South of the Canadian Shield, the Pine Warbler occurs predominantly in white and red pine plantations that are a minimum of 40-50 cm DBH (Lancaster et al. 2004; Speirs and Orenstein 1975). It also occurs in mixed and even deciduous stands in the south, provided that some mature white pines are present.

No bird is more characteristic of pine forests than the Pine Warbler. It is essentially confined to pine or pine-hardwood stands and is rare in other stand types. It frequently inhabits sugar maple–white pine and pine-oak stands. Occasionally, it occurs in pure hardwood stands, but even these typically have a few pines in them that it focuses on. In predominantly deciduous stands, it invariably moves from 1 pine to another, ignoring the deciduous trees between them. As little as 10% pine coverage may attract it to deciduous stands. It responds directly to pine foliage and its abundance increases with the abundance of pines. It avoids stands containing spruce, balsam fir, tamarack, or hemlock unless pines are common. The Pine Warbler has used 15 species of pines. In the northeastern United States, it shuns white pine stands and highly selects pitch pine stands. In Ontario, white pines are preferred. In the western portion of its range in the United States, it prefers jack pine stands. In Quebec, its distribution coincides with that of pines where it nests predominantly in white pine stands. It is chiefly an upland species that rarely occurs in wetlands, possibly due to the scarcity of pines in swamps. It readily nests in pine plantations. These typically must be 40-50 years old to provide suitable habitat, but plantations as young as 3-5 years may support sparse populations. In both natural forests and plantations, it prefers stands where woody and herbaceous understorey is sparse. These conditions usually do not occur until trees form a closed canopy. In Texas, it favoured mature pine stands and demonstrated a strong positive association with

increasing proportions of pole-sized pines and canopy height. It avoided sapling-sized stands. It was absent where the average tree height was 13.5 m or less and reached highest densities in stands 18.9-26.2 m tall. In Arkansas, numbers recorded on point counts were 0.015 in 3-5-year-old plantations, 0.163 in 12-15-year-old plantations, 0.661 in stands that were thinned 17-23 years previously, and 0.870 in mature pine forests. Higher breeding densities occurred in forests with a more open midcanopy, lower canopy coverage, lower basal area of conifers and hardwoods, and a dense ground cover of grasses and forbs. In regenerating pine-oak forests in Virginia, it was found in increasing abundance in stands older than 10 years and was most abundant in stands older than 80 years. In mixed hemlock–white pine–hardwood stands in Pennsylvania, the Pine Warbler occurred in 36.4% of old-growth stands, 6.0% of stands statewide, and 5.7% of stands in the Appalachian Plateau. It was considered to have old-growth affinities (Beals 1960; Bent 1953; Bielefeldt and Rosenfield 1994; Brooks 1940; Brush 1987; Capen 1979; Chapman 1907; Graber et al. 1983; Haney 1999; Harrison 1984; Morse 1989; Mossman et al. 1991; Rich et al. 1994; Rodewald et al. 2020; Schroeder 1985; Spencer and Cotter in Gauthier and Aubry 1999; Temple et al. 1979; Yahner 1993).

Several studies examined microhabitat preferences of the Pine Warbler. In Minnesota, average habitat characteristics included 64.0% ground cover, 44.3% shrub cover, 75.7% canopy cover, 22.0 m canopy height, 66.7% coniferous cover, 4.9 tree species per 0.04-ha, 8.4 trees 7.5-15 cm DBH, 8.3 trees 15.1-23 cm DBH, 4.1 trees 23.1-30 cm DBH, 4.1 trees 30.1-38 cm DBH, 5.7 trees 38.1-53 cm DBH, 2.0 trees 53.1-68 cm DBH, and 1.1 trees larger than 68 cm DBH. It was in a guild of warblers that occupied habitats with tall canopies, moderate coniferous cover, few small trees, and more large trees. Species in this guild occur mainly in mature undisturbed forests containing conifers. Territories of most of these species had moderate ground and shrub coverage and greater than 75% canopy closure. They also consistently supported more than 50% coverage by conifers, mostly in the large tree classes. The Pine Warbler occurred regularly in red pine, white pine, and jack pine stands and was associated with large trees and large conifers more than any other species. The average canopy closure for the Pine Warbler was the least for warblers in this group. It occurred in habitats with variable amounts of pine. The other species in this guild had at least some spruce and balsam fir in their territories (Collins 1983a; Collins et al. 1982). In Maryland, it was positively correlated with the abundance of pines and shrub density and negatively correlated with canopy closure. In the mid-Atlantic states, it was positively correlated with canopy height, percent coverage by pines, the number of trees larger than 3 cm DBH, and foliage density 0.3-1.0 m from the ground. It was negatively correlated with slope, moisture, percent ground cover, and number of trees per 0.04 ha (Robbins et al. 1989). It was closely associated with pines and its probability of occurrence reflected the proportion and distribution of this forest type (Lynch 1987). In Tennessee, it selected for several habitat variables. The strongest of these were related to the number of canopy trees, the average size of the understorey vegetation, and the average size of canopy vegetation. It foraged in the upper canopy and frequented areas with a dense canopy and sparse understorey (Anderson and Shugart 1974). In Texas, the Pine Warbler was associated with mature pine forests. It was positively correlated with vegetation height and percent coverage by pines 17-32 cm DBH. It was negatively correlated with foliage density 3 m from the ground, percent coverage by pines 5-16 cm DBH, and the total number of stems 5-16 cm DBH (Conner et al. 1983).

Schroeder (1985) prepared a habitat suitability index model for the Pine Warbler. Its density in pine forests was inversely related to the percent coverage by deciduous species in the canopy. Forests with 30-80% deciduous cover in the upper third layer of dominant pines were considered to have very low suitability, and areas with more than 80% deciduous cover in the canopy were deemed unsuitable. Despite this, it is often found in stands with even greater deciduous cover. Optimal cover was considered pure, dense, mature pine stands (excluding white pine and some other pine species that this author thought were unsuitable) lacking a tall deciduous understorey. The habitat suitability for percent canopy closure by pines was 0 (completely unsuitable) for 25% or less closure, with a slow increase to 0.1 at 50% closure, and a sharp increase to 1.0 (optimum) at 90% and 100%. For average tree height, habitat suitability was 0 for trees 7 m tall and shorter with a straight-line increase to 1.0 at 20 m height. It was considered most abundant in stands 35-100 years old.

The Pine Warbler is often considered a forest-interior species, although most studies present no supporting documentation (Freemark and Collins 1992; Rodewald et al. 2020). A Florida study concluded that it was an edge species, with higher densities near edge than in forest interior (Rodewald et al. 2020). In southern Ontario, Austen et al. (2001) classified it as an interior species. It was positively associated with the amount of forest cover 100 m or further from forest edge, and this correlation was significant at the 10% level. This correlation does not necessarily mean that the Pine Warbler avoided edge. Peck and James (1987) reported that nests were often at edges of woods and 1 nest was in a lone pine tree. Near Brantford, Pine Warblers nested in a small grove of mature pines that were originally part of a larger deciduous forest. Many of the hardwoods had been clear-cut such that the pines were about 15-20 m from the main forest (personal observation). It is most likely that this warbler simply selects nest sites wherever there are large pines and that it does not actively pick edge or interior areas.

Most authors consider the Pine Warbler an area-sensitive species (Rodewald et al. 2020), but there are few data to support or reject this hypothesis. Freemark and Collins (1992) noted that some studies concluded that it was area sensitive and others reported the opposite. James (1984b) stated that it appeared to be area sensitive in Ontario, requiring at least 15-30 ha to sustain a viable population. In central Ontario, Kirk et al. (2012) found that patch size was not a significant predictor of its presence or abundance. In southern Ontario, it was significantly correlated with woodlot size and the amount of forest cover within 2 km. It was also associated with regional forest cover, but not significantly (Austen et al. 2001). Some studies suggest that this warbler is area sensitive in the province, but the presence of a nest in a single tree contradicts this. More study is required to determine if the Pine Warbler is area sensitive in Ontario. Results from Maryland and the mid-Atlantic states are also contradictory. In Maryland, Robbins (1979) concluded that 30 ha of forest were required to support a viable population. In the mid-Atlantic states, its abundance was significantly correlated with forest area, yet it demonstrated a constant probability of occurrence of 30% across all sizes of woodlands, including the smallest. In that study, it was not identified as an area-sensitive species (Robbins et al. 1989). In Minnesota, 1 pair nested on a 0.1-ha island that was isolated from the mainland and other pairs nested on islands as small as 0.9-1.1 ha (Howe 1979; Rodewald et al. 2020). In Tennessee, forests 10-15 ha support breeding Pine Warblers. Schroeder (1985) considered 10 ha to be the minimum patch size to support it.

All Ontario nests were in coniferous trees and usually in pines. Of nests in pines, 45.5% were in white pine, 36.4% were in red pine, and 18.2% were in jack pine. One nest was in a spruce. Nests ranged from the lowest branch in the tree to treetops, with most near the tops of trees. Most were near the end of lateral branches and one was 1.1 m from the trunk. Two nests were saddled on a horizontal branch and 2 were in clusters of pine needles. Nests were 3.7-20 m from the ground, with 8 averaging 8.5-15 m up (Peck and James 1987, 1998a). In Algonquin Park, white pine is used most frequently for nesting (Tozer 2012).

Throughout its range, the Pine Warbler nests almost exclusively in pines, with nests having been found in 15 species of pine with no clear preferences for species. In addition to the Ontario record of it nesting in spruce, it has been documented nesting at least once in each of red cedar, bald cypress, oak, and possibly hemlock. One nest in the Dominican Republic was on the ground, but ground nesting has not been documented in North America. Nests are typically high in a pine tree atop a horizontal or nearly horizontal branch, in a fork of a branch, in twigs or needles at the tip of a branch, at the end of ascending branches, or hidden among cones near the top of a tree. Most nests are 10-15 m from the ground (range 0.6-41.1 m). Nest heights are strongly dependent upon tree height and may be only 3-7.5 m in jack pine and pitch pine. Nests may be near the trunk or as far as 4.6 m from it. It has collected nest materials from an active American Crow nest when the crow was absent, an old Summer Tanager nest, an old Pine Warbler nest, and a nest that the female had just deserted (Bent 1953; Chapman 1907; Graber et al. 1983; Harrison 1984; Rodewald et al. 2020).

In Wellington County, 10 nests were found close together in a mature coniferous woods and it was concluded that a colonial situation was approximated. No other information on clustering of territories by the Pine Warbler is available. It is possible that territories are clustered to facilitate extra-pair copulation, but this aspect of its breeding strategy has not been studied. Little information is available on territory size and it is highly variable depending upon habitat quality. In mixed forests or deciduous forests with scattered pines, only a portion of the territory is used with birds restricting their activity to the pines. In Arkansas, 2 territories were about 0.9 ha. In Minnesota, 1 pair nested on a 0.1-ha island 450 m from the lakeshore, but most birds nested on islands 1.0 ha or larger. A polyterritorial polygynous male was discovered north of Kingston. The primary territory encompassed 1.95 ha and the secondary territory was 0.54 ha. The minimum distance between the edges of the territories was 398 m. There was a zone of unsuitable habitat between the 2 territories that was not occupied by other Pine Warblers. The male sang on both territories and chased both conspecifics and Yellow-rumped Warblers. He was less aggressive to Pine Warbler broadcast calls in the secondary territory (Conboy 2011; Peck and James 1998a; Rodewald et al. 2020).

No information is available on natal philopatry or site fidelity by adults. Twelve birds banded in Massachusetts were recaptured in subsequent years in the same 10-minute block of latitude and longitude suggesting that some exhibit a certain degree of site fidelity (Rodewald et al. 2020).

Limiting Factors

Eggs have been reported in Ontario nests from the second week of June until the first week of July (Peck and James 1987). In Algonquin Park, nest building occurs from mid-May to late June and dependent fledglings have been observed from early July to late August (Tozer 2012).

Nest construction and egg laying combined take about 14 days in favourable weather, although a week may elapse between nest building and the initiation of egg laying. This period was 25 days in 1 case. Long periods between completion of the nest and egg laying are likely to occur only in the south where the Pine Warbler is a resident species. Due to the shorter nesting period in Ontario, it is unlikely that there is a lengthy delay between nest completion and laying. It is probable that 1 egg is laid per day, but this has not been confirmed. It is unknown when incubation is initiated. The incubation period is not well documented and has been estimated at 10-13 days. The nestling period is estimated at 10 days, but there appear to be no supporting data (Bent 1953; Chapman 1907; Harrison 1984; Rodewald et al. 2020).

There is no direct evidence for multiple brooding but egg dates in the United States strongly suggest that second and possibly third broods may be raised. The Pine Warbler may renest multiple times in an attempt to raise a brood if nests are lost due to predation or other factors. This may partially explain the different peaks in egg dates. Ontario egg dates suggest that only a single brood is raised but this is based upon very few nests. Ontario nests contained 3-5 eggs and this is typical throughout its range. The most frequent clutch size is 4 eggs and 5-egg clutches are infrequent. Clutch size declines significantly with the date of clutch initiation but suggestions that first clutches contain 5 eggs and second clutches contain 4 eggs are unsubstantiated. The range-wide average of 266 clutches was 3.73 eggs and an average of 3.90 eggs was obtained from published records (Bent 1953; Chapman 1907; Harrison 1984; Peck and James 1987; Rodewald et al. 2020).

The age at first breeding has not been documented, but both sexes are probably capable of breeding in their first year. The proportion of yearling males that are successful in attracting females and breeding is unknown, and this probably varies among populations. The Pine Warbler is predominantly monogamous. The first case of polygyny was documented in Ontario north of Kingston. This was an after-second-year male that maintained 2 separate territories almost 400 m apart (Conboy 2012; Rodewald et al. 2020).

The Pine Warbler forages mainly while creeping slowly along tree trunks or limbs and forages predominantly in pine trees during the breeding season. There are no significant differences in the foraging behaviours of the sexes. Females tend to forage slightly higher than males. Foraging of Maryland females was centred near the height of nests, an average of 9 m from the ground. The lower density of vegetation in pine forests relative to that in spruce forests diminishes the advantage of males singing in treetops. In Maryland, males foraged at heights of 0-18 m, but mostly from 3 to 15 m and the mode was 6-9 m. Females foraged mostly from 6 to 12 m and the mode was 9-12 m. In Minnesota, foraging occurred at heights of 3-15^{+} m, but predominantly at 6-12 m with a mode of 6-9 m. About 40% of foraging was proximal to the trunk and 60% was distal. Seventy-five percent of foraging occurred in red pine, 22% in white pine, and about 2% each in spruce and deciduous trees. In New Jersey pine and oak barrens, it foraged mainly in pines and used oaks less than their availability. Based on 2 Maryland studies, 50-80% of foraging was on the distal half of limbs, 10-16% was on the proximal half of limbs, 26% was at the tips of branches, and a small proportion of foraging occurred on dead (3.5%) or deciduous (2.4%) growth. It also forages near and on the ground, especially in nonbreeding seasons, and is an adept flycatcher. In Maryland, 98% of foraging was by gleaning, 2% by hawking, and 0% by probing in cones. About 1.2% of time in Maryland was spent

probing and gleaning on tree trunks. In some areas of Maryland, the Pine Warbler coexists with the Yellow-throated Warbler. The Pine Warbler appears to be the dominant species despite the fact that the Yellow-throated Warbler forages higher in trees. The Pine Warbler foraged similarly in areas with and without Yellow-throated Warblers indicating that the presence of Yellow-throated Warblers did not influence its foraging behaviour. The 2 species can coexist because the Yellow-throated Warbler obtains much of its food by probing in cones. The Pine Warbler is incapable of accessing prey in cones because its skull is too wide and its bill is too short. During the breeding season in North Carolina, 68.8% of foraging occurred in the canopy, 25.0% in low trees, 0% in shrubs, and 6.2% on the ground. In the canopy, 31.3% of foraging occurred at the top of the crown, 25.0% in the inner crown, 12.5% in the lower crown, and 0% on the bole. In low trees, 6.2% of foraging occurred at the top of the crown, 12.5% in the inner crown, 6.3% in the lower crown, and 0% on the bole. On the ground, 6.2% of foraging occurred in the open and 0% in dense thickets, in grass, or at water's edge. During the breeding season, birds in the Grand Bahamas foraged almost exclusively on pine foliage; those on Andros Island foraged about equally on foliage and bark. The Pine Warbler may respond to seasonal changes in arthropod abundance. In May in New Jersey, its density was similar in oak-pine forests, one of which was heavily dominated by pine. In June and July, arthropod abundance was higher in the pine-dominated forests and higher densities of Pine Warblers occurred there (Bent 1953; Brush and Stiles 1990; Emlen and DeJong 1981; Ficken et al. 1968; Howe 1979; Morse 1974, 1989; Parnell 1969; Rodewald et al. 2020).

Nestling food items include small caterpillars, spiders, flies, and other insects. Adults eat mostly arthropods but also consume fruits and seeds, especially during autumn and winter. Fifteen stomachs analyzed during the breeding season contained a mean of 450 mg of food including 45 mg of caterpillars, 40 mg of soft-winged bugs, 10 mg of orthopterans, 5 mg of spiders, 5 mg of beetles, 4 mg of lepidopteran pupae, and 3 mg of hymenopterans. Twenty-one collected in Florida at all times of the year had consumed (by volume) 25.5% lepidopterans, 19% adult hymenopterans, 15.9% orthopterans, 12.9% beetles, 8.9% soft-winged bugs, 5.6% spiders, 3.4% flies, and lesser amounts of neuropterans, mecopterans, dragonflies, and damselflies. Cockroach eggs accounted for 13.2% of the mean food volume. Other prey items the Pine Warbler may consume include locusts, weevils, aphids, insect eggs, ants, and scale insects. It is unique among warblers in its ability to eat large quantities of seeds, especially those of pines (Bent 1953; Rodewald et al. 2020).

The frequency of parasitism by the Brown-headed Cowbird on the Pine Warbler is uncertain. Most authors consider parasitism rare, with only 15 records of parasitism known by 1985. Only 1 of 50 nests (2.0%) reported to United States nest records schemes was parasitized, but this was considered an underestimate since many observations were incomplete. In Ontario, 4 of 8 nests (50.0%) were parasitized, but this percentage will probably decline as more nests are reported. It is likely that parasitism rates in the Shield are near 0. The Pine Warbler is probably an acceptor of cowbird eggs and adults have been observed feeding cowbird fledglings. Occasionally it buries cowbird eggs in the nest. It is uncertain if the warbler does this deliberately or if it is because the cowbird laid the egg before nest construction was complete. In North Carolina, a female cowbird pulled all 4 Pine Warbler nestlings out of their nest and dropped them on the ground. There were no cowbird eggs in the nest. Killing a potential host's nestlings may trigger a replacement nest

which may provide an opportunity for parasitism (Beane and Alford 1990; Bent 1953; Harrison 1984; Peck and James 1998a; Rodewald et al. 2020).

Habitat loss and degradation do not appear to be significant for the Pine Warbler in Ontario. Habitat has increased in the south in recent years due to maturation of pine plantations. Old-growth forests in the southeastern United States have been almost entirely replaced by even-aged stands on shorter rotation periods. Birds that occupy younger pine forests or plantations may have lower nesting success. Forest clear-cutting is detrimental because warbler densities are much lower in young stands. Forest management such as single-tree and group selection remove fewer canopy trees and may have less of a negative effect (Rodewald et al. 2020).

Fire suppression in pine stands promotes the growth of hardwood regeneration which tends to result in lower densities of Pine Warblers. In Georgia, there was no difference in its abundance in unburned stands and those where prescribed burns were conducted at low, medium, and high intensities. The apparent lack of response may have been because it was not very abundant within the study area (Klaus et al. 2010; Rodewald et al. 2020). Rose and Simons (2016) studied the effects of fire in pine-oak forests in North Carolina on the Pine Warbler. It responded positively to fire, but only after high-intensity fires.

In Delaware, Tymkiw et al. (2013) found no differences in the abundance of the Pine Warbler in areas of low, moderate, or high white-tailed deer density.

Pine Warbler mortality was reported in Michigan in the late 1950s where DDT was used to control Dutch elm disease. Mortality has also been reported where arsenial spray has been used (Rodewald et al. 2020).

The Pine Warbler may be affected by weather extremes. There were widespread declines in the southeastern United States after the severe winters of 1976-77, 1977-78, and 1980-81, and after the summer droughts in 1980 and 1981 (Rodewald et al. 2020).

Price (2004) concluded that the breeding range of the Pine Warbler might expand in southern Ontario if the average summer temperature increased by 2°C.

Status

The Pine Warbler was probably much more common in Ontario prior to the widespread cutting of pines in the last half of the 19th century for ships' masts. McIlwraith (1894) considered it rather common in the Hamilton area but noted that it was not known to breed in the London area. Baillie and Harrington (1937) concluded that it bred in small numbers locally from the southern border to northern Algoma District and Renfrew County. They also had summer records from the vicinity of Lake of the Woods, suggesting that it bred there. In Elgin County, it was not reported by 1891, was considered a possible summer resident in 1954, and was a common breeder wherever mature pine stands occurred by 2000 (Lancaster et al. 2004). In 1965 in the Kingston area, it was a rare summer resident but was fairly common by the turn of the 21st century. The increase was attributed to maturation of pine plantations (Weir 2008). The first atlas demonstrated that the Pine Warbler occurred throughout the Great Lakes–St. Lawrence and Carolinian forest regions. It was most widely distributed in the Canadian Shield. South of the Shield, the distribution was spotty and correlated with presence of red or white pine stands and plantations. Concentrations occurred at Pinery and

Rondeau provincial parks, Long Point, the moraines between Cambridge and Hamilton, and at the base of the Bruce Peninsula. It was absent in the urbanized Toronto area and the intensive agricultural areas of Essex, Chatham-Kent, Lambton, Huron, and Niagara except for the locations previously mentioned (Eagles in Cadman et al. 1987). James (1991) considered the Pine Warbler an uncommon to locally common summer resident in the south that was occasional and rare in the north to Kenora, Thunder Bay, and Wawa.

The second atlas demonstrated that the range of the Pine Warbler had apparently expanded northward into the Boreal Forest Region, north to Cochrane, Timmins, Nakina, Armstrong, and Ear Falls. Distribution continued to be local north of Sault St. Marie and Sudbury. Its distribution south of the Shield was much more continuous, but it was still absent in Essex County and the Region of Niagara. Its probability of observation increased significantly from the first atlas province-wide and in all regions where it occurred. Overall, there was more than a 100% increase in its probability of observation with greatest increases south of the Shield. These increases were attributed to the maturation of pine plantations, but it is possible that atlassers were more proficient at recognizing its song. Highest densities of the Pine Warbler occurred in the Shield portion of the Great Lakes–St. Lawrence Forest Region. Highest abundances occurred along the eastern shoreline of Georgina Bay, the southern edge of the Shield, on the Frontenac Axis, and from eastern Algonquin Park northeast to the Ottawa River. These areas consistently have higher coverage by pine forests (Crins in Cadman et al. 2007). Curry (2006) noted that the Pine Warbler had increased significantly in the Hamilton area in the past 25 years due to maturation of pine plantations and growth of white pine in conservation areas.

The Pine Warbler appears to have increased significantly rangewide. From 1966 to 1996, Breeding Bird Survey (BBS) data indicated that it increased at a rate of 1.2% per year (Rodewald et al. 2020). BBS results indicate that it increased at annual rates of 2.81% in Canada and 2.55% in Ontario 1970-2021. Trends for 2011-21 were annual increases of 2.08% in Canada and 1.83% in Ontario. The long-term trends were highly reliable; the short-term trends were of medium reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Once the young fledge, both young and adults may move out of typical pine breeding habitat, but very little information is available. Family groups are often seen after the young fledge and these may form larger flocks in late August. In Arkansas, a flock of 15 juveniles was seen in early July. In Michigan, adults and young may move from the nesting area with taller pines into regenerating, shrubby, burned areas. Birds have been documented during the postfledging period at the peak of Mount Mitchell (2,037 m) in North Carolina, where no breeding occurs in the spruce–balsam fir forests. In Missouri, mist-netting was conducted during the postfledging season in an oak-pine-hickory forest 2-15 years after it was clear-cut. Only 8 Pine Warblers were captured during this period: 1 2 years after harvest, 1 3 years after harvest, 3 6 years after harvest, 2 7 years after harvest, and 1 9 years after harvest. The Pine Warbler has been seen in small flocks around buildings during the postfledging period, associating with Eastern Bluebirds and Chipping Sparrows (Bent 1953; Porneluzi et al. 2014; Rodewald et al. 2020).

MIGRATION

The Pine Warbler is a short-distance migrant in the northern portion of its range and a resident in the south. Populations that breed north of central Arkansas, southern Tennessee, southern Virginia, and Missouri are migratory. Those breeding in the southeastern United States and the West Indies are resident non-migratory birds. Migratory birds travel no further south than central Florida. Kills at towers indicate that it is a nocturnal migrant. One bird used different wintering areas (Arkansas and Mississippi) in subsequent years suggesting that some individuals may use different migratory corridors in some years. During migration, Pine Warblers often occur in mixed flocks with other warblers (Rodewald et al. 2020).

The Pine Warbler is one of the earliest warblers to arrive in spring. In Ontario, it typically arrives in mid-April. Some arrive in early April and there are some records from March, but these may represent overwintering birds (Black and Roy 2010; Curry 2006; Fleming 1907; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008).

Average departure from the southern Shield is in late September and the latest birds occur in late October (Mills 1981; Tozer 2012). In the south, autumn migration extends from mid-August to mid-October, with rare records through to December (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008).

Even during migration, the Pine Warbler demonstrates a clear preference for pines. During spring migration in North Carolina, numbers seen per hour were 1.86 in pine forest, 0.75 in pine-hardwood forests, 0.37 in floodplain forests, 0.07 in oak-hickory forests, and 0 in wet and dry thickets, beech forests, and oak forests. These results are typical, with it selecting pines wherever they are available. If pines are absent or scarce, it may occur in deciduous habitats, especially in spring, but it tends to be more confined to pines in autumn. It may heavily use deciduous habitats in some areas, and may also occur in orchards, residential areas, and rural residential lots. During autumn migration in Pennsylvania, it was equally abundant in forest edges, shrub-sapling-stage forests, forest interior, forest-agricultural edges, and suburban forests. It was not observed in pole-stage forests (Chapman 1907; Graber et al. 1983; Parnell 1969; Rodewald and Brittingham 2002; Rodewald et al. 2020).

During spring migration in North Carolina, 61.4% of foraging occurred in the canopy, 38.6% in low trees, and 0% in shrubs and on the ground. In the canopy, 15.8% of foraging occurred at the top of the crown, 19.3% in the inner crown, 26.3% in the lower crown, and 0% on the bole. In low trees, 10.5% of foraging occurred at the top of the crown, 22.8% in the inner crown, 5.3% in the lower crown, and 0% on the bole. Singing males were observed at heights of 4.6 m to more than 15 m (average 13.5 m). Nonsinging birds ranged from 5 to more than 15 m (average 12 m; Parnell 1969). During autumn migration at Prince Edward Point, feeding heights were 3-17 m with a peak around 10 m. Forty-four percent of foraging occurred on outer leaves, 22% on twigs and inner leaves, 20% on sapling foliage, and 11% on outer branches. The Pine Warbler was not observed foraging in the air, on inner branches, trunks, sapling branches, low shrubs, or the ground (Keast 1980). In autumn and winter, it regularly forages in the leaf litter on the forest floor and sometimes in open habitats near forest edge. On the ground, it flips over leaves, pieces of bark, or small stones with its bill in search of prey (Bent 1953; Rodewald et al. 2020; Tozer 2012). The Pine Warbler is often aggressive while in mixed-species flocks during autumn and winter. Individuals that it chases or supplants often

have food items in their bills, suggesting that it may occasionally steal or catch dropped food items from other birds. During spring migration and summer in Arkansas, 53% of prey was obtained from pine foliage, 23% from bark, 8% from the air, 8% from deciduous foliage, 4% from leaf litter, and 4% from pine cones. In autumn and winter, 43% of foraging observations were in pine foliage, 30% on bark, 13% in the air, 5% in leaf litter, 2% in deciduous foliage, and 2% in pine cones. In autumn and winter in Louisiana, 94% of food items were obtained by gleaning, 4.5% by sallying, and 1.5% by hanging. In Arkansas during the same period, 68% of food items were obtained by gleaning, 16% by sallying, and 16% by hanging. During spring and summer in Arkansas, 63% of food items were obtained by gleaning, 22% by sallying, and 15% by hanging (Rodewald et al. 2020).

Early spring migrants may appear at feeders where they eat suet and peanuts (Tozer 2012; personal observation). In late autumn in New York, Russack (1955) observed Pine Warblers feeding on pine needle scale insects. This insect occurred in both white and Scotch pines, but warblers were not observed foraging in Scotch pine. This is the only warbler that is known to regularly consume seeds, predominantly pine seeds and seeds at feeders. Away from feeders, the importance of seeds in the autumn and winter diet is unknown. In addition to feeding on pine seeds, it also consumes the fruit of dogwoods, wild grape, bayberry, Virginia creeper, and sumac (Bent 1953; Rodewald et al. 2020).

The Pine Warbler may strike tall structures during migration, but is much less likely to do so than other species. Only 2 were killed at the Lennox generating station chimneys (Graber et al. 1983; Rodewald et al. 2020; Weir 2008).

James (1991) considered the Pine Warbler a rare migrant in Ontario. Most regional works concur that it is rare to uncommon during migration, but it is a common spring and autumn migrant in Algonquin Park (Tozer 2012).

WINTER

The Pine Warbler is typically absent in winter where the average minimum January temperature drops below –1°C. Although some birds regularly winter as far north as Massachusetts, most occur from Virginia and southern Illinois south to Florida and the Gulf states. Despite most birds remaining in areas where temperatures seldom drop below –1°C on average, individuals have withstood much colder weather. An Illinois bird survived temperature as low as –14.4°C with a high of –7.8°C. One bird apparently survived blizzards and temperatures as low as –31.7°C in Minnesota. Another Minnesota bird appeared to be suffering stress in a light wind and –17.8°C. Many were killed in South Carolina after 13 cm of snow and near 0°C temperatures. Lack of access to suitable foraging substrates due to snow or ice may be more harmful than cold temperatures (Bent 1953; Rodewald et al. 2020; Root 1988; Tamar 1997). It is an avoider of snow and is most likely to occur where there are frequent changes between snow cover and bare ground (Keyser et al. 2023).

In its typical winter range, the Pine Warbler is most common in pine habitats with low-growing or sparse understorey, and is particularly abundant in the loblolly–shortleaf pine forests of the southeastern United States. Pine barrens are also characteristic habitats. Smaller numbers may occur in shrub and forest edge habitats as well as suburban areas where individuals or small groups may attend bird feeders. It may also forage on the ground in fields and pastures near forest habitat. It may visit deciduous forests, orchards, and lowland thickets in winter (Bent 1953; Chapman 1907;

Rodewald et al. 2020; Root 1988). In Ontario, it is probably associated with feeders, with habitat type being secondary to food availability.

Although the Pine Warbler may be aggressive to other species, there is no evidence that it defends a winter territory.

In winter, the Pine Warbler normally forages on the ground and proximal parts of pine limbs. It wedges pine seeds into bark crevices and pecks them open. It has been observed foraging amidst fallen leaves and tearing apart old oak leaves to eat the eggs and young of gall insects. It eats large numbers of scale insects and has fed on bean sprouts in a dumpster and on Manitoba maple sap. Although it may occur singly in winter, it most frequently joins mixed flocks that may contain chickadees, Tufted Titmouse, Downy Woodpecker, Brown Creeper, kinglets, Eastern Bluebird, Palm Warbler, Chipping Sparrow, Yellow-rumped Warbler, Dark-eyed Junco, Hermit Thrush, and White-throated Sparrow. It readily visits bird feeders where it dominates the House Finch and Downy Woodpecker but is subordinate to the Tufted Titmouse, Mourning Dove, Red-bellied Woodpecker, and House Sparrow (Bent 1953; Rodewald et al. 2020; Root 1988; Tamar 1997). The Pine Warbler typically visits feeders only in the coldest parts of winter with few sites reporting regular sightings throughout the winter. Favourite feeder foods are bird puddings, suet, and peanut butter mixes. Infrequently consumed foods include mixed seeds, cracked corn, black oil and striped sunflower seeds (only if they are broken up), water, and baked goods (Dunn and Tessaglia-Hymes 1999). It also eats cornmeal, nutmeats, bread, niger seeds, piecrust, millet, and peanuts (Harrison 1984; Rodewald et al. 2020; Tamar 1997). A wintering bird in Illinois made most visits to a platform feeder where black oil sunflower seeds and bread granules were provided, followed by a suet feeder, niger feeder, and suet crumbs on the ground (Tamar 1997).

James (1991) considered the Pine Warbler a rare and occasional winter resident in the south. It has overwintered in London and is very rare in winter in Elgin County. There are 9 records of it overwintering in Hamilton (Curry 2006; Lancaster et al. 2004).

Yellow-rumped Warbler

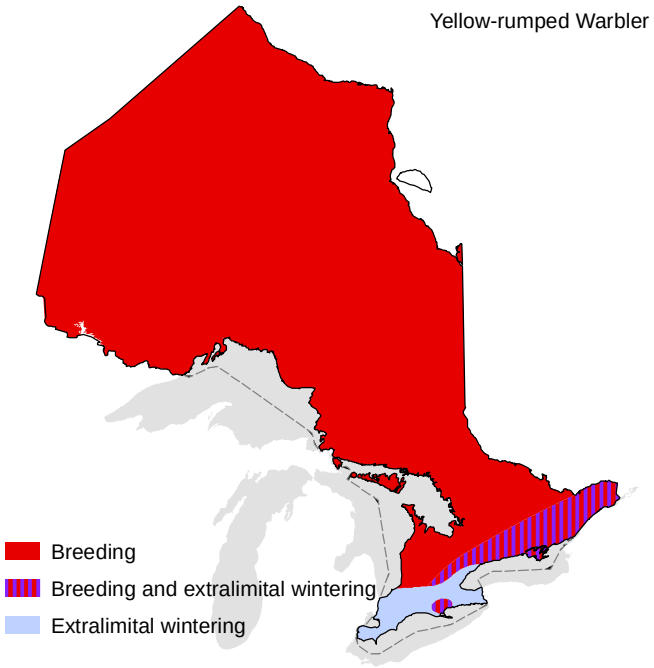
Setophaga coronata

BREEDING SEASON

Habitat Requirements

In Ontario, the Yellow-rumped Warbler usually breeds in mature and second-growth forests. It selected coniferous woods more (40.2% of nests) than mixed (37.3%) and deciduous (3.9%) woods; 81.4% of nests were in forested areas. Other nesting areas included on treed lawns and gardens of cottage and residential lots (6.9%), in spruce or tamarack bogs or fens (5.9%), at beaver ponds (2.9%), in hawthorn thickets (2.0%), and in a hedgerow (1.0%). Most nests were in open woods or at woodland edges, often near roads or water. Only 1 nest was reported from forest interior. It nested more frequently in dry than wet areas (Peck and James 1987). It breeds in coniferous and mixed forests where trees may range from short to very tall. Trees may be scattered, such as at edges or in openings and fens, or relatively dense. It has a wide tolerance to a variety of forest conditions, but prefers taller trees and open coniferous forests (James 1984b).

The Yellow-rumped Warbler occurred in all forested areas of the Hudson Bay Lowland. It was common in Moosonee, particularly in large forested areas (Wilson and McRae 1993). It bred in drier spruce forests on both the Hudson Bay and James Bay coasts (Manning 1952).



In the Boreal Forest Region from Pickle Lake north to the Manitoba border, the Yellow-rumped Warbler was most abundant in coniferous forests both with and without understorey, followed by deciduous scrub, mixed forests, heath, and coniferous scrub. It was absent in deciduous forests, mixed scrub, and tundra (McLaren and McLaren 1981). Near Pickle Lake, it was the most numerous warbler in all types of forest, but was still uncommon (James 1980). Near Lake Nipigon in spruce and balsam fir forests, it preferred semiopen to dense forests (Kendeigh 1947). Near Manitouwadge in spruce-fir forests, it was more abundant in stands 60-223 years old than in younger stands (Venier et al. 2009). In jack pine stands near White River, it was most abundant in stands 23-25 years old. It was a significant indicator of this age class of forest. Trees in this age class seldom exceeded 10 m in height. It was strongly associated with structure in the stratum 2.5-5 m from ground and negatively associated with coarse woody debris (Venier and Pearce 2005). Near Hearst, it nested in clear-cuts and uncut upland mixed and lowland coniferous forests. It occurred in clear-cuts as young as 6 years in both upland and lowland habitats (Welsh and Fillman 1980). In the Clay Belt, Welsh and Lougheed (1996) found breeding evidence in all types of forests that they examined: jack pine, black spruce, white spruce, white birch, trembling aspen, balsam poplar, white cedar, and tamarack. It occurred in stands situated on very wet to very dry soils on nutrient-poor to nutrient-rich sites.

In the Great Lakes–St. Lawrence Forest Region in the Canadian Shield, the Yellow-rumped Warbler occurred in mature and old-growth white pine stands in approximately equal densities (Kirk et al. 2012). In jack pine stands near Gogama, it was one of the most common species in all habitats but occurred in mixed forests only where jack pine was the dominant tree. It began to colonize habitats when jack pines were 5-6 m tall and reached maximum densities once pines attained heights of 10-12 m. It preferred areas of forest that were slightly open but occurred almost everywhere, including in some very dense patches (James and Peck 1995a). Near Parry Sound, it occurred in moderate densities in young open stands of jack pine mixed with a variety of deciduous tree species (James 1979a). It was the most common warbler in Parry Sound and Muskoka districts wherever conifers were available, especially pines (Mills 1981). In Algonquin Park, the Yellow-rumped Warbler bred in stands dominated by black spruce, black spruce–white cedar, balsam fir–spruce, white birch–poplar–balsam fir–spruce, white birch–poplar, and hemlock. In mixed forests, it was not observed above 12 m, which represented the top of the coniferous forest canopy. In balsam fir–spruce stands, it occupied the central portion of the canopy. In black spruce–white cedar, it occurred from the ground to the top of the cedars, although the spruce extended another 9 m

above this. In white birch–poplar, it occurred from just below the tops of the shrubs to about 5 m below the canopy. In hemlock, it occurred from the shrub layer to mid-canopy. It was third in abundance in hemlock stands. Martin (1960) considered it characteristic of boreal forest. Martin (1960) and Kingsley and Nol (1999) reported it in young white pine stands in Algonquin Park, and it may be the most common species in these stands. In Muskoka District and Haliburton County, it was associated with mixed woods with some understorey, moderate canopy volume and tree density, and very low amounts of understorey vegetation. Its habitat was characteristic of areas in mature woods where selective tree removal had occurred or of immature woods that were regenerating on cleared cottage lots (Clark et al. 1983).

South of the Shield, the Yellow-rumped Warbler is associated with natural coniferous and mixed forests and coniferous plantations. McIlwraith (1894) reported breeding in a black ash–white cedar–balsam fir swamp near Listowel. It first occurred during the breeding season in the Hamilton region in 1974 in a coniferous plantation (Curry 2006).

The Yellow-rumped Warbler is the most common and widespread forest-dwelling warbler in Canada and North America. It is a habitat generalist, but prefers coniferous and mixed forests to those dominated by deciduous species. Although it prefers forests containing confers, it also nests in deciduous stands dominated by aspen, birch, or willow, especially in the Yukon. It prefers more mature stands and those that are open in nature, but also occurs in immature and dense stands. Erskine (1977) stated that it was one of the most typical boreal species where it is ubiquitous and often a dominant species along with the Swainson's Thrush and Dark-eyed Junco. In the Yukon, these 3 species are dominant in all forest types whether they are coniferous or deciduous, successional, or climax. In the Boreal Forest Region, the Yellow-rumped Warbler is characteristic of spruce and balsam fir forests, is found in most jack pine stands, and is often present in black spruce and tamarack bogs with more or taller trees. It is also characteristic of tundra and alpine ecotones at the edge of boreal forest. Erskine's (1977) conclusions are supported by those of Hunt and Flaspohler (2020), Morse (1974, 1976), Letourneau and Lafontaine (in Gauthier and Aubry 1996), Campbell et al. (2001), and Sinclair et al. (2003). East of the Rocky Mountains, 88% of nests were in forests, 6% were in wet areas, and 2% were in open or orchard-like habitats. Of nests in forests, 92% were in coniferous forests, 7% in mixed forests, and 1% in deciduous forests. Further south, pine forests become important and plantations 40-50 years old and older provide suitable habitat. In addition to Ontario, plantations have contributed to its southward range expansion in New York, Pennsylvania, and West Virginia. This warbler also nests in fens, young strip-cuts in Quebec, regenerating clear-cuts, small treed islands, open pastures with clumps of conifers, windbreaks, and human-influenced habitats. In British Columbia, 25% of nests were in human-influenced habitats including suburban, urban, and rural areas; cultivated farmlands; recreational areas; pastures; orchards; and logged areas. Backyard gardens and residential areas were the most reported nesting areas in human-influenced habitats (Back 1979; Bent 1953; Campbell et al. 2001; Capen 1979; Crawford and Titterington 1979; Dawson 1979; DeGraaf and Chadwick 1987; Falardeau et al. 1999; Freedman and Johnson 1999; Hoffman 1989a; Holmes and Sherry 2001; Hunt and Flaspohler 2020; Lent and Capen 1995; Morgan and Freedman 1986; Mossman et al. 1991; Niemi and Hanowski 1984b; Noon et al. 1979; Temple et al. 1979).

Some studies examined the Yellow-rumped Warbler's habitat preferences at the landscape scale or at multiple scales. In Saskatchewan, it was randomly distributed in fragmented and contiguously forested landscapes. It was most common in large forest fragments in areas of low forest cover within 5 km, and this relationship was significant (Hobson and Bayne 2000). In New Hampshire, it was found throughout alpine treed areas, but the population centre was in the high-altitude conifer region just below the krummholz (Sabo 1980). In Quebec, Drolet et al. (1999) examined 100-ha landscapes where forest cover ranged from a few to more than 90 ha. There were no significant differences in its abundance related to the amount of forest cover, edge, or core area within these landscapes. In Michigan, where it was one of the most abundant species, Crozier and Niemi (2003) studied its abundance in a naturally heterogeneous landscape of upland and lowland forests and wetlands. Its abundance was not related to any landscape parameters. In Newfoundland, Taylor and Krawchuk (2006) studied Yellow-rumped Warbler abundance in relation to amount of woodland cover at radii of 1,250 m (landscape scale), 150 m (neighbourhood scale), and 12.5 m (local scale). It was negatively associated with the amount of forest at the landscape scale but positively associated with forest at the local scale. The relationships between occurrence and forest cover were weak suggesting either that alternative scales were important to the warblers or that the researchers did not study the appropriate parameters. Another possibility is that it is a habitat generalist that is minimally affected by vegetation variables. In Newfoundland, Dalley et al. (2008) compared vegetation near nest sites to that of random sites. They considered the Yellow-rumped Warbler an ecological generalist but one that was largely confined to coniferous forests for breeding. Compared with random sites, nest sites had significantly more large downed wood and more stems 1-2 m tall and more than 2 m tall within a 1-m radius. Within a 5-m radius, nest sites had more canopy cover, more stems 1-2 m tall, and fewer stems taller than 2 m than random sites. Within this radius, successful nests had less high ground cover vegetation than unsuccessful nests. Nest sites had fewer openings and were located in areas with denser understorey 1-2 m tall. Vegetation taller than 2 m is found within the territory at random sites and is characteristic of the nest site at the larger scale, but is not selected for at the nest microsite scale.

Other studies examined the Yellow-rumped Warbler's preference for forest type. Flack (1976) determined that it was common in pure aspen stands in the western mountains and was not dependent upon conifers. In the western Boreal Forest Region, it was most abundant in black spruce forests. It was associated with dry nutrient-poor stands and moderately old stands (Kirk et al. 1996). In New Brunswick, its presence was correlated with high densities of coniferous stems. Stand types that it selected, in order of preference, included pines, spruce–tolerant hardwoods, and spruce–intolerant hardwoods. Stand types it used less than their availability, in declining order of avoidance, included intolerant hardwoods–tolerant hardwoods, intolerant hardwoods, spruce–balsam fir, and intolerant hardwoods–spruce (Parker et al. 1999). In Saskatchewan, it significantly selected for forest type and was most common in white spruce stands that were large but isolated. Spruce stands were preferred, followed by mixed stands. It made little use of trembling aspen stands (Hobson and Bayne 2000).

Some studies determined the Yellow-rumped Warbler's preference for stand age or seral stage. In balsam fir stands in Newfoundland, it was significantly more abundant in uncut stands older than 80 years than in 40-year-old second growth. It was also more common in mature stands than 60-

year-old stands, but not significantly. Uncut old stands had a more open structure with lower tree and small tree density, more gaps, fewer small deciduous trees, more varied tree height profile, shorter small trees, larger diameter living and dead trees, more dead wood on the ground, less litter cover, and more moss cover. It was associated with intermediate-aged stands on nutrient-poor sites with moderate amounts of deciduous species (Thompson et al. 1999). In the western Boreal Forest Region, the Yellow-rumped Warbler was in a guild of species associated with conifers. It was absent in stands 9 years old and younger and increased with increasing stand age, being most abundant in stands 80 years old, the oldest age class studied (Kirk et al. 1996). In Pennsylvania, it occurred in 9.1% of old-growth forests, 6.4% of stands state-wide, and 12.6% of stands in the Appalachian Plateau. Haney (1999) did not consider it to have positive or negative affinities for old-growth forests. In Maine, Titterington et al. (1979) determined that it was associated with coniferous overstorey. In spruce–balsam fir forests, it was present in low density in very recent clear-cuts characterized by dense slash and abundant bare ground. It was absent in the next 2 seral stages of regeneration, reappeared in low density when hardwood regeneration consisted of trees taller than 4.5 m with a diameter at breast height (DBH) of 10-15 cm, and was most abundant in spruce-fir forests with a dense canopy and an open forest floor. In aspen stands in Alberta, it was significantly more abundant in stands older than 120 years than in stands 23-26 or 51-63 years old. Schieck et al. (1995) considered it a canopy species associated with tree richness, downed woody material larger than 20 cm, canopy height, shrub richness, trees larger than 20 cm DBH, and conifer density. It was negatively correlated with aspen density. In black spruce stands in Quebec, it was least abundant in recent burns and clear-cuts and most abundant in stands 120 and 200 years old and those where clear-cutting had occurred 5-11 years previously (Imbeau et al. 1999).

Several studies determined microhabitat preferences of the Yellow-rumped Warbler. In New Hampshire and Maine, it was associated chiefly with white pine and balsam fir. It was positively correlated with the number of conifers 2-10 cm DBH and negatively correlated with percent ground cover, the number of deciduous trees larger than 10 cm DBH, and foliage volume of conifers less than 2 cm and 2-10 cm DBH (DeGraaf et al. 1998). Collins (1983a) compared its habitat preferences in Maine and Minnesota and found significant differences in amount of ground cover, canopy cover, and trees 15.1-23 cm DBH in territories. In Minnesota, it was in a group of forest and edge species occupying areas with high ground cover (70%) and moderate canopy cover. In Maine, it was in a group of forest species in areas with high percent canopy cover, variable coniferous cover, and many trees in the smaller size classes. In Minnesota, it was associated with large trees and large conifers; in Maine, it was associated with large trees and moderate canopy cover. Collins et al. (1982) determined that it was associated with mixed and coniferous forests supporting spruce or balsam fir in Minnesota. It was in a guild of species that occurred predominantly in mature undisturbed forests containing conifers. Distinctive features of the habitat of this group included greater than 50% coniferous coverage, mostly in the larger tree classes. Average habitat conditions in territories included 84.0% ground cover, 44.0% shrub cover, 66.0% canopy cover, 16.2 m canopy height, 58.0% coniferous cover, 4.8 tree species per 0.04 ha, 31.4 trees 7.5-15 cm DBH, 11.8 trees 15.1-23 cm DBH, 6.4 trees 23.1-30 cm DBH, 3.2 trees 30.1-38 cm DBH, 1.6 trees 38.1-53 cm DBH, 0.2 tree 53.1-68 cm DBH, and 0 tree larger than 68 cm DBH. Sabo (1980) characterized average habitat conditions in subalpine forests in New Hampshire territories as being at mid-slope and containing damp

depressions, 7.9 m canopy height, 59% canopy coverage, 72% conifer foliage volume, 33% conifer foliage volume 0-2 m from the ground, 17% deciduous leaf foliage volume above 5 m, and average DBH of live trees 10 cm.

Freemark and Collins (1992) considered the Yellow-rumped Warbler a forest-interior species, but this is incorrect. Only 1 Ontario nest was in forest interior and the remainder were in edge habitats (Peck and James 1987). Taylor and Krawchuk (2006) and Taylor and Taylor (1979) concluded that it was a forest-edge species that also occupied small openings. In Vermont, territories commonly bordered clear-cuts and occasionally extended a short distance into them (Lent and Capen 1995). In Alberta, Villard et al. (2007) predicted that it would avoid clear-cut edges but it did not exhibit edge avoidance. In Minnesota, there was no difference in the distance from the centre of the territory to transects in forests and on electrical transmission line cuts (Niemi and Hanowski 1984b). In Newfoundland, it was ubiquitous in balsam fir forests. It was equally abundant in riparian edge, forest–clear-cut edge, and forest interior (Whitaker and Montevecchi 1997, 1999). In Quebec, there was no significant difference in its abundance in riparian and nonriparian balsam fir stands, although it tended to be more abundant in riparian edges (LaRue et al. 1995). Wiebe and Martin (1998) studied populations in coniferous forests and dense deciduous riparian strips at edges of these forests in British Columbia. It was less common in riparian edges than in coniferous forests, but not significantly.

Freemark and Collins (1992) stated that there was uncertainty as to whether or not the Yellow-rumped Warbler is area sensitive. There appear to be no references to its being area sensitive in the literature. No relationship between Yellow-rumped Warbler presence or abundance and forest size was found in New Hampshire, Maine, or Saskatchewan (DeGraaf et al. 1998; Hobson and Bayne 2000). In Michigan, it was positively associated with patch size in jack pine stands but negatively correlated with patch size in red pine stands (Crozier and Niemi 2003). In Maine, it bred successfully on islands where forest size was only 0.35-1.50 ha (Morse 1971b, 1977). In Minnesota, it nested on islands 0.04-1.1 ha that were 30-450 m from the mainland. Its frequency of occurrence was 81% on small islands, 100% on large islands, and 91% on the mainland (Howe 1979).

Most Ontario nests were in living trees and shrubs, although 4 were in dead trees, 1 was on the top of a rail of a vine-clad trellis, and another was in the hollow top of a dead stub. Coniferous trees (6 species) were selected more frequently (93.3% of nests) than deciduous trees or shrubs (4 species). The most frequently used nest trees were pines (58 nests of which 41 were in white pine), spruces (40 nests), white cedar (28 nests), balsam fir (10 nests), and birches (5 nests). Nests were on horizontal branches, supported and often concealed by adjacent branches (74.5% of nests); in crotches (23.6%); or among a group of almost vertical branches (1.8%). Most nests were well concealed with 56.8% near the trunk; others were 0.5-4.3 m from the trunk. Nests were 0.6-20 m from the ground with most 2-6 m up (Peck and James 1987, 1998a). MacLulich (1938) reported a nest in Algonquin Park 1.2 m from the ground in a white cedar. Forty-four nests in Simcoe County were mostly in white pines at heights of 1.8-12.2 m (average 8.5 m). Twenty-eight were on horizontal limbs approximately two thirds of the distance out from the trunk but none were at the outermost tip of branches. Two were in the top clump of needles in young trees, 5 were on horizontal branches 0.9-4.6 m from the ground in small spruces, 5 were 4.6 m up in the crotch of a small cedar, and

another was 1.8 m up in a small balsam fir. At Garrison Petawawa, it nested in small jack pines. In northern Ontario, it nests in any species of conifer, but 1 nest was in a hawthorn (Bent 1953). In Muskoka and Parry Sound districts, almost all nests were in conifers, typically white pines, at heights of 2.4-13.7 m. One nest was in a white birch and another was in a white spruce (Mills 1981).

Most nests are on horizontal branches of conifers including pine, spruce, balsam fir, tamarack, hemlock, white cedar, and red cedar. The Yellow-rumped Warbler has also nested in white birch, alder, trembling aspen, apple, maple, hazelnut, snowberry, oak, and dogwood. Nests are occasionally placed over water or in dead trees and are rarely on the ground. Forty-four Maine nests were all in white spruce, red spruce, or balsam fir at heights of 1.8-13.1 m, but mostly at 3-6.1 m. Nests have been reported as high as 15.2 m from the ground. Average nest heights were 7.6 m in Wisconsin, 10.7 m in Arizona, 4.0 m in Newfoundland, 2.3 m in the United States east of the Rocky Mountains, and 7.1 m west of the mountains. One nest was on a wooden beam (Bent 1953; Campbell et al. 2001; Chapman 1907; Cruickshank 1956; Dalley et al. 2008; Harrison 1984; Hunt and Flaspohler 2020; Mousley 1916a; Nice 1930b; Sinclair et al. 2003).

North of Lake Nipigon early in the season, 1 male quickly covered more than 0.8 ha while singing and feeding and another covered 1.6 ha (Kendeigh 1947). In Algonquin Park, territories averaged 0.47 ha (range 0.05-1.82 ha; Martin 1960). On small islands 0.04-1.1 ha in Minnesota, birds commonly visited other islands or the nearby mainland. During 9 surveys on the most isolated island, which was 450 m from the mainland, birds were observed flying to or from it on 11 occasions (Howe 1979). In New Hampshire subalpine meadows, territories averaged 1.0 ha (Sabo 1980). In Maine, territories averaged 0.35 ha on small islands and 0.8 ha on the mainland. Larger territories on the mainland were attributed to the presence of numerous competing species (Morse 1976, 1977, 1989).

No information is available on natal philopatry rates. Band returns in the eastern United States suggested that the survival rate in the first year was 27.9% (Stewart 1988). Return rates to natal areas are probably low.

In Newfoundland, annual return rates of adult males were 27.0% in natural landscapes and 20.4% in landscapes containing clear-cuts. Return rates for females were 25.1% in natural landscapes and 20.6% in cut landscapes. A high proportion of birds that were captured were unbanded: 31.0% and 39.0% of males and 32.5% and 38.4% of females in natural and cut landscapes, respectively. Whitaker et al. (2008) attributed the low return and apparent survival rates to regular landscape-level movements of individuals.

Limiting Factors

Peck and James (1987) reported eggs in Ontario nests from the last week of May until the end of July, with most present in the last 3 weeks of June. A female was observed on a nest on 12 May in Muskoka District, suggesting an earlier egg date (Peck and James 1998a). In Algonquin Park, nests are under construction from early May to mid-July, eggs are present from late May to mid-July but mostly in June, and dependent fledglings have been observed from mid-June to early September (Tozer 2012).

It has been reported that it takes 10 days to build a nest. Although this may be true for southern resident birds, it is unlikely that northern migratory birds would take this long. The first egg is usually

laid within a day of nest completion. Eggs are laid at the rate of 1 a day but occasionally a day is skipped. Ontario nests had incubation periods of 11 days and at least 11 days. Incubation periods of 12-13 days have been reported elsewhere. The nestling period is 10-14 days (Bent 1953; Hunt and Flaspohler 2020; Peck and James 1987).

The Yellow-rumped Warbler typically raises a single brood. It has been reported to produce second broods in Nova Scotia and New England, and possibly Quebec, but double-brooding has yet to be confirmed with banded birds. Renesting may occur if the first nest is lost. In Ontario, clutches of 2-6 eggs were reported (mode 4 eggs, mean 3.88 eggs). Usually 4 or 5 eggs are laid and clutches of 3-6 eggs have been reported elsewhere. Other average clutch sizes include 4.38 in Wisconsin, 4.13 in Maine and Vermont, 3.86 in Arizona, 4.09 in the Prairie Provinces, and 3.70 in Newfoundland. In British Columbia, 65% of clutches contained 3 or 4 eggs (Bent 1953; Campbell et al. 2001; Dalley et al. 2009; Hunt and Flaspohler 2020; Létourneau and Lafontaine in Gauthier and Aubry 1996; MacArthur 1958; Peck and James 1998a; Sodhi 1995).

The age at first breeding is unknown but is probably 1 year. Morse (1971b) observed that the Yellow-rumped Warbler occasionally occurred on small islands in Maine where it did not breed. He concluded that these birds represented a floater population, but it is equally as likely that these were breeding birds wandering about in their larger home ranges. Howe (1979) observed that birds breeding on small islands in Minnesota frequently flew to other islands and the mainland. In Maine, Hensley and Cope (1951) experimentally removed Yellow-rumped Warblers and they were quickly replaced. They concluded that there was a surplus nonbreeding population. This is a plausible explanation because 2 times the numbers of birds ingressed to the site as were removed. It is possible that these were breeding birds that wandered far from their breeding territories (Whitaker et al. 2008). The Yellow-rumped Warbler is presumed to be monogamous, but this has not been confirmed (Hunt and Flaspohler 2020).

Several studies examined the foraging strategies of the Yellow-rumped Warbler. Greenberg et al. (1999) studied its foraging patterns in the Ontario Clay Belt and Mackenzie District and found that it was associated mostly with conifers. In the Clay Belt, 69.0% of foraging was in conifers, 60.0% in foliage, 30.8% by aerial attacks, 4.2% by hanging, 14.4% by hovering, and 15.0% by reaching at an average height of 9.4 m, which was 63.0% of tree height. In Mackenzie District, 88.8% of foraging was in conifers, 86.0% in foliage, 44.3% by aerial attacks, 5.2% by hanging, 14.7% by hovering, and 18.3% by reaching at an average height of 10.4 m, which was 71.0% of tree height. In Parry Sound District, it foraged predominantly in conifers during the breeding and postfledging seasons as well as during autumn migration. The range of foraging heights was 4-14 m during the breeding season and 5-16 m in autumn (Mills 2007). Sabo (1980) characterized its foraging techniques in subalpine forests in New Hampshire as 0.8% aerial flycatching, 39.5% leaf gleaning, 15.2% leaf hawking, 9.6% leaf hovering, 5.1% twig pecking, 17.9% twig gleaning, 6.5% twig hawking and hovering, 1.1% branch pecking, 1.9% branch gleaning, 1.9% bole pecking, 1.0% bole gleaning, and 0% litter pecking, litter gleaning, and fallen log manoeuvres. Foraging was conducted 50.4% proximal to the trunk and 49.6% distal; 60.4% of foraging occurred in conifers, 36.5% in deciduous foliage, and 0.3% on the forest floor. Foraging occurred from the ground to the upper canopy: 3.5% at 0.1-2 m, 39.9% at 2-5 m (the midstorey), 37.3% at 5-8 m (the midcanopy), and 19.1% above 8 m (the upper canopy). North

of Lake Nipigon, it foraged from the ground to treetops (Kendeigh 1947). On small islands in Minnesota, it foraged from the ground to above 15 m, but mostly at 3-12 m; 48% of foraging was on branches and twigs proximal to the trunk and 52% was distal. Sixty percent of foraging time was spent in red pine, 28% in white pine, 3% in balsam fir, 3% in spruce, 2% in deciduous trees, and 4% in other. It preferred medium-height pine foliage, which was the most abundant substrate, and used all parts of the tree. It foraged in many of the same locations as the Pine Warbler, but spread its activity among more tree species and heights. The Yellow-rumped Warbler appeared to be the most generalized of all pine forest canopy foragers on the islands (Howe 1979). On small islands in Maine, the Yellow-rumped Warbler demonstrated more plasticity in foraging than the Black-throated Green Warbler and in several cases deviated markedly from the mean of the large population of warblers. The Yellow-rumped Warbler foraged mostly on small limbs and spent lesser amounts of time on large limbs, tips of branches, dead limbs, and deciduous growth. In the absence of the Black-throated Green Warbler, it had a strong tendency to use the outer parts of foliage and small limbs on 1 island and regularly used the abundant deciduous vegetation on another island. The Yellow-rumped Warbler may modify its foraging techniques in the absence of the Black-throated Green Warbler. Male Yellow-rumped Warblers displayed greater foraging diversity on small islands than on the mainland where there was a larger guild of spruce-foraging warblers. Males had greater foraging diversity on islands supporting 2 warbler species than on islands with 3 species, but there was no evidence of this for females. The tendency of the Yellow-rumped Warbler to expand its areas of foraging in the absence of the Black-throated Green Warbler suggests that it restricts the foraging activities of the Yellow-rumped Warbler. In turn, the Yellow-rumped Warbler restricts the foraging activities of the Northern Parula (Morse 1971b). Also in Maine, Morse (1976) observed that the activity of the Red-breasted Nuthatch overlapped mostly with that of the Yellow-rumped Warbler, but the warbler did not forage on trunks. No simple relationship was found between the abundance of the Yellow-rumped Warbler and variables such as foliage characteristics and insect abundance and biomass. Prey abundance did not influence territory size. Maine birds foraged at heights of 0-13.7 m in a forest averaging 21.3 m tall. Mean foraging height was 7.8 m, 36.6% of tree height. On spruce, 14.6% of foraging occurred at the tips of foliage, 17.7% on twigs 5 mm or less in diameter, 0.8% on dead twigs, 30.0% on dead branches, 19.2% by flycatching, 0.8% on deciduous growth, and 3.1% on the ground. Gleaning represented 10.8% of foraging activities at the tips of foliage, 0.8% on dead twigs, and 29.2% on dead branches. Hovering constituted 3.8% of foraging at tips of foliage and 0.8% on dead branches. In branches covered with beard lichen, 1.5% of foraging was distal to the trunk and 12.3% was proximal (Morse 1967). Morse (1989) concluded that the Yellow-rumped Warbler concentrates foraging in the lower parts of trees where the habitat is open. It is one of the most flexible of the spruce-woods warblers that hawks for insects more than the other warblers, often from lower dead branches of the understorey. MacArthur (1958) observed the foraging locations and methods of warblers in spruce forests in Maine and Vermont. He concluded that differences in diet result from differences in feeding behaviour and positions in trees and that each species eats what food is available within the characteristic feeding zones by the characteristic methods of foraging. Trees were broken into 15 different feeding zones: 5 3-m tall intervals and 3 horizontal zones: B, which was the inner bare or lichen-covered branches; M, the middle area of old needles; and T, the terminal zone of new needles or buds. The area below the tree constituted a 16th zone. The areas with the highest percentage of observations were: below the tree, 12.9%; 3-6

m up in zone B, 11.8%; 15-18 m up in zone T, 11.8%; 12-15 m up in zone T, 10.6%; 6-9 m up in zone B, 9.1%. The percent time spent in the major areas was: 27.7% below the tree, 15.9% in zone B 3-6 m from the ground, and 9.8% in zone M 9-12 m from the ground. At least some foraging occurred in all zones, but it was least frequent in the interior and middle of the top 2 zones. It moved predominantly in a tangential direction while feeding, significantly different from the other warblers studied (Blackburnian, Bay-breasted, Cape May, and Black-throated Green warblers). Yellow-rumped and Cape May warblers hawked and undertook long flights significantly more than other species, which tended to search trees more thoroughly before moving on. The Yellow-rumped Warbler had the most widely distributed feeding zone and foraged extensively on the ground, predominantly on emerging crane flies. Its feeding behaviour was so flexible that there was no correlation between the insects captured and specific feeding zones. Its abundance was constant in plots with varying foliage volume over 6 m, only increasing slowly as foliage volume increased. This was probably due to its flycatching and ground-feeding habits that make it less dependent upon foliage. In these study areas, it was present in many habitats but never abundant. It may be a marginal species in New England spruce woods but, by being less specialized and more flexible in its foraging, it manages to maintain a constant low population. Cumming (2004) conducted a similar study in old-growth mixed woods in Saskatchewan. In conifers, 15% or more of foraging occurred in the middle outer zone, 10-14.9% in each of the outer and central parts of the second zone from the top and the central portion of the central zone, and 5-9.9% each in the top outer zone, in the inner portion of the second and third zones from the top, and in the inner and outer areas of the fourth zone from the top. Foraging was not documented in the inner and central portions of the top zone, the inner portion of the fourth zone, and the entire bottom zone. It used white spruce more than its availability and trembling aspen less than its availability, and was the most diversely foraging species in conifers. The bottoms of trees and large inner branches were used less than their availability. It appeared to be less affected by branch structure in conifers than the other warblers and used balsam fir in proportion to its availability. It used tall canopy trees significantly more than the Magnolia Warbler and Boreal Chickadee, and experienced the most overlap and probably the most competition from these species and the Ruby-crowned Kinglet. It occurred mostly in mid- to outer branches at mid- to upper heights in both coniferous and deciduous trees, the same areas used by Black-throated Green Warblers in the Maine and Vermont studies. No interaction was observed between these species and the Yellow-rumped Warbler was 8 times more abundant than the Black-throated Green Warbler. For this study, deciduous trees were divided into 3 vertical zones. In deciduous trees, 15% or more of foraging occurred in the outer top zone, 10-14.9% in the outer central zone, and 5-9.9% in the middle zone of all height classes. No foraging was observed in the inner zone of all height classes and in the lowest outer zone. Mean foraging heights were 7.0 m in conifers and 11.2 m in deciduous trees. The foraging strategies of the sexes were compared by Franzreb (1983) in Arizona and by Morse (1968) in Maine. In both cases, males foraged significantly higher than females: 17.7 m for males and 14.7 m for females in Arizona and 3-9 m for males and 3-6 m for females in Maine. In Maine, males hawked significantly more than females; females gleaned significantly more than males. Males foraging higher in trees may have increased opportunities for hawking. In Arizona, there was no difference between the sexes in methods of prey procurement, perch type, diameter of perch, or distance from the branch tip to the foraging site. Tree species selection differed significantly with females relying heavily on fir and males selecting spruce more frequently than

females. In both cases, habitat partitioning by the sexes appeared to be a result of concentrating their foraging activities near the location of their most important reproductive duties: singing and territorial defence by males and nesting by females. In Maine, males foraged lower than they sang, but their principal foraging areas were closer to their singing height than nest height. Malmborg and Willson (1988) studied Yellow-rumped Warblers feeding on fruit in Illinois woodlots in late summer and autumn. Ninety-six percent of foraging occurred in forest gaps, more than expected based on availability. In 1 year, it fed almost exclusively on fruits in treefall gaps, but not in the other year. It favoured foraging on isolated shrubs rather than clumps of shrubs. All birds left the area immediately after foraging, considerably more than expected, suggesting that it is a good disperser for the species that it consumed. More unusual foraging techniques include taking insects from spider webs and manure piles and skimming over water, gleaning insects from the surface (Harrison 1984; Hunt and Flaspohler 2020).

Nestlings are fed beetles, caterpillars, moths, lice from the adults' feet, and probably a variety of insects and possibly spiders (Bent 1953; Hunt and Flaspohler 2020; Nice 1930b). Adults eat predominantly insects and other small invertebrates early in the breeding season, but may eat some fruit and seeds late in the breeding season. Invertebrates that the Yellow-rumped Warbler has consumed include caterpillars, sawfly larvae, small grubs, leaf beetles, bark beetles, weevils, metallic wood-boring beetles, ants, scale insects, aphids and their eggs, grasshoppers and locusts, bugs, house flies and other flies, crane flies, caddisflies, chalcid wasps, ichneumonid wasps, gnats, spiders, budworm larvae and pupae, neuropterans, stink bugs, leafhoppers, and treehoppers. Six adults north of Lake Nipigon consumed 34.8% spiders, 28.9% beetles (scarab, ground, click, and leaf beetles), 11.8% lepidopterans, 7.8% hymenopterans, 5.9% aphids, 3.5% planthoppers, 2.4% neuropterans, 2.4% caddisflies, 1.6% mayflies, and 0.9% flies. In California, the diet consisted of 85% animal matter and 15% plant matter. The animal matter consisted of 26% hymenopterans (almost entirely ants but with some wasps and parasitic wasps), 20% bugs (scale insects, aphids, stink bugs, leafhoppers, and treehoppers, with aphids appearing to be favoured), 16% flies (house flies, crane flies, and gnats), 14% caterpillars, 6% beetles, and 2% other insects and spiders. Vegetable matter consisted of fruits and seeds, including those of beach grass; it has been documented puncturing grapes. In Maine, the average number of caterpillars in males' stomachs was 11.8, 57.1 times more than would be expected based upon availability. The caterpillar biomass in stomachs was 1.4-7.1 times greater than predicted if they ate average-sized larvae indicating that they selected for larger larvae. Caterpillars were the only food item taken more than expected. Foliage samples were dominated by aphids, but few were consumed. In Illinois woodlands in late summer and autumn, 100% of the diet was frugivorous in a year when fruit abundance was high. No fruit was consumed the following year when fruit abundance was moderate. In the year that it ate fruit, 77% was poison ivy, 15% was grape, and 8% was Virginia creeper. Fruit of elderberry, pokeweed, greenbrier, moonseed, and spicebush was present but not consumed. In Quebec, it eats red cedar berries and contributes to the dispersal of this plant. It was considered an important disperser of poison ivy in Illinois. It also eats the fruit of poison sumac and cranberries (Bent 1953; Hunt and Flaspohler 2020; Kendeigh 1947; Létourneau in Gauthier and Aubry 1996; Malmborg and Willson 1988; Morse 1976).

The Yellow-rumped Warbler readily consumes larger larvae and pupae of the black-headed budworm and the spruce budworm. In New Brunswick, variations in its density appeared to be

unrelated to black-headed budworm density. In Ontario near Manitouwadge and New Hampshire, its abundance did not change with increasing abundance of spruce budworms. In New Brunswick, it declined with increasing spruce budworm density. This was thought to be a response to the explosion in numbers of the budworm specialist warblers that may have outcompeted the Yellow-rumped Warbler. Over 2 years in Maine, spruce budworm larvae and pupae constituted 26% and 7% of the invertebrates it consumed (Crawford and Jennings 1989; Gage et al. 1970; Gillespie and Kendeigh 1982; Mitchell 1952; Morris et al. 1958; Venier et al. 2009).

The Yellow-rumped Warbler typically accepts Brown-headed Cowbird eggs. If a cowbird egg is laid before the first warbler egg, it may abandon the nest. It rarely buries cowbird eggs in the nest. It is likely that this occurs only when the egg is laid before the nest is completed. In Ontario, 39 of 139 nests (28.1%) were parasitized; 65% of nests in Simcoe County were parasitized. In Quebec, 6% of 33 nests were parasitized and in British Columbia, 21% of 118 nests were parasitized and 43 cases of adults feeding cowbird fledglings were documented. There is a case of a warbler feeding a young cowbird from the Yukon. In Maine, 5 of 13 nests (38.5%) were parasitized. In unfragmented forests in Wisconsin, 2 of 8 nests (25.0%) were parasitized, and 1 was 6 km from the nearest grassland opening. Of nests reported to United States nest records schemes, 11 of 79 (13.9%) east of the Rocky Mountains were parasitized and 2 of 9 (22.2%) west of the Rockies were parasitized. It may be subject to parasitism because of its preference for nesting near forest edges. Both warblers and cowbirds may fledge from parasitized nests but the effects of parasitism on the reproductive productivity of the warbler are unknown (Bent 1953; Campbell et al. 2001; Harrison 1984; Hunt and Flaspohler 2020; Létourneau and Lafontaine in Gauthier and Aubry 1996; Peck and James 1998a; Sinclair et al. 2003).

Habitat loss and degradation is currently not an issue for the Yellow-rumped Warbler. Considerable habitat was undoubtedly lost when European settlers cleared the forests. Maturation of coniferous plantations south of the Canadian Shield has increased the amount of available habitat.

In the Boreal Forest Region of Ontario, there was no change in abundance of the Yellow-rumped Warbler when 30-50% of trees were harvested, but populations began to decline once 70% of trees were removed. Harvesting with only 10% retention of trees caused 50-75% reductions. When data from the west and east were included, it exhibited a 25% decrease at less than 24% tree retention and a 50% decrease with less than 13% tree retention. It does not appear to be unduly affected by harvesting as long as residual trees are retained (Vanderwel et al. 2007, 2009). In Ontario in the Canadian Shield in early successional stands, there was no difference in its abundance in clear-cuts and burns. In mid-successional stands, it was significantly less abundant in clear-cuts than in stands created by fire. It was equally abundant in mid-successional and mature stands but significantly less abundant in early successional than mature stands (Zimmerling et al. 2017). Tittler et al. (2001) examined the effects of retaining residual trees in clear-cuts in Alberta. The Yellow-rumped Warbler population remained stable in control areas but declined in clear-cuts. In the third year after logging, it increased with increasing basal area in clear-cuts. It was the only forest species that benefitted from residual tree retention. Dalley et al. (2009) studied warbler survival rates relative to the amount of forest removed by clear-cutting in Newfoundland. Daily survival rate was essentially the same when 5-40% of the area within 20 m of the nest was harvested and, at the 115-m and 1,250-m scales,

survival remained steady regardless of intensity of harvest but it declined steadily as 10-100% of harvest was removed at these scales in a year with highly variable and inclement weather. The authors concluded that the Yellow-rumped Warbler may be threatened by high levels of harvesting. Also in Newfoundland, Whitaker et al. (2008) observed that there were apparently higher survival rates in natural landscapes than those containing clear-cuts. Nonetheless, they concluded that the Yellow-rumped Warbler is a habitat generalist that is typically unaffected by clear-cuts. It usually exhibits no response to selective thinning or a slightly positive response. In Algonquin Park, Jobes et al. (2004) found no differences in its numbers in control plots and those selectively thinned 1-5 and 15-20 years previously. It was associated predominantly with the presence of small conifers. Tozer et al. (2010) found no differences in abundance in controls and typical- and group-selection cuts in the park. In shelterwood cuts in white pine in the park, it occurred on 85.7-100% of control plots over 2 years, 90-100% of 10-16-year-old cuts, and 75% of 2-9-year-old cuts (Kingsley and Nol 1999). In New York, there was no significant difference in its abundance in stands where 0%, 25%, 50%, 75%, or 100% of merchantable trees were removed. In all forest types in Alberta, it increased when 25-75% of trees were harvested but declined when 80-100% of trees were removed (Harrison et al. 2008). In Minnesota, it tended to increase slightly when partial harvesting occurred (Hanowski et al. 2003, 2005) and it responded positively to single-tree selection in Idaho (Medin and Booth 1989).

In California, Bock and Lynch (1970) reported identical densities of the Yellow-rumped Warbler in areas burned by a natural fire and unburned areas. The fire affected most of the area except for several small pockets where a few mature spruce and fir remained. These were sufficient to maintain the low density of this species. Stephens et al. (2015) found that severity of burns affected the response of this warbler in Oregon. It decreased with increased severity of burns.

On Anticosti Island, the Yellow-rumped Warbler was negatively affected by deer browsing in mature forests. In areas of high deer density, white birch and balsam fir were scarce but abundance of spruce regeneration was unaffected (Cardinal et al. 2012). In Oregon, Earnst et al. (2012) monitored bird populations 1-3 and 10-12 years after cattle were removed from a formerly heavily grazed area. In the absence of cattle, substantial regeneration of aspen occurred and the Yellow-rumped Warbler increased significantly.

The Yellow-rumped Warbler may be adversely affected by chronic noise. In Alberta, it was significantly less abundant at noisy compressor stations than at quiet well pads. Bayne et al. (2008) concluded that noise could affect birds as far as 700 m into the forest.

In Wyoming, Gutzwiller and Anderson (1999) deliberately disturbed plots by having a person walk through them for an hour. In 1 area in 1 of 3 years, the mean abundance of the Yellow-rumped Warbler was 71% higher outside intruded areas. At another site, there was no significant difference over a 5-year period. The researchers acknowledged that the single significant difference could be spurious.

Blake et al. (1992) studied the effects of drought on breeding bird populations in Michigan and Wisconsin. The Yellow-rumped Warbler increased in drought areas, possibly because of the warmer winters associated with drought.

Cold and rainy or snowy springs may result in high mortality. Daily survival rates of nestlings were significantly lower in Newfoundland in a year with cold, inclement weather. On small islands in Maine, essentially all nest losses were due to weather events such as high winds and rain (Dalley et al. 2009; Hunt and Flaspohler 2020; Morse 1971b).

In Alberta, the Yellow-rumped Warbler exhibited no response to energy sector disturbances. There was no difference in its abundance at seismic lines, pipelines, or well pads than in forest interior adjacent to these features (Bayne et al. 2016).

No significant effects due to environmental contaminants have been documented. Levels of DDE, DDT, and dieldrin in birds collected at a Florida tower were too low to have deleterious effects and no adverse effects have been documented from insecticides used to kill spruce budworms (Hunt and Flaspohler 2020).

Competitive interactions among the Yellow-rumped Warbler and other warblers occur, but the relationships do not appear to be consistent geographically. Morse (1971b, 1989) studied the relationships of the wood-warblers in Maine. On small islands, a maximum of 3 warbler species was present, including the Black-throated Green Warbler, Yellow-rumped Warbler, and Northern Parula. This was the order of dominance. The presence of the Black-throated Green Warbler inhibited the Yellow-rumped Warbler from accessing some foraging locations. Because the Yellow-rumped Warbler had large territories and low density on the Maine mainland, it was concluded that the Magnolia Warbler and Blackburnian Warbler, in addition to the Black-throated Green Warbler, are socially dominant to the Yellow-rumped Warbler and may limit its numbers. During a spruce budworm infestation in New Brunswick, Yellow-rumped Warblers declined and Tennessee and Bay-breasted warblers increased significantly. This suggested that one or both of these species are socially dominant to the Yellow-rumped Warbler (Morris et al. 1958). This is the only location where a negative response to budworm populations has been reported for the Yellow-rumped Warbler. In most cases, its population does not fluctuate with changing budworm populations. In Minnesota, the Yellow-rumped Warbler displaced the Pine Warbler and Bay-breasted Warbler on 2 islands, suggesting that it was socially dominant to them (Howe 1979). In Alberta, the Yellow-rumped Warbler foraged in the portions of trees that were dominated by the Black-throated Green Warbler in Maine and Vermont, and the Yellow-rumped Warbler was 8 times more abundant than the Black-throated Green Warbler (Cumming 2004). This suggests either that the dominance roles were reversed or that there were sufficient resources that competition was not required. From Quebec westward, the Yellow-rumped Warbler is one of the most abundant forest-breeding warblers and its territory sizes are about half the size reported in Maine. This suggests that competition from other warbler species is not a significant limiting factor in most of its range.

Price (2004) concluded that the Yellow-rumped Warbler might disappear in southern Ontario if the average summer temperature increased by 2°C.

Status

Baillie and Harrington (1937) considered the Yellow-rumped Warbler a common summer resident, breeding from Wellington, north York, and Frontenac counties to the transcontinental railway (and probably to James Bay) west to Lake of the Woods. Several were observed in July 1930 along the Ontario-Manitoba border between latitudes 53°N and 54°N, suggesting that breeding occurred in

this area. The centre of abundance was between Georgian Bay and Ottawa where it was the most common warbler in many places. The first atlas defined its distribution better. It was widespread from the southern edge of the Canadian Shield to the Hudson Bay Lowland where it was ubiquitous, except in extreme northern squares that consisted entirely of tundra with no tree cover. It was rather spotty in distribution in the Great Lakes–St. Lawrence Forest Region south of the Shield, except for in the Bruce Peninsula and on Manitoulin Island, where it was widespread. It was rare in the Carolinian Forest Region, with scattered records at Turkey Point, Long Point, Kettle Point, and Woodstock. Highest abundance was reported from Algonquin Park, Parry Sound District, and Manitoulin Island (Crins in Cadman et al. 1987). James (1991) considered it a common summer resident across the province, south to Georgian Bay and Ottawa, rarely south to Norfolk County.

The second atlas revealed that the distribution of the Yellow-rumped Warbler was similar in the north to the first atlas, but it was much more widespread in the off-Shield portion of the Great Lakes–St. Lawrence Forest Region. Although it was found in a few more squares in the Carolinian Forest Region, it remained rare there where it was associated mostly with coniferous plantations on sandy soils. Its probability of observation increased significantly province-wide and in every region. The increase was attributed to colonization of maturing coniferous plantations and areas where mixed forests have regenerated on previously cleared land. Highest densities occurred in the northwest in the Boreal Forest Region. Moderate to high densities occurred from the southern edge of the Shield northward through the Hudson Bay Lowland (Crins in Cadman et al. 2007).

Hunt and Flaspohler (2020) stated that Breeding Bird Survey (BBS) data indicated a significant increase range-wide of 1.8% per year 1966-94, but with apparent declines of the Yellow-rumped Warbler in Ontario, Manitoba, central Alberta, and Newfoundland. Increases were particularly great in the northeastern United States where it has been expanding its range. BBS data indicate that it increased at annual rates of 0.2922% in Canada and 0.311% in Ontario 1970-2021. Trends for 2011-21 were annual decreases of 2.07% in Canada and 2.5% in Ontario. All results were of low reliability (A.C. Smith et al. 2023).

In Maine, MacArthur (1958) observed that the Yellow-rumped Warbler tends to increase following a decline and decline following an increase. The period of oscillation was 2.6 years indicating that populations were largely regulated by density-dependent factors rather than density-independent events such as catastrophes (storms and severe winters), some predation, and certain types of disease. It is uncertain if these regular population fluctuations occur throughout its range.

POSTFLEDGING PERIOD

Brood division appears to occur as soon as the fledglings leave the nest, but all fledglings may associate with the male if the female initiates another clutch. Juveniles have been found within 80 m of the nest 14 days after fledging. Young are dependent on the adults for at least 14 days after leaving the nest (Hunt and Flaspohler 2020).

As early as late July, both adults and juveniles form flocks and may join chickadees and other species. In the Yukon, the Yellow-rumped Warbler is most abundant in August when large numbers of juveniles congregate at productive wetlands. In Quebec clear-cuts in mature balsam fir, black spruce, and white birch forests, only 5 were captured during the postfledging period in 2 years.

Forty-eight juveniles were captured in Newfoundland clear-cuts in 2 years. At the 5-m scale, they were associated with dense understorey vegetation and dense foliage above breast height. At the 115-m scale, they were associated with patches downslope from their previous location in areas characterized by dense cover, but this relationship was significant in only 1 of 2 years. Small changes in elevation (10-30 m) were associated with significant changes in productivity and prey availability, so juveniles may continually move downslope to increasingly productive habitats. Juveniles appear to seek areas of dense vegetation that provide shelter from predators and the elements and that have high prey availability (Hunt and Flaspohler 2020; Major and Desrochers 2012; Mitchell et al. 2010b; Sinclair et al. 2003).

In Newfoundland, Mitchell et al. (2010a) documented broadscale movements of juveniles prior to migration. Young moved an average of 4,071 m (range 377-9,468 m). Juveniles moved both toward and along river valleys, moving down the elevational gradient of the rivers and in a clear orientation to the east. River valleys were associated with significantly higher productivity and prey availability and may provide optimal foraging habitat.

Mitchell et al. (2009) examined the effects of clear-cuts on the movement of recently independent Yellow-rumped Warbler fledglings through boreal forest habitat in Newfoundland. Median movement rate of juveniles was 353 m per day (range 24-6,154 m). Movement rate increased and residency time decreased as the proportion of clear-cut land increased, but if there was a high proportion of clear-cut land along the pathway used to exit the neighbourhood, movement rate was reduced and connectivity was impeded. Clear-cut lands may represent low-quality habitat for it during the postfledging period.

MIGRATION

The Yellow-rumped Warbler is a short-distance migrant. Populations in the southeastern United States and Pacific Coast of the United States are permanent residents; more northerly populations are migratory. Migration is predominantly nocturnal but movements may also occur during the day. Birds have been observed migrating along the Ohio River in Illinois during the day. During autumn in Louisiana, diurnal northeastward flights were made following a cold front with northeastward winds. All flights were into the wind, but this reverse migration allowed migrants to make a shorter over-water flight. Migration is quicker in spring than autumn, averaging 312 km per day in spring compared with 88 km per day in autumn. In Ohio, 2 Yellow-rumped Warblers stayed at a stopover site 4 and 8 days. One Wisconsin spring migrant stayed 5 days and the mean stopover duration in spring in Ohio was 5.9 days for 32 birds. It exhibits a facultative autumn migration that may continue into late winter. Birds may linger north of the typical wintering range when weather is favourable and food is abundant. If conditions decline, birds may move further south, and this is a common occurrence even in Florida and Arizona within the heart of the wintering range. In Arizona at the most northern study area, numbers peaked in October and declined to near 0 in November, typical of normal autumn migration. At the central study area, maximum numbers occurred in mid-December with a decline from then through early January. By early February, only 6 birds per km^2 were present compared with 1,125 in mid-December. At the southern site, there was an increase in January, consistent with the fact that birds moved further south as winter progressed. Changes in abundance at the northern sites coincided with declines in insect abundance, and cold fronts may

have been an influence in 1 year. In Florida, 67% of tower kills occurred in late December, 27% in January, and 6% in February. The distribution of dead birds around the towers correlated with wind direction, the same as for autumn migration. Both studies suggested that it may resume migration in late autumn or winter to avoid adverse weather or food shortages. In Alberta, autumn migration was initiated when the moult was approximately 50% complete. Two peaks of abundance were observed during migration. This may represent breeding populations near and distant to the study area moving past at different times, earlier migration of failed breeders, or differences between single- and double-brooded birds. During winter, males predominate in the northeastern and north-central United States. Females predominate in Florida, the West Indies, and Central America. Yearling males winter north of older males and yearling females winter south of older females. During winter, the number of females increases in the southeastern United States, suggesting that they may be more likely to exhibit facultative migration than males (Flockhart 2010; Graber et al. 1983; Hunt and Flaspohler 2020; MacDade et al. 2011; Slager and Rodewald 2015; Terrill and Crawford 1988; Terrill and Ohmart 1984; Yaukey 2010).

During spring migration, males arrive a few days to more than a week in advance of females. Adult males arrive before yearling males and adult females arrive before yearling females. At Prince Edward Point, the mean date of arrival for males (9.4 May) was 4 days earlier than for females (13.4 May). The difference may have been greater because many males arrived in April before sampling began. At Long Point, the mean capture dates for males was 0.3 May for adults, 3.6 May for yearlings, and 2.9 May for those of undetermined age. For females, median capture dates were 10.3 May for adults, 11.8 May for yearlings, and 10.6 May for those of undetermined age (Flockhart 2010; Francis and Cooke 1986; Hunt and Flaspohler 2020; Stewart et al. 2002). In southern Ontario, the Yellow-rumped Warbler arrives in early to mid-April and is common until mid-May. Most are gone by the end of May but a few remain into early June (Black and Roy 2010; Curry 2006; Fleming 1907; Keast 1980; LaForest 1993; Lancaster et al. 2004; Weir 2008). The midpoint of migration at Long Point is 8 May (Mills 2005a). In the southern Shield, average arrival is around the third week of April and the earliest birds arrive in early April (Mills 1981; Tozer 2012).

In autumn, there appear to be no differences in passage dates of the sexes or age classes (Dean et al. 2004; Flockhart 2010). In the southern Shield, migration may extend from mid-August until mid- to late October, with rare records in November and December (Mills 1981; Tozer 2012). Migration is also underway in mid-August in the south; 50% of the flight has gone through by mid-September with peaks in late September to mid-October. There are late records from November and December and some birds overwinter (Black and Roy 2010; Curry 2006; Fleming 1907; Keast 1980; LaForest 1993; Lancaster et al. 2004; Weir 2008). The midpoint of migration at Long Point is 8 October (Mills 2005a).

Four studies examined the phenology of Yellow-rumped Warbler migration in relation to climate change. At Long Point, there was no significant difference in timing of the first spring arrival date 1975-2000, although there was a trend toward earlier arrival. In autumn, it migrated significantly later at a rate of 3.5 days per decade. Only females showed a significant change in phenology, delaying migration by 2.3 days per decade (Mills 2005a). In Rhode Island, Smith and Paton (2011) analyzed 45 years of banding data and determined that it significantly delayed autumn migration

in recent years. All short-distance migrants combined delayed migration by an average of 3.0 days per decade. Over a 157-year period in Massachusetts, spring arrival of this warbler was significantly correlated with the mean temperature in the study area during the 2 months prior to its arrival (Ellwood et al. 2010). Strode (2003) analyzed arrival times of spring migrants over 100 years in Illinois and 40 years in Minnesota. Spring is arriving later in Illinois than formerly but earlier in Wisconsin so that migrants may have 20 fewer days to complete migration between these states. Over the 100 years, the Yellow-rumped Warbler was 1 of 2 out of 8 warblers that arrived significantly earlier in Illinois than in previous years, and it also arrived significantly earlier in North Dakota in recent years.

During migration, the Yellow-rumped Warbler may occur almost anywhere. It may inhabit forests of any type, all age classes, and both open and closed stands. In addition to forested areas, it occurs in shrubby areas, alpine meadows, backyard gardens, treed boulevards, orchards, power-line rights-of-way, hedgerows, city parks, and rural and suburban residential areas. It is much less frequent in grasslands and fallow and cultivated fields. Despite being a habitat generalist, it exhibits some habitat preferences during migration, and these are frequently related to food abundance. In western Canada, it is most abundant in shrubby riparian areas along lakes, rivers, and wetlands. In southern Illinois, highest densities of spring migrants occurred in pine plantations where it foraged in deciduous shrubs in the understorey. It made heaviest use of bottomland forests in central Illinois, but it also occurred in mature upland forests, forest edges, and shrubs, and rarely in corn stubble and pastures. In South Carolina, numbers seen per hour during spring migration were 4.36 in beech forests, 2.81 in oak-hickory forests, 2.23 in floodplain forests, 0.91 in pine forests, 0.78 in dry thickets, and 0.64 in wet thickets. During spring and autumn migration in British Columbia, it was negatively associated with deciduous riparian habitat in coniferous forests, and this relationship was significant in spring. In South Dakota during autumn migration, more were captured in a 3.5-ha woodlot than in contiguous riparian forests, but not significantly. On 2 islands in Maine, it was significantly more abundant in both spring and autumn on the island dominated by low sapling and shrub vegetation than on the treed island. Three birds, 1 in spring and 2 in autumn, that were banded on the treed island were recaptured on the shrubby island 0.7 km distant. Although habitat structure was probably an important factor in island selection, food abundance may also have affected its distribution. Bayberry, a favoured food, was moderately abundant on the shrubby island and absent on the treed island. In New Mexico, it was more abundant in cottonwood–Russian olive communities in autumn and declined in agricultural edges in autumn compared with spring. This may have been due to the greater abundance of fruit in communities with Russian olive in autumn. During spring migration in Wisconsin and Minnesota, it was significantly more abundant in floodplain forests. This was probably due to leaf phenology, with leaf-out occurring slightly earlier in floodplain forests. During autumn migration in Ohio, it was equally abundant in all habitats studied in 1 year. In another year, it was significantly more abundant in shrub-sapling-stage forests than other habitats, and was not detected in suburban habitats. Abundance in forest-agricultural habitat was significantly greater than in suburban forests and greater than in forest interior, but not significantly (Campbell et al. 2001; Chapman 1907; Dean et al. 2004; Graber et al. 1983; Kelly et al. 2000; Kirsch et al. 2013; Leighton et al. 2002; Létourneau and Lafontaine in Gauthier and Aubry 1996; Parnell 1969; Rodewald and Brittingham 2002, 2004; Sinclair et al. 2003; Suomala et al. 2010, 2012; Wiebe and Martin 1998).

Strode (2009) examined tree usage by the Yellow-rumped Warbler during spring migration in Illinois. Foraging was distributed unevenly among tree species in all 3 years. The greatest numbers of observations (40-48%) were in hackberry with 5-34% in white elm, red elm, bur oak, and sugar maple. Less than 5% of observations were in other trees (ash, basswood, black walnut, red oak, Ohio buckeye, and hickory), and none were observed in Kentucky coffee-tree. Early migrants selected hackberry in all 3 years and white elm in 2 of 3 years. Other species were used less than their availability, particularly ash, sugar maple, and basswood. Late-arriving migrants selected both white and red elm in 3 years, black walnut in 2 years, and bur oak and hickory in 1 year; other trees were used less than their availability. Preferences for tree species were linked both to tree phenology and insect availability. The median date of Yellow-rumped Warbler arrival was correlated with the date of 100% bud break on tree species. The date of median warbler counts in each of the 7 tree species surveyed for caterpillars correlated with the date of the maximum number of caterpillars. A preference for hackberries occurred early in the season because of its early leaf-out and the abundance of hackberry gall psyllids. Both elm species and bur oak supported higher densities of caterpillars and were preferred later in migration. Later migrants were females, suggesting that tree species selection may differ between the sexes. Opportunistic timing and tree species use suggest that it may experience little to no negative effects from climate change.

During spring migration in Wisconsin, Slager and Rodewald (2015) radiotracked a Yellow-rumped Warbler that left its diurnal home range to roost overnight. It flew about 2.6 km from its daytime activity centre to roost overnight in pine windbreaks within agricultural row crops. Shortly after sunrise the next morning, it flew 3.2 km to a different location for the day and returned to the same roost site that evening. No attempt was made to relocate it in subsequent evenings, so it was unknown if it returned to the same roost each night. It was also unknown if it roosted alone or communally. The bird roosted in dense coniferous cover that may have offered better protection from predators because deciduous trees had just begun to leaf out. Disjunct roosting was observed by only 1 of 30 birds, so this may be a rare behaviour. It is possible that migrants may take the presence of suitable roosting habitat into account when selecting stopover sites. In British Columbia, migrants roosted on small ledges on a face in a gravel pit (Campbell et al. 2001).

During spring migration in Wisconsin, 1 Yellow-rumped Warbler used different home ranges in each of 5 days, but all were within 1-2 km of each other. Daily home ranges were 5.1-9.0 ha (Slager and Rodewald 2015). In South Dakota, autumn migrants exhibited high site tenacity, with 30 of 33 radiotracked birds (90.9%) remaining at their relocation site. Birds that were captured were randomly relocated at a woodland corridor or woodlot site other than where they were initially captured. For the 3 individuals that moved, maximum distances moved were 2.5, 1.9, and 1.5 km. Minimum stopover duration was 1-17 days and more than 80% of birds left for migration within a week. Mean temporary home ranges were 0.08 km^2 in corridors and 0.03 km^2 in woodlots. Birds at stopover sites with smaller woodland areas had smaller home ranges. Habitat type did not have a significant effect on stopover duration, movement rate, or temporary home range size. Birds with lower movement rates tended to stay longer. Birds moved at higher rates later in autumn. Birds departed more frequently on clear nights with a mean cloud cover of 15.9% on departure nights. Departure nights had less tail wind and more head wind, lower temperatures, and lower barometric pressure than nondeparture nights (Liu and Swanson 2015).

During the daytime, the Yellow-rumped Warbler may join mixed-species flocks, particularly in autumn. It is an early spring migrant that is most likely to be found in the company of kinglets, Pine Warblers, and Palm Warblers. It may accompany a wide variety of species in autumn. When resources are limited, the Yellow-rumped Warbler may attack other species, but typically only those that have food in their bills or that are close to fruit-bearing shrubs. Kilham (1961) observed it attacking Red-bellied Woodpecker, Red-headed Woodpecker, Hairy Woodpecker, Downy Woodpecker, Carolina Chickadee, Blue Jay, and Northern Cardinal. No aggression occurs if food is abundant.

At Prince Edward Point, the Yellow-rumped Warbler fed at heights of 0-9 m during autumn migration, most frequently around 2 m, and mostly at heights of 7 m or less. It fed only to a small extent in the outer foliage, concentrating mainly in the outer branches and core of the tree and occasionally descending to the ground. Foraging locations consisted of 21% on outer leaves, 18% on the ground, 15% on inner branches, 12% on twigs and inner leaves, 12% on outer branches, 10% on sapling branches, 9% on sapling foliage, and 3% on low shrubs. No foraging was observed in the air or on trunks (Keast 1980). During spring migration in South Carolina, singing birds were observed at heights of 0-15 m (average 6 m). Nonsinging birds occurred within the same range of heights, but at an average of 10 m. It was the only species studied for which singing males were not higher up than other birds. Fifty-three percent of foraging occurred in the canopy, 40.4% in low trees, 6.7% in shrubs, and 0% on the ground. In the canopy, 24.0% of foraging occurred at the top of the crown, 18.5% in the inner crown, 10.5% in the lower crown, and 0% on the bole. In low trees, 8.7% of foraging occurred at the top of the crown, 18.8% in the inner crown, 12.9% in the lower crown, and 0% on the bole. In shrubs, 1.1% of foraging occurred at the top of the crown, 1.4% in the inner crown, 2.4% in the lower crown, 1.8% in dense thickets, and 0% in brush piles and grasses (Parnell 1969). From early to late spring, foliage gleaning increases; hovering and hawking decrease (Hunt and Flaspohler 2020). During migration, the Yellow-rumped Warbler may cling to walls and gutters of houses in search of insects. It may drink sap (and probably eat insects) from Yellow-bellied Sapsucker wells and injured sugar maple trees and probe burdock burs for insects (Bent 1953; Graber et al. 1983; Létourneau and Lafontaine in Gauthier and Aubry 1996; Mousley 1917; Underwood and Underwood 2013). Moore and Simm (1985) artificially prolonged daylight to stimulate migration response in captive warblers. Those in migratory disposition foraged more efficiently by consuming more food items per foraging bout, handling food items more rapidly, and feeding selectively on larger prey. Harrison (1984) reported an autumn migrant that followed the wake of a boat in Delaware Bay, feeding on the insects that were stirred up. Two separate incidents of it feeding on ice during adverse weather conditions in spring in Manitoba have been documented. Warblers appeared to be foraging on small flies, midges, beetles, and spiders that were on the ice (McNicholl and Goossen 1980). During adverse conditions during autumn migration in Ohio, a juvenile crept through a lawn apparently picking tiny arthropods off the undersides of grass blades and violet leaves. By this time, all local fruit supplies had been depleted (Tramer and Tramer 1977). During autumn migration in New York, large numbers foraged nocturnally, using aerial sally movements to capture insects from foliage or in the air. The area was illuminated by lights from a football stadium (Lebbin et al. 2007). In Algonquin Park during autumn migration, it caught insects on exposed waterlily roots in the mud of a pond, 50 foraged along the muddy shores of a pond, and one captured insects on the walls of the visitor centre (Tozer 2012).

The diet of the Yellow-rumped Warbler changes from predominantly insects in spring to fruit in autumn and winter, although it still consumes insects where they are available. In April and May in Illinois, it fed heavily on geometer moth and other caterpillars. The stomachs of 5 birds contained 4 hymenopterans (1 ichneumonid wasp), 3 beetles (2 scarab beetles), 3 true bugs, 2 flies, 1 caterpillar, 1 spider, and 1 seed (Graber et al. 1983). In Arizona, insect sweep samples reflected the diets of the birds collected. At 1 site, aphids constituted the vast majority of available insects and these represented the greatest volume of food consumed. At another site, midges comprised the majority of both the available insects and the diet. Items comprising at least 10% of the diet at 3 locations included leafhoppers, aphids, hymenopterans, beetles, midges, and assassin bugs. Other food items included adult and larvae lepidopterans, ants, metallic wood-boring beetles, weevils, spiders, true bugs, flower flies, treehoppers, and sap beetles (Terrill and Ohmart 1984). MacDade et al. (2011) studied the breath composition of spring migrant Yellow-rumped Warblers along the Lake Erie shoreline of Ohio. A combination of aquatic and terrestrial food items was consumed. Midges were the dominant aquatic prey and results demonstrated increasing consumption of aquatic prey as the season progressed. Midge emergence is temperature sensitive and increases in frequency as spring weather and water temperatures become more favourable. It opportunistically supplemented its diet with midges as their availability increased. In Idaho, Carlisle et al. (2012) compared the diet of autumn migrants to the availability of arthropods. Prey items consumed in greater proportion than their availability included, in order of preference, beetles, spittle bugs, leafhoppers, larvae, and lepidopterans. Invertebrates consumed less than their availability, in order of greatest avoidance, included bugs, spiders, stilt bugs, jumping plant lice, hymenopterans, flies, stink bugs, ants, and moths. In the eastern United States, it feeds extensively on bayberry in autumn and winter, and its abundance and distribution is closely tied to this plant. In the west, it eats waxmyrtle. The pulp of these fruits is covered with a solid waxy material that consists predominantly of saturated long-chain fatty acids. The Yellow-rumped Warbler possesses several gastrointestinal traits that allow it to assimilate more than 80% of this wax, compared with less than 50% for most vertebrates (Place and Stiles 1992). S.B. Smith et al. (2007) determined that it could not satisfy its daily protein requirement by eating high-energy fruits such as bayberry and southern arrowwood. It must eat both insects and fruit to satisfy its dietary needs in autumn and winter. Although bayberry is a staple in much of its range, it eats other fruits, seeds, and insects in autumn and winter. There are numerous records of it eating poison ivy berries and this is probably a staple in Ontario where bayberry is rare. Other fruits it eats include those of red cedar, juniper, Virginia creeper, viburnums, honeysuckles, mountain-ash, spikenard, greenbriers, and dogwoods. It also eats sunflower and goldenrod seeds. During autumn migration in Illinois, it fed on hackberry thorn gall midges as they emerged by the thousands (Bent 1953; Graber et al. 1983).

During migration, the Yellow-rumped Warbler commonly strikes communication towers, lighthouses, and other tall structures. It was the most commonly killed species at a Florida tower, constituting 7% of all casualties. It is rare at tower kills in Pennsylvania. At the Lennox generating station chimneys near Kingston, 55 were killed 1972-82 out of 22,779 songbirds (Bent 1953; Graber et al. 1983; Hunt and Flaspohler 2020; Weir 2008).

DeGroote and Rodewald (2010) examined blood parasites in Ohio spring migrants. Avian haematozoa occurred in 58.3% of spring migrant Yellow-rumped Warblers and the intensity of

infection increased with later capture, a relationship that was most pronounced for yearling birds. Parasitism could influence birds during migration and the subsequent breeding season, with reduced reproductive performance, particularly by yearlings.

James (1991) considered the Yellow-rumped Warbler a common to locally abundant migrant. At Long Point, it is the third most frequently banded species (Anonymous 2010b). At Long Point, Hussell et al. (1992) reported a significant increase of migrant Yellow-rumped Warblers of 2.6% per year 1961-88. Trends by period were: 1961-70, –0.2%; 1970-79, +0.7%; and 1979-88, +8.7%. More recent results from Long Point confirm that it continues to increase in both spring and autumn (Anonymous 2010b).

WINTER

Root (1988) concluded that the winter distribution of the Yellow-rumped Warbler was strongly influenced by temperature. In most areas where it occurs, the annual frost-free period is at least 180 days and the January temperature rarely drops below –4°C. Highest concentrations in the east are coincident with the distribution of bayberry, which covers the coastal plain from New Jersey to Louisiana.

In Illinois, Graber et al. (1983) observed that the Yellow-rumped Warbler could withstand a temperature of –29°C provided that poison ivy fruit was abundant. It was consistently more numerous in bottomland forests than other habitats, although good numbers also occurred in upland pine forests. In bottomland forests, there appeared to be an alternate-year pattern of high and low numbers that did not occur in upland forests. This may be related to availability of poison ivy berries, but this requires further study. It also appeared to be correlated with the number of trees at least 10 cm DBH, increasing as the number of trees increased above 395 per ha and declining as the number of trees declined. This relationship may also be correlated with fruit abundance. In Pennsylvania, Wilz and Giampa (1978) observed the Yellow-rumped Warbler in 2 habitats, and it was the dominant species in both areas. These habitats included pines 15-18 m tall with scattered 1-m tall bayberry in the understorey, and cottonwood 4.5-18 m tall with the highest density of bayberry 0.9-3 m tall in the area. In South Carolina, Kwit et al. (2004) could not conclusively separate the effects of habitat type from fruit availability. When habitat type was held constant, there was a positive correlation between this warbler's abundance and bayberry fruit mass. It occurred in pine stands, regenerating clear-cuts, and bottomland forests. Twelve percent of observations were in bottomland hardwoods and 11% in upland habitats even though bayberry did not occur in these areas. It remained uncertain whether it used regenerating habitats because of plentiful bayberry fruit. In an urban area and urban edge in northern California, its abundance increased with the availability of shrubs and/or trees and decreased with abundance of roads and structures. Kalinowski and Johnson (2010) concluded that it may be among the most vulnerable species to habitat changes associated with urbanization. In winter in Louisiana, it prefers open deciduous woods but also inhabits bare open fields, roadsides, hedgerows, neglected city lots, and trees and shrubbery in parks. It may also occur on sandy ocean beaches where it flycatches from half-buried logs and posts (Chapman 1907).

In winter, the Yellow-rumped Warbler roosts nocturnally in the thickest available treetops, which are mostly conifers, but also in nooks and crannies about buildings and even in holes in hay and

straw stacks in barnyards. Occasionally, as many as 50 roost together but more often individuals roost alone. In Arizona, one fluttered against a glass door through which it could see a Christmas tree. The homeowners opened the door and it flew in and roosted in the tree overnight until it was let out the following morning. It returned the following evening, but was not let inside (Bent 1953; Dunn and Tessaglia-Hymes 1999; Graber et al. 1983).

Monroy-Ojeda et al. (2013) studied winter fidelity of the Yellow-rumped Warbler in Mexico. Six percent of migratory birds exhibited winter site fidelity, 5.1% were residents that occurred in more than 1 year, and 0.6% exhibited both winter site fidelity and residency.

The Yellow-rumped Warbler may defend food resources from other species during adverse weather conditions when food is limited. In Florida, 1 warbler set up in an area of 2,000 m^2 in urban backyards. It remained there for 14 days while the temperature remained below 21°C with nightly decreases to below 4°C. During this period, it searched the lawn for food or sat on an exposed perch from which it sallied for passing insects. It attacked Palm Warblers and Ruby-crowned Kinglets when they attempted to forage in this area and was usually successful in driving them away. American Robins, Northern Cardinals, and White-throated Sparrows were attracted to the yard by bread and seeds. This food was not used by the warbler and it did not attack these species. When the weather warmed up to 23°C and above 4°C nightly, it joined a flock of foraging birds that contained Yellow-rumped Warblers and was not seen again. It was possible that the colder than normal temperatures and consequent shortage of insects caused it to form a temporary territory, but it reverted to more normal flock-foraging behaviour when temperatures increased (Woolfenden 1962).

In its main winter range, the Yellow-rumped Warbler is closely associated with bayberry in the east and waxmyrtle in the west. Autumn migration may be delayed where bayberry abounds, with birds moving further south once weather deteriorates or bayberry fruit becomes depleted. In many areas, it appears to subsist almost entirely on bayberry and has little competition for them from other species because few can digest it. Even low numbers of bayberries can support large numbers of warblers. At a Pennsylvania site, birds were never observed feeding where bayberry was absent. During periods of heavy snow cover, warblers fed almost exclusively on bayberry. Ground foraging became more common once bayberry fruit became scarce, and it also fed at fallen, partly decayed logs and on spider eggs under the eaves of a beach house (Bent 1953; Borgmann et al. 2004; Campbell et al. 2001; Chapman 1907; Hausman 1927; MacArthur 1958; Root 1988; Wilz and Giampa 1978). Outside the range of bayberry, poison ivy fruit is probably the most important winter food. In Illinois, fluctuations in warbler numbers were thought to be related to the abundance of poison ivy berries, and these were the most important food. Wintering birds in Elgin County were observed eating poison ivy berries, suggesting that they may be an important food item in Ontario (Graber et al. 1983; Lancaster et al. 2004). In winter, the Yellow-rumped Warbler may consume other types of fruit, including all those identified in the autumn diet; it may also consume some nectar. In winter, it gleans fruit or insects from leaves or branches, and rarely from dead leaves. Sixteen stomachs collected in Alabama in winter contained predominantly flies, beetles, ants and other hymenopterans, caterpillars, aphids, and spiders. Other winter foods include gall-forming insects, willow buds, frozen apples, honeydew from aphids, insect eggs, pitch pine seeds, and grass seeds (Bent 1953; Chapman 1907; Hunt and Flaspohler 2020). Beal and McAtee (1912) summarized the

contents of 383 stomachs collected in the western United States during winter. The diet was comprised of 84.7% animal food and 15.3% vegetable matter. Hymenopterans (wasps and ants) were the dominant food item, constituting 26.2% of the diet; most were ants. Flies comprised 16.4% of the diet, mostly gnats, house flies, and crane flies. Bugs constituted 19.1% of the diet, including aphids, scale insects, stink bugs, leafhoppers, and treehoppers. Lepidopterans formed 14.2% of the diet with a few adult moths and pupae consumed in addition to caterpillars. Beetles constituted 6.7% of the diet and included carrion and lady beetles and weevils. A few other insects and spiders constituted the remainder of the animal food. The vegetable food consisted of 9.2% weed seeds, 5% wild fruits, and vegetative rubbish.

The Yellow-rumped Warbler visits all designs of feeders and samples a variety of foods. It is an irregular feeder visitor, with only about 10% of sites hosting it all season. It is less likely to visit rural than urban feeders, possibly because there is more natural food in rural areas. Favourite foods include suet, bird puddings, and water, and small numbers show a preference for peanut hearts, peanut butter mixes, and fresh fruit. Infrequently chosen items include black oil sunflower seeds, sugar water, and baked goods (Dunn and Tessaglia-Hymes 1999). In Muskoka, one coming to a feeder ate oatmeal (Mills 1981). In Illinois, it ate cheese at feeders (Graber et al. 1983).

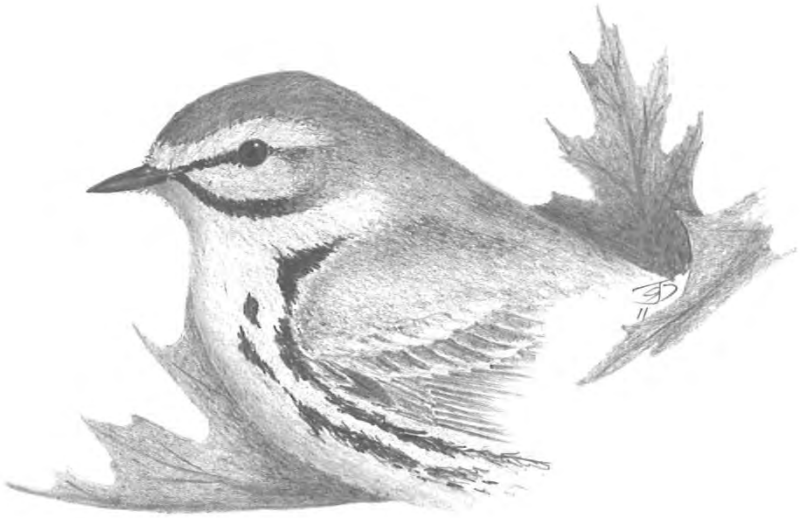
Graber et al. (1983) observed great variations in the number of wintering Yellow-rumped Warblers and tentatively concluded that this could be related to the supply of poison ivy berries, the staple in the diet. Regardless of initial numbers, declines of 40-45% occurred from before 10 January to after 31 January. They were uncertain if this decline was due to migration or mortality. Given this species' penchant for facultative winter migration, it is likely that some of the decline was attributable to migration. Nonetheless, mortality may also occur during severe winters. During very cold weather and heavy snow that persisted for a month in Illinois, Graber and Graber (1979) noted significant changes in its density. Density in bottomland forest was 16.8 per km^2 prior to the adverse weather and 1.5 afterwards, a decline of 91.2%. In upland forest, density was 7.9 before and 12.6 after, an increase of 59.4%. No birds were observed in urban residential areas during either period. Some birds appeared to have switched from bottomland forest (the preferred winter habitat) to upland forest as a result of the adverse weather, possibly because some upland forests had an abundance of poison ivy berries. Overall densities were much lower and 2 dead warblers were observed, indicating that some mortality had occurred. When sudden severe winter weather occurs, some birds may not be able to find adequate food resources or move further south in time to avoid mortality.

James (1991) considered the Yellow-rumped Warbler a rare winter resident in the south north to Peterborough and Ottawa. In the Hamilton area, McIlwraith (1894) stated that it stayed into late autumn but there were no winter records. The first Hamilton winter record occurred in 1951 and it has gradually become more common in winter, with as many as 7 or 8 occurring some winters. The increase is probably due to a combination of increased observer effort and milder winters (Curry 2006). Scattered winter records are available from Kingston (Weir 2008) and Elgin County (Lancaster et al. 2004).

Christmas Bird Count data indicate that the Yellow-rumped Warbler increased at an annual rate of 1.86% in Ontario 1970-2021 and decreased at an annual rate of 6.72% 2009-21 (National Audubon Society 2022).

Prairie Warbler

Setophaga discolor

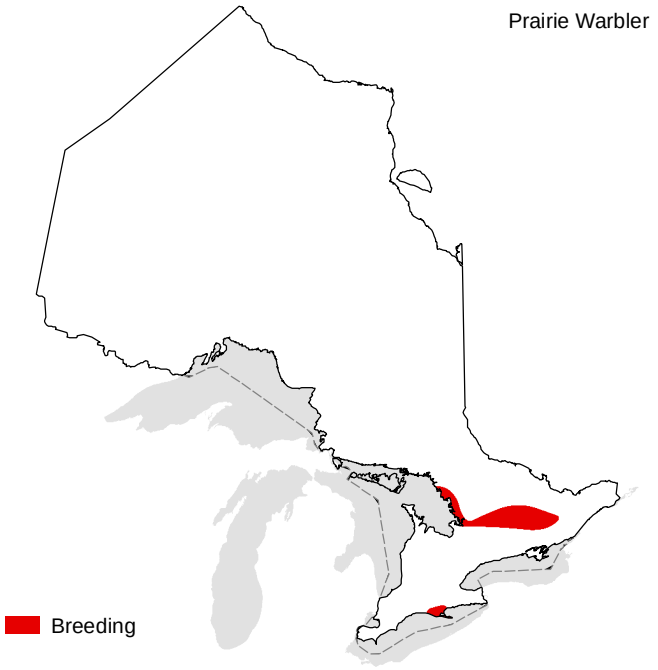


BREEDING SEASON

Habitat Requirements

Ontario Prairie Warbler nests were usually in areas of open, low growth, with juniper and stunted oak predominating. Breeding sites were either sandy (54.5% of nests) or rocky (45.5%) and almost always dry. One nest was in a pine plantation and another was in an overgrown meadow. Many nests were near shorelines of lakes (Peck and James 1987).

Most of Ontario's population breeds in the southern Canadian Shield in the Great Lakes–St. Lawrence Forest Region. The main habitat the Prairie Warbler uses is granite rock barrens along the Georgian Bay coast that are sparsely vegetated with stunted white pine, red pine, and red or white oak with patches of common juniper. This habitat is open in nature and only about 50% vegetated. It occurs in similar habitat along the southern edge of the Shield, particularly in Peterborough and Frontenac counties. In Frontenac County, cliffs and steep rocky inclines along lakes are favoured habitats, especially if fire has recently opened the forest. In the same county, it nests on wide hydro transmission line corridors where they pass through areas of exposed bedrock. Almost all occupied habitats on the Shield are characterized by sparse vegetation on exposed bedrock with common juniper and stunted oaks and pines (Austen et al. 1994; Harrington 1922; James 1996c, 1999e;



Lambert and Smith 1984, 1985; Mills 1981; Weir 2008). North of Parry Sound and Dillon Cove, Niskanen (1997) reported a pair nesting in unusual habitat. The territory included a bare bedrock outcrop with fairly typical habitat, although all the pine trees were dead. The nesting area was in the drier margins of a wetland dominated by sweet gale, reed canary grass, reed grass, and manna grass. The territory had a newly constructed cottage road on 1 side and a small back bay on another.

The Prairie Warbler inhabits a variety of habitats south of the Shield, almost all of which are on sandy or rocky substrates. The sand dunes along Lake Huron from Pinery Provincial Park to Wasaga Beach formerly supported the highest population south of the Shield. It used the interdunal meadows for nesting. These consist of open habitat with scattered oaks and clumps of low woody vegetation including common juniper, fragrant sumac, grape, chokecherry, sand cherry, and red cedar. It is likely that the presence of common juniper and red cedar saplings made this area most attractive. Near St. Williams and Turkey Point, it formerly nested in young red pine and white pine plantations and deciduous shrubby areas on the Norfolk Sand Plain. These areas were abandoned once the pines matured, but a few pairs still occur irregularly. A third habitat used south of the Shield is limestone alvar planted with conifers and these provided good habitat when the trees were small. Nesting in this habitat occurred on the Flamborough Plain near Rockton and Kirkwall. It rarely nests in regenerating old fields in Ontario. It has been documented using this habitat in Waterloo Region, Prince Edward County, and near Campbellville. This habitat is clearly not preferred because it is abundant but rarely used. Another potential habitat used in Ontario is bog or fen, but this is hypothetical. A singing male was present for about 10 days in June 2001 in the Wainfleet Bog but was not found after that. It is most likely that this was an unmated male that subsequently moved on (Austen et al. 1994; Bent 1953; Black and Roy 2010; Curry 2006; Lambert and Smith 1984, 1985).

Most Prairie Warblers in the United States breed in disturbed anthropogenic habitats. In many states, breeding is confined to upland old-field meadows that are often on poor soils that inhibit regeneration. Although it may nest in habitats over a wide moisture regime, it is typically found in dry areas. In addition to old fields, it nests in logged areas, power-line rights-of-way, strip-mined areas, young plantations, and in openings in pine forests that are as old as 40 years. In Indiana, it bred in abandoned fields 0.8-4 ha in area, separated from each other by fragments of woods and treed fence lines. Trees were scattered in distribution in most fields, but some contained planted rows of black locust, black walnut, sugar maple, or white pine. One territory supported a total of 2,263 trees at a density of 1,594 trees per ha. Half the trees were 1.5 m or less in height and 90% were

a maximum of 4.6 m tall. Tangles of blackberry and other raspberries were common in these fields. The principal grasses present included little bluestem, oldfield three-awn, and Canada bluegrass and the prominent herbaceous species were plantain-leaved pussytoes, oxeye daisy, and goldenrods. Average habitat characteristics consisted of trees 6-13 m tall, 5-25% tree cover, 9-24% shrub coverage, and 1-10% bare soil. In Indiana, occupied areas were hilly and had no standing water except for puddles after rain. Limestone bedrock outcrops occurred on steep slopes and erosion had stripped away topsoil in other areas so that regeneration was inhibited within the territories. It also breeds in unmowed orchards, Christmas tree plantations, and logged, burned, and grazed forests. It is predominantly an open-country bird breeding in areas with high ground cover and few trees. Ordination studies indicated that the Prairie Warbler was the terminal or extreme species at the xeric, upland, low-biomass, open-country end of the spectrum when all species were considered. In Missouri and other locations, it breeds in clear-cuts, predominantly those dominated by oak-hickory-pine communities. In mountainous areas, it breeds in dry open habitats such as brushy ridges where forest removal has created suitable habitat. It may occasionally inhabit natural woodland openings. In New England, it nests in pastures overgrown with white cedar and hillsides with an understorey of barberry. In Massachusetts, it nested in hazel shrubs along roadsides. It may use low growths of deciduous saplings, such as oak, maple, elm, tulip tree, black cherry, sassafras, red cedar, and ash, and these areas often contain clumps of shrubs, especially sumac, raspberries, sweet fern, and greenbrier. In South Carolina, number of observations per hour during the breeding season included 4.55 in dry thickets, 1.00 in pine-hardwoods, 0.59 in pine forest, 0.26 in wet thickets, 0.21 in floodplain forest, and 0 in beech and oak-hickory forests (Bent 1953; Brooks 1940; Chapman 1907; Graber et al. 1983; Harrison 1984; Lehnen and Rodewald 2009a; Nolan 1955, 1963, 1978; Nolan et al. 2020a; Noon et al. 1979; Parnell 1969; Wells 2007).

The Prairie Warbler nests in a variety of natural habitats in the United States. Pitch pine barrens on sandy soils are the most frequently used natural habitat and it is locally common in Massachusetts and New Jersey barrens. In these areas, pitch pine forms an open canopy with lesser numbers of black oak, white oak, and white pine. A dense shrub layer is present in occupied areas, predominantly of scrub oak and ericaceous species such as black huckleberry, sheep laurel, lowbush blueberry, wintergreen, and bearberry. In Massachusetts, there was a strong discrimination between occupied and unoccupied sites. It avoided areas with high coverage by oak trees and those with high coverage, height, and basal area of pitch pine. It decreased in abundance in a curvilinear fashion with increasing height of vegetation, percent cover and basal area of pitch pine, and vertical and horizontal heterogeneity (Brush 1987; Chapman 1907; Morimoto and Wasserman 1991a). In New Jersey, it was equally abundant in oak-pine forests and hardwood swamps, although it tended to be more common in oak-pine (Rich et al. 1994).

The Prairie Warbler uses 2 natural habitats in Michigan. The most important are Great Lakes sand dunes similar to those in Ontario. Less frequently, it may occupy habitat similar to that of the Kirtland's Warbler. This consists of young jack pines on acidic, nutrient-poor, well-drained sand. The pines are short with an open canopy and often clumped and may either be natural or planted. The Prairie Warbler rarely occurs in prime Kirtland's Warbler habitat, selecting areas with an admixture of deciduous shrubs that are unattractive to the Kirtland's Warbler (Nolan 1978).

In New York, the Prairie Warbler breeds on alvars where it is locally common. This habitat consists of calcareous pavement barrens mixed with limestone woodland communities characterized by open forests of small trees containing substantial amounts of red cedar interspersed with areas of exposed limestone bedrock and open grassy areas (G.A. Smith 1988).

The Prairie Warbler occasionally breeds in forests in the United States, notably in the Great Dismal Swamp in Virginia which has a closed canopy. It also nests in Hickory Point Swamp in Maryland and the Great Cypress Swamp that is predominantly in Delaware, but partially in Maryland and Virginia. In the latter swamp, it was associated with Atlantic white cedar stands where it nested in clear-cuts at the edge of the swamp. It did not occur in forest interior. In Rhode Island, it nests in red maple swamps surrounded by upland forest. In this habitat, it is associated mostly with shrub coverage in the interface between the upland and wetland forests. The Florida subspecies nests in mangrove forests where nests are often over water (Golet et al. 2001; Heckscher 2000; Nolan 1978; Nolan et al. 2020a; Prather and Cruz 1995).

In the mid-Atlantic states, the Prairie Warbler was positively correlated with percent canopy coverage by conifers and mean canopy height and negatively correlated with canopy closure. It preferred open coniferous stands with tall trees (Robbins et al. 1989). In Texas, its abundance was positively correlated with the number of shrub species, number of shrub stems, foliage density at 1 m, and percent coverage by pines 5-16 cm diameter at breast height (DBH). It was negatively correlated with vegetation height, canopy closure, foliage density at 12-15 m, percent coverage by pines 17-32 cm DBH, and the number of tree stems 17-32 cm DBH (Conner et al. 1983). Also in Texas, it built nests in dense areas with a few large trees, with more shrubs and vines and bigger trees (Novak et al. 2016). In Kentucky and Tennessee, its abundance was positively correlated with shrubs (Lituma and Buehler 2016). Nolan (1978) analyzed densities reported from a variety of breeding bird surveys and reached 7 conclusions. There was no difference in breeding densities between entirely deciduous and pine-deciduous communities. Density appeared to be positively correlated with the biomass of green vegetation above ground level and especially with density of the shrub layer, provided that the canopy was not closed. The most common characteristic of plots with densities of 75-100 pairs per km^2 was abundant foliage widely distributed on twigs and small branches that were considerably exposed to sunlight. Population density may be correlated with insect abundance. High density in the sparse scrub of Indiana dunes may be attributable to the ribbon-like configuration of territories. Xeric communities support higher densities than mesic communities. Numbers per tract and size of the total bird population are closely correlated. Populations appear to be unusually dense in Maryland and possibly Virginia and North Carolina. In North Carolina, the Prairie Warbler was negatively correlated with the amount of tree canopy within 200 m. As tree canopy increases, shrub coverage decreases (Gilbert and Ferguson 2019).

Shake et al. (2012) examined the effects of patch size and shape on occupancy by the Prairie Warbler. Patch area was a good predictor of occupancy and they considered it an area-sensitive species with low occupancy in the smallest patches. They estimated a minimum area requirement of 1.1 ha and an optimal area of 5.5 ha. Nonetheless, occupancy rate was approximately 40% in the smallest patches (0.3 ha), 50% at 1.1 ha, 90% at 5.5 ha, and 100% at approximately 13 ha. Because many occurred in patches smaller than average territory sizes, the Prairie Warbler cannot be

considered an area-sensitive species. There was no evidence for effects due to patch shape or the amount of forest cover within 1 km on site occupancy. In Ohio, annual survival and productivity were unrelated to patch size (Lehnen and Rodewald 2009a). Nolan (1978) demonstrated that it did not avoid edge. Females actively selected territory edges for nesting even when territories bordered on unsuitable habitat. Nests were occasionally a few metres into wooded areas. In Texas, all nests were within 100 m of edge and none were found in the core of woodlands (Novak et al. 2016). Rodewald and Vitz (2005) detected edge avoidance in 4-6-year-old clear-cuts in Ohio. Captures of both juveniles and older birds increased with distance from forest edge, with more than twice as many captures of both age classes 80 m from edge than at 20 m from edge. Although more were captured in large (13-16 ha) than small (4-8 ha) clear-cuts, the difference was not significant. In Missouri, Woodward et al. (2001) analyzed distance from forest edge of nests in shrub habitat. The Prairie Warbler avoided nesting within 20 m of forest; 29% of nests were within this distance category but it represented 45% of available habitat and was underutilized. It moderately preferred the 21-40-m distance-from-edge category, although this preference was not statistically significant. Nest predation rates were greatest within 20 m from edge, declined 21-40 m from edge, and increased further than 40 m from edge. Predation rates were lower more than 40 m from edge than within 20 m of edge. In Kentucky and Tennessee, its abundance was similar at roads and 300 m distant from roads, but was 40% greater 600 m from roads. This difference was not significant and evidence of road avoidance was weak (Lituma and Buehler 2016).

Nolan (1978) compared the habitat requirements of the Prairie Warbler with coexisting warbler species. Where it occurs with the Yellow Warbler, the Yellow Warbler is found in more moist areas, often willow shrubs, or less shrubby habitats. The Chestnut-sided Warbler has extremely similar ecology and the 2 species rarely occur together. Where they do, territories do not overlap. Where both these warblers are present, the Prairie Warbler is confined to hotter drier scrub in which there are often pines as well as deciduous trees. The Chestnut-sided Warbler occupies cooler, moister, more deciduous cover on north-facing slopes. The Pine and Prairie warblers frequently coexist, with the Pine Warbler foraging and nesting higher, preferring larger trees, and usually gleaning exclusively from conifers. The Common Yellowthroat and Yellow-breasted Chat often share habitat with the Prairie Warbler. Both prefer lower, denser, and possibly moister locations and rarely forage as high in open situations as the Prairie Warbler. The Blue-winged Warbler may occur with the Prairie Warbler, but invades regenerating fields much earlier and prefers denser growth than the Prairie Warbler.

During the breeding season in Indiana, the nocturnal roosts of 7 birds were at heights of 74-150 cm near the tops of small trees standing in herbaceous vegetation in open fields (Nolan 1978).

Nests reported to the Ontario Nest Records Scheme were typically in low shrubs, especially common juniper that supported 65.7% of nests. Other nest species included viburnums (including downy arrowwood and maple-leaved viburnum, 11.4% of nests), hazel (8.6%), white oak (5.7%), and 2.9% each in dogwood, sumac, and pin cherry. Nests were in crotches in the upper parts of the shrub or sapling or, less frequently, in the outer branches or between 2 branches. Nests were 0.24-1.5 m from the ground, with most 0.6-0.9 m up (Peck and James 1987, 1998a). Harrington (1922, 1924) reported 5 nests from Nottawasaga Bay on Georgian Bay. All were in common junipers with 4 about

30 cm from the ground and the other 60 cm up. All were about halfway up the stem on the outer portion of a branch. One nest was on an outer branch of a juniper on the edge of a large clump of this shrub. Another 4 Georgian Bay nests were in common juniper in open rock barrens within 100 m of shore (Matis and Squarek 2023). North of Parry Sound, Niskanen (1997) found a nest 0.8 m from the ground attached to 2 meadowsweet branches. It was hidden beneath sweet gale. It was only about 6 m from a cottage road. Curry (2006) reported a nest 1.8 m from the ground in a hawthorn near Campbellville.

The female prefers to select a nest site at the periphery of the territory; the central portion of the territory is avoided for nesting. Boundaries between territories are also avoided, presumably so the female is not disturbed by quarrelling males. Undisputed territory boundaries are selected for nest sites where available, and these usually abut unsuitable habitat. Nests may be at edges of woods or as far as 20 m into them. Nests have been found in branches overhanging mowed fields. In 1 year in Indiana, many nests were in tall trees of woods and fence lines at edges of territories after a late frost withered the leaves of many small trees and shrubs. Nests are in shrubby vegetation, including tree saplings. Most nests are in the third quarter of the plant, with the lowest quarter avoided. In Indiana, 1.9% of nests were in the lower quarter of the plant, 21.7% in the second quarter, 62.1% in the third quarter, and 14.3% in the top quarter. The lowest quarter usually consisted of a leafless stem or trunk that offered few forks and little concealment. Branches and forks of the right size were most numerous in the third quarter where shelter and concealment was also highest. Where nests were in dense clumps, these tended to be composed of trees of approximately the same size. In these cases, nests were almost invariably in branches projecting 0.1-1.0 m above the top of the clump, analogous to a nest in a low tree standing among forbs and grasses. The proximity of other habitats appeared to be of little or no importance in nest-site selection except that mature woods were usually avoided. In Indiana, 555 nests occurred in 7 different types of placement: 47% in an upright fork, 27% against the trunk on twigs, 18% on a horizontal or diagonal branch (12% on small branches, 4% on small arched trees, and 2% on large branches), 3% in vines, 2% wedged among small branches, 2% fastened to vertical branches, and 1% in broom-like growths. About half of Indiana nests were sheltered by Virginia creeper or fox grape vines, but very few nests were in deep shade: 14% were in direct sunlight much of the day, 6% were exposed no more than 1-2 hours, 52% were never exposed to direct sunlight but received flickering sunlight for several hours, and 28% were probably never touched by direct sunlight. Nests do not appear to be oriented in any particular direction. Conifers are seldom used for nesting in the remainder of its range, and this typically occurs prior to leaf-out of deciduous species. About 750 Indiana nests were in 40 species of plants. White elm was highly preferred and selected, supporting 50.8% of nests. Other nest-tree species included sugar maple (9.4% of nests), hawthorn and plum (7.1%), flowering dogwood (5.1%), sassafras (2.6%), blackberry (2.1%), pines (2.1%), red cedar (1.5%), and other species (17.6%). Other species it has nested in include black walnut, hackberry, black locust, black cherry, honey locust, apple, ash, red maple, sycamore, sumac, chinquapin oak, red mulberry, hophornbeam, tulip tree, red elm, black gum, shagbark hickory, smooth and shining sumac, Manitoba maple, rough-leaved dogwood, coralberry, Ohio buckeye, basswood, mangroves, sweet fern, poplar, laurel, sand cherry, and gray and silky dogwoods. Nests may be in vines of Virginia creeper, Japanese honeysuckle, and bittersweet; it also nests in barberry and hazel. In Indiana, white elm was the only species selected

more than its abundance. The many crooked branches and twigs of elm and frequent forking of upright branches offered favoured nest placement sites. The distribution of leaves and twigs appeared important in nest-site selection but shape and size of leaves were not important. Sugar maple and flowering dogwood were used in proportion to their availability and all other species were used less than their availability. Despite almost unlimited nest-site availability at an Indiana study area, at least 12 trees were selected more than once and 4 were used 3 times. Within the 12 trees, 10 nests were placed in the exact site of a previous nest. No reuse of a nest site occurred by the same female and in only 3 cases was the same male present. Nests have been reported at heights of 0.025-13.7 m, but the extreme heights are rare. Of 608 nests in Indiana, the median height was 1.74 m, the mean height was 2.29 m, 77% of nests were within 3 m of the ground, and 38% of nests were 1-2 m from the ground. Median nest height increases with the season. In 2 Illinois study areas, median height increased from 1.3 to 2.4 m on 1 study area and 1.7 to 4.8 m on the other. Increasing nest height was likely related to the probability of predation. Prior to leaf-out, branches and stems provided the most concealment and they were densest below 2 m, but nest height increased as leaves became available. In Virginia, the Prairie Warbler commonly nests at heights of 3-4.6 m in pitch pines, often as far as 3 m from the trunk on a horizontal branch. Nests are not reused by the same female, but 1 female used a nest that had been abandoned by another female. Old Prairie Warbler and American Goldfinch nests are occasionally dismantled to obtain nesting material (Bent 1953; Chapman 1907; Graber et al. 1983; Harrison 1984; Nolan 1955, 1978; Prather and Cruz 1995).

Some authors stated that the Prairie Warbler occurs in small colonies, but this is because birds congregate in what are often small patches of suitable habitat. Territories are vigorously defended and there is no evidence of any true coloniality. Nearest-neighbour distances in Massachusetts indicated that it was dispersed evenly in preferred habitat with no indication of clustering of territories. In spring, the earliest arriving males exhibit few signs of territoriality and may range over areas as large as 4 ha in a few minutes that cover part of 6 previous territories. As more males arrive, they become confined to progressively smaller areas until the arrangement of territories is finalized for the season. In Indiana, the closest nests on active adjoining territories were 55-95 m apart. Males with large territories spent most of their time in only the part of it where the nest was located. The activity centre shifts if a replacement nest is initiated. Many Indiana territories were in fields large enough to support only a single pair, and the boundaries of these remained constant from year to year. Territory boundaries are often zones about 10 m wide that both neighbours enter regularly. These may be treed fence lines or unvegetated strips that are rarely visited by any birds. Males preferred to sing and watch their territory from tall trees in fence lines and each male had the right to use them but not go beyond. Territory size was correlated with the number of large trees, possibly because males could defend more land from a tall tree. Individual males have similar-sized territories each year after they are yearlings. Old males had significantly larger territories (0.6-3.5 ha, mean 1.73 ha) than yearlings (0.5-2.8 ha, mean 1.37 ha). Territories were larger if they adjoined suitable unoccupied habitat. Territory size decreased significantly as the number of neighbours increased: 2.1 ha with no neighbours, 2.3 ha with 1 neighbour, 1.7 ha with 2 neighbours, 1.3 ha with 3 neighbours, and 1.1 ha with 4 neighbours. Mean size of territories and core areas in Indiana were 2.00 and 1.43 ha for polygynous males, 1.5 and 1.13 ha for males that were monogamous season

long, 1.46 and 1.03 ha for males that remained on territory all season and mated monogamously with more than 1 female, and 1.39 and 1.01 ha for males with short-term monogamous relationships that ended before 25 June. Territories of polygynous males were significantly larger than those of monogamous males; large territories were more likely to attract more than 1 female. As the population declined as a result of succession decreasing habitat quality, territory sizes increased. Indiana territories ranged from 0.4 to 3.5 ha (average 1.56 ha). In younger habitat, territories averaged 1.62 ha (range 0.5-3.5 ha) compared with 1.47 ha (range 0.4-2.4 ha) in older habitat with more and larger trees. In Georgia, 1 pair nested on a 0.24-ha island (Bent 1953; Lambert and Smith 1985; Morimoto and Wasserman 1991a; Nolan 1978; Nolan et al. 2020a).

Natal philopatry rates are low. The return rate of yearlings to their natal area was 1% of 166 banded nestlings (Schlossberg 2009). In Indiana, 10 of 272 fledglings (3.7%) returned, 2% of males and 5% of females. It was estimated that 11% of survivors returned, 7% of males and 16% of females. Two juvenile males that returned to breed did so 2.6-2.9 km from their natal site and 4 returning females nested 100-800 m from the natal site. Three of 10 returning fledglings never nested on the study area (Nolan 1978).

Schlossberg (2009) estimated an adult return rate of 29% based on 429 birds and 2 studies in Ohio and Indiana. In Ohio, 92.1% of returning adults exhibited site fidelity. There was some evidence that dispersing birds moved to younger patches but no evidence of their moving to areas with more shrubland habitat. The mean age of patches where birds were originally captured was 6.6 years compared with 5.6 years for dispersal patches. The latter estimate was for all shrub-nesting birds combined and was not specific to the Prairie Warbler (Lehnen and Rodewald 2009b). In Indiana, 65% of males that bred on the study area were seen in subsequent years and 60% returned the first year after banding. Essentially all surviving males returned to the most recent breeding site or its immediate vicinity. In the first year following banding, only 19% of females returned but there was a striking rise to a total of 55% the second year. If a female came back once, the probability that she would again was almost as high as it was for males. Virtually all survivors returned with 61% of females observed during the postfledging period returning. Significantly more successful breeding females (47%) returned than unsuccessful females (17%). Breeding success did not affect male return rates. Of 75 returning males, 55 (73.3%) reoccupied their former territory and small areas adjoining it. Four returned to their original territory, behaved territorially in other locations, then returned to the former territory to breed. The distance between permanent and temporary territories was 200-500 m (mean 350 m). In 90% of territory reoccupations, the latest territory overlapped the former one by at least 80%, but some males substantially shifted their centre of activity. Twenty males (26.7%) returned and relocated their territories, and 6 disappeared from the study area. All relocations occurred before the females arrived. Distances between nearest boundaries of old and new territories were 10-3,400 m (average 710 m). Only 5 males selected the nearest suitable habitat with the remainder passing over nearby habitat to chose sites further away. There were no perceptible differences in habitat of abandoned and selected territories and almost all abandoned territories were subsequently claimed by another male. Site fidelity was independent of male age. For females, selection of a breeding site also involves finding and selecting a mate. In only 14 of 137 cases (10.2%) did a female reoccupy and breed on her former territory; 3 females occupied sites in 3 consecutive years. Of the remaining cases, 73.3% of females were unbanded and

new to the area and 16.8% had been banded at a different location. Of returning females selecting new sites, 39.1% remained in the study area to nest 260-2,350 m from their previous year's nest. In 11 of 14 cases (78.6%) when a female returned but shifted territories, a male was present but already mated or no male had claimed the territory. In all cases when a female reoccupied her former territory, an unmated male was present. Both sexes may occasionally shift territories within the breeding season in response to predation or the loss of a mate. Two females bred on 2 separate territories within a year 125 m and 500 m distant from the study area. Many birds left the Indiana study area after nest failure, but may have nested elsewhere. New birds arrived in mid-season and these may have been failed breeders from other areas (Nolan 1978).

Jackson et al. (1989) studied within-season breeding dispersal in Indiana. For nests that failed after 10 June when females pass out of breeding condition, most females remained in the original territory without renesting. During this same period, females that nested elsewhere earlier in the season began to arrive and did not attempt to breed. Females were equally likely to leave their mate's territory and remate after unsuccessful (18%) and successful nests (17%). They hypothesized that females that lost nests due to predation would be more likely to move if predation was by an animal with a larger home range than a Prairie Warbler (larger mammals, snakes, and Brown-headed Cowbirds) than if it was by an animal with a smaller home range. In theory, it would have to move a longer distance to be outside the home range of the larger mammals whereas they could avoid chipmunk home ranges by relocating to another area within their own home range. This prediction was not substantiated with no difference in the rate of dispersal where depredation was by a species with a large home range (19%) or a small home range (6%). The authors regrouped the species and included the cowbird with the chipmunk as a species having a smaller home range than the Prairie Warbler. When these data were reanalyzed, significantly more females that suffered depredation due to animals with larger home ranges (22%) dispersed than those whose nests were depredated by chipmunks and cowbirds (8%). The reason for reclassifying the cowbird was that dispersal by the warbler would take it out of the range of that particular cowbird, but not outside the range of other cowbirds.

Limiting Factors

Nests have been reported in Ontario from mid-May until the second week of July, with most present 11-20 June (Peck and James 1998a).

Males usually acquire a territory on the day they arrive. Females sometimes move around before pairing, probably scouting the quality of habitat and potential mates. Females continue to arrive and mate throughout the season. Seventy percent of Indiana pair bonds were established within a few hours of the females' arrival. Thirty percent of older females settled 1-5 days on temporary territories before mating on their permanent territory. The period between the male's arrival in spring until pairing was 1-22 days (average 7.8 days). Several partial nests may be built before the final one is completed. These may be used for replacement or second nests. Early nests take 3-8 days to build, but mostly 3 or 4 days. Nests of pairs formed in mid-season were uniformly built in 3 days. Nest for second broods take 3-5 days to build, slightly longer because the female is interrupted by feeding the first brood. Nest building begins 0-15 days after pairing (average 5.0 days). Earlier-pairing females wait longer to build but also tend to initiate nest building earlier. Replacement nests are

initiated 0-14 days after loss (mean 1.7 days); 67% were begun the day after nest failure. Initiation of nests for second broods began 1-26 days after the first young fledged (mean 9.6 days). Females that renested after the second-brood nest failed did so 0-3 days after the loss (average 1.0 day). Development of vegetation in the spring was not related to the timing of nest initiation. Temperatures 2.5°C or more below normal retarded the initiation of first nests; 17.2°C was the lowest maximum daily temperature on which a first nest was started. Rain inhibited nest initiation during each phase of nesting. Females typically wait 1 day after the nest is complete before laying the first egg (range 0-8 days). One egg is laid per day. In only 5 cases of about 1,100 occasions did a female resume laying after skipping 1 or more days. It was more likely that a predator or a cowbird removed an egg than the female skipped a day laying. Most females begin roosting on the nest at night the day before they lay the final egg, but a few do not. Females spent 20-30% of their time on the nest the day the penultimate egg was laid, 3 times the amount of time spent the day the first egg was laid. In Indiana, the incubation period was 10.5-14.5 days (mean 12 days, mode 11.5-12.0 days). Cool weather prolonged incubation and therefore first nests took longer to incubate. Parasitism lengthens the incubation period and small clutches hatched quicker than larger clutches. The hatching interval ranged from 4 hours 45 minutes to more than 48 hours (average 13.5 hours). Young in Indiana left the nest when they were 8.00-11.25 days old (mean 9.34 days) and mostly when they were 9-10 days old. Those that left at age 8 days probably did so prematurely due to factors such as damage to the nest or ant infestations. Small broods tended to remain in the nest longer with young in larger broods probably feeling discomfort due to crowding. Nestling periods in Florida were longer and ranged from 10 to 14 days (Nolan 1955, 1978; Prather and Cruz 1985).

It is probable that only a single brood is raised in Ontario, but this has not been studied. In Indiana, 7% of pairs raised second broods. Renesting is common is a nest fails. Indiana females built 1-7 nests in a season (mean 3.2, mode 3). The numbers of nests built depended largely on success in escaping predation. In 1 case, the researcher took new nests from a female and she built 8 replacement nests. The mean distance between failed and replacement nests was 85 m (range 10-250 m), and the mean distance between successful nests and second-brood nests was 81 m (range 34-200 m). These distances did not differ from random. Clutch size appears to increase with latitude, although there are some exceptions. Ontario clutches contained 3-6 eggs, mostly 4-5 (mean 4.11 eggs, mode 4). In Indiana, clutches of 3-5 eggs occurred (mean 3.89 eggs, mode 4); only 7% of clutches contained 5 eggs. Data are sparse, but no 5-egg clutches have been reported from Tennessee or Kentucky, but some have been documented in Virginia, Oklahoma, North Carolina, and Georgia. In Florida, clutches consisted of 2-4 eggs (mean 2.86 eggs, mode 3). Ontario appears to be the only location where 6-egg clutches have been documented. In Indiana and probably elsewhere, clutch size declines with the season. Until 15 June, at least 75% of clutches contained 4 eggs with 5-egg clutches gradually disappearing and 3-egg clutches becoming more common. After 15 June, 3-egg clutches predominated. Larger clutches occurred in years when the first half of May was warmer. In Indiana, the mean clutch size of older females was 3.89 eggs compared with 3.73 eggs for yearlings. Older males and females were more productive than yearlings (Bent 1953; Nolan 1955, 1978; Peck and James 1998a; Prather and Cruz 1995).

Both sexes are capable of breeding when they are 1 year old. In Indiana, all males were mated in spring, but 6% were unmated on 1 June, 13% on 15 June, and 18% on 1 July. Few females were

unmated until early June, but by mid-June 13% were unmated and by 1 July 20% were unmated, when they were probably incapable of breeding. The instability of pair bonds in this population was probably caused in part by heavy nest losses due to predation. The mating system is predominantly monogamous but a small proportion of birds are polygynous. Only 5% of males were polygynous in mid-May but 10% were by 1 June. Most polygynous bonds were formed in mid-season when few unmated males were present. Females still selected superior males with larger territories and did not suffer any reproductive loss by mating with a polygynous male. When both females of a polygynous male nested on the same territory, their nests were separated by 50-300 m (mean 124 m). Only twice did a female build a nest within 60 m of her mate's other female's nest. Three males held 2 distinct territories with a female nesting on each of them. In 1 case, the territories were in different fields but contiguous at their corners. In another case, the territories were 100 m apart separated by a wooded ravine; in the final case, the territories were 1,300 m apart. Polygynous pair bonds involving a single territory were as stable as monogamous bonds. Seven categories of male pair bonds occurred in Indiana: season-long monogamy, short-term monogamy with 1 mate for less than a full season, successive monogamy without a location change, successive monogamy with a location change, polygyny on 1 territory, polygyny on 2 territories, and possibly polygyny with a location change. There were also 7 types of female bonds: season-long monogamy with a monogamous male, season-long monogamy with a polygynous male with 1 territory, seasonal monogamy with a polygynous male with 2 territories, short-term monogamy with a monogamous male, short-term monogamy with a polygynous male, successive monogamy with successively monogamous males, and successive monogamy with 1 or more polygynous males. The type of pair bond that an individual was involved in often changed as the season progressed, often repeatedly. Of 18 females raising second broods, 15 built and laid in second-brood nests without changing mates, 1 retained her mate but did not lay in her second-brood nest, and 2 changed mates before building and laying. Yearling females were more likely than older females to leave their first mate and pair again. In 13 cases, a female returned when her mate from the previous season was defending all or a part of that territory. Six of these remated and 5 did so at the beginning of the season. The other was courted by her former mate but paired with a neighbour and raised a brood and subsequently paired with her former mate and raised another brood. In the 7 cases of failure to reunite, 3 females reoccupied the site but paired with another male whose territory overlapped and 4 moved to different locations, probably because the male in their territory was already mated. It appeared as though females were attached to sites and not to mates (Ford 1995; Nolan 1978).

In Indiana, Nolan (1978) observed males 50 m to 1.2 km (mean 280 m) beyond their territory boundaries. Some, or all, males left their territory as often as once a day, especially when their mates were incubating. Most forays lasted 15-60 minutes (mean 30 minutes); 1 male was gone 3.5 hours. In unoccupied areas, roaming males sang repeatedly but were quiet and stealthy in occupied territories. The purpose of these forays appeared to be to establish another territory or to solicit extra-pair copulations (Morse 1989; Nolan et al. 2020a).

In Indiana, both sexes foraged from the ground to the tallest treetops and took food items from most or all vascular plants as well as from midair. The most common foraging technique was gleaning while perched followed (in order of frequency) by flycatching, hovering, clinging to vertical stems, hanging upside down, feeding on the ground, and seizing flying insects while perched.

Gleaning, flycatching, feeding on the ground, and feeding from bark were most common before leaves and most insects appeared. The Prairie Warbler specifically targets immature spittle bugs and is the only species known to do so. It relies on the froth to detect the insect's presence and may search for it with considerable persistence. Adults of both sexes fly plant to plant, probing into the masses of spittle and consuming the insect inside. In June, males foraged significantly higher (mean 6.1 m) than females (1.6 m). During the postfledging period, males foraged at an average height of 1.8 m compared with 1.6 m for females; these differences were not significant (Nolan 1956, 1978; Nolan et al. 2020a). Parnell (1969) summarized foraging strategies of the Prairie Warbler during the breeding season in South Carolina. Of the total time, 16.7% was spent in the canopy, 54.7% in low trees, 28.6% in shrubs, and 0% on the ground. In the canopy, 2.4% of foraging occurred in the top of the crown, 9.5% in the inner crown, 4.8% in the lower crown, and 0% on the bole. In low trees, 19.0% of foraging occurred in the top of the crown, 19.0% in the inner crown, 16.7% in the lower crown, and 0% on the bole. In shrubs, 2.4% of foraging occurred in the top of the crown, 9.5% in the middle crown, 4.8% in the lower crown, 9.5% in dense thickets, 2.4% in brush piles, and 0% in grass. In pitch pine barrens in Massachusetts, Morimoto and Wasserman (1991b) compared the foraging strategies of the Prairie Warbler and Common Yellowthroat. The Prairie Warbler foraged less in herbaceous plants and more in pines than the yellowthroat. Male Prairie Warblers differed significantly from yellowthroats in foraging height, use of plant species, foraging manoeuvres, and location in trees. There were no significant differences in these parameters for female Prairie Warblers and male yellowthroats. Both sexes of the Prairie Warbler foraged at heights of 0 to more than 6 m, but the female foraged lower. Yellowthroats and female Prairie Warblers exhibited a pronounced preference for foraging in scrub oak. Male Prairie Warblers divided their foraging more evenly between pines and oaks. Males spent 43% of their time foraging in pines, 46% in scrub oak, 7% in other deciduous species, 3% in ericaceous shrubs, and 1% in herbaceous plants. Females spent 67% of their time in oak, 23% in pine, 3% in other deciduous species, 3% in ericaceous shrubs, and 2% in herbaceous species. Prey was obtained most frequently from foliage, with males foraging distally more than females. Males selected higher (3-6 m) than lower song perches and preferred to sing and forage at heights above 3 m. Widely scattered trees in open habitat provided important song perches for males. Females foraged below 1.5 m near nest height where they remained fairly inconspicuous. Female Prairie Warblers were more similar to male yellowthroats in their foraging behaviour than they were to male Prairie Warblers.

When adults first arrive in spring, caterpillars large enough to eat may be rare. At this time, the Prairie Warbler spends much time in pine trees eating jumping plant lice. Males bring food to the nest 1-3 times per day during the incubation period. They do this even if the female is absent. This food is not fed to the female, although occasionally she eats it. This has been termed anticipatory food-bringing. The male is apparently unaware of hatching until he brings food and discovers young. Polygynous males fed nestlings at both nests equally, but none had 2 sets of nestlings simultaneously. Some had both nestlings and fledglings. The male may feed both fledglings and nestlings, terminate feeding the fledglings prematurely and feed nestlings, or abandon the fledglings and feed only the nestlings. When females attempted second broods, they usually did not feed their first brood, although 1 female did. Based on visual observations, 82% of the diet of nestlings consisted of caterpillars, 88.4% of which were green. These were mostly 20-25 mm in

length but some were as long as 50 mm. Sixteen percent of the nestling diet consisted of other insects (moths, flies, orthopterans, bugs, wasps, and a damselfly), and 2.2% of the diet was spiders; 1 millipede was consumed. During the breeding season, all but 0.3% of the diet of adults consisted of animal matter, including arthropods and fragments of a single snail shell. Spiders and 5 orders of insects (beetles, lepidopterans, flies, hymenopterans, and bugs) constituted 97% of the diet. It ate beetles in proportion to their availability and leaf beetles and weevils were prominent in the diet. It may take caterpillars more than their availability, perhaps because of their low mobility and high efficiency as a food item. Seventy-six percent of stomachs contained beetles, 35% contained lepidopterans, 34% contained flies, 30% contained hymenopterans, 24% contained spiders, 17% contained soft-winged bugs, and 6% contained true bugs. Volumes of food items ranked in approximately the same order. One ate a dobsonfly larva that was presumably captured in a stream while the bird was bathing. Other items consumed included crickets, jumping plant lice, aphids, green lacewings, and millipedes. Some birds consumed large quantities of insect eggs. In early spring, 1 female drank sap from a wound in a black locust (Nolan 1958, 1978; Nolan et al. 2020a). In Parry Sound District, both sexes at 1 nest fed on green larvae that they captured in red oaks and sweet gale (Niskanen 1997).

The Brown-headed Cowbird commonly parasitizes the Prairie Warbler. Rothstein (1975) artificially parasitized 2 nests and concluded that it was an acceptor of cowbird eggs. Bent (1953) stated that often a false bottom was built over the cowbird egg. Neither of these statements is strictly correct. In Indiana, desertion of parasitized nests was common, especially if the cowbird egg was laid at an inappropriate time in the warbler's nesting cycle. Seventy-four percent of nests that were being incubated when they were parasitized and 56% of nests when the cowbird egg was laid in an empty nest were deserted. Warblers always deserted nests when an egg punctured or broken by a cowbird leaked into the nest, but not necessarily when the egg dried out without leaking. Of several hundred Indiana nests, only 2 or possibly 3 cases of embedding cowbird eggs in the nest were observed. In all cases, the nest was still in the process of being built. Parasitism rates are highest early in the year. In May in Indiana, 29-40% of nests were parasitized annually, 25% of nests were parasitized 1-10 June, 20% were parasitized 11-20 June, and parasitism rates fell rapidly to 0% after then. Parasitism rates increased with increasing nest height, although not significantly. Presence of a cowbird egg did not significantly affect the hatching rate of warbler eggs: 95% of eggs hatched in unparasitized nests compared with 92% in parasitized nests. Parasitized nests produced few fledglings. Mean brood size in Indiana was 3.21 young warblers in unparasitized nests compared with 0.78 in parasitized nests. In this population, it was estimated that parasitism lowered production of young by 13.3% because fewer nests succeeded, female cowbirds removed warbler eggs, and presence of cowbird nestlings further reduced brood size. In Ontario, 10 of 37 nests (27.0%) were parasitized. In Indiana, 83 of 248 nests (33.5%) that contained warbler eggs on 10 June or earlier were parasitized. In Illinois, 2 of 9 nests (22.2%) were parasitized and another nest contained a punctured egg, possibly by a cowbird. In Michigan, 5 of 18 nests (27.8%) were parasitized; 0 of 6 were parasitized in Texas; 11 of 53 (20.8%) were parasitized in Missouri; and 7 of 30 (23.3%) were parasitized in Mississippi (Graber et al. 1983; Hackemack et al. 2016; Harrison 1984; Jackson et al. 1989; Nolan 1978; Novak et al. 2016; Peck and James 1998a; Roach et al. 2018).

Habitat loss and degradation are not significant issues in Ontario now, but affected the Prairie Warbler historically. The largest population south of the Canadian Shield was in the interdunal habitat at Wasaga Beach and Pinery Park. Habitat at Wasaga Beach, where an estimated 150 pairs once bred, was destroyed by cottage development by the late 1940s. Dune habitat has become unsuitable in some areas due to planting of pines that are now too mature to provide habitat, dune stabilization projects, and human disturbance. These were probably the greatest threats south of the Shield but, with the exception of a few pairs at Pinery Park, this population was extirpated decades ago. Pine plantations at St. Williams and Turkey Point formerly provided habitat but these have become too mature. Relict populations may be retained there if areas are set aside and managed to provide early successional habitat. Birds nesting on hydro rights-of-way may have their habitat abruptly destroyed by herbicides, but these can typically recolonize as other areas reach appropriate successional levels. Good habitat is often created by forest fires, so fire suppression may have negative effects. Natural succession in these types of habitat gradually makes the habitat unsuitable. A population in a burn in Frontenac County was most active for 30-40 years during the appropriate levels of succession, but small numbers of pairs persisted for 3-4 decades after optimum conditions prevailed. Most of Ontario's population breeds along the eastern shoreline of Georgian Bay. Habitat there is stable due to the bedrock outcrops, limited soil depth, and harsh microclimate adjacent to Lake Huron (Austen et al. 1994; James 1996c, 1999e; Lambert and Smith 1985).

Habitat loss is the most significant limiting factor for the Prairie Warbler in the United States, where it is mostly dependent on early successional habitats created by humans. This habitat has been declining since the 1970s, predominantly due to natural succession and tree planting, but also to development in some areas. Fire suppression also limits the amount of available open habitat. Populations waxed and waned in direct proportion to the amount of available shrubby habitat (Morse 1989; Nolan et al. 2020a; Wells 2007).

In North Carolina, the Prairie Warbler was significantly more abundant in burned than unburned areas, and exhibited the most positive response to fire of all species studied. It occurred more frequently only after high severity burns. It occurred less frequently as the time since the burn increased and was most frequent 5-10 years after burning. Large patches of severe burns should be beneficial to it (Rose and Simons 2016).

Harsh spring weather can affect reproductive success, particularly in the core of the Ontario range along the eastern shoreline of Georgian Bay. Late springs there can result in late melting of snow, retarded vegetation growth, and cold winds off the bay. Ice may remain piled up along the shoreline well into June (Harrington 1924). When this occurs, it is possible that some birds may not nest at all. Those that do initiate clutches later and are likely to have smaller clutches and be less likely to renest in the event of nest loss.

Alterman et al. (2005) examined the effects of forest management on the Prairie Warbler in Arkansas. The 2 harvest types investigated were seed-tree cutting, which consists of retaining 10-25 mature trees per ha in clear-cuts, and group selection, where 10% of the stand is cut every 10 years in patches 0.8 ha or smaller and allowed to regenerate. All 14 nests they found were in seed-tree cuts. Males were observed at 3 of 21 group-selection openings, but no females were present. They

concluded that group-selection openings were too small to support nesting Prairie Warblers, but seed-tree cuts provided suitable habitat.

In Indiana, 0.8% of nests failed due to blow fly infestations. In some nests that were infested with ants, the young fledged prematurely, but there was no indication that this was deleterious to the young (Nolan 1978).

Price (2004) predicted that the range of the Prairie Warbler might expand in southern Ontario if the average summer temperature increased by 2°C.

Status

The early status of the Prairie Warbler in Ontario is uncertain. In the United States, deforestation associated with European settlement resulted in creation of much new habitat and a marked population increase. It seems unlikely that this major event had any effect on Ontario populations if there were actually any in the province at that time. In Ontario, it is restricted predominantly to natural habitats and has not adapted to using the anthropogenic old fields in which it frequently occurs in the United States. It was first documented in Ontario in 1900 in Toronto and breeding on the Bruce Peninsula was suspected by 1906. Nesting was not confirmed until 1922 at Wasaga Beach. It has been suggested that the breeding population along Georgian Bay has been present for centuries or even millennia because of the stable habitat, and this theory appears to have been generally accepted. In the late 19th and early 20th centuries, the Prairie Warbler significantly expanded its range northward as a result of the abundance of newly created habitat. It became established in the northern states (Connecticut, Ohio, Indiana, Illinois, and Michigan) between 1870 and 1910. The rationale for the conclusion that the Georgian Bay area was always inhabited is based on larger numbers seen during spring migration on islands in Lake Erie in 1912 and on the Ohio Lake Erie shoreline in 1907 (Austen et al. 1994; James 1999e; Lambert and Smith 1985; Nolan 1978). These observations were made during the period when it was expanding its range northward, and are not conclusive evidence that the Georgian Bay population was always present. It seems unlikely that a small disjunct population would persist several hundred kilometres north of the core range even if suitable habitat were present.

Baillie and Harrington (1937) classified the Prairie Warbler as a local summer resident from Lake Erie north to Parry Sound District and Renfrew County and reported a single summer occurrence at Frank's Bay on Lake Nipissing in 1933. Within this broad range, they concluded that it bred fairly commonly along the shores of southern Georgian Bay and southern Lake Huron, but not elsewhere in the province. In 1914-15, it was common at Wasaga Beach and an estimated 200 pairs formerly nested there and in the Pinery and Ipperwash areas. By the late 1940s, the Wasaga Beach population had been extirpated due to cottage development and disturbance with only a few pairs persisting in the Pinery area. A population was present in Frontenac County as early as 1933 and peaked in the late 1940s and early 1950s at 35-40 pairs. Because of natural succession, this population declined to 6-7 pairs in 1963 but a few birds still persisted as late as 1989. Additional populations were subsequently found along the southern edge of the Canadian Shield in Frontenac and Peterborough counties. It bred many times on the Bruce Peninsula until the 1950s, but was not detected there during the first atlas. Small numbers formerly bred in the young plantations in the St. Williams–Turkey Point area but most of these disappeared by the late 1970s with only scattered

pairs persisting. By the mid-1980s, the population south of the Shield had all but disappeared except for isolated small populations. At that time, it was estimated that 90% of the Ontario population nested along the Georgian Bay coast in Muskoka and Parry Sound districts and along the southern Shield in Frontenac and Peterborough counties. Historically, the Prairie Warbler had been documented nesting in 10 upper-tier municipalities, but as of 1984, it bred regularly in only 6: Lambton, Simcoe, Muskoka, Parry Sound, Peterborough, and Frontenac. In 1985, 310-325 pairs were known to breed in the province, but numbers could have been as high as 462-702. It was estimated that about 500 pairs were present. Although the population and its habitat appeared to be stable at that time, the Committee on the Status of Endangered Wildlife in Canada (COSEWIC) designated it special concern because of the low population occurring in localized habitats (Austen et al. 1994; Bent 1953; James 1996c; Lambert and Smith 1984, 1985). Results of the first atlas were similar to what had been reported in the COSEWIC status report, primarily since most of the atlas data were available when it was written. The atlas documented about 10 pairs in the Pinery area and a few in the St. Williams area, with the bulk of the population along the eastern Georgian Bay coast and the southern Shield. Breeding along hydro rights-of-way was documented for the first time and isolated breeding records were obtained for the first time in Haliburton, Hastings, Lennox and Addington, Lanark, and Middlesex counties and the regions of Waterloo and York. The most northerly location where it was found nesting along the Georgian Bay coast was Pointe au Baril. Based upon the atlas results, Lambert (in Cadman et al. 1987) concluded that the breeding population could be somewhat less than 500 pairs. James (1991) concluded that the Prairie Warbler was a rare to locally uncommon summer resident in the south north to Parry Sound District and Frontenac County.

From 1990-94, a new population was discovered in pine plantations near Rockton. Only about 3 pairs were present and the Prairie Warbler later disappeared or became irregular once the trees grew taller. Breeding was also confirmed near Campbellville in 1982, so these 2 records provided breeding evidence for Hamilton and Halton for the first time (Curry 2006). In 1997, the Natural Heritage Information Centre conducted a systematic survey of the Georgian Bay shoreline for breeding Prairie Warblers. A total of 349 singing males were documented at 174 of the 420 sites (41.4%) investigated. The largest population occurred in the Honey Harbour to Cognashene area of Muskoka District where 108 males were present at 69 of the 107 (64.5%) sites visited. Other concentrations included 29 at Go Home Bay, 28 at San Souci, and 49 at Massasauga Provincial Park (Sutherland 1998). James (1999e) prepared an update COSEWIC status report on the Prairie Warbler and estimated that there were still about 500 pairs in the province, with about 20 pairs in Peterborough County and 65 in Frontenac County in addition to the Georgian Bay population. He concluded that any losses in the population were historical and that numbers and habitat had remained stable since the last report. He recommended that its status be maintained at special concern, but COSEWIC downgraded it to not at risk.

The second atlas confirmed that most of the population occurred along the shore of Georgian Bay between Pointe au Baril and Port Severn, with discontinuous populations along the southern edge of the Shield from Simcoe to Frontenac counties. It declined or disappeared from many areas in which it occurred during the first atlas and the small population (never more than 8 pairs) persisting in the St. Williams–Turkey Point area represented 2 of only 4 squares reporting breeding evidence south of the Shield. It was estimated that the total Ontario population did not exceed 320

breeding pairs, 270 of which occurred along the Georgian Bay coast (Sutherland and Harris in Cadman et al. 2007).

Hannah et al. (2024a) completed a detailed inventory of the Georgian Bay population in 2015 and detected 388 singing males. This was a considerable increase over the 1997 estimate of 270 singing males, but the 2015 survey checked locations that were previously missed. Even the later survey missed some sites due to inaccessibility, so the population may be around 427 singing males. Most suitable habitat appeared to be occupied.

The Breeding Bird Survey (BBS) indicates that the Prairie Warbler has been declining significantly in the United States since 1966. This survey is not relevant to Ontario as it is rarely detected by it so there are no trend data available. BBS data indicate a significant decline of 54%, or about 2% per year, from 1966 to 2005. Approximately 96% of the global population occurs in the southeastern United States and about 90% of the habitat is in the 4 southernmost counties of Florida (Austen et al. 1994; Nolan et al. 2020a; Wells 2007). Hanberry and Thompson (2019) compared BBS trends and forest composition over time in the eastern United States. They attributed the Prairie Warbler's decline in part to the reduction in the amount of early successional habitat and the increase in the amount of closed-canopy forest.

POSTFLEDGING PERIOD

In Georgian Bay, all Prairie Warblers left their breeding territories and travelled long distances, with one travelling as far as 40 km. They appeared to prefer outer edges of islands where common juniper was the dominant vegetation (Rusak 2025).

In old-field habitat in Indiana, brood division occurred shortly after young left the nest. Even when both sexes remained on the territory and a single brood was raised, fledglings remained with a single parent. In every case where the female attempted a second brood, the male took care of all independent young (Nolan 1978). The earliest that fledglings in Indiana could survive unassisted was 34-35 days, and young from first broods were often abandoned at this age. Extreme periods of fledging dependence were 34 to 55 days with a mean of 40.8 days (Nolan et al. 2020a).

The direction of first flight of fledglings was random and by the end of the first day young were scattered 30-35 m from the nest. Young produced on territories in low and open vegetation moved toward edges of woods or overgrown hedgerows and were often near the territory boundary. Before age 25 days, young averaged 45 m from where they had been the previous day, with a range of 12-110 m moved daily. Sometimes the daily movements were in the same direction but more frequently the movements cancelled each other out and the group remained within the territory. Birds whose parents were involved in a second brood tended to remain near the nest. After age 25 days, family units often travelled far and quickly (100-250 m in 10 minutes) and some moved 400-500 m per day. During this period, fledglings often had a preference for a particular thicket that they repeatedly moved to. Of males with fledglings 20 days old or less, 80% remained on the territory. The mean distance from the territory for those that left was 100-125 m (maximum 500 m). Sixty percent of females with young of the same age remained on the territory. The mean distance moved by those that left was 200-225 m (maximum 600 m). Groups led by females often began to move when they were quite young compared with those led by males. Of 50 family units, 38% rarely if ever left the breeding territory. Females that were moulting at the end of the reproductive cycle

tended to remain on or near the breeding territory. Brood home range sizes averaged 1.5 ha, similar to the breeding territory. Groups that moved appeared to set up similar-sized home ranges but some groups led by females did not establish fixed home ranges. Soon after independence, young left the site where they were last dependent and moved randomly in the region for several weeks. Fledglings probably remain near the hatching site for 20-30 days after independence. The distance between the last sighting of the year and the area where they were last dependent was 0-900 m for 26 young (mean 460 m). The final sighting was not always the furthest observation from the site of last dependence. Only 1 juvenile settled into what appeared to be a territory in September. Once young became fully independent at the age of 30-55 days, they left the study area (Nolan 1978).

After the young became independent, 49% of males were seen repeatedly within 200 m of the territory; 22% moved considerable distances, remained away for days or weeks, then returned in September; and 29% left the breeding territory and did not return. Only 13% of females remained within 100 m of the breeding site. A few left with young once they were independent, but most moved away permanently. A female moved 500 m to an area that she had occupied in 5 successive years during the postfledging period, even though she had no young. Fidelity to postfledging home ranges was not affected by reproductive success (Nolan 1978).

In addition to the old-field habitat used in Indiana, juveniles, adults, and family groups have inhabited clear-cuts, mostly in oak, hickory, or pine stands, during the postfledging period. Use of clear-cuts has been confirmed in Missouri, West Virginia, Virginia, and Ohio. In Missouri clear-cuts, where the Prairie Warbler also nested, numbers declined significantly with time after cutting. Numbers peaked at 19 birds per year 3 years after harvest and declined to 13 at 4 years and 12 at 5 years. No Prairie Warblers were captured 11-15 years after harvesting except for a single bird in year 14 (Marshall et al. 2003; Porneluzi et al. 2014; Vitz and Rodewald 2006).

On 1 night in Indiana, fledglings 25-29 days old roosted together 1 m up in a sumac thicket with the male, and 1 fledgling and the female roosted together in a flowering dogwood 1 m away. This roost was not used the following evening. Another group of 40-day-olds roosted together 1-2 m from the ground in a thicket (Nolan 1978).

MIGRATION

The migratory race of the Prairie Warbler winters in Florida and the West Indies. The Florida subspecies is largely sedentary. Collisions with tall structures indicate that much migration is nocturnal, but diurnal migration also occurs. Large daytime overwater movements toward Florida have been reported in spring. It is unknown if it migrates singly or in flocks at night, but it may fly with other warblers. Spring movement is associated with south winds. During the daytime, it often joins flocks of other warbler species. The maximum number of Prairie Warblers in a flock is 8 and 2-3 is normal (Nolan 1978; Nolan et al. 2020a). In Ontario, it would be exceptional to see 2 in a single flock.

In spring, older males arrive before older females and older birds arrive before yearlings. At a Florida television tower, the median date of death of old males was 6 April compared with 21 April for old females. The median date of death for yearling males was 21 April compared with 23 April for yearling females (Nolan and Mumford 1965). In Indiana, the mean date of the first arrival for males was 18.6 April (range 11-27 April) and the mean date of arrival for females was 23.4 April (range 19-

28 April). The earliest females never preceded the earliest males. The mean interval between the first male and female of the season was 5.1 days (range 1-9 days). When males were late arriving, the females were not similarly late and the gap between the arrival of the sexes was shorter. Birds arrived on the breeding grounds a few days before or after 30-50% of the dominant woody plants had leaves or were in flower. Many grasses and forbs began their annual growth at about the same time. Insects had emerged prior to the birds' arrival but were still far below their summer levels. Prairie Warblers appeared to arrive as early as sufficient food was available to sustain them. Most individual males consistently arrived early, late, or in the mid-period of arrival from year to year. Early arrival results in earlier nesting and opportunities for renesting and second broods. The beginning of egg laying was advanced by 1.4 days for each day that a male's arrival was accelerated and increased the length of period during which he had the opportunity to have a mate in reproductive condition by 3% (Nolan 1978). Spring migration south of the Shield in Ontario is throughout May, with some occurring in mid- to late April and others remaining into early or mid-June (Black and Roy 2010; Curry 2006; LaForest 1993; Lambert and Smith 1984; Weir 2008). The earliest that birds arrived at Go Home Bay in Muskoka District was 18 May (Mills 1981).

In autumn, young birds begin to migrate before adults and continue to do so as long as adults and consequently have a longer migration period. There appears to be no difference in the timing of migration of the sexes (Nolan 1978; Nolan and Mumford 1965). Migration probably begins in August in Ontario. In some breeding areas in Muskoka, it is seldom seen after the first week of August, but has been seen as late as 3 October at Go Home Bay (Lambert and Smith 1985; Mills 1981). In the south, autumn migration is typically from mid-August to mid-September, with some arriving in early August (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008). Most birds have probably left the province by the end of September; there are very few October records (Lambert and Smith 1984, 1985).

During migration in Ontario, the Prairie Warbler occurs in slightly or very open habitats such as overgrown fields, forest edges, scrubby open areas at edges of pine-oak or beech–sugar maple forests, beach strands, open hawthorn thickets, wild plum thickets, mixed woodlands, and abandoned orchards (Lambert and Smith 1985). Eifrig (1909) observed one in alders prior to leaf-out along the shoreline of Lake Doré in Renfrew County. During spring and autumn migration in Illinois, most were found in shrubs and forest edges although a few occurred in mature upland forests (Graber et al. 1983). In pitch pine barrens in New Jersey, most spring migrants were seen in oaks (Brush 1987). During spring migration in South Carolina, numbers seen per hour were 7.58 in dry thickets, 1.09 in pine forests, 0.97 in pine-hardwood stands, 0.48 in wet thickets, 0.14 in floodplain forests, 0.13 in oak-hickory forests, and 0 in beech forests. It was significantly more abundant in dry thickets than other habitats and was the most abundant warbler in dry thickets (Parnell 1969).

Parnell (1969) studied the foraging habits of the Prairie Warbler during spring migration in South Carolina. The time spent foraging on different substrates was 15.8% in the canopy, 54.5% in low trees, 29.7% in shrubs, and 0% on the ground. In the canopy, 5.9% of foraging occurred at the top of the crown, 6.9% in the inner crown, 3.0% in the lower crown, and 0% on the bole. In low trees, 21.8% of foraging occurred at the top of the crown, 22.8% in the inner crown, 9.9% in the lower crown, and 0% on the bole. In shrubs, 9.9% of foraging was at the top of the crown, 6.9% was in the

inner crown, 4.0% in the lower crown, 7.9% in dense thickets, 1.0% in grasses, and 0% in brush piles. Singing males were recorded from the ground to over 15 m (mean 5.2 m). Nonsinging birds occurred at the same range of heights with a mean of 4 m.

In Florida, the Prairie Warbler is commonly killed during migration by striking television towers (Nolan 1965, 1978; Nolan and Mumford 1965). It undoubtedly strikes tall structures elsewhere, but this has seldom been documented. Graber et al. (1983) had no records of Prairie Warbler casualties at Illinois television towers. It has not been reported as a casualty at the Long Point Lighthouse, but 1 was killed at the Lennox generating station chimneys in 1981 (Lambert and Smith 1985; Weir 2008).

The Prairie Warbler is a rare migrant in Ontario, although there are records from every municipality from Algoma and Sudbury districts southward. An average of 2 per season annually is captured at Long Point. In the 20 years preceding 1984, 2.7 Prairie Warblers were captured at Long Point for every 10,000 warblers banded. The maximum number recorded during spring migration at Prince Edward Point is 3 (James 1991; Lambert and Smith 1984, 1985; Weir 2008).

Black-throated Green Warbler

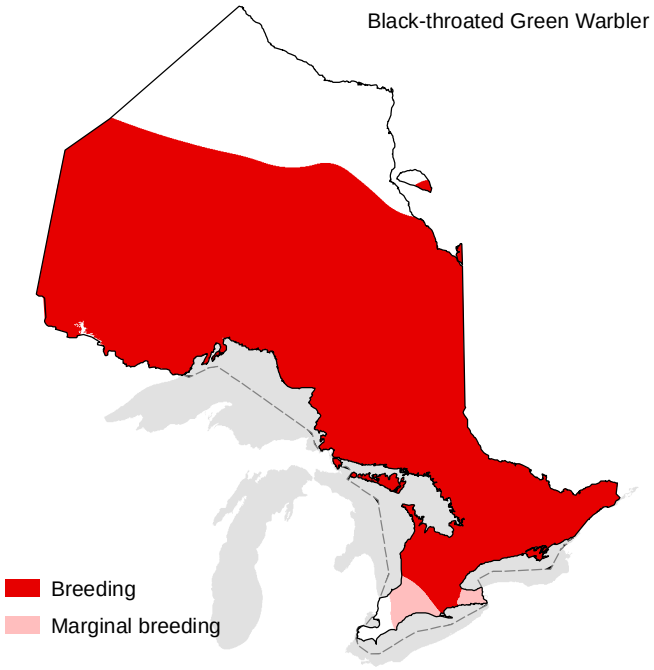
Setophaga virens

BREEDING SEASON

Habitat Requirements

Ontario Black-throated Green Warbler nests were within wooded areas: 51.7% of nests were in coniferous woods, 31.0% were in mixed woods, and 17.2% were in deciduous woods. Some were at forest edges near roads or water (Peck and James 1987). James (1984b) reported that it nested in coniferous or mixed forests where the trees were older second growth or mature. In mixed forests, it prefers hemlock. It prefers closed-canopy forests, especially those with some shrub growth.

In the Boreal Forest Region near Pickle Lake, the Black-throated Green Warbler occurred in low density in mixed forests and coniferous forests with an understorey. It was occasional in deciduous forests and absent in coniferous forests without an understorey, heath, tundra, and coniferous, mixed, and deciduous scrub (McLaren and McLaren 1981). James (1980) encountered it irregularly in small numbers in predominantly deciduous forests near Pickle Lake. In jack pine stands near White River, it was significantly more abundant in stands 40-100 years old with a large component of jack pine. It was a significant indicator of mature forest (Venier and Pearce 2005). Near Manitouwadge, it was more abundant in stands 60-223 years old than those 24-36 years old. It occurred at very low densities in stands 1-21 years old (Venier et al. 2009). Near Hearst, it was the most abundant species



in clear-cuts 13 and 19 years old in upland mixed forests. It was common in 24-year-old clear-cuts and uncommon in 11-year-old clear-cuts in upland mixed forests. It was not observed in lowland coniferous forests of any age (Welsh and Fillman 1980). In the Clay Belt, it was most abundant in trembling aspen stands followed by white cedar–tamarack, balsam poplar, and white spruce–white birch stands. It was least abundant in black spruce stands and not observed in jack pine stands. It occurred in very dry to wet areas and nutrient-poor to nutrient-rich sites (Welsh and Lougheed 1996). In the Boreal Forest Region, Erskine (1977) considered it one of the 3 most distinctive species of balsam fir stands. The Black-throated Green Warbler often attains much higher densities in pure hemlock stands than in any more boreal forest types. It is more common in mature coniferous stands. It is characteristic of the most fertile coniferous stands whether they are dominated by hemlock, balsam fir, or white spruce amidst poplar. It may use the richest white spruce stands if mature balsam fir or hemlock are unavailable. Higher densities are attained south of the boreal forest than in it.

In the Great Lakes–St. Lawrence Forest Region in the Canadian Shield, the Black-throated Green Warbler occurred in both old-growth and mature white pine stands. It was more abundant in old-growth forests, but not significantly. Presence of supercanopy white pine with a diameter at breast height (DBH) of 60 cm or larger was a significant predictor of its abundance. Kirk et al. (2012) estimated that it required 23 supercanopy stems per ha. It was the fifth most abundant species in mature and old-growth white pine stands. In Quetico Park, it was most abundant in stands 112-370 year old, although it occurred in low density in 1-23-year-old stands. In 112-year-old stands, it was equally abundant as the Black-throated Blue Warbler and Red-eyed Vireo in heavier spruce–balsam fir cover (Apfelbaum and Haney 1985). In Muskoka and Parry Sound districts, the Black-throated Green Warbler was common in pine, hemlock, and hardwood forests and also in pastures with scattered spruce (Mills 1981). In young open jack pine stands mixed with deciduous species in Parry Sound District, James (1979a) reported it on 1 of 5 transects at low density. In northern hardwoods near Sault Ste. Marie, it was positively correlated with the basal area of small trees (Holmes and Pitt 2007). MacLulich (1938) concluded that it was abundant in both coniferous and deciduous stands in Algonquin Park. In the park, it nests in forests consisting of 85% sugar maple with the remainder mostly beech, hemlock, and yellow birch. It usually selects a territory that contains a group of hemlock and other conifers, with some territories containing only 1 or 2 canopy-sized conifers or none at all (Tozer 2008, 2012). Martin (1960) reported it in a variety of forest types in Algonquin Park. It was most abundant in hemlock stands where it was second in abundance. In these stands, it

ranged from the sapling layer to the top of the canopy. It was common in sugar maple–yellow birch stands where it was third in abundance and ranged from the middle of the shrub layer to midcanopy. It occurred in lower density in balsam fir–spruce-hardwood stands and in even lower density in poplar–white birch stands where it ranged from the mid-level of shrubs to the top of the canopy. It was absent in balsam fir–spruce stands, balsam fir and spruce mixed with poplar and white birch, and immature white pine stands. He considered it characteristic of hemlock but noted that it also occurred in hardwoods where hemlock was absent. In white pine stands in Algonquin Park, it was significantly negatively correlated with high percent coverage by conifers at heights of 2-5 and 5-10 m, and dense ground cover layer. These represented stands with a well-developed herbaceous layer and a well-developed coniferous subcanopy, features seen most frequently in recently cut areas (Kingsley and Nol 1999). In Haliburton County and Muskoka District, it was associated with high canopy volume, intermediate tree density, and above-average amount of understorey. Its habitat was indicative of undisturbed forest and it was associated with mature coniferous woods with considerable understorey (Clark et al. 1983).

In the Great Lakes–St. Lawrence Forest Region south of the Canadian Shield, McLeish and Robertson (1997) concluded that upland white cedar stands could provide quality habitat for the Black-throated Green Warbler. In Durham Region, it was common in a mature pine plantation and uncommon in a mature sugar maple–oak forest. Speirs and Orenstein (1975) considered it associated with pines.

In the Carolinian Forest Region in Elgin County, Lancaster et al. (2004) documented the Black-throated Green Warbler breeding in a mixed forest where hemlock was the dominant conifer. In the St. Williams Forest, it breeds in mature pine plantations that have evolved into naturally appearing forests of mixed pines and oaks; it also occurs there in sugar maple–beech forest with inclusions of hemlock (personal observation).

The Black-throated Green Warbler typically nests in forests, but may rarely nest in nonforested areas. It has nested in pastures and old fields containing scattered red cedars or pitch pine and possibly white cedars. There are rare reports of it nesting on a vine-covered pagoda on an open hillside some distance from forest and in a solitary spruce near a chapel with mixed woods nearby. It also nests in open pitch pine barrens (Bent 1953; Brewster 1895; Brown 1889; Chapman 1907; Morse and Poole 2020; Reading and Hayes 1933).

The Black-throated Green Warbler has been termed a wide-ranging habitat generalist that exhibits substantial geographic variation in its use of forested habitat, and particularly its requirement for conifers. Habitat selection differs among populations depending upon the forest type it inhabits (Robichaud and Villard 1999). It is most abundant in coniferous and mixed woods and tends to associate with conifers in mixed stands. It also occurs in pure deciduous stands. One subspecies breeds from southeastern Virginia and northeastern North Carolina in an exclusively deciduous area (Morse 1989, Morse and Poole 2020).

One habitat characteristic that is uniform throughout its range is that the Black-throated Green Warbler is most frequently associated with upland stands. There are some exceptions to this. In Michigan, it nested in bog communities treed with spruce (Pitelka 1940). In the northeast and New Jersey, it breeds in low to moderate densities in white cedar swamps (Brush 1987; Dawson 1979)

and it occasionally nests in red maple swamps in Rhode Island (Golet et al. 2001). In eastern Quebec and Labrador, its abundance was correlated with breeding-season precipitation, suggesting that it selected moister habitats (DesGranges and LeBlanc 2012).

Lanoue and Lafontaine (in Gauthier and Aubry 1996) provided an overview of the Black-throated Green Warbler's habitat preferences in different ecoregions of Quebec, and these closely match conditions in Ontario. It is infrequent in the black spruce zone of the northern Boreal Forest Region where it nests in intolerant hardwood stands. Further south, it becomes more abundant in the balsam fir ecosystem where it prefers mixed stands of balsam fir, white spruce, and poplar, or riparian habitat of white spruce and shrubs. It is most abundant in the south which contains mixed and deciduous forests, especially those dominated by sugar maple and yellow birch. Numbers are low in agricultural landscapes where it frequents rich, conifer-dominated sites, particularly those with hemlock, pine, balsam fir, white cedar, or white spruce.

Most authors consider the Black-throated Green Warbler a conifer specialist. It occurs in a wide range of coniferous and mixed forest types and focuses on conifers within mixed forests. Even in predominantly deciduous stands, territories may contain a few canopy-level conifers. In certain areas, it may exhibit a preference for 1 species of conifer over another, but these preferences are not consistent throughout its range. In Maine it prefers white and red spruce stands along the coast where red spruce is highly preferred to white spruce. Less than 10 km inland, it selects stands dominated by white pine (Morse 1976, 1989). It avoids black spruce, which occurs to the northern extent of its range and in boreal inclusions in the mixed-wood forest ecoregion (Kirk et al. 1996; Morse and Poole 2020; Whitaker and Montevecchi 1997). One constant is that it is strongly prefers hemlock. In certain areas of New Jersey, the Black-throated Green Warbler is considered an obligate hemlock species. Optimum habitat may not be pure hemlock stands but rather a combination of hemlock and hardwoods. The combined presence of hardwoods and hemlock results in layering of vegetation and a dense upper to mid-level concentration of foliage in the zone it prefers for foraging. The requirement for this layering may explain its absence or scarcity in spruce plantations and black spruce stands, because densely spaced spruce are self pruning leaving foliage concentrated in the upper canopy (Benzinger 1994; Brooks 1940; Keller et al. 2003). In New Jersey and Pennsylvania over a 15-year period, hemlock declined from representing 56% of the total basal area to 46% due to the hemlock woolly adelgid; the amount of deciduous understorey increased. This warbler declined in response to the decline in hemlock (Toenies et al. 2019).

Coniferous forest types that the Black-throated Green Warbler has nested in include those dominated by pine (especially white, red, and pitch pine, less frequently in jack pine), spruce (especially red and white spruce, infrequently in black spruce), white cedar and Atlantic white cedar, balsam fir, hemlock, spruce–balsam fir, balsam fir–white cedar, and plantations dominated by pines (Bent 1953; Benzinger 1994; Bielefeldt and Rosenfield 1994; Brooks 1940, 1947b; Capen 1979; Chapman 1907; Collins 1983b; Crawford and Titterington 1979; Dawson 1979; Drolet et al. 1999; LaRue et al. 1995; Morse 1976; Pitelka 1940; Thompson et al. 1999; Titterington et al. 1979; Whitaker and Montevecchi 1997).

The Black-throated Green Warbler breeds in a variety of mixed forest habitats. In the northern portion of its range, these are usually a mix of intolerant hardwoods (poplar and white birch) and

white spruce and balsam fir. Either the conifers or the hardwoods may dominate. Further south, the mix is often sugar maple and yellow birch and miscellaneous hardwoods with hemlock, pine, or white spruce. Even further south, it may use oak-pine associations. Less frequently used mixed stands include white cedar and intolerant hardwoods (Beals 1960; Campbell et al. 2001; Kendeigh 1945; Pitelka 1940; Robichaud and Villard 1999; Schieck et al. 1995; Temple et al. 1979).

The Black-throated Green Warbler also nests in pure deciduous stands. These may either be intolerant hardwoods or tolerant hardwoods such as sugar maple, beech, and yellow birch. Other types of deciduous stands that it may nest in include those dominated by red maple, oak-hickory, and white birch–red oak (Back 1979; Beals 1960; Brooks 1940, 1947b; DeGraaf and Chadwick 1987; DeGraaf et al. 1998; Freedman and Johnson 1999; Freedman et al. 1981; Harrison 1984; Holmes and Sherry 2001; Noon et al. 1979).

Several studies examined forest type preferences of the Black-throated Green Warbler. In New Hampshire and Maine, it was most abundant in hemlock stands, followed by those dominated by white birch, northern hardwoods, and swamp hardwoods. It was present but in lower numbers in stands dominated by poplar, balsam fir, white pine, and spruce–balsam fir (DeGraaf et al. 1998). On Wisconsin islands, it was one of the most common forest species and occurred in all stand types. It was most abundant in white birch–yellow birch–white cedar stands followed by those dominated by pines (jack, white, and red), hemlock–yellow birch, white birch–red oak, and poplar. It was significantly associated with yellow birch and also correlated with spruce, balsam fir, white cedar, and hemlock. It exhibited a lack of preference for pines but occurred in moderate numbers where pine was mixed with white cedar or balsam fir. It also inhabited stands lacking conifers but was more common when at least a few conifers other than pine were present. In New Brunswick, forest types that were used more than their availability, in order of preference, included intolerant hardwoods, spruce–tolerant hardwoods, intolerant hardwoods–spruce, and intolerant hardwoods–tolerant hardwoods. Stand types used less than their availability, in order of avoidance included pine, spruce–intolerant hardwoods, and spruce–balsam fir (Parker et al. 1999). In British Columbia, it inhabited trembling aspen and balsam poplar stands only if they contained mature white spruce (Campbell et al. 2001). In Maine, it greatly preferred red spruce stands to white spruce stands. Morse (1976) concluded that red spruce provided a better foraging substrate. This was because the thinner red spruce boughs provided better access to resources than the thick white spruce boughs, the longer branches of red spruce facilitated its preferred radial movement pattern while foraging in trees, and red spruce needles lay flat whereas white spruce needles project nearly perpendicularly to the branch, possibly inhibiting movement of the warblers. It preferred red spruce despite the fact that insect numbers and biomass were higher on white spruce.

The Black-throated Green Warbler prefers mature forests but also occurs in younger stands at low densities (Benzinger 1994; Morse and Poole 2020). In New Hampshire and Maine, it was most abundant in large sawtimber sized stands (DBH 60 cm or greater), followed by sawtimber and poletimber stands. It was absent in sapling stands (DeGraaf et al. 1998; DeGraaf and Chadwick 1987). In New York clear-cuts, hemlock did not become prominent in the canopy and subcanopy until 55-75 years after cutting. The Black-throated Green Warbler was the dominant species in a guild that was the last to appear during succession, with numbers peaking in the oldest forest stands (Keller

et al. 2003). Also in New York, it was associated with second-growth and mature coniferous and mixed forests with more than 75% canopy cover and moderate ground and shrub cover (Litwin and Smith 1992). In northern hardwoods in the northeast, it was documented on 55% of surveys in mature undisturbed habitat and 40% of surveys in disturbed and successional habitats (Noon et al. 1979). In northeastern poplar–white birch communities, it occurred only in poletimber and mature stands and was absent in seedling-sapling and sapling-poletimber stands (Back 1979). Temple et al. (1979) reported that it was associated with mature mixed-wood stands in the northeast. In northern hardwoods in Nova Scotia, it was one of the most important species in stands 20 years old and older. It was usually absent in younger stands, but occurred in low density in stands 1-2 years old (Freedman and Johnson 1999; Morgan and Freedman 1986). In New Brunswick, Zitske et al. (2011) considered its habitat to be mature forest at least 60 years old. In balsam fir forests in Newfoundland, it was significantly more abundant in 40-year-old second-growth stands than in uncut mature stands at least 80 years old; abundance was intermediate in 60-year-old stands. Forty-year-old stands were characterized by a well-developed small-tree layer that had a high deciduous component, although deciduous stems constituted only 6% of the small trees. This deciduous component was mostly absent in older stands. The 2 most abundant deciduous trees, white birch and pin cherry, are short-lived and were mostly absent in 80-year-old stands. Thompson et al. (1999) concluded that this warbler may have declined with the decline of deciduous trees and leaf litter. Old stands also had fewer and shorter small trees. Other studies demonstrated that midcanopy vegetation is important to this warbler. In this study, it was significantly more abundant on nutrient-rich than nutrient-poor sites. In northern hardwoods in New Hampshire, Holmes and Sherry (2001) reported that the Black-throated Green Warbler increased over a 30-year period and attributed this to forest maturation. Although the forest was mature at the beginning of the study, it became more open due to treefalls and beech bark canker fungus. With the more open patchy canopy, a dense layer of tall shrubs and subcanopy developed and the low shrub layer became sparser. In spruce–balsam fir forests in Maine, it was one of the dominant species in older clear-cuts characterized by hardwood regeneration taller than 4.5 m with a DBH of 10-15 cm, and a slower-growing understorey of conifers. It was less than half as abundant in dense fir-spruce forests with an open understorey. It was uncommon in the early seral stages of succession (Titterington et al. 1979). In northern hardwood stands in Wisconsin, it does not appear until the average tree size is at least 23 cm DBH (Hoffman 1989a). In Pennsylvania, Haney (1999) documented it in 100% of old-growth mixed forests, 15.1% of forests statewide, and 31.5% of forests on the Appalachian Plateau. He considered it to have positive old-growth affinities. In poplar-dominated forests in Alberta, it was significantly more abundant in old-growth stands than in mature and young stands (where it was not detected). Old-growth stands had significantly more conifers than the other age classes (Schieck et al. 1995). In the Prairie Provinces, it was in a guild associated with conifers and was most prevalent in old stands on nutrient-rich sites (Kirk et al. 1996). In British Columbia, it is associated mainly with old-growth white spruce and balsam poplar on moist sites along major rivers. It may also use shrubbier habitat such as willows, white birch, alder, and trembling aspen thickets along edges of lakes, rivers, and ponds (Campbell et al. 2001).

Some studies examined landscape variables that may affect the distribution or abundance of the Black-throated Green Warbler. In southern Ontario, its abundance was significantly correlated

with the amount of forest cover within 2 km and the regional amount of forest cover (Austen et al. 2001). This appears to be consistent with the pattern of distribution identified by the second atlas. In the Carolinian Forest Region, the main area of concentration is on the heavily forested Norfolk Sand Plain and there is a clear concentration along the Niagara Escarpment (Crins in Cadman et al. 2007). Near Quebec City, Drolet et al. (1999) studied 100-ha landscapes in an area consisting of 3 general habitats: large tracts of coniferous forests, small (less than 30 ha) clear-cuts imbedded in a forest matrix, and large clear-cuts that delineated small coniferous patches. Forest cover within the 100-ha landscapes varied from a few to 90 ha. The Black-throated Green Warbler responded significantly to forest cover, edge, and core area combined, although it was not significantly correlated with any of these parameters individually. The authors concluded that it may avoid sparsely forested areas. In Michigan, Crozier and Niemi (2003) studied naturally heterogeneous landscapes and found that it was unaffected by landscape variables such as the proportion of habitat within the landscape.

In Alberta, Robichaud and Villard (1999) studied Black-throated Green Warbler territories in mixed-wood forests dominated by trembling aspen and balsam poplar with irregularly spaced mature white spruce. Conifer density was significantly higher in territories than it was over entire plots. It avoided areas without conifers, except that 3 territories occurred where conifers were sparse or absent. Trees with a large DBH and that were taller were more likely to be used for both singing and foraging than smaller trees. White spruce was significantly larger than other species and was used significantly more than trembling aspen. The preference for white spruce over balsam poplar was marginally nonsignificant; white birch was not avoided or preferred. For singing, the odds of usage increased 4-fold regardless of tree species for every 10 cm increase in DBH. In 1 plot, 97% of trees used were white spruce; 64% of trees used were spruce in the other plot. Spruce represented 36% of all trees in both plots. Despite its strong preference for large spruce, it still used deciduous trees for singing, foraging, and nesting.

Several studies examined microhabitat preferences of the Black-throated Green Warbler. Because of its usage of a wide variety of forest types, there is a great disparity in its habitat preferences. Habitat features that are selected in 1 geographic area may be avoided in another. There are 2 habitat components that are consistent throughout its range: a preference for large trees in the canopy in stands that are often fairly open, and a well-developed tall shrub or midcanopy level. Collins (1983b) compared its habitat preferences in Maine, New York, New Hampshire, and Minnesota. Six habitat variables were significantly different among the 4 sites and these were related to canopy height, the percentage of conifers in the canopy, and selection of different tree-size classes. Canopy height was greatest in Minnesota due to the presence of large red pines and white pines, and these also contributed to a higher percentage of conifers. More northern areas contained more trees in the smaller size classes. In some plots in other states, there were no conifers. The most consistent parameters were the number of trees 15-23 cm and 23-30 cm DBH. The presence of many small trees may be an essential feature of its habitat, or presence of small trees may simply be a consequence of forest structure. In these 4 states, there were gradients in habitat from tall to shorter canopies, large to smaller trees, and coniferous to deciduous forests. Collins (1983a) did another analysis of its habitat preferences in Minnesota and Maine. Habitat preferences varied significantly for 9 of the 11 parameters that were tested. These were related to percent ground cover, canopy

cover, canopy height, percent conifers, and tree size classes. In Minnesota, it was associated with large trees, more so than for any other warbler species, and fairly large conifers. In Maine, it was associated with large deciduous trees. Collins et al. (1982) characterized the habitat of the Black-throated Green Warbler in Minnesota, but Collins (1983a, 1983b) determined that results were significantly different in Maine, New York, and New Hampshire. Average habitat characteristics in Minnesota included 52.7% ground cover, 39.0% shrub cover, 84.3% canopy cover, 20.2 m canopy height, 50.3% coniferous cover, 5.7 tree species per 0.04-ha circle, 15.1 trees 7.5-15 cm DBH, 10.5 trees 15.1-23 cm DBH, 5.7 trees 23.1-30 cm DBH, 4.4 trees 30.1-38 cm DBH, 3.3 trees 38.1-53 cm DBH, 1.9 trees 53.1-68 cm DBH, and 0.9 tree larger than 68 cm DBH. It was associated with the highest number of trees larger than 68 cm DBH of all warblers studied. It was within a guild of warblers that occurred predominantly in undisturbed habitats containing conifers. Distinctive features of the habitat of this group consisted of moderate ground and shrub cover and more than 75% canopy closure. Territories of these species consistently contained more than 50% coniferous cover, mostly in the large tree categories. Conifers in territories of the Black-throated Green Warbler were typically white, red, or jack pine rather than spruce or balsam fir. In New Hampshire and Maine, it was positively correlated with coniferous trees 2-10 cm DBH, total foliage volume of both deciduous and coniferous trees larger than 10 cm DBH, and the total foliage volume of deciduous stems less than 2 cm DBH. It was negatively correlated with the number of conifers larger than 10 cm and the number of woody stems per ha (DeGraaf et al. 1998). In spruce–balsam fir forests in Maine, it was associated with deciduous trees 10-15 cm DBH and both deciduous and coniferous trees larger than 20 cm DBH (Titterington et al. 1979). In Maine and Vermont, its abundance was nearly proportional to the foliage volume above 6 m. Abundance fell off in 2 plots where very tall trees were present. It seldom used tall treetops for foraging so this foliage volume did not contribute to the usable habitat. In 1 area, the Bay-breasted Warbler was the most abundant species in spruce and the Black-throated Green Warbler occupied ridges forested with mixed hemlock and hardwoods (MacArthur 1958). Morse (1976) found no correlation between foliage volume and its abundance in Maine. In the mid-Atlantic states, it was positively correlated with the number of tree species, percent coverage by conifers, the number of trees larger than 38 cm DBH, and percent ground cover (Robbins et al. 1989). In northeastern mixed forests, it was associated with increasing coverage by yellow birch and sugar maple (Temple et al. 1979). In subalpine forests in New Hampshire, Sabo (1980) considered this warbler a lowland deciduous forest user. It was associated with lower-slope northern hardwoods and, to a lesser extent, mixed northern hardwoods, balsam fir, red spruce, white birch, and American mountain-ash. The main population was below mid-slope with average territory characteristics consisting of areas where some wet depressions were available, with a canopy height of 12.5 m, 79% canopy coverage, 37% coniferous coverage, 15 m^3 conifer foliage volume 0-2 m from the ground, 113 m^2 deciduous foliage volume above 5 m, and 13 cm DBH for living trees. In Vermont, the Black-throated Green Warbler was associated with closed-canopy mixed forests with a dense understorey. Average habitat parameters included 13.7% green ground cover, 13.6% ground cover slash, 88.4% canopy cover, 22.1 m canopy height, 12.5 m canopy depth, 13.3 m^2 BA of deciduous species, 12.7 cm DBH for deciduous species, and 17.0 cm DBH for conifers (Thompson and Capen 1988). In poplar-dominated forests in Alberta, it was positively correlated with tree species richness, downed woody material larger than 20 cm, canopy height, and trees larger than 20 cm DBH. It was negatively correlated with aspen density (Schieck et al. 1995).

Some studies identified other species that are in guilds with the Black-throated Green Warbler. In New Hampshire and Maine, it was in a guild associated with trees larger than 60 cm DBH (DeGraaf et al. 1998). In the northeast, Niemi and Pfannmuller (1979) placed it in a guild that was associated with moderate numbers of saplings and low shrubs, few tall shrubs, and increased numbers of trees and saplings. In Vermont, it was in a guild associated with closed-canopy mixed forest (Thompson and Capen 1988).

In Maine, Morse (1967) stated that the Black-throated Green Warbler typically occurred in the interior portion of the forest and Morse and Poole (2020) concluded that it was a forest-interior species. This was despite the work by Morse (1971b) on small islands in Maine where he documented breeding by this warbler. In no case did a part of an occupied forest lie more than 50 m from edge. Freemark and Collins (1992) considered the Black-throated Green Warbler a forest-interior species based upon a literature review. In southern Ontario, Austen et al. (2001) determined that its abundance was significantly correlated with the amount of forest cover 100 m or more from edge. Peck and James (1987) reported that some Ontario nests were found at forest edges near roads or water. In Maine, Stanwood (1910b) reported a nest at the edge of a woodlot. Chapman (1907) reported that it avoided deeply shaded forest interiors. Some studies specifically analyzed the response of the Black-throated Green Warbler to forest edge. In New Hampshire, King et al. (1997) examined the locations of territories in mature northern hardwoods adjacent to clear-cuts 6 years old and younger. There was no significant difference in the number of territories within 100 m of edge or within forest interior. Villard et al. (2007) conducted a similar experiment in Alberta. Experimental plots were 10 or 40 ha surrounded by clear-cuts at least 100 m wide. A significant edge avoidance response was exhibited by the Black-throated Green Warbler. The dominant pattern by all species combined was one of neutral short-term response to clear-cut edges, especially in the 10-ha fragments. The authors concluded that proximity to edge played a minor role in breeding site selection and questioned the validity of the forest-interior concept. In Quebec balsam fir stands, LaRue et al. (1995) found no difference in Black-throated Green Warbler density in forest interior and in riparian edge stands. In Newfoundland balsam fir stands, it was significantly more abundant in forest interior than in riparian edge stands. There was no significant difference in its abundance in forest interior and in forest–clear-cut edges. Riparian areas supported black spruce, a species not characteristically used by this warbler. The presence of black spruce in the riparian edges may have made this habitat less suitable and this may have been the cause of the apparent edge avoidance. It did not avoid clear-cut edges (Whitaker and Montevecchi 1997). In the same area, Whitaker and Montevecchi (1999) determined that the Black-throated Green Warbler was equally abundant in riparian buffers where adjacent upland forest had been retained and where it had been clear-cut. In Maryland, Gates and Giffen (1991) observed no edge effects for this warbler. The Black-throated Green Warbler is not a forest-interior species. In areas where it is more abundant in forest interior, it is likely that habitat along the edge is less than optimum and that birds are not responding to the edge itself.

Two studies examined the effects of gaps within forests on the Black-throated Green Warbler. In Michigan, Smith and Dallman (1996) compared usage of forest interior to gaps in canopy that were a minimum of 5 m in diameter extending through all vegetation layers down to an average height of 2 m above ground. Birds were considered to be using a gap if they were observed foraging

or singing within 1 m of it. Males used forest gaps significantly more (52.1% of all observations) and forest interior significantly less (30.9% of observations) than expected. Females demonstrated an even greater difference in use, using gaps 55.0% of the time and forest interior 25.0% of the time. Some males appeared to use gaps as territorial boundaries. Gaps may be important because they support more insects, have a warmer microclimate due to sun penetration thereby increasing insect activity, and males may have increased visibility and better song delivery in gaps. In Quebec balsam fir forests, Rail et al. (1997) studied how the Black-throated Green Warbler responded to treeless gaps 3-100 m wide. Five types of gaps were studied with all having similar habitat on both sides: trails 3-15 m wide, unpaved roads 4-35 m wide, clear-cuts 12-100 m wide, unpaved roads with clear-cuts on 1 or both sides 18-65 m wide, and hydro rights-of-way 38-55, 70-80, or 84-100 m wide. Broadcast calls were used to determine if warblers would cross gaps. Gap type had no effect on the probability of crossing. The probability of a Black-throated Green Warbler crossing a gap was 90% at 15 m width, 80% at 20 m, 70% at 35 m, 50% at 50 m, and 30% at 80 m.

Freemark and Collins (1992) concluded that it was uncertain if the Black-throated Green Warbler was area sensitive due to conflicting conclusions in the literature. In southern Ontario, Austen et al. (2001) determined that its abundance was significantly correlated with woodlot size. James (1984b) did not consider it area sensitive in Ontario whereas Coleman et al. (2000) did. In Michigan, its abundance was correlated with patch size (Crozier and Niemi 2003). In Connecticut, Askins et al. (1987) detected it in only 5 of 46 forests where it was restricted to larger tracts. The average patch area that it inhabited was 354 ha and the minimum patch size was 187 ha, significantly different from random woodlots. Robbins et al. (1989) found no relationship between its abundance and woodlot size in the mid-Atlantic states and did not consider it area sensitive. In Wisconsin, Beals (1960) reported that it was not confined to the larger islands that he studied. In Maine, it nested on islands that supported only 0.53-1.50 ha of forest cover, but was absent on islands with less than 0.35 ha of forest (Morse 1971b; Morse and Poole 2020). The disparity in the reported results may be related to the habitat requirements of the Black-throated Green Warbler. Its abundance appears to be depressed in landscapes that support limited suitable habitat. Within these landscapes, it may be restricted to larger high-quality forests and therefore be area sensitive. In highly forested landscapes, it is unlikely to be area sensitive. If this species is area sensitive in Ontario, it is likely to be so only south and west of the Niagara Escarpment, with the exception of the heavily forested portion of the Norfolk Sand Plain.

Nests reported to the Ontario Nest Records Scheme were in both small and large trees. Coniferous trees were much preferred to deciduous trees, with 82.9% of nests in 6 species of conifers and 17.1% in 4 deciduous species. Hemlock (11 nests), white cedar (10 nests), spruce (5 nests), and pine (5 nests) were used most frequently. Most nests were on a living, but rarely dead, horizontal branch (70.8% of nests) and were either saddled on the branch or supported by adjacent branches; 16.7% were in crotches of branches; and 12.5% were in crotches at the trunk. Most (73.9%) were distant from the trunk and the remainder were at or near the trunk. Distances from the trunk were 0.2-4.5 m, mostly 0.9-3.7 m. Nests were 0.5-15 m from the ground with most 2.3-7.6 m up (Peck and James 1987, 1998a). In Muskoka and Parry Sound districts, most nests were in hemlock but some were in birches and maples at heights of 3-15 m (Mills 1981). An Elgin County nest was 8.25 m from the ground in a fork of yellow birch (Lancaster et al. 2004). Bent (1925) reported 2 nests in deciduous

woods in Ontario. One was 12.2 m from the ground in a hophornbeam and the other was 6.1 m up in a small elm. Near Lake Nipigon, Kendeigh (1947) found a nest in a tangle of dead branches of a fallen tree 0.3 m from the ground. It rested on 1 branch and was supported around the sides by twigs and was partly concealed by beard lichen and fern leaves. It typically nested there in trees as high as 21.3 m from the ground. Of 6 nests that Tozer (2008) found in Algonquin Park, 4 were in tree cavities. Three were in Pileated Woodpecker foraging cavities and the fourth was at the bottom of a sugar maple borer scar. The scar had protruding bark at the bottom that supported and concealed the nest from above, below, and three quarters of the sides. These nests were at heights of 1.5-4.5 m in a balsam fir snag, a beech snag, a sugar maple snag, and a live sugar maple. There were at least 5 mature canopy-sized hemlocks within 75 m of each nest suggesting that lack of conifers was not a factor influencing birds to nest in cavities. Cavity nesting may be a regular but infrequent occurrence in Algonquin Park, but has not been reported elsewhere.

Most nests reported elsewhere were in trees, but there were a few exceptions. One was 3 m from the ground in a grapevine surrounding a small pagoda in Maine. It was on the main stem of the vine (Brown 1889). One Connecticut nest was on the ground among a large clump of ferns in a very low and damp site under a heavy growth of hemlock (Brewster 1895). A New Jersey nest was between the stems of a skunk cabbage and fastened to a greenbrier and the twigs of a dead shrub 0.36 m from the ground in a very wet location (Chapman 1907). A Massachusetts nest was 0.20 m from the ground in a red cedar in an old pasture. In Michigan, nests in northern hardwood forests were 0.6-0.9 m from the ground in American yew. One nest was in a barberry shrub 100 m from the nearest forest (Bent 1953). Typical nests are in trees, usually on a horizontal branch distant from the trunk but occasionally near the trunk. The Black-throated Green Warbler prefers conifers for nesting throughout its range, with hemlock highly selected. Other conifers it has nested in include Norway spruce, white spruce, red pine, balsam fir, pitch pine, and red cedar. Eighty percent of New York nests were in hemlock. Most Maine nests were in spruce or pine. The Black-throated Green Warbler nests much less frequently in deciduous species such as beech, yellow birch, balsam poplar, white birch, gray birch, sugar maple, white oak, American chestnut, alder, and elm. Nests have been reported 0-20 m from the ground, but most are 2-6 m up. Almost all of 58 Maine nests were in conifers at heights of 0.9-15.5 m, with most 3-6 m up (Bent 1953; Benzinger 1994; Brewster 1895; Brooks 1947b; Chapman 1907; Cruickshank 1956; Harrison 1984; Kotesovec 1994b, 1995; Morse and Poole 2020; Nice and Nice 1932; Philipp and Bowdish 1917; Pitelka 1940; Reading and Hayes 1933; Stanwood 1910b, 1914).

Males establish territories shortly after their arrival in spring and maintain them until the young fledge and leave the territories. Most activities are conducted within the territory, but birds occasionally wander outside them. Although interspecific territoriality does not occur, the Black-throated Green Warbler appears to be socially dominant to the Blackburnian Warbler, Yellow-rumped Warbler, American Redstart, and Northern Parula and may depress their populations where it is abundant. In turn, the Black-throated Green Warbler appears to be subordinate to Magnolia and Bay-breasted warblers. Territories tend to be smaller in coniferous forests than in mixed forests due to its preference for conifers. In Maine, it preferred red spruce and territories were smaller in red spruce than white spruce stands. There is an inverse relationship between territory size and food density, and territory sizes decrease as warbler density increases. When a Maine population declined,

remaining males trebled their territory boundaries. In Algonquin Park, territories averaged 0.26 ha (range 0.008-2.35 ha). Near Lake Nipigon, 5 territories averaged 0.49 ha (range 0.32-0.85 ha). In New York, 21 territories averaged 0.65 ha (range 0.24-1.01) in hemlock-beech forest. Territories in subalpine forests in New Hampshire averaged 1.2 ha. In Maine, average territory size was 0.25-0.28 ha in red spruce stands and 0.40-0.43 ha (range 0.35-0.55 ha) in white spruce stands (Kendeigh 1945; MacArthur 1958; Martin 1960; Morse 1976, 1977; Morse and Poole 2020; Sabo 1980). Near Quebec City, Bourque and Desrochers (2006) found no evidence of territorial aggregation at any scale.

No information is available on natal philopatry, but it is probably low. Limited data are available on adult site fidelity. Morse and Poole (2020) stated that, after first breeding at a site, individuals frequently return in subsequent years. One male returned to a Maine study area in 4 years. In New Brunswick, Zitske et al. (2011) banded 356 males over 7 years and reencountered 105 (29.5%) at least once. Five individuals moved 65-650 m from their original capture location. The apparent annual survival rate based on band recoveries was 34.1%, with experienced breeders having significantly higher survival rates. There was some evidence that survival, or return rates, increased as the amount of habitat at the 2,000-m scale increased. Survival was 12 times greater in landscapes with 85% habitat than those with 10% habitat. Areas supporting lower amounts of habitat had a lower number of individuals that had lower survival rates. The authors found evidence of long-term breeding dispersal away from original sightings and acknowledged that their survival estimates were low.

Limiting Factors

Eggs have been reported in Ontario nests from the beginning of June until mid-August, with most present in the last 3 weeks of June (Peck and James 1987, 1998a). In Algonquin Park, nests are under construction from mid-May to late June, eggs are present from late May to late June, nestlings are present early June to mid-July, and dependent fledglings have been observed mid-June to late August (Tozer 2012).

Pair formation occurs shortly after the females arrive and nest building commences soon thereafter. Nests typically take about 4 days to build. In 2 cases, the nest exterior was completed in 4 days and an additional 4 days were spent lining the nest. One day may elapse between completion of the nest and initiation of egg laying. The egg-laying rate is 1 per day. Incubation begins with the laying of the last egg. Two Ontario nests had incubation periods of approximately 11 days and eggs took 13 days to hatch in another nest. The incubation period has been reported to be 12 days elsewhere. The nestling period is 8-11 days, mostly 9-10 days (Bent 1953; Kotesovec 1994b, 1995; Morse and Poole 2020; Nice and Nice 1932; Peck and James 1987; Pitelka 1940; Stanwood 1910b).

Ontario egg dates suggest that second broods occur (Peck and James 1987). Nice and Nice (1932) thought that double broods were probable in Massachusetts due to the late dates that fledglings were observed. Double broods have never been confirmed for the Black-throated Green Warbler. It is a persistent renester if clutches are lost (Morse and Poole 2020). Clutches of 3-5 eggs have been reported in Ontario (average 3.64 eggs). Most clutches (17) contained 4 eggs but 16 contained 3 eggs (Peck and James 1987). Elsewhere, the clutch size is 3-5 eggs (mode 4 eggs). Mean clutch size in Vermont and Maine was 4.04 eggs. Clutch size does not vary with the abundance of spruce budworms (MacArthur 1958; Morse and Poole 2020).

The mating system is monogamous. Birds occasionally leave their territories suggesting that extra-pair copulations may be part of the mating strategy. Males can breed at the age of 1 year but it is unknown if yearling females are capable of breeding. Some yearling males remain unmated and do not breed (Morse and Poole 2020).

The Black-throated Green Warbler is a generalist, foraging in both deciduous and coniferous species. In specific locations, it exhibits preferences. Ninety percent of foraging is in conifers in coastal Maine, 60% in inland mixed forests, 43% in subalpine forests in New Hampshire, 26% in the Clay Belt of Ontario, 5-10% in New Hampshire in predominantly deciduous woods, and 0% in pure deciduous woods in West Virginia. In Alberta, males selected white spruce for foraging over trembling aspen. It used white birch according to its availability. It preferred conifers at both the territory and 25-ha scales. It was more likely to use larger-diameter trees for foraging, and most were spruce. Conifers have stronger branches and offer more support than deciduous trees, which also vary in their leaf morphology and attachment. White birch has shorter petioles than trembling aspen and balsam poplar, which gives foraging Black-throated Green Warblers easier access to prey. The 2 poplar species were significantly avoided for foraging but white birch was not and was slightly preferred. In Michigan, it used white cedar less than its availability during the breeding season and autumn migration. In New Hampshire, it foraged more frequently on tree species such as yellow birch that have foliage arrayed continuously and close to the branches. It tended not to forage in trees with a different foliage configuration. In an aviary experiment, warblers from Maine, where more than 90% of foraging occurs in conifers, and from New Hampshire, where 90-95% of foraging occurs in deciduous species, were tested for their substrate preferences. When prey was distributed equally among the types of vegetation, Maine birds spent 75% of their time in conifers and New Hampshire birds spent 80% of their time in deciduous vegetation. When prey densities were distributed away from the preferred substrate, Maine birds spent 68% of their time in conifers but captured 74% of prey in deciduous vegetation. New Hampshire birds spent 55% of their time in deciduous vegetation but captured 81% of their prey in conifers. Most birds captured all the available prey from their preferred substrate before beginning to forage in the less preferred vegetation (Greenberg et al. 1999; Morse 1989; Parrish 1995; Robichaud and Villard 1999; Robinson and Holmes 1982; Sabo 1980; Smith et al. 1998). In the Clay Belt of Ontario, 94.0% of foraging was on foliage, 46.3% by aerial attacks, 2.0% by hanging, 31.0% by hovering, and 22.1% by reaching at an average height of 11.3 m or 73.0% of tree height (Greenberg et al. 1999). In Parry Sound District during the breeding season, foraging by this warbler was restricted to northern hardwoods. In late summer, it foraged in hardwoods, intolerant hardwoods, and conifers. In autumn, it foraged predominantly in white birch. It foraged at heights of 5-16 m during the breeding season and 4-13.5 m in autumn. It was in a foraging guild that fed predominantly by gleaning on the under and upper surfaces of leaves (Mills 2007). MacArthur (1958) studied foraging strategies of the Black-throated Green Warbler in Maine and Vermont. He identified 6 vertical zones in conifers including the area beneath the tree and 5 equal zones within the tree. Three horizontal zones were also identified: the inner zone of bare or lichen-covered branches, the central zone of old needles, and the outer zone of new needles and buds. Most foraging time was spent in the outer portion of the middle zone of the tree (21.8%), followed by the central portion of the middle zone (14.1%), and the outer portion of the zone second from the top of the tree (17.3%). Usage of the outer top zone was 12.1%. At each

level, highest use was made of the outer zone. Least use was made of the inner zone, with a total of 2.6% for all horizontal zones combined. No foraging occurred beneath trees. It moved predominantly in a tangential direction within trees, significantly different from the other warbler species that were studied. It did not take long flights (7.6 m) between trees or hawk, but hovered significantly more than Cape May, Yellow-rumped, Blackburnian, and Bay-breasted warblers. The Black-throated Green Warbler was quite restricted in its feeding habits compared with the Yellow-rumped Warbler. Almost all foraging by the Black-throated Green Warbler was by rapid peering, hopping actively on thick foliage at ends of branches looking into the vegetation above, springing into the air, and hovering under a branch to capture prey. Although other warblers occasionally forage in this manner, it is characteristic of the Black-throated Green Warbler. It occasionally hawks for flying insects, missing a substantial portion of them, but this is atypical behaviour because it seldom sits motionless watching for insects. The 5 warbler species behaved in manners such that they would be exposed to different foods and the Black-throated Green Warbler was regulated by the amount of foliage volume at mid-height of trees. Cumming (2004) completed a similar study in Saskatchewan. Fifteen or more percent of foraging observations were in the outer portion of the top zone of conifers, 10-14.9% were in the central and outer portions of the central zone of the tree, 5-9.9% were in the central and outer portions of the second from the top zone, and 0-4.9% were in all other zones including the 2 lower vertical zones. In conifers, it was one of the least diverse foraging species along with the Blackburnian Warbler and Blue-headed Vireo. In deciduous trees, only 3 vertical zones were identified. Fifteen percent or more of foraging occurred in the outer portion of the top zone, 10-14.9% in the central portion of the top zone, 5-9.9% in the inner portion of the top zone, and 0-4.9% in all portions of the 2 lower zones. The mean foraging height of the Black-throated Green Warbler in conifers was 12.7 m, significantly lower than the Blackburnian Warbler and significantly higher than the Bay-breasted Warbler, Magnolia Warbler, and Blue-headed Vireo. The mean foraging height of 11.4 m in deciduous trees was not significantly different from the height in conifers. The Black-throated Green Warbler was seen in canopy-level trees in 77.3% of observations. Both it and the Blackburnian Warbler appeared to be specialized in a treetop niche and their foraging techniques overlapped by 85%, more than with any other species. There was no evidence that the Black-throated Green Warbler was socially dominant over any other species, possibly because it was the least abundant species. In Michigan during the breeding season, there were no significant differences between Lake Huron shoreline and inland habitats in its use of foraging manoeuvres, horizontal position, foraging height, and tree species used for foraging. In conifers, it favoured the top of trees more near the shoreline than inland (67.1% of foraging compared with 46.5%) and the bottom of the substrate more inland than at the shoreline (53.4% of foraging compared with 32.9%). There was no significant difference in deciduous species (Smith et al. 1998). In an aviary experiment, the Black-throated Green Warbler searched both sides of leaves and then focused on either the upper or lower leaf surface after the first capture. The contrasting foliage structure of sugar maple and yellow birch did not affect the ability of birds to learn about the distribution of prey (Whelan 1989). Morse (1968) compared the foraging strategies of the sexes in Maine. Males foraged significantly higher than females. Males foraged at heights of 0.3 m to more than 18 m and females foraged at 0.3-18 m. Males foraged at a lower height than they sang, but foraging areas were closer in height to singing perches than nests. Females usually foraged closer to the height of the nest. There were no significant differences in the foraging locations of the sexes:

78% on small limbs, 5-10% on large limbs, 3% at branch tips, and 5-8% on deciduous species. Males hawked significantly more than females; hovering was the dominant method of movement for both sexes. Most food was obtained by gleaning. In another Maine study, the Black-throated Green Warbler foraged at heights of 10.7 m to more than 19.8 m (mean 15.2 m). In spruce, 26.3% of foraging was at the tip of foliage (14.1% by gleaning, 1.3% by stretching, 10.9% by hovering, and 0% by hover-walking and hanging), 38.2% on live twigs 5 mm and smaller, 0.7% on dead twigs (all by gleaning), 8.2% on dead branches (7.5% by gleaning and 0.7% by hovering), 0.7% on beard-lichen-covered branches, 3.9% distally on branches, 14.4% proximally on branches, 0.7% on trunks, 2.0% by flycatching, 3.9% on deciduous growth, and 1.0% on the ground. The Black-throated Green Warbler and Northern Parula foraged at similar heights and in similar areas of the foliage, and hovered more than the other warblers (Morse 1967). On small islands in Maine, 65-80% of male foraging occurred on small limbs, 2-15% on large limbs, 2-10% on foliage tips, 2-8% on dead limbs, and 0-15% on deciduous growth. One female foraged 70% of the time on small limbs, 10% on large limbs, 10% on foliage tips, 6% on dead limbs, and 4% on deciduous vegetation. Both sexes foraged at heights of 0-21 m on 4 islands, with a different profile on each island. They generally foraged at the heights represented on each of the islands. The Black-throated Green Warbler appeared to be socially dominant to the Northern Parula and Yellow-rumped Warbler because these species altered their foraging behaviour in its absence (Morse 1971b). In subalpine areas of New Hampshire, its foraging techniques included 0.5% aerial flycatching, 38.8% leaf gleaning, 14.0% leaf hawking, 15.5% leaf hovering, 1.7% twig pecking, 18.5% twig gleaning, 7.8% twig hawking and hovering, 0.1% branch pecking, 1.9% branch gleaning, 0.1% bole pecking, 1.1% bole gleaning, and 0% litter pecking, litter gleaning, and fallen log manoeuvres. Foraging substrates included 57.0% distal to the trunk, 43.0% proximal to the trunk, 43.1% in coniferous foliage, 56.9% in deciduous foliage, and 0% in herbaceous foliage and on the ground. Foraging heights included 0% at 0.1-1.2 m, 23.8% in the midstorey at 2-5 m, 51.5% in the midcanopy at 5-8 m, and 24.8% above 8 m in the upper canopy. The Black-throated Green and Bay-breasted warblers foraged at greater heights than the other species that were present (Sabo 1980). In northern hardwoods in New Hampshire, 73.9% of prey attacks were on leaves and 13.6% were on bark. Most available prey consisted of adult and larval moths, adult flies, wasps, beetles, nymphal and adult leafhoppers and froghoppers, and spiders. Most of these were on leaves and not on twigs or small branches. Foraging techniques included 54.2% gleaning, 35.4% hovering, 6.6% flush-chasing, 2.0% hawking, 1.6% hanging, and 0% probing. Most hovers were directed vertically because most prey was on the underside of leaves. The Black-throated Green Warbler was in a foraging guild with the Black-throated Blue and Blackburnian warblers. These were near-surface searchers that predominantly gleaned small- to medium-sized, often cryptic, insects and made frequent short movements between perches. The Black-throated Blue Warbler was separated from the other 2 species by feeding exclusively in the understorey (Robinson and Holmes 1982). During wet periods, the Black-throated Green Warbler forages more frequently on bark and even on tree trunks and increases its frequency of hovering. Overall, more than 80% of foraging actions are by gleaning and another 10% consists of hovering at branch tips. Less frequent motions include hawking, chasing fallen food, and hanging upside down. Few items shorter than 2 mm in length are consumed although these dominate numerically (Morse and Poole 2020).

At an Ohio nest, caterpillars constituted 67.5% of the food items provided to nestlings and the remainder was predominantly tiny unidentified insects. At a Michigan nest, the male usually brought green caterpillars to the nestlings. The female provided small flies and various larvae. At a Maine nest, the nestling diet consisted of a large number of smooth green and brown caterpillars, flies, bee-like insects, beetles, and moths. In Massachusetts, young were fed green caterpillars and small insects. At a Connecticut nest, young were fed spiders, mayflies, green caterpillars, ants, small owlet moths, ichneumonid wasps, crane flies, and many smaller flies (Harrison 1984; Kotesovec 1994b; Nice and Nice 1932; Pitelka 1940; Reading and Hayes 1933; Stanwood 1914).

Stomachs of 5 adults near Lake Nipigon contained 45.0% lepidopterans, 27.5% spiders, 18.7% soft-winged bugs (mostly froghoppers with some planthoppers and seed bugs), 3.4% soldier beetles, 2.9% flies (house flies and 1 march fly), and 2.5% hymenopterans (Kendeigh 1947). Stomachs of 23 New Hampshire Black-throated Green Warblers contained 47.8% caterpillars, 34.8% soft-winged bugs (mostly leafhoppers), 13.1% beetles, and 4.3% adult lepidopterans. The diet determined by visual observations consisted of 82.8% caterpillars, 8.6% adult lepidopterans, 6.9% beetles, and 1.7% adult flies plus unidentified items (Robinson and Holmes 1982). In Maine, males actively selected large prey items and caterpillars. The number of caterpillars in stomachs was 15.1-61.3 times that expected based upon the proportion of caterpillars in sample collections. Caterpillars were the only food item taken more than expected. Foliage samples were dominated by aphids but few were eaten (Morse 1976). One bird collected in Maine during a spruce budworm outbreak had consumed 35% budworm larvae and pupae by volume (Mitchell 1952). A warbler in an orchard infested with cankerworms had eaten 70% cankerworms, 15% beetles, 5% true bugs, and 10% hymenopterans, gnats, beetle larvae, and mites. Other food items this warbler has consumed include locusts, leafroller moths, aphids, tent caterpillars, budworm larvae, and juniper and poison ivy berries (Bent 1953). In an aviary study, gypsy moth larvae were presented to Black-throated Green Warblers. Eight of 9 second-instar offerings and 3 of 5 third- to sixth-instar offerings were accepted. Warblers were simultaneously offered gypsy moth larvae (11 of 30 accepted), tussock moth larvae (4 of 20 accepted), cabbage loopers (all 30 accepted), and mealworms (all 18 accepted). It exhibited a preference for hairless larvae. Whelan et al. (1989) concluded that it was likely to eat gypsy moth larvae only when no alternative prey was available.

The Black-throated Green Warbler may respond positively, neutrally, or negatively to insect outbreaks. In Maine, Morse (1976) found a direct correlation between both the numbers and biomass of caterpillars and numbers of this warbler. In New Hampshire, it fluctuated irregularly but appeared to be more abundant during an outbreak of the saddled prominent (Holmes and Sturges 1975). Near Manitouwadge, it did not respond numerically to increasing spruce budworm populations (Venier et al. 2009). During a spruce budworm outbreak in New Hampshire and Maine, Crawford and Jennings (1989) found an average of 1.0 budworm per stomach. This rate of consumption was low to moderate compared with other species. Black-throated Green Warbler populations were unaffected by budworm numbers. In New Brunswick, Gage et al. (1970) concluded that its density was not related to the population size of the black-headed budworm. No first-instar budworms were consumed even through this invertebrate was most abundant at this stage. Consumption increased to a maximum as prey size increased and then declined to 0 as prey density also declined to 0. Few pupae were eaten when they first entered the population but consumption

increased to a maximum when pupa density peaked, followed by a decline in consumption as pupa density decreased. In New Brunswick, the population of the Black-throated Green Warbler decreased when spruce budworm populations increased (Morris et al. 1958). Declines during spruce budworm outbreaks may be due to competition from the abnormally high populations of the budworm specialist warblers or it is possible that its preferred prey decreases in abundance or availability in the presence of abundant budworms (Morse 1989).

Morse and Poole (2020) considered the Black-throated Green Warbler an infrequent host of the Brown-headed Cowbird. The effects of parasitism on the reproductive success of this warbler are unknown. Tate (1967) observed a female cowbird removing a warbler nestling from a nest that contained 3 warbler and 1 cowbird nestlings. In Ontario, 11 of 42 nests (26.2%) were parasitized, suggesting that it may be more than an infrequent host, at least south of the Canadian Shield (Peck and James 1998a). Two of 18 nests (11.1%) in Maine were parasitized (Harrison 1984).

The Black-throated Green Warbler appears to be vulnerable to habitat fragmentation at the landscape level. It has been documented disappearing from several woodlands smaller than 100 ha that became isolated from similar habitat, although the habitat did not noticeably change within these woodlands (Benzinger 1994; Morse and Poole 2020). This lends credence to the hypothesis that it may be area sensitive in landscapes with low amounts of forest cover.

In many areas, the Black-throated Green Warbler is highly dependent upon hemlock. This tree is being threatened by the introduced hemlock woolly adelgid, and the balsam woolly adelgid is threatening other conifers. Major declines of this warbler occurred following habitat changes caused by the death of conifers. This has resulted in major declines or disappearances in southern non-montane areas and in high-elevation populations of Fraser-fir (Benzinger 1994; Morse and Poole 2020).

The Black-throated Green Warbler appears to be adversely affected by even low-intensity housing or cottage lot development. In North Carolina, its abundance was negatively correlated with the number of houses and buildings within 200 m (Lumpkin and Pearson 2013). In Michigan, it was significantly more abundant on the forested side of shoreline access roads than on the other side of the roads where cottages had been built. Higher abundance of coarse woody debris, canopy cover, and understorey density 0-1 m above ground in the undeveloped areas may have influenced its abundance (Ford and Flaspohler 2010).

The Black-throated Green Warbler is often unaffected by single-tree selection cuts or low-intensity group selection cuts, but occasionally even this level of forest management has negative effects. It is adversely affected by more intensive cuts. In Algonquin Park, it was not affected by single-tree selection or typical or intensive group selection harvesting (Jobes et al. 2004; Tozer et al. 2010). Kingsley and Nol (1999) examined the effects of shelterwood cuts in white pine stands in Algonquin Park. It was observed on 42.9-53.3% of plots in stands with no recent history of logging, 20-45.4% of plots in 10-16 year-old cuts, and 8.3% of plots in 2-9 year-old cuts. Kirk et al. (2012) cautioned that it may be vulnerable to forest harvesting practices in central Ontario that reduce the number of supercanopy white pines. The shelterwood harvest prescription has a short rotation period that would not allow the development of supercanopy pines. In northern hardwoods near Sault Ste. Marie, it was associated predominantly with controls and unharvested plots rather than

areas where single-tree selection occurred (Holmes and Pitt 2007). In the Canadian Shield of Ontario, there was no difference in its abundance in early successional and mid-successional clear-cuts and burns in the same seral stages. It was significantly less abundant in early successional and mid-successional stands than in mature stands (Zimmerling et al. 2017). Haché et al. (2013) studied the effects of selection harvesting in New Brunswick. This treatment removes 30-40% of basal area of all stems 10 cm DBH and larger over a 20-25-year rotation period. It also reduces canopy cover by about 20% but there was no significant reduction in density or basal area of conifers. Density of the Black-throated Green Warbler was significantly lower in treated plots 2-5 years postharvest. In Pennsylvania, Stribling et al. (1990) compared abundance of the Black-throated Green Warbler in woodlots where timber stand improvements had been undertaken. Snags were removed in some plots and retained in others. It was significantly more abundant in woodlots where snags were removed. There were fewer trees in snag retention plots and they had a more patchy and open canopy and more low-growing vegetation. In Ontario, it exhibited a stronger negative response at a given harvest level in the Boreal Forest Region than elsewhere. It declined when 30% or 50% of trees were removed and became extirpated when 70% of trees were removed. It was expected to decline by 25% when 20% of trees were removed, decline by 50% when 35% of trees were removed, and decline by 75% when 55% of trees were removed (Vanderwel et al. 2007, 2009). Webb et al. (1977) examined its response when 25%, 50%, 75%, and 100% of merchantable trees were removed from northern hardwood stands in New York. It appeared to be unaffected by lower logging intensities but exhibited a decline in population with increasing intensity of harvest. Harrison et al. (2005) examined the effects of partial forest harvest on the Black-throated Green Warbler in Alberta. In mixed forests, it increased with removal of 25% of trees, decreased at 50% removal, and became extirpated when 90-100% of trees were removed. In coniferous forests, it became extirpated with 25% tree removal, colonized stands with 50% tree removal, decreased with 80% tree removal, and became extirpated when 90-100% of trees were removed. In Minnesota, it responded negatively to all types of forest management prescriptions, including in uncut buffers adjacent to clear-cuts, although buffers as narrow as 30 m were sufficient to support the species. It was among the species that responded most negatively to forest harvesting. Negative effects disappeared 4 years after harvest (Hanowski et al. 2003, 2005). In Alberta, it was not more abundant in clear-cuts where some residual trees had been retained. Tittler et al. (2001) established that it would be necessary to retain more than 40% of the trees and 46% of the basal area to maintain habitat for it. In Minnesota, Niemi and Hanowski (1984a) found it in only 1 of 8 clear-cuts. The plot that supported it had the highest density of living trees and low shrub density. In New Brunswick, Zitske et al. (2011) noted that intensive forestry activities had reduced the amount of mature forest to 12-50% of the landscape. The amount of mature mixed woods was declining at a rate of approximately 1.5% per year due to short-rotation clear-cutting. This did not appear to have an impact on the Black-throated Green Warbler population. In British Columbia, its primary habitat of mature spruce and mature spruce–trembling aspen–balsam poplar stands has high timber value and is being harvested rapidly. These stands tend to be converted to agricultural uses or pure deciduous or spruce stands due to short rotation periods, so some habitat may be permanently lost.

In Alberta, the Black-throated Green Warbler was significantly less abundant at seismic lines than in adjacent forest interior. There was no difference in its abundance at pipelines or well pads than in

forest interior adjacent to these habitats (Bayne et al. 2016). Farwell et al. (2019) conducted a similar study regarding shale gas infrastructure (well pads, access roads, and pipelines) in contiguous forest in West Virginia. It avoided all types of infrastructure and was significantly more abundant distant from them than close to them.

Numbers of the Black-throated Green Warbler are thought to have decreased during the period of usage of pesticides such as DDT and fenitrothian. It may also decline in response to current spraying practices for the spruce budworm (Morse and Poole 2020).

Blake et al. (1992) demonstrated that this warbler responded negatively to drought in Michigan and Wisconsin. Drought was accompanied by hotter than average temperatures. This may have caused poor reproductive success that in turn affected populations.

Nestlings may die of exposure or starvation during cold rainy weather or thunderstorms. Late spring snow storms may cause heavy mortality, depressing populations for years. Extensive rainy periods in late June and early July of both 1972 and 1973 decreased fledging success and severely reduced the 1974 Maine coastal population (Morse and Poole 2020).

Price (2004) predicted that the Black-throated Green Warbler could disappear as a breeding species in southern Ontario if the average summer temperature increased by 2°C.

Status

McIlwraith (1894) did not identify the Black-throated Green Warbler as a breeding species in Ontario, but most of his observations were in the Hamilton area. Baillie and Harrington (1937) considered it a common summer resident from the southern boundary of the province north to Lac Seul and Moose Factory. Summer records at that time extended north to the intercontinental railway and they concluded that it likely bred throughout its observed range. The first atlas confirmed that it bred from the shorelines of Lakes Erie and Ontario north to Little Sachigo Lake and to slightly north of Moosonee. It was largely absent in agricultural southwestern Ontario except in more heavily forested areas such as Rondeau, Long Point, the Niagara Escarpment, northern Grey and Bruce counties, and the eastern shoreline of Lake Huron. It was most abundant in Haliburton County and Parry Sound and Manitoulin districts (Crins in Cadman et al. 1987). James (1991) stated that it was a common summer resident across the province, north to Sandy Lake and Moosonee, becoming rare south of the Canadian Shield to Norfolk County and Rondeau.

The second atlas revealed that there had been no significant changes in the distribution of the Black-throated Green Warbler. It was found somewhat further north than during the first atlas to the Ekwan River in the east, but it was not documented in some of the northern blocks where it had been recorded previously. The range south of the Shield was similar, but it was much more widespread in this area. It continued to be absent in Essex County with only scattered records in Chatham-Kent, Lambton County, and Niagara Region. Its probability of observation increased significantly since the first atlas province-wide and in all atlas regions except the Hudson Bay Lowland where it experienced a nonsignificant decline. It is rare within this region where it was documented in only 22 squares during the first atlas and 11 during the second atlas. Highest densities occurred along the northern and eastern shores of Lake Superior east to Georgian Bay and Algonquin Provincial Park, as well as on the Bruce Peninsula and the southern shore of Manitoulin

Island. These areas support extensive mixed forests with high coverage by coniferous species, especially white pine and hemlock (Crins in Cadman et al. 2007).

The Black-throated Green Warbler was probably much more common in southern Ontario and in much of its range prior to deforestation by European settlers. Breeding Bird Survey data indicate that it decreased at annual rates of 0.793% in Canada and 0.482% in Ontario 1970-2021. The trends 2011-21 were annual decreases of 2.48% in Canada and 3.93% in Ontario. All results were of medium reliability except that the long-term Canadian trend was highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Brood division may occur once young leave the nest. Young often wander from the natal territory as soon as they can fly and do not return (Morse and Poole 2020).

Both adults and juveniles may inhabit clear-cuts 2-10 years old during the postfledging period. In Minnesota, 14 adults and 5 juveniles were caught in clear-cuts during the postfledging period but none were caught during the breeding season. During the postfledging period in Pennsylvania, 24 adults and 15 juveniles were captured in clear-cuts compared with 2 adults and 0 juvenile in adjacent mature forests. The percent shrub coverage was equal in the 2 habitats. Raspberries and cherry seedlings dominated the shrub layer in clear-cuts. Beech and red maple seedlings dominated in forests (Stoleson 2013; Streby et al. 2011b).

In Maine spruce forests, the Black-throated Green Warbler often occurs in 0.1-5-ha white birch stands generated from logging or windthrow. Leafrollers and other caterpillars are abundant in birch at this time (Morse and Poole 2020).

In Alberta, shrubs are an important substrate for foraging by fledglings (Robichaud and Villard 1999).

MIGRATION

The Black-throated Green Warbler is predominantly a nocturnal migrant. It is likely to be seen migrating in the day only over large bodies of water, typically returning to land. During the day while on migration, it often joins mixed-species flocks, especially in autumn, consisting of chickadees, nuthatches, kinglets, and other warblers. Autumn migration is often precipitated by high-pressure cells that generate favourable strong northwesterly winds. A bird banded in extreme western Quebec just east of Ontario was recovered in Guatemala (Bent 1953; Brewer et al. 2018; Graber et al. 1983; Morse and Poole 2020).

In spring, males arrive before females and adults arrive before juveniles. At Prince Edward Point, the mean arrival date of males (20.0 May) was 4 days earlier than for females (24.0 May). Mean capture dates for males at Long Point were 10.5 May for adults, 17.2 May for yearlings, and 11.5 May for those of undetermined age. Mean capture dates for females were 18.0 May for adults, 22.8 May for yearlings, and 10.3 May for those of undetermined age. The Black-throated Green Warbler exhibited the greatest intervals in arrival dates between adult and yearling birds for all species studied. All differences at both sites were significant (Francis and Cooke 1986; Stewart et al. 2002). In southern Ontario, spring migrants first appear in late April or early May and are often found into early or mid-June (Black and Roy 2010; Curry 2006; Fleming 1907; Flinn 2003; Keast 1980; LaForest 1993; Lancaster et al. 2004; Weir 2008). In the southern Shield, average arrival is early to mid-May, with

some arriving in mid-April (Mills 1981; Tozer 2012). Kendeigh (1947) first saw this warbler on 22 May near Lake Nipigon.

In Virginia and West Virginia, Stewart (1986) found no differences in timing of autumn migration between sexes and age classes. Most Black-throated Green Warblers pass through the southern Shield in September. Most are gone by the end of September with a few remaining until early October (Mills 1981; Tozer 2012). In southern Ontario, migrants are observed by mid-August. Most are gone by early to mid-October, with rare stragglers until early November (Black and Roy 2010; Curry 2006; Fleming 1907; Keast 1980; LaForest 1993; Lancaster et al. 2004; Weir 2008).

In British Columbia, habitat used during migration is similar to breeding habitat (Campbell et al. 2001). McIlwraith (1894) noted that the Black-throated Green Warbler used all types of trees during migration, but appeared to prefer pines for foraging. In most areas, it may be found anywhere that there are trees, including woodlands, roadside trees and shrubbery, gardens, and parks. It is also common where there are no conifers and may not exhibit a preference for conifers even where they are available. During migration in Maine, it occurs on treeless islands where it forages in herbaceous vegetation and along the shoreline. In Illinois, highest densities during both spring and autumn migration were in forest edges and shrubs, but it was well represented in all woody habitats (Bent 1953; Chapman 1907; Graber et al. 1983; Morse and Poole 2020). During spring migration in Pennsylvania, Smith and Hatch (2008) detected it on transects significantly more in forested habitat than in shrubs, but the capture rate in mist nets was significantly higher in shrubs than in forests. Invertebrate numbers and biomass were significantly higher in shrubs. During spring migration in Ohio, it was significantly more abundant in mature upland forests than in mature riparian forests. Upland forests had less canopy cover (74% compared with 83%) and more shrub coverage (39% compared with 19%; Rodewald and Matthews 2005). Rodewald and Brittingham (2002, 2004) determined relative abundance of this warbler in different forested habitats. In the first study, it was equally abundant in all habitats examined. In the second study, it was significantly more abundant in forest edges than in forest interior, shrub-sapling-stage forests, suburban forests, pole-stage forests, and forest-agricultural edges. During spring migration in Pennsylvania, its abundance was positively correlated with woodlot size, but no such relationship existed in autumn (Keller and Yahner 2007).

Keast (1980) studied the foraging behaviour of the Black-throated Green Warbler at Prince Edward Point. Foraging height was 1.5-18 m, with a peak around 7 m. It fed part of the day at 17-18 m, then in the tops of saplings and subsequently descended for short periods into shrubbery only 1.0-1.5 m tall. Forty-six percent of foraging occurred on outer leaves, 29% on sapling foliage, 10% on twigs and inner leaves, 10% on outer branches, and 0% in the air, outer and inner branches, sapling branches, low shrubs, and the ground. Occasionally it made aerial pursuits after flying insects. He also reported on its foraging behaviour at Point Pelee when several were grounded by adverse weather. Sixty percent of foraging occurred on bare twigs, 20% on branches, and 20% on sapling trunks; some aerial foraging also occurred. It foraged on bare trunks and branches along with the Black-and-white Warbler. Foraging heights were 0% at 17 m or higher, 50% at 13 m, 20% at 10 m, 10% at 7.5 m, 10% at 3 m, and 0% at 0.6-1.8 m and on the ground. During autumn migration, Lebbin et al. (2007) observed nocturnal foraging by the Black-throated Green Warbler in an area illuminated

by football stadium lights. It made aerial sallies after insects and appeared to glean arthropods from foliage. R.J. Smith et al. (1998, 2007) examined the foraging of the Black-throated Green Warbler during migration in Michigan. They compared foraging along the Lake Huron shoreline with areas more than 0.4 km from the lake. There was no significant difference in foraging in autumn except for foraging height, with an average of 9.34 m inland and 8.34 m at the shorelines. This difference was attributable to shrub use. It did not vary in foraging heights in any of the 5 most frequently used trees. During spring migration, inland birds gleaned significantly less (56.6%) than shoreline birds (69.1%) and sally-hovered more (23.0% inland, 14.1% shoreline) and sally-struck more (26.5% inland, 16.8% shoreline). There were no significant differences in where birds foraged within trees at the 2 sites. Inland birds used white cedar less and balsam fir, trembling aspen, white birch, and white spruce more relative to birds foraging near the shoreline. The most pronounced difference was the use of white cedar along the shoreline. It foraged substantially more in cedars than in other tree species along the shoreline. In early spring, the biomass of midges, spiders, and total arthropods was higher in shoreline habitat. In late spring, midge and spider biomass was higher in shoreline habitat. The arthropod biomass, excluding spiders and midges, was higher inland. Large hatches of midges occur within 0.4 km of the lake in early spring and their abundance attracts large numbers of spiders. The phenology of leaf development was inhibited near the lake which probably explained the preference for foraging on cedars. Due to retarded leaf-out near the shore, caterpillars were scarce and it is likely that warblers were foraging on the abundant midges. Emergent aquatic insects such as midges may be an important source of prey for spring migrants. Climatic influences from the lake affected vegetation development, invertebrate activity, and warbler foraging behaviour.

The diet during migration consists almost entirely of arthropods, predominantly insects but spiders are often consumed. Along the Great Lakes shorelines, midges and spiders may be locally important in the diet. Stomachs of Illinois migrants contained 70% caterpillars, 15% beetles, and 5% bugs, with the remainder comprised of a wide range of insects and spiders. Autumn migrants occasionally eat small amounts of fruit, such as poison ivy and juniper berries (Bent 1953; Morse and Poole 2020; R.J. Smith et al. 2007).

The Black-throated Green Warbler is commonly killed at television towers and other tall structures during migration (Graber et al. 1983; Morse and Poole 2020). A total of 435 were killed at the Lennox generating station chimneys 1972-82 (Weir 2008).

Strode (2003) studied the effects of climate change on the migration of the Black-throated Green Warbler in Illinois and North Dakota. Over 100 years, there was no significant spring temperature change in Illinois but spring had advanced an average of 8.6 days in North Dakota since 1961. Spring had also advanced north of Illinois. The Black-throated Green Warbler exhibited no response to changing temperature patterns and now has as many as 20 fewer days to travel between southern Illinois and northern Minnesota.

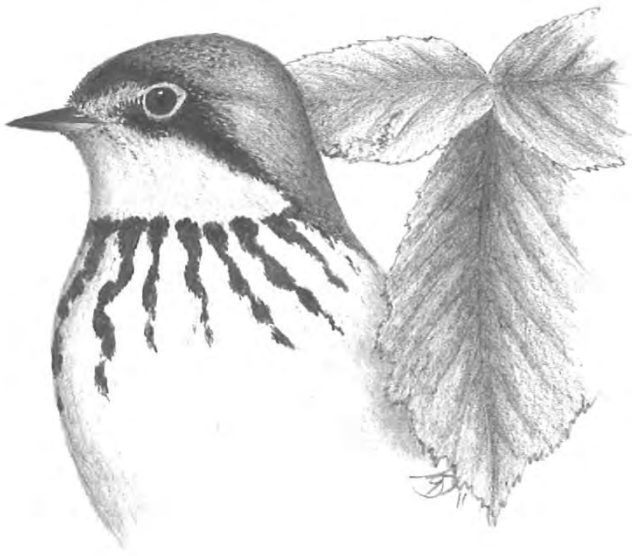
James (1991) considered the Black-throated Green Warbler a common migrant in Ontario. Flinn (2003) concluded that it was one of the more abundant migrants in Toronto.

At Long Point Bird Observatory (LPBO), Hussell et al. (1992) reported a nonsignificant decrease of 1.5% per year 1961-88. Trends by period were: 1961-70, −1.3%; 1970-79, +4.2%; and 1979-88, −8.2%. It demonstrated a similar but less pronounced change in population indices as the budworm

specialists suggesting that it might be affected to some degree by spruce budworm outbreaks. A more recent analysis of LPBO data revealed that it increased significantly at a rate of 1.4% per year 1961-2001. A significant increase of 5.6% per year was experienced at Prince Edward Point 1998-2002 and a nonsignificant decline of 2.8% per year occurred 1996-2002 at Selkirk Provincial Park. In the Toronto area, numbers were highest in the 1970s followed by a decline in the 1980s and an increase in the 1990s, a trend similar to that at LPBO. There appears to have been a decline over time in the Toronto area (Flinn 2003).

Canada Warbler

Cardellina canadensis



BREEDING SEASON

Habitat Requirements

Most Ontario Canada Warbler nests were in forests (86.7% of nests). Equal numbers of nests were found in deciduous and mixed forests, but only one was in a coniferous forest. One nest was in a swamp thicket and another was in a sphagnum bog. Although some wooded areas supporting nests were dense, most nests were in open stands, in clearings, or at woodland edges. It slightly favoured dry sites over those that were wet or swampy. Five nests were on slopes and knolls and another 5 were in rocky areas. Many nests were in areas with a heavy undergrowth of bracken fern, blueberry, poison ivy, clubmoss, hazel, alder, or other plants, shrubs, or saplings. Others were in or near brush piles and fallen logs (Peck and James 1987). James (1984b) reported that it nested in deciduous, mixed, and coniferous forests, often in swampy and riparian areas. Trees may be short in breeding habitat, but it prefers taller trees and requires a dense layer of shrubs under an open forest canopy, or areas at edges or in clearings.

In the Boreal Forest Region near Pickle Lake, McLaren and McLaren (1981) detected the Canada Warbler only in mixed scrub habitat. In the same area, James (1980) observed it only in alders at margins of lakes. Near Lake Nipigon, it was one of the most abundant species in overmature

trembling aspen stands, but it was rare to absent in spruce–balsam fir stands with no budworms (Sanders 1970). Near Manitouwadge, it was equally abundant in stands 1-21, 24-36, and 60-223 years old (Venier et al. 2009). Welsh (1993) considered it a species that nested in all ages of stands in the Boreal Forest Region. He detected it in stands 6-220 years old. Near Hearst, it nested in upland mixed clear-cuts 3-24 years old and in uncut upland mixed stands. It reached its greatest abundance in a 6-year-old stand and was not observed in lower-slope mixed or lowland coniferous stands (Welsh and Fillman 1980). In the Clay Belt of Ontario, it was most abundant in trembling aspen and balsam poplar stands, followed by those dominated by black spruce, white cedar, white birch–white spruce, and jack pine. It reached maximum density in nutrient-rich vegetation that contained at least some deciduous trees. It was found in both wet and dry forests (Welsh and Lougheed 1996).

In the Great Lakes–St. Lawrence Forest Region in the Canadian Shield, the Canada Warbler nested in mature and old-growth white pine stands. It was slightly more common in old-growth stands but not significantly (Kirk et al. 2012). In Algonquin Park white pine stands, it occurred in shelterwood cuts. It was observed in 14.3-20% of stands with no recent history of logging, in 10-18.2% of cuts 10-16 years old, and in 25% of cuts 2-9 years old (Kingsley and Nol 1999). Tozer (2012) noted that white pine stands logged in Algonquin Park from 1970 to 1978 had significantly more understorey than those logged in other years, creating ideal habitat for the Canada Warbler. In jack pine stands near Gogama, it was not specifically associated with pines. It was rare and occurred only in an area of dense deciduous shrubs with moist depressions (James and Peck 1995a). Near Parry Sound, it was absent in pure jack pine stands but occurred in low density in open jack pine stands mixed with a variety of deciduous species (James 1979a). It bred in areas of dense deciduous undergrowth in Parry Sound and Muskoka districts (Mills 1981). In Algonquin Park, Martin (1960) considered the Canada Warbler characteristic of pioneer deciduous forest. Highest densities occurred in balsam fir–spruce-hardwood stands where it was third in abundance. Moderate densities occurred in stands dominated by white birch–poplar, white birch–poplar–balsam fir–spruce, black spruce–white cedar, and in plots at edges of forest stands. It was rare in black spruce stands and absent in bogs, immature white pine stands, hardwood stands, and hemlock stands. In all types of stands, it confined its activities from the ground to the lower tree branches. MacLulich (1938) stated that it was distributed throughout Algonquin Park where there was shrubbery and mixed forest. Tozer (2012) noted that it bred in Algonquin Park in cedar woods, swampy forests, sphagnum bogs, moist forest clearings, woodland edges, spruce-tamarack bogs, poplar and moist

spruce–white birch forests, alder and willow along stream banks, and in cut-over forests. Back (1979) reported it nesting in Ontario in pole-sized to mature poplar–white birch stands but not in younger stands of similar species composition.

In Durham Region in the Great Lakes–St. Lawrence Forest Region south of the Shield, Speirs and Orenstein (1975) considered the Canada Warbler associated with balsam fir. It occurred in moderate density in a young open-canopy forest with poor drainage. It supported many balsam fir thickets and this is where it reached its greatest abundance. It also occurred in a hilltop covered with sugar maple sloping down to a stream bordered by white cedar, balsam fir, spruce, and dense deciduous shrubs, and presumably was found in the lowland habitat. These researchers also reported it in a black spruce bog bordered by a red maple–poplar swamp with an understorey of black ash. McIlwraith (1894) reported that it bred in low damp woodlands near Listowel. Near Kingston, all nesting areas were near wet areas or along streams within forests (Weir 2008). At Luther Marsh, it nested at edges of mixed swamps (Sandilands 1984). In Richmond Hill, territorial males were observed in the interior of an old-growth white cedar–yellow birch swamp (personal observation).

Black and Roy (2010) reported a number of breeding records in Wainfleet bog in the Carolinian Forest Region. Lancaster et al. (2004) reported 18 territories at 8 different sites in Elgin County, including in a white cedar swamp. It also nested at the Chesney bog in Oxford County in the surrounding swamp of red maple and white pine, with lesser amounts of white cedar and yellow birch (personal observation).

The Canada Warbler breeds in a wide range of forest types, including coniferous, mixed, and deciduous forests that may be either wet or dry. It occurs mostly in nutrient-rich sites but also uses nutrient-poor stands. In the east, mixed stands appear to be preferred to pure deciduous or coniferous stands. In the west, it often occurs in deciduous stands where conifers are completely lacking. In Quebec, it is less abundant in the north where the proportion of conifers is too high and declines in the south where the proportion of deciduous trees is too high. It occurs mostly in mixed stands dominated by deciduous species. In New Brunswick and Nova Scotia, it nests predominantly in northern hardwoods, mixed stands of intolerant and tolerant hardwoods, and spruce stands mixed with tolerant hardwoods. It selects these forest types more than their availability for breeding. Stand types used less than their availability, in order of greatest avoidance, included intolerant hardwoods, pine, spruce–intolerant hardwoods, intolerant hardwoods–spruce, and spruce–balsam fir. In the Prairie Provinces, it is usually absent in black spruce and species-poor jack pine stands and is associated mainly with mixed or deciduous stands. It tends to occur in drier, nutrient-rich sites. In British Columbia and areas of the Prairie Provinces, it prefers pure trembling aspen forests. At 103 occupied sites in British Columbia, 78 (75.7%) were composed of 80-100% hardwoods, 17 (18.4%) had 60-79% hardwoods, and 6 (5.8%) had 40-59% hardwoods. Trembling aspen occurred at every site, balsam poplar at 42.7% of sites, and white birch was present at 32.0% of sites. Trembling aspen was the dominant canopy species at 102 sites (99.0%) with a mean diameter at breast height (DBH) of 24.7 cm. White spruce was the dominant conifer at occupied sites; it occurred at 81.6% of sites. Where spruce was present, it was typically a secondary species and always had a smaller DBH (19.6 cm) and lower crown height than trembling aspen. There were only 4 sites dominated by white spruce, suggesting that as it becomes dominant a site gradually becomes less suitable for the

Canada Warbler. In the Yukon, it breeds in white spruce forests or white spruce stands mixed with trembling aspen or balsam poplar. At a site in Minnesota, it was most abundant in mixed forests followed by lowland conifers and upland deciduous stands. At another site, it was most abundant in lowland conifers and upland conifers. It was most common in wet mixed deciduous-coniferous forests with a well-developed shrub layer. In Vermont, it nested in northern hardwood forests, lowland spruce-fir forests, oak-hickory forests, white cedar–balsam fir swamps, and red maple–white cedar swamps. In New Hampshire, it nested in a 20-year-old clear-cut and a red maple swamp. In West Virginia, it was most likely to occupy northern hardwood forests and least likely to occupy oak-pine forests. The Canada Warbler has nested in several other forest types. These include upland red maple, upland and swamp white cedar, tamarack swamp and bog, willow-poplar, hemlock with a rhododendron understorey, American chestnut stands with many snags and dense regenerating chestnut, hemlock–white pine–red pine, sugar maple–yellow birch–beech, white pine–red oak, beech-oak, oak, and hemlock–yellow birch. In the Boreal Forest Region, it is one of the dominant and characteristic species in poplar and birch stands (Beals 1960; Brooks 1940, 1947b; Brush 1987; Campbell et al. 2001, 2007; Capen 1979; Chace et al. 2009; Crawford and Titterington 1979; DeGraaf and Chadwick 1987; Dimmig et al. 2022; Erskine 1977; Faanes and Andrew 1983; Gates and Giffen 1991; Golet et al. 2001; Grinde and Niemi 2016; Hallworth et al. 2008a; Hobson and Bayne 2000; Kirk et al. 1996; Krause 1965; LaRue et al. 1995; Morse 1989; Parker et al. 1999; Perreault and Tardif in Gauthier and Aubry 1996; Reitsma et al. 2020; Savignac 2008; Sinclair et al. 2003).

Many authors considered the Canada Warbler a species associated with mature or old-growth stands. Others classified it as a mid-successional or early successional species. In trembling aspen forests in Alberta, it was significantly more abundant in stands older than 120 years than those 51-63 years old. It was not detected in stands 23-26 years old (Schieck et al. 1995). Ball et al. (2016) examined results of point counts conducted throughout Alberta and found that it had a strong association with older deciduous, and to a lesser extent, older mixed forests compared with younger age classes and other forest types. Swamps and shrubby lowland areas were of intermediate suitability. Open and shrubby upland habitats and all types of human footprint areas were of low suitability. Young forests were unsuitable regardless of whether they had been modified by fire or forest management. Older forests were predicted to support 31.9% of the population. Kirk et al. (1996) considered it an old-forest species in the Prairie Provinces, although it occurred in low density in stands 1-20 years old. In the Yukon, it nests predominantly in old-growth spruce and spruce-poplar stands (Sinclair et al. 2003). In northeastern poplar–white birch stands, Back (1979) reported it only from pole-sized and mature stands. It was not detected in seedling-sized or sapling-sized forests. In northeastern mixed stands, Temple et al. (1979) considered it a late-succession species but not an associate of mature forests. In Quebec, Perreault and Tardif (in Gauthier and Aubry 1996) concluded that it frequented predominantly mid-successional forests. In Maine and Vermont, highest numbers occurred in intermediate-aged mixed woods 20-60 years old, more than in late successional forests. Lowest numbers occurred in intermediate-aged to mature hardwood stands 60-100 years old. In British Columbia, it nested predominantly in mature stands. The youngest occupied sites were 20-25 years old (Campbell et al. 2007). The Canada Warbler may be locally abundant in regenerating forests following fires or clear-cutting activities. Regenerating forests 6-20 years old are occupied in the east and those 20-30 years old are occupied in the west (Reitsma et al.

2020; Savignac 2008). Chace et al. (2009) stated that, in upland habitats, it appeared to specialize in disturbed areas where windthrow, ice damage, or timber removal created suitable habitat. In Manitoba, forest age significantly affected the probability of site abandonment, or local extinction. Probability of extinction was lower in stands older than 80 years. In upland deciduous stands, the probability of occurrence was higher in younger stands (average age 41 years, range 5-89 years), but these stands were more likely to be abandoned than older stands (Grinde and Niemi 2016).

Shrubs or saplings in the understorey are an essential habitat component and this, as well as forest structure, is more important than forest type or age. The Canada Warbler may also nest in wet, treeless alder or willow thickets but those with scattered trees are superior because they provide singing perches for males. If shrubs or saplings are absent, the habitat is unsuitable. It inhabits forests with an open canopy where light penetrates to the forest floor, promoting shrub growth. In British Columbia, occupied sites were moderately open, with 15-40% canopy cover, to moderately closed, with 60-80% canopy closure. The mean canopy closure was 62.0%. Stands with patchy canopies were used more than stands with uniform canopies. Average shrub coverage was 79% (range 20-95%, median 80%) with 80% of sites having shrub heights of 2.5-3.5 m. The space between the lower leafy branches of trees and the upper shrub understorey appears to be important for singing males. When viewed from the side, stands often had a well-developed shrub layer that was distinctly separate from the upper canopy. Herbaceous plants less than 50 cm tall were abundant in territories, with average coverage of 73% (Campbell et al. 2007). In mature and old-growth forests, the Canada Warbler may be restricted to areas where treefalls have created gaps in the canopy and allowed shrub growth to occur (Campbell et al. 2001; Reitsma et al. 2020). Almost all studies have identified that the Canada Warbler requires shrubs (Beals 1960; Bent 1953; Golet et al. 2001; Hallworth et al. 2008b; Harrison 1984; Litwin and Smith 1992; Perreault and Tardif in Gauthier and Aubry 1996; Reitsma et al. 2020; Savignac 2008; Sinclair et al. 2003; Stewart et al. 2009). In West Virginia, it was most likely to occur in areas with high rhododendron density in the understorey and those that were close to riparian areas (Dimmig et al. 2022). In Minnesota, Niemi and Hanowski (1984a) found this warbler in 1 of 8 clear-cuts they examined. This site was characterized by high foliage density and moderate shrub density. In New York clear-cuts, it was in a guild associated with homogenous patches of dense sprouts and shrubs. The density of this guild was highly correlated with leaf area and it increased significantly over a 4-year period postharvest. These species were absent during later stages of succession, except for the Canada and Black-throated Blue warblers that persisted in forest openings. The Canada Warbler was associated with low dense seedlings and shrubs as tall as 3 m (Keller et al. 2003). In spruce–balsam fir stands in Maine, it was absent in the earliest stages of clear-cuts and in mature closed-canopy forests. It was common in stands with hardwood regeneration taller than 2 m with a well-developed but slower-growing coniferous layer, and in hardwood regeneration taller than 4.5 m with trees 10-15 cm DBH (Titterington et al. 1979). In New Brunswick, it was positively correlated with the density of saplings 3-8 cm DBH, and preferred coniferous saplings (Parker et al. 1999). In the mid-Atlantic states, its abundance was correlated with foliage density 0.3-1.0 m from the ground (Robbins et al. 1989). In northeastern northern hardwoods, Noon et al. (1979) reported it on 3% of plots in mature and undisturbed habitats and 27% of plots in disturbed and successional plots, which presumably would have higher shrub densities. Crawford and Titterington (1979) stated that it bred and foraged in the shrub-sapling stratum in northeastern

upland spruce–balsam fir stands. In northeastern mixed stands, Temple et al. (1979) concluded that it was associated with increasing density of the understorey. In balsam fir–white cedar stands in Quebec, it was more common, but not significantly, in riparian plots where there was an edge community of alders and reed grass (LaRue et al. 1995). In Maine and Minnesota, the Canada Warbler was a shrub-forest edge species. It was in a guild of warblers that inhabited forests with high coverage of shrubs, moderate canopy cover, and low coverage by conifers in the canopy (Collins 1983a). In New Hampshire, Reitsma et al. (2008) compared habitat in territories of adult and yearling males. Territories of older males had lower canopy height, which provided more song perches, and higher shrub stem density than territories of yearlings (42.05 compared with 26.60 in a 5-m radius). In a red maple swamp, adult males occupied most of the dense deciduous thickets where stems were mostly smaller than 2.5 cm DBH. Yearlings occupied peripheral areas that had larger-stemmed shrubs (10.13 stems larger than 2.5 cm DBH in a 5-m radius for yearlings compared with 2.29 for adults). Shrubs were an integral component of the habitat and small-diameter stems appeared to provide superior habitat. In the same area, Hallworth et al. (2008b) compared habitats at sites settled first in spring to those settled later, at successful and unsuccessful nests, and on and off territories. Males that arrived within the first week of the breeding season held territories with greater shrub-stem density (48.76 in a 5-m radius) than late-arriving birds (39.74). Males that were successful in fledging at least 1 young had a greater total shrub density (42.98 within 5 m) than unsuccessful males (40.34) and higher densities of shrub stems smaller than 2.5 cm DBH (36.48 compared with 25.0). Compared with nonterritories, territories contained denser shrub foliage 2.0-2.5 m above ground, lower canopies, and a greater number of perch sites. Females appeared to select males whose territories contained high densities of shrubs. Birds in the red maple swamp had territories 40-50% smaller than those in an adjacent regenerating clear-cut, suggesting that the swamp was of higher quality. Density of shrubs was 2 times higher in the swamp, and it also had more moss coverage. Dufour-Pelletier et al. (2025) analyzed breeding habitat selection by the Canada Warbler in Quebec in 3 habitats: mixed boreal forest, agroforest, and riverine deciduous forest. The mixed boreal forest was dominated by balsam fir, trembling aspen, and white birch. The agroforest was characterized by sugar maple–basswood and sugar maple–bitternut hickory communities. The riverine deciduous forest was dominated by sugar maple–yellow birch and sugar maple–basswood. In the mixed boreal forest, stands dominated by deciduous species had a higher probability of Canada Warbler occurrence than those dominated by coniferous species. In the agroforest, it had a higher probability of occurrence in mixed stands than in coniferous stands. Presence of small saplings had a slightly positive effect in both these regions. Mountain maple, beaked hazel, and pin cherry were positively associated with its presence in the mixed boreal forest; it was negatively associated with saplings of trembling aspen, white spruce, and black spruce as well as large balsam fir saplings. In the agroforest, it was associated with small saplings of balsam fir, rhododendrons, viburnums, and blueberries, and large red maple saplings. In the riverine forest, it was positively associated with beech. Most of the species associated with the Canada Warbler's occurrence were shrubs. In New Hampshire, Goodnow and Reitsma (2011) examined nest-site selection by the Canada Warbler. Nest sites had significantly more concealment (86.7%) than mock nest sites on territories (39.8%). Mock nest sites on and off territories were not significantly different. Successful nests had higher stem density and greater nest concealment than failed nests. Densities of smaller stems (less than 1 m tall and 1 cm DBH) were particularly high around nests when compared with

either category of mock nest sites. Emergent trees above the understorey were also important for singing perches.

Coarse woody debris in the form of fallen trees and logs, woody detritus, and logging debris may be an important habitat component. The Canada Warbler uses fallen logs for foraging and occasionally as singing perches. In British Columbia, coarse woody debris was observed at every site supporting the Canada Warbler, with a mean of 7 pieces per 10 m^2 (range 2-24; Campbell et al. 2007). In New Hampshire, nest sites included high amounts of coarse woody debris, ferns, and moss as components of the ground cover. Coarse woody debris, including stumps and downed logs, contribute to ground substrate complexity and often provide highly concealed nest sites and shelter from the weather (Goodnow and Reitsma 2011).

Many authors concluded that the Canada Warbler occurs mostly in cool, moist forests and some stated that it is confined to these habitats (Baker et al. 2016b; Bent 1953; Chapman 1907; Harrison 1984; Reitsma et al. 2020). In Rhode Island, it is restricted to breeding in red maple swamps and in the mid-Atlantic states its abundance was significantly correlated with moisture (Robbins et al. 1989). In most areas, it is as likely to occur in dry as wet habitats. Adults are equally likely to home to nesting sites in wet and dry habitats (Campbell et al. 2001, 2007; Goodnow and Reitsma 2011; Hallworth et al. 2008a, 2008b; Niemi and Pfannmuller 1979; Reitsma et al. 2008; Welsh and Fillman 1980). Reitsma et al. (2020) stated that the Canada Warbler often breeds near water and is often associated with areas with abundant sphagnum moss. He concluded that suitable habitat often has a well-developed layer of moss on an uneven forest floor. It also frequently breeds where there is no water or moss, so these are not essential habitat components. Abundance of shrubs is a more significant habitat component than moisture and presence of water or mosses.

The Canada Warbler often nests in gullies and on slopes (Campbell et al. 2001, 2007; Reitsma et al. 2020; Savignac 2008). It also nests in wetlands and other areas where slopes are lacking. In British Columbia, the mean slope at 103 sites was 17° with a range of 0° (43 sites, 41.7% of sites) to 75° at 1 site. Most sites had gentle slopes of 1-5°. It is unlikely that the slope itself is important, but conditions created by slopes may create important microhabitats: moist areas, nutrient-rich spots, breaks in the canopy, and lush understorey growth (Campbell et al. 2007). Ball et al. (2016) determined that it was associated with locations near incised streams in Alberta rather than broad wet areas. Westwood et al. (2019) modelled factors affecting its abundance in Nova Scotia and New Brunswick. Highest densities were predicted in stands with a high proportion of balsam fir, alders, spruce species, and black spruce. Lowest densities occurred in stands dominated by maples, tamarack, white spruce, and pine species. Highest densities occurred in areas defined as wet with a depth to water table of 1 m or less; larger effects occurred at the territory scale of 250 m. High population densities were associated with medium values of standard deviation of canopy closure and height and mean canopy height. Higher complexity and connectivity of landscapes were predicted to support higher densities. It was less abundant near roads and in landscapes with more human disturbance.

Some studies determined Canada Warbler habitat requirements at the landscape level. In southern Ontario, there was no relationship between its abundance and the amount of forest cover in the region. It was negatively correlated with the amount of forest cover within 2 km, but not significantly (Austen et al. 2001). In Saskatchewan, it was randomly distributed within fragmented

landscapes and there were no significant relationships between its abundance and forest size, the amount of forest cover within 5 km, or forest type. It was significantly more common than expected in contiguous woodlands than in fragmented woodlots (Hobson and Bayne 2000). In Rhode Island, the only variable that made a contribution to its abundance in red maple swamps was the amount of upland forest within 1 km (Golet et al. 2001). In Alberta, the availability of deciduous and mixed forests at the 1-km scale was important in determining occupancy of stands, regardless of forest size (Ball et al. 2016). In Nova Scotia, its presence was positively correlated with canopy height heterogeneity and landscape complexity. It was negatively correlated with depth to water table, distance to a coniferous or deciduous stand, and distance to a stand with dead material. Presence of a high water table was the most important factor (Bale et al. 2020).

Several studies examined macrohabitat and microhabitat requirements of the Canada Warbler. In northwestern Ontario in and near Quetico Park, its occurrence was higher where shrub coverage was greater than 55%. Shrub coverage was the top predictor of its presence. The dominant shrubs present were mountain maple and beaked hazel. Canopy height and cover were also important. Canopy height averaged 12.3-13.0 m where it was present and canopy cover was 55.6-57.9%. The dominant trees were white birch and white spruce. Seventy-three percent of sites where 2 or more individuals were present were in landscapes that were 20-70% harvested. Sixty-nine percent of locations where only a single bird was detected were where no tree harvesting had occurred. Recently harvested sites supported higher levels of social aggregation, probably due to the increase in shrub growth (Cupiche-Herrera et al. 2024a). In Minnesota lowland coniferous stands, its probability of extinction was lower in older stands and stands with greater percent coverage by conifers within 100 m and 500 m. In deciduous stands, its probability of extinction was lower in older stands and stands with greater coverage by deciduous species within 500 m. Its probability of extinction in upland deciduous stands decreased with increasing open land within 500 m. In lowland conifers, its probability of occupancy decreased as the amount of open habitat increased within 500 m (Grinde and Niemi 2016). In New Hampshire and Maine, it was most strongly associated with sapling stands followed by poletimber stands, large sawtimber stands, and sawtimber stands. Its abundance was correlated with both coniferous and deciduous trees larger than 10 cm DBH, deciduous trees 2-10 cm DBH, the number of woody stems per ha, and the foliage volume of conifers 2-10 cm DBH. It was negatively correlated with conifers 2-10 cm DBH, snags larger than 10 cm DBH and taller than 5 m, and the foliage volume of deciduous trees smaller than 2 cm DBH and 2-10 cm DBH (DeGraaf et al. 1998). In trembling aspen forests in Alberta, it was associated with large sparse trees, snags and trees larger than 20 cm DBH, shrub richness, and canopy height (Schieck et al. 1995). In Minnesota, average habitat characteristics consisted of 88.3% ground cover, 73.3% shrub cover, 56.7% canopy cover, 18.8 m canopy height, 33.3% coniferous cover, 5.3 trees 7.5-15 cm DBH in a 0.04-ha circle, 9.7 trees 15.1-23 cm DBH, 8.0 trees 23.1-30 cm DBH, 3.7 trees 30.1-38 cm DBH, 4.3 trees 38.1-53 cm DBH, 0 tree 53.1-68 cm DBH, and 0.3 tree larger than 68 cm DBH. It was associated with medium-sized to larger trees and was in a guild of warblers that represented second growth and forest edge habitats with a high percentage of ground cover (Collins et al. 1982). In subalpine areas of New Hampshire, average territories contained wet depressions, had a canopy height of 10.4 m, 76% canopy coverage, 44% total coniferous foliage volume, 27% coniferous foliage volume 0-2 m from the ground, 68% deciduous foliage volume above 5 m, and trees with a DBH of

11 cm (Sabo 1980). In northern hardwoods in Vermont, its abundance was correlated with a lower canopy height and higher percent cover of shrubs and ferns than areas where it was not detected. These conditions were created naturally by windthrow, ice storms, and insect damage, and also by forest management (Chace et al. 2009). In West Virginia, successful nests had more low cover, less vertical diversity, more woody debris, more saplings, and greater edge density than failed nests (Becker et al. 2012). In New Brunswick, it was associated with the density of large deciduous trees, suggesting selection for mature forest (Parker et al. 1999). In the mid-Atlantic states, the Canada Warbler was correlated with foliage density 0.3-1.0 m from the ground, moisture gradient, basal area, and forest size. It was negatively correlated with canopy height and percent ground cover (Robbins et al. 1989).

Freemark and Collins (1992) considered the Canada Warbler a forest-interior species. Most studies demonstrated that it occurs in edge habitats as well as deep within forests. In the Yukon, it is found in the interior of forests in small openings in the forest canopy that encourage shrub growth. It also occurs rarely along edges created by roads or logging (Sinclair et al. 2003). In British Columbia, it is common in forest interior, but often occurs along roadsides where forest stands are fragmented. It often nests at edges between forest cover, shrubby areas along roads, hydro transmission line corridors, and ski hills (Campbell et al. 2001, 2007). In Alberta, its abundance at roads was 79% of that at off-road counts (Ball et al. 2016). In Maryland, it was more abundant in hemlock stands near an edge created by a stream than in forest interior. No edge effect was exhibited by this warbler and habitat type was more important than distance from edges (Gates and Giffen 1991). In Illinois, 1 pair nested in a clearing in an oak-hickory forest in an urban park (Graber et al. 1983). Reitsma et al. (2020) stated that it nested in forest edge habitats. In southern Ontario, its abundance was negatively correlated with the amount of forest cover 100 m or more from edge, but not significantly (Austen et al. 2001). The Canada Warbler occurs in both edge and forest-interior habitats. In forest interior, it is often restricted to gaps in canopy, especially if the forest cover is mature.

Based upon a literature review, Freemark and Collins (1992) concluded that the Canada Warbler was area sensitive. Field studies have demonstrated that it is area sensitive in some areas and not in others. Robbins et al. (1989) were the only researchers to document area sensitivity in this species. In the mid-Atlantic states, its abundance was strongly correlated with forest size. Its probability of occurrence was at a maximum in woodlands larger than 3,000 ha, probability of occurrence was reduced to 50% of the maximum at 400 ha, and the 3 smallest woodlots it was detected in at least twice were 883, 883, and 187 ha. In Wisconsin, it was not restricted to the larger islands studied by Beals (1960). In red maple swamps in Rhode Island, it was equally abundant in stands smaller than 1 ha and those 11-20 ha in size. These swamps were surrounded by upland forest, so this may not have been a true test of area sensitivity. In southern Ontario, its abundance was negatively correlated with forest size, although this relationship was not significant (Austen et al. 2001). Coleman et al. (2000) concluded that the Canada Warbler was area sensitive in the province. They listed Bent (1953) as their source of information but he made no mention of area sensitivity. The results for Ontario are equivocal and warrant more research to determine if this warbler is area sensitive within the province. Its distribution in the extreme southwestern portion of the province suggests that factors

such as area sensitivity or low forest cover at the landscape level may be preventing apparently suitable habitat from being occupied.

Ontario nests were on or near the ground. Ground nests (64.7% of nests) were in grass clumps (29.4%), at the base of stumps or beside fallen logs (23.5%), and in rock cavities (11.8%). Five other nests were elevated in recessed pockets of upturned tree roots (23.5% of nests) or in a brush pile (5.9%). One nest (5.9% of nests) was 0.9 m from the ground in the crotch of a maple sapling. This may be the only documented record of this species nesting in a tree or shrub (Peck and James 1987). McIlwraith (1894) reported that nests near Listowel were in cavities of upturned roots of trees and in depressions in banks near pools of water. In Elgin County, a nest was in a steep bank along a stream (Lancaster et al. 2004).

Throughout its range, the Canada Warbler builds its nest on the ground and in cavities in roots of upturned trees. Less frequently, nests are in steep overhanging banks along watercourses. Ground nests tend to be in the middle of dense shrub thickets, well concealed by the surrounding vegetation. They are often among woody debris and at the base of a shrub, occasionally concealed under dead grass. Many are sunken into moss hummocks where they are very cryptic and difficult to find. Nests may also be in clumps of ferns or grasses, under fallen trees, in rotted stumps, on top of mossy logs where they are usually concealed by additional overhead logs, under leaves on the forest floor, or in brush piles. Nests in upturned roots may be over standing water. One nest was built on top of an old nest and occasionally old nests are refurbished and used again (Bent 1953; Campbell et al. 2007; Chapman 1907; Goodnow and Reitsma 2011; Harrison 1984; Krause 1965; Mousley 1916a; Reitsma et al. 2008, 2020; Stewart et al. 2009).

Birds may pack into areas of suitable habitat where the habitat is heterogeneous such that territories are clustered into neighbourhoods. Territories may overlap to some degree, but such boundaries frequently remain in dispute. Nests are often within 30 m of each other. In Algonquin Park, territory size averaged 0.22 ha (range 0.03-0.74 ha). In New York, 1 male initially defended a territory of 0.24 ha but wandered over 0.8 ha after nesting. Another male with a nest roamed over 1.2 ha or more, an expansion of an earlier singing area. In both cases, a larger area was used once nesting began, and the entire larger area was defended. A territory in a hemlock stand in Quebec was 0.40 ha. In subalpine areas of New Hampshire, average territory size was 0.7 ha. In another area of New Hampshire over a 7-year period, the mean territory size of older males was 0.67-1.16 ha and 1.16-1.36 ha for yearlings. Over 4 years, average territory sizes were 0.88 ha in red maple swamp and 1.5 ha in early to mid-successional mixed forest, suggesting that the swamp was superior habitat. Mean territory size was 0.97 ha (range 0.15-3.36 ha) and the mean core area, where 50% of activity occurred, was 0.17 ha (range 0.02-0.77 ha). Mean core areas of adults (0.19 ha) and yearlings (0.23 ha) did not differ. In Vermont, average territory size was 0.38 ha and average home range size was 2.0 ha. Average territory size near Fort Liard, Northwest Territories, was 0.75 ha; territories averaged 0.31 ha in British Columbia. In Vermont, an unpaired male ranged over 7 ha in a single day. In Alberta, home ranges of males covered 0.18-9.87 ha. Males may occasionally travel as far as 1 km from their territories. In Alberta, mean territory size of 40 males was 0.47 ha. Territory size decreased as percent shrub coverage increased and was smaller where red squirrels were present. Territories tended to be smaller at shoreline sites than interior sites, and territory sizes were also more variable at shoreline

sites. There was a weak negative correlation between density and territory size. Insect abundance appeared to have no effect on territory size. There was a direct effect of territory size on breeding success, with success increasing with territory size. Breeding success declined with warbler density, and when squirrels were present in territories with dense shrub cover near shorelines. Warblers with larger territories are likely to have higher breeding success because they have greater access to resources, have higher quality mates, or are of higher quality themselves. Another Alberta study determined that home range sizes averaged 0.94 ha: 1.27 ha in harvested stands and 0.72 ha in unharvested stands (Baker et al. 2016b; Campbell et al. 2007; Flockhart et al. 2016; Hallworth et al. 2008a, 2008b; Hunt et al. 2017; Kendeigh 1945; Martin 1960; Perreault and Tardif in Gauthier and Aubry 1996; Reitsma et al. 2008, 2020; Sabo 1980; Savignac 2008).

Natal philopatry rates are uncertain but are probably low. In New Hampshire, 3 male and 3 female fledglings returned, but the number of young that were banded was not specified. Some returned late, presumably as nonbreeding floaters. One male nested as a yearling 5 km from its natal site. In Massachusetts, 2 juveniles returned to the same location (Reitsma et al. 2020).

Adult site fidelity rates are high. Return rates of 48.2% in Alaska and boreal Canada and 37.4% in the northeastern United States were reported. In New Hampshire, return rates of males over 3 years were 57%, 50%, and 47% (average 52%). Twenty-five percent returned in 2 years and 10% returned in all 3 years. The mean distances of territory shifts over the 3 years were 27.6, 36.9, and 31.1 m. Distance that a territory shifted was not influenced by pairing or fledging success the previous year. There were no significant differences in return rates in a clear-cut (44%) and a red maple swamp (53%). In New York, a female returned to the same general area to breed 2 years later and was recovered 5 years later during spring migration in Ohio, approximately 800 km west of the original capture site. Adult females exhibited site fidelity in New Hampshire, settling 0.5-1.0 km from their previous year's territory. In North Carolina, 12 of 109 adult males (11.0%) returned the following year. All were recaptured within 200 m of their original capture locations and all were seen at only 1 of 9 study areas. This was a declining population near the southern extent of this warbler's range (Chandler et al. 2018; Hallworth et al. 2008a, 2008b; Reitsma et al. 2020; Savignac 2008).

Limiting Factors

Eggs have been reported in Ontario nests from the last week of May until the end of June, with most present in the first 3 weeks of June (Peck and James 1987). In Algonquin Park, eggs are present from early to mid-June, nestlings are present in early July, and dependent fledglings have been seen from mid- to late July (Tozer 2012).

Males establish a territory as soon as they arrive. Upon arrival and pairing, the female assesses potential nest sites and selects one in an area of dense shrubs as large as 5 cm DBH. In New Hampshire, a male and female arrived on the same day and the female began lining the previous year's nest later that day. Nests typically take 3-5 days to build. When an old nest is reused, nest construction may take less than 2 days. Eggs are laid at the rate of 1 a day and incubation begins with the laying of the last egg. The incubation period is 11-12 days and all eggs usually hatch within 24 hours. The average nestling period is 8.1 days, but young may be as old as 10 days when they leave the nest (Campbell et al. 2007; Krause 1965; Reitsma et al. 2020).

A single brood is raised annually. It has been suggested that 2 broods are raised in Pennsylvania, but late nests are probably replacement nests and not second broods. No second broods have been positively confirmed. Renesting may occur until late June. Clutches of 3-6 eggs have been reported in Ontario (mean 4.43 eggs, mode 4 eggs). North American clutch sizes range from 2 to 6 eggs and most nests contain either 4 or 5 eggs. Mean clutch sizes reported elsewhere include 4.45 eggs in unparasitized nests reported to 5 nest record schemes, 4.8 and 4.36 in Michigan, and 4.13 for North America (Bent 1953; Campbell et al. 2007; Chapman 1907; Peck and James 1987; Reitsma et al. 2020).

Both sexes are capable of breeding when they are yearlings. In New Hampshire, adults paired at significantly higher rates (96%) than yearlings (64%) but there was no significant difference in the proportion of adult males (76.7%) and yearlings (67%) that successfully fledged young. Proportionately fewer yearlings persisted throughout the breeding season than older birds. Some yearlings were successful in rearing young in the same year that adults were unsuccessful. Differences in pairing success may occur because adult males secure territories in areas that females find more attractive or adults may be more attractive to females because of their brighter and bolder necklaces. Adults may arrive on the breeding grounds paired or, if the females arrive later, pairing occurs shortly after their arrival. Some New Hampshire females paired with a male that was a neighbour the previous year, even if she was successful in fledging young that year. The Canada Warbler is typically socially monogamous. In 1 territory in New Hampshire, there were 2 active nests 32 m apart, suggesting polygyny (Campbell et al. 2007; Reitsma et al. 2008, 2020).

Extra-pair fertilizations occur but there is limited information on the incidence of this. In New Hampshire, Reitsma et al. (2018) determined that 35 of 61 nests (57.4%) had at least 1 extra-pair young and 77 of 185 nestlings (41.6%) were extra-pair. Males were equally likely to be cuckolded by neighbours and non-neighbours. The probability of siring extra-pair young declined significantly with distance from the male's nest, but 1 male sired extra-pair young in a nest 2 km from his own and 5 extra-pair young were sired by a male at nests more than 1 km from his own. There was no difference in the cuckold rate of nests of yearling and older males, but older males accounted for 83% of extra-pair young. Males that sired more extra-pair young sired fewer of their own young compared with males that did not sire extra-pair young, or sired few. Males that sired extra-pair young in multiple nests sired the least of their own nestlings.

The Canada Warbler typically feeds in shrubs and low tree branches at heights of 3-5 m. In northern British Columbia, it foraged mostly in red-osier dogwood and young white birch. It also forages aerially and occasionally on the ground. In New Hampshire, the mean foraging height was 3.8 m (range 2.6-5.2 m). In Wisconsin, it always foraged in the shade. It uses a variety of foraging techniques, including flycatching, sallying, hover gleaning, foliage gleaning, and ground gleaning. Its flycatching ability is comparable to that of the American Redstart. In some areas, the Canada Warbler forages mostly by flycatching but prefers to glean and hover in other areas (Bent 1953; Chapman 1907; Hallworth et al. 2008a; Savignac 2008). In the Clay Belt of Ontario, 15.0% of foraging occurred in conifers, 92.0% in foliage, 82.1% by aerial attacks, 0% by hanging, 30.7% by hovering, and 0% by reaching at an average height of 4.3 m, which represented 58.0% of tree height (Greenberg et al. 1999). In subalpine New Hampshire, foraging techniques included 0.9% aerial flycatching, 29.0% leaf gleaning, 9.9% leaf hawking, 8.6% leaf hovering, 2.5% twig perching, 36.0%

twig gleaning, 10.4% twig hawking and hovering, 0.3% branch pecking, 1.8% branch gleaning, 0.1% bole pecking, 0.5% bole gleaning, and 0% litter pecking and gleaning and fallen log manoeuvres. Most (56.3%) foraging occurred proximal to the trunk and 43.7% was distal. Only 36.3% of foraging occurred in conifers, 63.4% was in deciduous foliage, 0.2% was in herbaceous foliage, and 0% was on the ground. Foraging heights included 4.3% at 0.1-2 m, 71.7% at 2-5 m, 22.4% at 5-8 m in the midcanopy, and 1.8% above 8 m in the upper canopy. It preferred to forage at low heights in deciduous vegetation (Sabo 1980). In Wisconsin, Sodhi and Paszkowski (1995) compared the foraging behaviours of the Canada Warbler to those of the Nashville, Mourning, and Chestnut-sided warblers. All species used young disturbed forests characterized by high light penetration and a well-developed layer of shrubs and herbaceous plants. This habitat was quite heterogeneous, but warblers did not use a particularly wide variety of the tree and shrub species present. The Canada Warbler was the most distinctive of these warblers because it foraged in coniferous trees scattered through a forest dominated by deciduous species. Of the other species, the foraging techniques of the Chestnut-sided Warbler were most similar to those of the Canada Warbler. Male Canada Warblers foraged more frequently in aspen, spending 38% of their time in aspens, 18% in hardwoods, 20% in shrubs, and 24% in conifers. Females spent 34% of their time in aspens, 15% in hardwoods, 21% in shrubs, and 31% in conifers. Both sexes foraged more in conifers than the other species. The mean foraging height for males was 4.06 m (range 0.3-23.0 m). Mean foraging height of females was 3.18 m (range 1.0-8.3 m). Canada Warblers foraged lower than Nashville and Chestnut-sided warblers and higher than Mourning Warblers. Male Canada Warbler foraging substrates included 59% on branches, 19% on twigs and leaves, 18% in the air, and 4% on limbs and trunks. Females foraged 61% of the time on branches, 22% on twigs and leaves, 8% in the air, and 7% on limbs and trunks. Males foraged by hovering 40% of the time, 31% by gleaning, 25% by sallying, and 4% by pouncing. Female foraging techniques included 58% gleaning, 20% hovering, 20% sallying, and 2% pouncing.

Young were fed 45.4% adult flies and 34.0% caterpillars in New Hampshire. Nestlings have been documented consuming crane flies, yellow grubs, mosquitoes, caterpillars, and adult moths. Adults eat some spiders but mostly insects including mosquitoes, flies, moths, adult and larval beetles, hairless caterpillars, ants, bees, other hymenopterans, scale insects, and insect eggs (Bent 1953; Harrison 1984; Krause 1965; Reitsma et al. 2020). The Canada Warbler also eats spruce budworms, although its consumption of them was low compared with other species in New Hampshire and Maine. In these 2 states, its population increased significantly with increasing budworm numbers, but the reason for this was uncertain given its low dependence on budworms (Crawford and Jennings 1989). Near Manitouwadge, it exhibited no significant response to budworm populations, although the trend was a decline with increasing numbers of budworms (Venier et al. 2009). Although it is not a budworm specialist, Savignac (2008) and Stewart et al. (2009) concluded that its population may correlate with budworm numbers and that current budworm management and the resulting decline in budworm outbreaks may be contributing to its decline. Sleep et al. (2009) used Breeding Bird Survey (BBS) data for the Canada Warbler and compared these abundance estimates with the area defoliated each year by the spruce budworm. They concluded that the Canada Warbler may be even more closely associated with the spruce budworm than known budworm-associated species. Venier et al. (2012) examined this conclusion using 60 years of BBS

data rather than the 30 years used in the first analysis. They determined that there were insufficient observations in Alberta and Manitoba to support the conclusions because most Canada Warbler observations occurred more than 100 km from any budworm defoliation. They concluded that there was little evidence to support the theory that the Canada Warbler decline was a function of spruce budworm decline. In an aviary experiment, Whelan et al. (1989) offered a Canada Warbler a second-instar gypsy moth larva and it was refused; no older larvae were offered. When different food items were offered simultaneously, 3 of 6 gypsy moth larvae were accepted, 0 of 4 tussock moth larvae were accepted, 5 of 6 cabbage loopers were accepted, and 4 of 4 mealworms were accepted. All the cabbage loopers and mealworms were eaten before any gypsy moth larvae were consumed. It demonstrated a clear preference for hairless larvae. In Maine, Mitchell (1952) examined the contents of 1 Canada Warbler stomach in 1949 and 3 in 1950; spruce budworms were abundant in the latter year. In the first year, the stomach contained 0% budworms and 100% other insects and invertebrates. In the second year, 3% of the volume of food consumed consisted of spruce budworms and 97% were other insects and invertebrates.

The Canada Warbler is a moderately common host of the Brown-headed Cowbird where the ranges of the 2 species overlap. The warbler appears to accept cowbird eggs and frequently fledges cowbirds. Mean warbler clutch size in parasitized nests was 2.5 eggs (range 1-4 eggs). Parasitism results in the loss of an average of 1.5 warbler eggs per clutch; effects on warbler fledging success are unknown. In Ontario, 5 of 25 nests (20.0%) were parasitized. In British Columbia, 5 of 34 breeding records (14.7%) involved parasitism, mostly of adults feeding cowbird fledglings. In Michigan, 21.4% of 14 nests and 54.5% of 11 nests were parasitized; 0 of 72 New Hampshire nests were parasitized (Campbell et al. 2007; Peck and James 1987; Reitsma et al. 2020).

Habitat loss and fragmentation may be limiting factors in agricultural landscapes but do not appear to be an issue in forested landscapes. Reduction in forest size or in the amount of forest cover within agricultural areas have the potential to make otherwise suitable habitat less attractive. Most large woodlands south of the Canadian Shield are designated significant woodlands and these areas are usually protected from development. Forest clearing can still occur for agricultural purposes and treed swamps may also be drained. These 2 activities combined have resulted in extensive habitat loss in the east. Most of this occurred from the 1950s to 1980s, but losses are still occurring due to agriculture and development (Reitsma et al. 2020; Savignac 2008; Stewart et al. 2009; Wells 2007). Even the construction of a single house within a woodlot inhabited by this warbler may have adverse effects. In North Carolina, its abundance was negatively correlated with the number of buildings within 200 m (Lumpkin and Pearson 2013). In Rhode Island, it was negatively affected by the proximity and length of roads in forested habitat (Savignac 2008).

Forest management practices that maintain or enhance the shrub layer are beneficial to the Canada Warbler. In northwestern Ontario, its probability of occurrence was 70% in unharvested forests but was 60% within 6 years of forest management indicating that it talks advantage of regenerating forests. Cupiche-Herrera et al. (2024b) recommended retention of tall trees and managing logged areas to retain shrub and riparian habitat. Clear-cuts provide good habitat 6-20 years after harvesting as long as they are allowed to regenerate naturally. Clear-cuts have the potential to create habitat where none previously existed or enhance habitat where the existing

forest had a full canopy with limited understorey. In Quebec and Minnesota, its abundance was lower in landscapes where forests were managed than in natural landscapes. In Alberta, the more extensively harvested a stand was and the more recently it had been harvested, the less likely that males were to use it. Over 50% of males' home ranges did not include any postharvest habitat and the average proportion of postharvest habitat in home ranges was only 14%. Males were more likely to use postharvest stands in areas supporting high densities, suggesting that usage of postharvest stands was more dependent upon conspecific attraction than the suitability of the habitat. Another Alberta study concluded that loss of older forests due to forest harvesting may be contributing to the decline of the Canada Warbler. In British Columbia, retained trees in clear-cuts provided important habitat in the form of singing perches. Retained residual trees had no effect on it in Alberta. In this study, the residual trees were used for perches by birds of prey and the retained trees were inadequate to provide cover from predators. In the Boreal Forest Region of Ontario, it increased when 30% or 50% of trees were removed from stands and decreased when 70% of trees were removed. In New York, it exhibited no response when 0-75% of merchantable trees were removed, but increased when 100% were removed. This still left a forest community, but one with many canopy openings that would favour shrub growth. In Quebec, it responded positively to strip-cuts and increased with the amount of deciduous regrowth in the strip. It bred at higher densities in old (14-15 years) cuts than in young cuts. In Minnesota, the Canada Warbler did not exhibit a significant response to harvesting in riparian buffer strips. In deciduous forests in Alberta, it declined significantly when 25% of trees were removed and became locally extirpated when 50% or more of trees were harvested. The effects of forest harvesting are variable and largely a function of what impact the management has on shrubs. Activities that decrease the amount of shrubs are detrimental; those that encourage shrub growth are beneficial. Excessive tree loss may be detrimental even where shrub growth increases. The amount of tree cover that can be removed may vary geographically and by stand type. Removal of a high proportion of trees may be beneficial in northern hardwoods. The same intensity of logging in intolerant hardwoods may be detrimental. In Ontario, removal of as many as 50% of the trees in a stand may be beneficial to the Canada Warbler. Clear-cuts are occasionally sprayed with herbicides to kill deciduous woody regeneration and release conifer species; this practice is detrimental. Short rotations may also be detrimental where it prefers mature or old-growth forest (Baker et al. 2016b; Ball et al. 2016; Becker et al. 2012; Campbell et al. 2007; Falardeau et al. 1999; Hallworth et al. 2008a; Hanowski et al. 2005; Harrison et al. 2005; Hunt 2016; Reitsma et al. 2020; Savignac 2008; Stewart et al. 2009; Tittler et al. 2001; Vanderwel et al. 2009; Webb et al. 1977). In Ontario in the Boreal Forest Region, there was no difference in its abundance in early successional and mid-successional clear-cuts than in burns of the same successional stage. There was no difference in its abundance in young clear-cuts and mature forests, but it was significantly less abundant in mid-successional than mature stands (Zimmerling et al. 2017). In Alberta, Hunt et al. (2017) examined the effects of forest harvesting and male density on reproduction in the Canada Warbler. They surveyed 132 plots 17.3 ha in area within aspen-dominated stands with a gradient of 0-100% of the plot harvested and 1-30 years postharvest. Male density was 86% lower in harvested than unharvested stands. Males were 16.6 times more likely to place their home ranges in harvested stands within 100 m of unharvested stands than 300 m into harvested stands. Males were also 3 times more likely to place their home ranges 100 m from conspecifics than 300 m from them. The mean size of home ranges that included harvested areas

was significantly larger (1.27 ha) than those that had not been harvested (0.72 ha). In harvested portions of home ranges, use of space was 1.1 times greater within 50 m of conspecifics than 350 m from conspecifics, but space use in unharvested stands was unrelated to proximity of conspecifics. Pairing success was higher for males at low and mid-densities than at high densities. Forestry impacts may be greater in western boreal forests where it prefers deciduous stands older than 125 years. In clear-cuts, territories were near the edge and retention of unharvested fragments 5 ha or smaller did not mitigate the effects of forest harvesting. There was no evidence that harvesting had an effect on pairing or fledging success. The authors concluded that forest harvesting seems to constitute a threat to Canada Warbler breeding habitat in this area because it results in lower use and density of birds. Postharvest stands are more likely to be used if they are near unharvested stands. Territories were clustered, so large tracts of unharvested forest should be retained.

Populations of the Canada Warbler respond to any factor that affects the abundance of shrubs. These factors may affect regional (forest maturation and grazing) and local (forest fires, insect invasions, diseases, and windthrow) populations. In eastern North America, much farmland was abandoned from the 1950s to early to mid-1990s. These areas initially provided good habitat, but continued forest maturation resulted in a reduction in understorey and amount of suitable habitat. Natural openings in the forest canopy do not occur again until later in succession when overmature trees die. Forest maturation in Algonquin Park has probably reduced the understorey and the Canada Warbler population. Two long-term studies in New York concluded that it declined due to forest maturation and the loss of understorey (Keller et al. 2003; Litwin and Smith 1992; Reitsma et al. 2020; Tozer 2012; Wells 2007). Overbrowsing by white-tailed deer has been cited as a significant problem in many areas and may be a limiting factor to the Canada Warbler south of the Canadian Shield. It has been identified as an issue in Algonquin Park. In some areas, cattle-grazing in woodlots is an issue, but this is not much of a problem in Ontario now (Baker et al. 2016b; Campbell et al. 2007; Gates and Giffen 1991; Reitsma et al. 2020; Savignac 2008; Stewart et al. 2009; Tozer 2012; Wells 2007). Forest fires have varying effects depending upon the severity of the burn. Severe burns may damage soils to the extent that regeneration is greatly inhibited. An Ontario forest fire in a mixed-coniferous forest caused a decline in the Canada Warbler. In New York, it was more abundant in old regenerating burns than in unburned forest. It appears to decrease initially after fire due to the loss of understorey vegetation, but eventually benefits once regeneration becomes established (Reitsma et al. 2020). Defoliating insects do not appear to have an adverse effect provided that understorey vegetation is not killed (Campbell et al. 2007). It is possible that it will benefit from the emerald ash borer because the loss of these trees in the forest canopy may promote the growth of shrubs. The Canada Warbler benefits from windstorm damage in woodlands. The fallen trees provide excellent cover and open up the canopy and create a dense shrub layer. In an aspen forest in Manitoba, populations increased 400% due to blowdowns (Reitsma et al. 2020).

In Alberta, the Canada Warbler was more abundant along pipelines and seismic lines than in undisturbed forest. It is probable that the disturbed habitats supported more shrub cover than the undisturbed forests (Bayne et al. 2016).

Probably the greatest limiting factor to the Canada Warbler is habitat loss in the wintering grounds. It winters in the dense undergrowth of Colombia's forests in the northern Andes and in

the lower slopes of the Andes in Ecuador and Peru. Approximately 90% of the forest in the northern Andes has been removed (Baker et al. 2016b; Stewart et al. 2009; Wells 2007).

Other potential threats have been suggested, but these are all currently of minor concern and some have not been documented as actually occurring. These include reduced availability of insects, acid precipitation that may affect abundance of aquatic insects and result in bioaccumulation of toxins such as mercury, habitat shifting and alteration due to climate change, changes in the timing of insect abundance due to climate change, temperature extremes and storms, and pesticides (Baker et al. 2016b; Wells 2007).

Price (2004) predicted that the Canada Warbler might disappear as a breeding species in southern Ontario if the average summer temperature increased by 2°C. In North Carolina near the southern extent of its range, Chandler et al. (2018) determined that it was most abundant at the highest elevations and absent in low areas. They considered the distribution shift to higher elevations a response to climate change and predicted that it may only persist at high-elevation sites in future.

Status

McIlwraith (1894) reported that a few Canada Warblers remained in the Hamilton area to breed. Baillie and Harrington (1937) concluded that it was well distributed but not very common. They had breeding season records from the southern portion of the province north to southern Kenora District and James Bay and it had also been reported along the Ontario-Manitoba boundary between latitudes 53°N and 54°N. It was known to breed north at least to the transcontinental railway. MacLulich (1938) stated that it was not very abundant in Algonquin Park. The first atlas confirmed that it bred from the southern boundary of the province north to the Wetiko Hills in the west and Attawapiskat in the east. It was not documented in many blocks in the central Boreal Forest Region. It was concluded that this may have been due to inaccessibility combined with scarcity of areas with deciduous undergrowth. Distribution south of the Shield was spotty. No breeding records were obtained in Essex County and the western portions of Lambton and Chatham-Kent. It was suspected that it was overlooked in some areas south of the Shield (McLaren in Cadman et al. 1987). James (1991) considered it a common breeder across central Ontario north to Sandy Lake and Attawapiskat, rare in southern agricultural areas, and absent in the extreme southwest.

The second atlas confirmed that there had been no change in the distribution of the Canada Warbler since the first atlas. There were no significant changes in its probability of observation province-wide, but significant declines occurred in the Carolinian Forest Region and the Great Lakes–St. Lawrence Forest Region in the Canadian Shield; trends in other regions were negative (McLaren in Cadman et al. 2007). There was a province-wide decline of 0.8% per year between atlases, a 16% decrease (Baker et al. 2016b). It was most abundant in the Boreal Forest Region and in the Great Lakes–St. Lawrence Forest Region in the Canadian Shield. Areas of higher densities occurred in a band from Rainy River to Cochrane, along the eastern shoreline of Lake Superior, and from Georgian Bay through Algonquin Park (McLaren in Cadman et al. 2007).

BBS data indicate that the Canada Warbler is declining rangewide and in Canada and Ontario. Rangewide, it declined at a rate of 2.3% per year 1966-2007. The BBS is not effective in monitoring this warbler. Much of its range is outside the area covered by this survey, its habitat is patchy in

distribution and this survey is best for widespread species, and the roadside survey is not well suited to detecting it. South of the Canadian Shield, Forest Bird Monitoring Program data for Ontario indicated an annual decline of 6.3% (Baker et al. 2016b; Campbell et al. 2007; Reitsma et al. 2020; Savignac 2008). BBS results indicate that it decreased at annual rates of 2.09% in Canada and 1.8% in Ontario 1970-2021. Trends for 2011-21 were annual decreases of 2% in Canada and 1% in Ontario. All results were of medium reliability (A.C. Smith et al. 2023).

Based predominantly on BBS results, the Committee on the Status of Endangered Wildlife in Canada designated the Canada Warbler threatened nationally. It was designated special concern in Ontario. The recovery strategy acknowledged that there was uncertainty in estimating its population size and trends using the BBS, and the strategy includes approaches to improve monitoring Canada Warbler populations. The short-term objective of the recovery strategy is to halt its decline by 2025 while ensuring that the population does not decline more than 10% over this time. The long-term objective is to ensure a positive 10-year trend after 2025 (Baker et al. 2016b).

POSTFLEDGING PERIOD

Brood division may occur once the nestlings fledge. Fledglings remain near the nest for a few days, usually close to the ground in thick cover such as bracken ferns, clumps of balsam fir, or small dense shrubs. There is high variation in the distances initially dispersed by fledglings. One was found 370 m from the male's territory 6 days after fledging and another stayed within 50 m of the nest for at least 18 days. Young are fully independent by age 2 weeks (Reitsma et al. 2020).

Young, adults, and family groups have been captured in clear-cuts 1-10 years old during the postfledging period in West Virginia, Virginia, Minnesota, and Pennsylvania. It is probable that widespread use of regenerating areas occurs after fledging, but limited study has been done on this. Although some Canada Warblers breed in this habitat, many move to early successional areas after breeding in forested habitat. In Minnesota clear-cuts, 43 adults and 16 juveniles were captured during the postfledging period over 4 years. In a single breeding season, only one was captured. In Pennsylvania, 5 adults and 6 juveniles were captured in clear-cuts and none were captured in adjacent mature forests (Marshall et al. 2003; McDermott and Wood 2010; Stoleson 2013; Streby et al. 2011b).

In West Virginia clear-cuts, caterpillar biomass was a positive predictor of captures of adult Canada Warblers. Juvenile abundance was significantly negatively correlated with basal area, arthropod density, stem density, and vertical complexity of vegetation. Although adults were correlated with arthropod biomass, juveniles were negatively correlated with food abundance. It is likely that juveniles are too inexperienced to recognize food-availability cues (McDermott and Wood 2010).

Adults and juveniles also inhabit forested habitat during the postfledging period. In 100 net-hours, 0.3 Canada Warblers were captured in upland forests and 1.4 were captured in riparian forests; 75% of juveniles captured were in riparian habitat. Upland forests consisted of 100-year-old trembling aspen and large-toothed aspen. Riparian forests were a mix of alder, honeysuckle, and trembling aspen. It is likely that the higher shrub abundance in the riparian stands was attractive to this warbler (Akresh et al. 2009).

MIGRATION

The Canada Warbler is a nocturnal migrant that often spends its diurnal stopovers in flocks of other warblers and small passerines, particularly in autumn. Some arrive on the breeding grounds paired so these presumably migrate together (Campbell et al. 2007; Reitsma et al. 2020; Tozer 2012).

Males usually arrive in spring before females but occasionally pairs arrive simultaneously, apparently already mated; adults arrive before yearlings. At Prince Edward Point, the mean capture date of males (24.4 May) was 3.2 days earlier than for females (27.6 May), a significant difference. At Long Point, the mean capture dates of males were 21.0 May for adults, 24.3 May for yearlings, and 22.1 May for males of undetermined age. Mean capture dates of females were 24.3 May for adults, 27.9 May for yearlings, and 26 May for females of undetermined age. All differences between age classes and sexes were significant. In Alberta, adult males arrived an average of 3.5 days earlier than adult females. Mean arrival dates were 30.5 May for adult males, 1.5 June for yearling males, 3 June for adult females, and 3.5 June for yearling females. Males may occasionally precede females by as much as 5 days and males arrived an average of 4 days earlier than females in Maine (Campbell et al. 2007; Flockhart 2007, 2010; Francis and Cooke 1986; Reitsma et al. 2020; Stewart et al. 2002).

In southern Ontario, the Canada Warbler typically arrives in mid-May, with some arriving in early May or very late April. Most are gone by the end of May but a few remain into June (Black and Roy 2010; Curry 2006; Fleming 1907; Keast 1980; LaForest 1993; Lancaster et al. 2004; Weir 2008). Average arrival in the southern Shield is mid-May with the earliest records in the second week of May (Mills 1981; Tozer 2012).

Autumn migration timing of adults appears to be linked to the timing of the moult, with birds initiating southward movement approximately 2 days after the moult is complete. In Alberta, old females departed on 3 August, juvenile females and juveniles of unknown sex departed on 5 August, juvenile males departed on 6 August, and adult males departed on 9.5 August. It has been confirmed in other areas that females and juveniles migrate earlier than adult males. In western Pennsylvania, the peak for adults was 5 days after the peak for juveniles. Males spent 72 days on the breeding grounds, significantly more than the 62 days spent by females. The Canada Warbler spends the least amount of time on the breeding grounds of any warbler. This inhibits its ability to renest and have second broods (Flockhart 2007, 2010; Graber et al. 1983; Reitsma et al. 2020). In Maine, autumn stopover times averaged 3.4 days (range 1-10 days), longer than in spring (Reitsma et al. 2020).

In the southern Shield, the Canada Warbler is fairly common through August and into September, with the latest records in late September (Mills 1981; Tozer 2012). In the south, average arrival is in mid-August and average departure is in mid-September, but migrants may be present from early August with stragglers to mid-October or rarely November (Black and Roy 2010; Curry 2006; Fleming 1907; Keast 1980; LaForest 1993; Lancaster et al. 2004; Weir 2008).

During migration, the Canada Warbler occurs in habitats similar to those used during the breeding season. These include shrubby edges of wooded areas, forests with a shrubby understorey, floodplains and riparian habitats, utility and railway corridors, and occasionally sloughs and marshes with some shrubby cover. It may also occur almost anywhere that there are trees, shrubs, or tangles of vines including in urban parks, villages, rural residential lots, and margins of beaver ponds. Presence of shrubs appears to be essential in areas where it stops over for a day or more (Campbell

et al. 2001, 2007; Leighton et al. 2002; Reitsma et al. 2020; Stewart et al. 2002). During autumn migration in Pennsylvania, it was equally abundant in forest interior, forest edges, forest-agricultural edges, suburban forests, pole-stage forests, and shrub-sapling-stage forests (Rodewald and Brittingham 2002). In Illinois, it was most abundant in both spring and autumn in bottomland forests and also occurred in forest edges and shrub habitats. In spring, it occurred in mature upland forests but numbers were consistently low in this habitat in autumn (Graber et al. 1983). In spring in North Carolina, it was most abundant in floodplain forests followed by wet thickets. It was not observed in dry thickets or upland forests dominated by pine-hardwoods, pine, beech, or oak-hickory (Parnell 1969). During spring migration in Ohio, it was most prevalent in lower portions of swampy woods or in dense undergrowth and preferred swamps with an understorey of spicebush (Bent 1953). During spring migration in Pennsylvania, it was significantly more abundant in shrub habitat than in forested habitat. The number of captures per 1,000 mist-net hours was 1.8 in shrubs and 0.1 in forests (Smith and Hatch 2008). Suomala et al. (2010) compared usage of 2 islands in the Gulf of Maine during migration over 2 years. During spring, there was no significant difference in island usage in 1 year, but in the other year it was significantly more abundant on the island with greater tree density and canopy cover and with high density of shrubs taller than 3 m. In autumn, more birds used this same island, but the differences between the 2 islands were not significant. During autumn migration in South Dakota, twice as many Canada Warblers were captured in a 3.5-ha woodland than in a contiguously forested riparian corridor (Dean et al. 2004).

During migration at Prince Edward Point, the Canada Warbler fed at heights of 1.5-7 m, mostly around 3 m. It foraged consistently in the lower parts of branches of saplings and spent much time in low shrubs. Foraging substrates included 5% on outer leaves, 10% on outer branches, 25% on inner branches, 13% on sapling branches, 25% on low shrubs, and 0% in the air and on twigs, inner leaves, trunks, and the ground (Keast 1980). During spring migration in North Carolina, Parnell (1969) considered it a low-tree user in floodplain forests. Foraging occurred 13.3% of the time in the canopy, 80.1% in low trees, 6.7% in shrubs, and 0% on the ground. In the canopy, 13.3% of foraging occurred in the lower crown and 0% occurred at the top of the crown, in the inner crown, or on the bole. In low trees, 0% of foraging occurred at the top of the crown, 46.7% in the inner crown, 26.7% in the lower crown, and 6.7% on the bole. In shrubs, 6.7% of foraging occurred in the inner crown and 0% at the top of the crown, in the lower crown, in dense thickets, in brush piles, and in grasses. During autumn migration, it has eaten fruit, locusts, and other insects (Reitsma et al. 2020).

Graber et al. (1983) stated that the Canada Warbler was an uncommon victim at Illinois television towers during migration. Other reports indicate that it is highly vulnerable to striking tall structures and this is considered a high threat to the population. It has been estimated that approximately 20,600 are killed annually in central and eastern North America at communication towers. Thirty-four were killed in 5 of 7 years at the Barrie television tower. From 1972 to 1982, 325 were killed at the Lennox generating station chimneys near Kingston; 131 were killed on 5 September 1981 (Baker et al. 2016b; Devitt 1967; Reitsma et al. 2020; Weir 2008). Loss et al. (2014) examined bird-building collision data for the United States and determined that the Canada Warbler was highly vulnerable to being killed at buildings. It was 17.9 times more likely to strike buildings of all types than the average for birds. It was 46.7 times more likely to strike low-rises and 25.8 times more likely to hit high-rises than average. It was not on the top 20 list of birds striking residences 1-3 storeys tall.

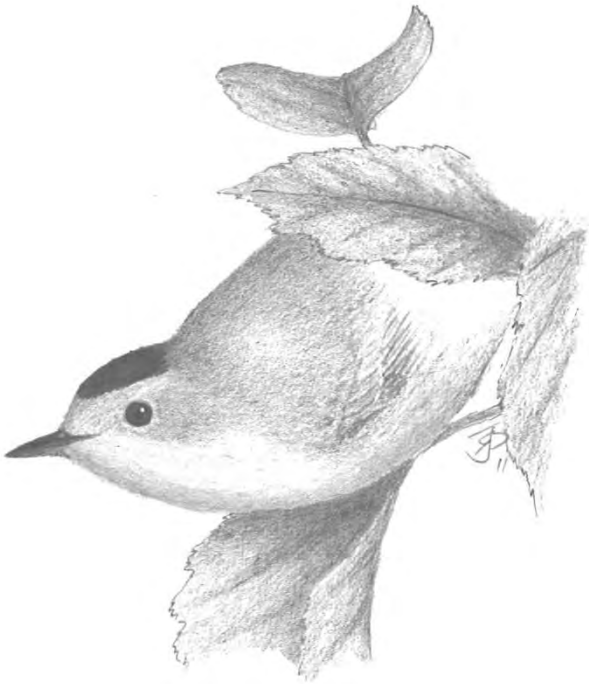
The Canada Warbler may be vulnerable to predation by cats while it is on migration. Birds nesting in agricultural landscapes are also vulnerable to predation and depredation of nests by cats (Baker et al. 2016b).

James (1991) considered the Canada Warbler an uncommon migrant, but it may be locally common in southeastern Ontario (LaForest 1993; Weir 2008).

At Long Point Bird Observatory from 1961 to 1988, captures of the Canada Warbler decreased significantly by 3.7% annually. Trends by periods included: 1961-70, –7.3%; 1970-79, +5.6%; and 1979-88, –8.3% (Hussell et al. (1992). More recent data for Long Point indicate that it decreased at a nonsignificant rate of 0.2% per year 1967-2005. During 1995-2005, it decreased significantly at a rate of 8.5% annually at Thunder Cape (Savignac 2008).

Wilson's Warbler

Cardellina pusilla



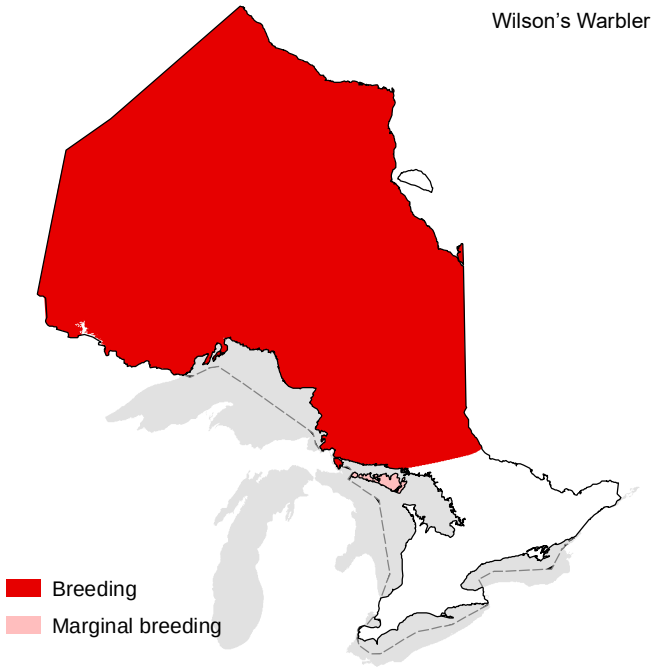
BREEDING SEASON

Habitat Requirements

There are 3 subspecies of the Wilson's Warbler, 2 in western North America and 1 in the east. The range of the eastern subspecies extends from Newfoundland and the Maritime Provinces west to central Alberta and the south-central District of Mackenzie, with a small proportion of its range in northern New England (Ammon and Gilbert 2020). Genetic analyses determined that the eastern subspecies is strongly differentiated from the western group. The eastern and western groups winter in different areas, are different morphologically, the eastern subspecies occupies a narrower ecological niche than the western group, and there is no evidence of breeding between the eastern and western groups. It has been suggested that the Wilson's Warbler may be treated as 2 separate species, with the eastern subspecies comprising one of the species and the western subspecies comprising the other (Ruiz-Sánchez et al. 2015). Information on both groups is provided in this species account, but in a manner such that it can be determined which group it pertains to.

Ontario nests were all in wet areas. Sixty percent of nests were in alder or willow thicket swamps with associated growths of black spruce, tamarack, dwarf birch, and Labrador tea; 30% were in grass, herbaceous plants, or raspberry thickets near streams or ponds; and 10% were in a drained area with dead cedars (Peck and James 1987).

In the Tundra Region and Hudson Bay Lowland, Wilson and McRae (1993) documented the Wilson's Warbler breeding in riparian willow thickets. Manning (1981) reported that it probably bred in willow thickets on the Twin Islands in James Bay.



In the Boreal Forest Region from Pickle Lake north to the Wetiko Hills, the Wilson's Warbler was most abundant in deciduous scrub followed by mixed scrub. It occurred in much lower densities in deciduous forests, coniferous forests with and without an understorey, and mixed forests. It was absent in heath and tundra habitat (McLaren and McLaren 1981). Near Pickle Lake, James (1980) found it only in shrub habitat at edges of forests. Near Hearst, it was fairly common in clear-cuts in lowland coniferous forests 3-19 years old, with highest densities in 11-13-year-old stands. It was absent in upland or lower-slope mixed forests and uncut coniferous lowland stands (Welsh and Fillman 1980). Near Manitouwadge, it was most abundant in mixed-wood stands 1-21 years old, but was still uncommon in these areas. Its abundance declined with forest age. Its abundance in 24-36-year-old stands was 14.6% of that in young stands and its abundance in 60-223-year-old stands was 6.25% of that in young stands (Venier et al. 2009). In the Clay Belt, it was most abundant in jack pine stands followed by those dominated by balsam poplar, black spruce, white cedar, and white birch–spruce. It occurred in wet to dry sites, but was most common in wet areas. It was present in stands at both extremes of the nutrient-richness scale, but occurred mostly in nutrient-poor sites (Welsh and Lougheed 1996).

Although the Wilson's Warbler has nested in a variety of forest types, it is usually confined to shrub thickets or wetland pockets within a forested matrix. Forest type is not significant to it and the general habitat descriptions of these stands may not be representative of the area that it actually inhabits. Its typical habitat includes shrub thickets that are in moist or wet habitat in nutrient-poor areas. Willow and alder swamps are prime habitat and these are often along streams, rivers, or lake shorelines, or in open wet depressions within forests. Bogs and fens with scattered conifers such as black spruce, tamarack, and white cedar provide suitable habitat in Ontario. Clear-cuts with patches of willows, alders, or regenerating saplings provide temporary habitat until the site reverts to forest-like conditions.

Limited information is available from other locations on the habitat requirements of the eastern Wilson's Warbler. In Newfoundland balsam fir–spruce stands, it was absent in undisturbed forests but occurred in low density in riparian buffer strips within 30 m of water. The riparian vegetation mostly consisted of alders and other tall shrubs, often in dense thickets. Whitaker and Montevecchi (1999) classified it as a riparian species. In New Brunswick, it nested in a bog surrounded by forest, with considerable growths of small white cedar, tamarack, spruce, and balsam fir saplings (Philipp and Bowdish 1917). In Maine, several inhabited a wet alder swale adjacent to a highway. The nest was on a dry slope above the swale vegetated with raspberries. In Maine, it nests in sphagnum bogs, and in willow thickets and shrubby pastures bordering young growth (Chapman 1907; Harrison 1951, 1984; Tyler in Bent 1953). On Anticosti Island, the Wilson's Warbler nested in clear-cuts 6-7 years old. Cardinal et al. (2012) considered it strongly dependent on the shrub layer for foraging and nesting. Near Quebec City, it occurred in very low density in a recent burn. It was not detected in clear-cuts, older burns, or uncut forests (Imbeau et al. 1999). In Quebec, it is uncommon in deciduous forests but becomes more abundant as conifers predominate and latitude and altitude increase. It is most numerous in the boreal spruce forest and in montane balsam fir–spruce forests. In the boreal forest, it does not nest within the forest itself, but in wet habitats with tall shrubs or short deciduous trees, mostly alders and willows. Boggy areas with nearby tamarack or stunted spruce are typical habitat and there is often a stream near occupied areas. Highest densities in the south occurred in balsam fir–spruce–white birch stands and abandoned fields overgrown with willow and alder thickets. In the north, highest densities were associated with shoreline shrub thickets. It frequently inhabited burns and ecotones between burns and coniferous forest (Alvo in Gauthier and Aubry 1996). In Quebec, extensive logging of mature boreal forests produced habitats with a patchy structure similar to that found in alder and other wet scrubland. The water table can rise in the 5 years following clear-cutting creating favourable mesic conditions and promoting growth of alders. The clear-cuts were less than 15 years old and regenerating with balsam fir, white birch, white spruce, raspberries, elderberries, and alder. Usage of clear-cuts was compared with usage of natural alder thickets 0.2-4.8 ha in area. There was similar use of clear-cuts and alder thickets, with 34% of 39 alder sites and 40% of 97 clear-cuts used. In both habitat types, it was more abundant in larger patches. In clear-cuts, it was more abundant in older cuts. This warbler is more abundant in landscapes affected by forest management than in natural landscapes. Occupancy of a given area increased with the amount of alder or clear-cut within 400 m of point-count stations. Desrochers et al. (2012) considered the Wilson's Warbler area sensitive because its probability of occupancy increased with patch size. It is not truly area sensitive because many of the smallest patches were inhabited. Even when very small amounts of habitat occurred within 400 m of a point-count station, the occupancy rate was 60% for alders and 64% for clear-cuts. This study demonstrated that clear-cuts, at least up to 100 ha, are beneficial and provide good habitat. In lowland coniferous stands in the northeast, Dawson (1979) reported it in low densities in shrubs with scattered conifers and in young or low black spruce, but stated that it was locally common. Near Churchill, it nests in tall willow thickets (Jehl 2004). In the Prairie Provinces, it was in a guild concentrated in young aspen stands, but it also occurred in wet marshy or bog habitats. It was observed in stands 0-20 years old but not in those 40 years old or older. It was associated with nutrient-poor wet sites and younger stands (Kirk et al. 1996). In the Boreal Forest Region, Erskine (1977) considered the Wilson's Warbler characteristic of tundra and alpine ecotones with boreal forest. Ammon and Gilbert (2020)

summarized the habitat of the eastern subspecies as clearings or bogs in moist early successional forests or stunted conifers, and in alders, sphagnum moss, and Labrador tea. In eastern Canada and the United States, occurrence of vegetation at 20 nests consisted of 60% alder, 45% grasses, 25% conifers (spruce and balsam fir), 25% mosses, and 15% Labrador tea. Other species at nests included willows, shrubby cinquefoil, pine, blackberry, nettles, ferns, and huckleberries. Seventy-nine percent of nests were adjacent to bogs and 21% were in drier cleared areas. Nest sites were near streams, on shrubby hillsides, in tundra, in moist meadows, in willow thickets, by lakes, in shrub thickets other than willow, in woods or swamps, and at edges of marshes. Its abundance was positively correlated with deciduous tree and shrub cover.

Much more research has been conducted on the western subspecies of the Wilson's Warbler. Western populations breed in mesic shrub thickets at edges of beaver ponds, lakes, and bogs and in clear-cuts. It also may breed within forests, particularly deciduous forests with sparse canopy closure. It is less abundant in young clear-cuts than in uncut forests but is more abundant in 10-20-year-old clear-cuts than in uncut forests. In the Yukon, it inhabits shrubby draws and wetlands interspersed within extensive black spruce forests. It is also found at the treeline, in shrubby areas along rivers, and at high elevations. It is uncommon to rare in lowland areas. It also occurs in streamside thickets in uplands and shrubby riparian forests, particularly those dominated by balsam poplar. In British Columbia, it breeds in dense low shrubby vegetation. It is characteristic of willow shrub thickets, but uses a variety of other shrubs. It may use clear-cuts for nesting but it is much more common in trembling aspen forests. Most nests were in forests where the cover was predominantly deciduous and the moisture level encouraged growth of a ground cover of mosses or grasses. It tends to avoid British Columbia coniferous forests for nesting but riparian shrub thickets at edges of coniferous forests provide suitable habitat. In many regions, particularly in alpine areas, the Wilson's Warbler nests almost exclusively in willow thickets. Alder thickets are also important and it may use thickets of bog birch, shrubby cinquefoil, rhododendrons, raspberries, young conifers, and maple seedlings. In most areas, it is a forest edge species but in California it nested throughout coniferous forests. In South Dakota, it nested in green ash woodlands with an understorey of chokecherry. It may nest in dry shrubby meadows. The most consistent habitat requirement for all subspecies of the Wilson's Warbler is dense growths of deciduous shrubs. For the most part, these are in wet areas and are mostly dominated by willows or alders (Ammon and Gilbert 2020; Bent 1953; Brand and George 2001; Campbell et al. 2001; Douglas et al. 1992; Finch 1989b, 1991a; Harrison 1951; Hutto 1981; Matsuoka et al. 2001; Michaud et al. 2004; Morrison 1981; Raley and Anderson 1990; Rumble and Gobeille 1998; Sinclair et al. 2003; R.M. Stewart 1973; Stewart et al. 1977; Whitmore 1977; Wiebe and Martin 1998).

All Ontario nests were on the ground sunken in grass or moss hummocks or in clumps of grass or herbaceous species. One nest was under the edge of a small bank in a low area. Four were at the bases of small trees (willow, white cedar, and tamarack; Peck and James 1987).

All reported nests of the eastern subspecies were on the ground or slightly below ground in a small depression. They were frequently sunk into mounds of sphagnum moss in bogs or at the bases of shrubs or small trees. Nests are usually well concealed under grasses, sedges, Labrador tea, low branches of shrubs, or other ground vegetation. Nests are not reused, but nest depressions are

frequently reused, often by birds other than the original breeder. One nest depression was used 10 years (Alvo in Gauthier and Aubry 1996; Ammon and Gilbert 2020; Harrison 1951; Phillip and Bowdish 1917; Tyler in Bent 1953). Nests of the western subspecies are similar, except along the Pacific coast where they may be elevated in shrubs. In California and Oregon, 7 nests were on the ground and 274 (97.5%) were elevated at a mean height of 1.7 m (maximum 10.0 m). Almost all nests are less than 2 m from the ground. A variety of plants may be used to support the nest, but blackberries, alders, willows, and ferns are favoured. Unusual nest sites include in a cavity under the root of a stump, in sparsely vegetated areas, on top of an old Barn Swallow nest under a bridge, and in an axe notch in an old stump (Ammon and Gilbert 2020; Bent 1953; Campbell et al. 2001; Michaud et al. 2004; Sinclair et al. 2003; R.M. Stewart 1973; Stewart et al. 1977).

The Wilson's Warbler is territorial, with boundary conflicts occurring 0.5-1.5 m from the ground in dense tangles. In Quebec, its occurrence was strongly clustered at scales of 240-420 m, which corresponded to the size of territorial neighbourhoods. The tendency to form clusters of territories may explain why it was more abundant in larger patches. Birds may wander from their territories. In California, males were seen 125-300 m from their territories and a pair was seen 135 m from the territory in the extreme edge of the adjacent territory. Nonetheless, most foraging and other activities occur within the territory. During the breeding season in California, groups of 3-8 birds may remain in an area of 10 m^2 or less for several minutes, eventually moving through the underbrush slowly or departing with 1 individual in the lead. These groups pass through the territories of mated pairs without invoking any agonistic reactions. The composition of these groups is uncertain and they may be nonbreeding floaters. This population was very high and contained many nonbreeders. Territory sizes have not been determined for any eastern populations. In Colorado, mean territory size was 0.19 ha (range 0.06-0.31 ha). In California, mean territory size in high altitude areas of the Sierra Nevada was 1.17 ha (range 0.7-2.0 ha) compared with coastal populations with a mean of 0.57 ha (range 0.2-1.3 ha) in oak-mixed forest and 0.48 ha (range 0.3-1.0 ha) in willows (Ammon and Gilbert 2020; Desrochers et al. 2012; R.M. Stewart 1973; Stewart et al. 1977).

All information on natal philopatry and adult site fidelity is for the western subspecies. In California, the annual return rate of juveniles to the natal area ranged from 0% to 11.1% and averaged 2.1% (49 of 2,289). In Colorado, 3% of 214 fledglings returned to the natal area (Ammon and Gilbert 2020; Chase et al. 1997).

In coastal California, at least 6 males returned to breed, mostly in their previous territories, but it was not specified how many were banded. Only slight modifications to territories occurred between the 2 years of study. One male moved his territory 150 m the second year. One male returned to find his territory occupied by a younger male. After an hour-long territorial dispute, the territory was divided (R.M. Stewart 1973). In the high Sierra Nevada of California, 9 of 20 (45.0%) males and 8 of 18 (44.4%) females returned the year after they were banded. Eight of the 9 males defended the same territory as in the previous year; 3 of 8 females returned to the same territory but only one had the same mate. This female nested 30 m from her previous nest. She had been 1 of 2 females involved in a polygynous relationship the previous year. The second female did not return and the returning female nested in the exact location where the other female's nest had been (Stewart et al. 1977). In coastal California, the probability of a breeding bird returning was 69% compared with only 7% of

birds that were transients during the breeding season. There was no significant difference in the recapture rates of the sexes. The overall annual survival rate was estimated at 50.3%, but Chase et al. (1997) acknowledged that this may have been an underestimation. There was a strong relationship between the capture rate of juveniles in 1 year and the capture rate of new adults in the following year. The capture rate of summer residents was related to productivity the previous year. In central Colorado, 32-34% of adult males and 28-30% of adult females returned; the overall return rate was 30-31%. In northern Colorado, 44% of adult males and 27% of adult females returned (Ammon and Gilbert 2020).

Limiting Factors

Eggs have been reported in Ontario nests from the second week of June until the first week of July, with most present in the last half of June (Peck and James 1987). Most information on the timing of reproductive activities is for the western subspecies. In coastal California, the time between arrival of the first males and the beginning of pair formation was 15 days. In the interior of California, an average of 8.9 days (range 1-25 days) elapsed between male arrival and pairing. Males arrive there in late March. In Ontario, where birds arrive much later, it is likely that pair bonds are formed shortly after females arrive. In California, nest completion averaged 2.8 days (range 2-6 days). First nests averaged 4.0 days (range 2-6 days) and replacement nests averaged 1.7 days (range 1-2 days). The first egg was laid an average of 1.9 days after the nest was complete (range 1-3 days). The average for first nests was 2.4 days (range 2-3 days), and the average for replacement nests was 1.3 days (range 1-2 days). Eggs are laid at the rate of 1 per day. Incubation begins with the laying of the last egg or during the night following laying of the penultimate egg. The incubation period of the eastern race is 10-11 days, based on a limited number of nests. In California, the incubation period was 11-12 days for 3-egg clutches and 13 days for 4-egg clutches. The average incubation period in Colorado was 11.2 days. All eggs hatch within a 24-hour period in the west. The nestling period in the east is 10-11 days. In Maine, young left the nest at ages 7 and 8 days due to disturbance. In the west, young fledge when they are 8-11 days old (Ammon and Gilbert 2020; Harrison 1951, 1984; Stewart et al. 1977; Tyler in Bent 1953).

In coastal California, 4 of 22 pairs (18.2%) attempted a second brood and 2 were successful. In this area, birds arrive on the breeding grounds in late March or early April, giving them adequate time to raise a second brood. There is no evidence of double broods anywhere else, including in other areas of California. Egg dates in Ontario suggest that no second broods are attempted. In the same area of California where double broods were confirmed, all 15 females that lost nests laid a replacement clutch and 1 female renested 4 times. In the high Sierra Nevada of California, no renesting occurred after clutch loss. No information is available on whether the eastern population renests. Ontario egg dates suggest that renesting may not occur. Clutches of 3-5 eggs were reported in Ontario (average 4.67 eggs, mode 5 eggs). Throughout its range, the Wilson's Warbler lays 2-7 eggs, but mostly 3-6 eggs. The single 7-egg clutch was from Alaska, where most nests contained 6 eggs. In California, the most common clutch size was 5 eggs in the Sierra Nevada and 4 eggs on the coast. Mean clutch sizes include 4.4 eggs for the eastern race, 4.5 eggs in Alaska and the Rocky Mountains, 4.5 eggs in the Sierra Nevada, and 3.9 eggs on the Pacific coast (Alvo in Gauthier and Aubry 1996; Ammon and Gilbert 2020; Bent 1953; Campbell et al. 2001; Harrison 1951, 1984; R.M. Stewart 1973; Stewart et al. 1977; Tyler in Bent 1953).

Both sexes are capable of breeding when they are 1 year old. Yearling males have limited success in establishing territories and breeding. In Colorado, only 2 of 37 territories were held by yearlings and both failed to attract a mate. Over 2 years, 20 floaters were identified in these 37 territories. In the Sierra Nevada, 15% of males were unmated but the age class of these birds was not stipulated (Ammon and Gilbert 2020). The mating system is typically monogamous, but 3 cases of polygyny were confirmed in 1 year in the Sierra Nevada. No polygyny occurred in the same study area in the previous year. Two years later, an additional 2 males were polygynous and one may have been involved in extra-pair copulation with a third female. Polygynous males had larger territories than normal and their females nested approximately 200 m apart on opposite sides of the territory. Polygyny was reproductively advantageous for males but not for females. Two of 7 polygynous males successfully raised 2 broods and 5 raised at least 1 brood. The 7 polygynous males fledged 35 young, an average of 5.0; 13 monogamous males fledged 36 young, an average of 2.8. Females in polygynous relationships raised an average of 2.5 young compared with an average of 2.8 for females in monogamous relationships. In polygynous relationships, males do not feed the young of secondary females until the nestlings of the primary females fledge. Primary females are then left to care for their fledglings without assistance from the male. Over 4 years in the Sierra Nevada, 59% of males were monogamous, 26% were polygynous, and 15% were unmated (Stewart et al. 1977). The pair bond is maintained throughout the breeding season. In California, the pair bond persisted in all 32 pairs, including 13 pairs that lost a nest and attempted renesting. In Colorado, only 1 female returned to her territory and mate of the previous year. None of her eggs were fertilized by that male in the previous year. Males commonly intrude into neighbouring territories and inspect the nest sites. Intrusions are more frequent at replacement than first nests when nesting chronology becomes asynchronous. In Colorado, 53% of broods had evidence of extra-pair paternity, with 20-100% of clutches affected and 32% of young resulting from extra-pair fertilizations. Neighbouring males usually sired extra-pair young, even though floater males were common. The high prevalence of extra-pair fertilization in the reproductive strategy of the Wilson's Warbler may partially explain the tendency for territories to be clumped. No intraspecific egg dumping has been observed, but there was 1 possible case based on DNA analysis (Ammon and Gilbert 2020).

All available information on the Wilson's Warbler breeding season foraging behaviour and diet is for the western subspecies. It typically forages in the shrub layer and rarely on the ground. Most studies demonstrated that it forages at low heights. In the Sierra Nevada, optimum habitat consisted of dense thickets of willow with scattered pines extending 10-13 m above the willows. The pines were a source of abundant prey and females feeding nestlings foraged heavily in the pines. It tended to forage as high as the upper limits of vegetation. Although it favoured pines for foraging in the Sierra Nevada, it avoided conifers in Oregon (Hutto 1981; Morrison 1981; Stewart et al. 1981). Foraging tactics of the Wilson's, Orange-crowned and MacGillivray's warblers were compared in Oregon by Morrison (1981). The Wilson's Warbler was associated with trees, the MacGillivray's Warbler with shrubs, and the Orange-crowned Warbler was intermediate in its foraging height. In this study area, trees consisted of alders about 7 m tall. Where trees were present, the Wilson's Warbler was usually separated from the other 2 species but Orange-crowned Warblers occasionally used trees. Where trees were removed, the Wilson's Warbler increased its use of shrub cover for foraging. It exhibited limited adaptation to foraging in shrubs and declined when trees were

removed. Its abundance was correlated with the abundance of deciduous trees. Where trees were removed, each foraging substrate was used in proportion to its availability. Foraging heights were significantly higher in areas with trees (2.4 m compared with 0.8 m); 17.7% of foraging occurred 0-1 m from the ground in treed areas compared with 68.5% in untreed areas; 56.3% occurred at 1.1-3 m in treed areas compared with 28.4% in untreed area; and 25.9% occurred above 3 m in treed areas compared with 3.2% in untreed areas. In Wyoming and Mexico, Hutto (1981) compared the foraging strategies of the Wilson's, Yellow, and MacGillivray's warblers and the Common Yellowthroat. The Wilson's Warbler predominated in willows; the Yellow Warbler in taller alders, aspens, or cottonwoods; the Common Yellowthroat in cattails and bulrushes; and the MacGillivray's Warbler in wet thickets. The Wilson's Warbler foraged from the ground to more than 4.9 m above it. Six percent of foraging was at a height of 0-0.3 m, 15% at 0.3-0.6 m, 44% at 0.6-1.2 m, 20% at 1.2-2.4 m, 10% at 2.4-4.9 m, and 5% above 4.9 m. It differed significantly from the other species for absolute foraging height and from the MacGillivray's Warbler and yellowthroat for relative foraging height, vegetation density, foraging position, foraging substrate, and feeding methods. The feeding methods differed because the 2 high-foraging species (Wilson's and Yellow warblers) sallied more frequently for aerial insects. The 4 species were least similar in the absolute heights at which they fed and most similar in their feeding methods. Foraging locations may be important in promoting ecological isolation. The Wilson's Warbler foraged higher in August than in June at heights most similar to those of the Yellow Warbler. Late-summer foraging heights were 4% at 0-0.6 m, 10% at 0.6-1.2 m, 31% at 1.2-2.4 m, 46% at 2.4-4.9 m, and 9% above 4.9 m. In June, vegetation density at foraging locations was 0-15% at 28% of sites, 15-50% at 49% of sites, 50-85% at 18% of sites, and 85-100% at 6% of sites. In the Sierra Nevada, aerial foraging occurred at heights of 0.6-16.8 m. Foraging occurred as high as 12.2 m in pines (Stewart et al. 1977). On the California coast, both sexes fed in the understorey and trees, but usually not higher than 1.5 m below the top of the canopy (R.M. Stewart 1973). Foraging is predominantly by gleaning, although the Wilson's Warbler also hovers and sallies. In the Rocky Mountains, 75% of foraging was by gleaning, 15% by hovering, and 10% by sallying. In Wyoming, 56.6% of foraging was by gleaning, 37.4% by sallying, and 5.9% by hovering; 1.8% of foraging was on the ground, 35.2% on bark, 25.6% on foliage, and 37.4% in the air. In the Sierra Nevada, 34.3% of foraging was by gleaning, 41.3% by hovering, 20.0% by partial hovering (moving through the air without flycatching or wing fluttering), and 4.3% by flycatching. On the California coast, 45.1% of foraging was by gleaning, 32.4% by hovering, 21.1% by partial hovering, and 1.4% by flycatching. On San Clemente Island, 63.1% of foraging was by gleaning, 23.3% by hovering, 7.8% by partial hovering, and 5.8% by flycatching. When all 3 California sites were combined, adults hovered or flycatched on 51.2% of food-catching attempts. Hovering and flycatching allows it to capture insects that land on leaves, especially those at the tips of branches that would not support the weight of the bird. Of California prey-catching attempts on solid substrates, 97% were on leaves and 3% were on twigs smaller than 6 mm in diameter (Ammon and Gilbert 2020; Hutto 1981; Stewart et al. 1977).

Nestlings are fed small soft-bodied insects and very small caterpillars (Ammon and Gilbert 2020; Bent 1953; Harrison 1951; R.M. Stewart 1973; Stewart et al. 1977). An analysis of 53 stomachs of one of the western subspecies revealed that the breeding season diet consisted entirely of insects with a few spiders; some fruit was consumed in autumn. The diet consisted of 35% bugs (mostly leafhoppers), 31% hymenopterans (wasps and ants), 11% flies (including many crane flies), 9%

beetles (mostly leaf beetles with a few weevils), less than 5% caterpillars (which were eaten very irregularly), and 1% spiders (Bent 1953). Raley and Anderson (1990) analyzed the contents of esophagi and gizzards in Wyoming and sampled arthropod populations on willows where warblers had been observed foraging. The Wilson's Warbler was selective in the size of prey it consumed. Arthropods 1-3 mm in length were consistently underrepresented in the diet. The size of mayflies consumed was similar to what was available. A total of 53 families of arthropods, excluding spiders, most lepidopterans, and miscellaneous orders such as springtails and book lice, were identified in the diet. Beetles were most preferred, followed by mayflies, stoneflies, flies, and hymenopterans. These were consumed in greater proportion than their availability. Soft-winged bugs were least preferred, followed by larvae (immature beetles, hymenopterans, and caterpillars), spiders, adult lepidopterans, and true bugs. These were consumed in lower proportion than their availability. No clear distinctions could be made about preferences within these groups. Use of beetles, mayflies, and stoneflies was statistically higher than for the 5 groups that were avoided. Use of soft-winged bugs and larvae was statistically lower than for all other groups. Stoneflies larger than 7 mm were underrepresented in the diet although these were more abundant than the size class of stoneflies that it consumed. Large stoneflies may take too long to handle to be profitable. Even though soft-winged bugs were least preferred, leafhoppers comprised 16% of the diet and were therefore important. The larvae group ranked low but comprised 30% of the diet. The larvae and soft-winged bugs are cryptic and leafhoppers respond to disturbance with very quick and erratic jumps. These factors may make these 2 groups of prey less available than their abundance would suggest. Soldier beetles represented a large proportion of the beetles that were consumed. These are noncryptic, have soft elytra, are relatively large (7 mm), are slow fliers, and tend to crawl away from disturbance rather than fly. Consequently, they are easy and profitable prey. All arthropods that ranked high in the diet were noncryptic and patchy in distribution. Hagar et al. (2007) analyzed 87 fecal samples in Oregon and identified 15 groups of taxa. The percent occurrence of taxa within the samples was: 99% flies, 86% soft-winged bugs, 85% spiders, 84% beetles, 63% caterpillars, 46% wasps, 23% leafhoppers, 20% sawfly larvae, 18% adult lepidopterans, 14% arthropod eggs, 5% neuropterans, 5% springtails, 2% mites, 2% book lice, and 1% true bugs. Nine families within 4 orders were also identified: soft-winged bugs: achilid planthoppers, aphids, and froghoppers; neuropterans: green lacewings; beetles: soldier beetles and tumbling flower beetles; and flies: dance flies, fungus gnats, and dark-winged fungus gnats. The average size of prey was 4 mm (range 2-10 mm). The Wilson's Warbler consumed prey that was larger than the most abundant items available. It did not consume the largest available size classes (longer than 12 mm) of adult arthropods, including flies, beetles, and spiders. Larvae, predominantly caterpillars and sawflies, were the largest prey items consumed, ranging from 6 to 26 mm in length. It ate mostly larva longer than 6 mm, which were less frequent than those in the smaller size classes. It consumed a wide variety of prey but ate caterpillars, flies, beetles, and soft-winged bugs more frequently than expected. Caterpillars and sawfly larvae have high calcium concentrations relative to other species and provide an essential resource for egg laying. Regardless of taxa, arthropods 2 mm in length and less were infrequent in the diet even though this size-class was abundant.

Brown-headed Cowbird parasitism does not appear to have been documented for the eastern subspecies of the Wilson's Warbler. In the west in some areas, no parasitism occurs; it is the most

frequent host in other areas. In British Columbia, 1 of 46 nests (2.2%) was parasitized. In the Sierra Nevada, no parasitism occurred in 1 year and 1 nest was parasitized in another year. At 1 California site, the parasitism rate was 0% over 5 years, 0-3% of nests were parasitized in Colorado over 3 years, 2 of 71 Colorado nests (2.8%) were parasitized, and 55% of nests in southern California and 43% of nests at another California site were parasitized. At the 2 latter sites, the Wilson's Warbler was one of the most common hosts. In coastal California, 30 of 90 nests (33.3%) were parasitized. Only 1 (3.3%) successfully fledged a warbler compared with 25% of unparasitized nests. Parasitism significantly affected reproductive success at every stage. The clutch size of parasitized nests was 1.96 eggs compared with 3.48 eggs in unparasitized nests. Hatching success was 36% in parasitized nests and 64% in unparasitized nests, brood size was 0.71 nestlings in parasitized nests and 2.31 in unparasitized nests, and fledging success rate was 4% in parasitized nests and 28% in unparasitized nests. Parasitized nests failed completely except for 1 nest (Ammon and Gilbert 2020; Campbell et al. 2001; Harrison 1984; Michaud et al. 2004; Stewart et al. 1977).

Habitat loss and degradation do not appear to be significant for the Wilson's Warbler in Ontario. Loss of riparian habitat may be contributing to its decline in the west. In Ontario, forest harvesting is not allowed within 200 m of watercourses and water bodies, so its preferred riparian thickets of alder and willow are not affected. Clear-cutting may create wet patches of shrubs that provide suitable habitat until a tree canopy develops (Alvo in Gauthier and Aubry 1996; Ammon and Gilbert 2020; Desrochers et al. 2012).

In Ontario in the Canadian Shield, there was no difference in its abundance in early and mid-successional stages of clear-cuts compared with similar stages after fire. There was no difference in its abundance in mid-successional and mature forests, but it was significantly more abundant in early successional forests than in mature forests (Zimmerling et al. 2017).

In Alberta, the Wilson's Warbler was significantly more abundant near well pads than in adjacent forest interior. There were no significant differences in its abundance near seismic lines and pipelines and adjacent forest interior (Bayne et al. 2016).

Factors that change the density of shrubs may affect the Wilson's Warbler abundance. On Anticosti Island, browsing by white-tailed deer reduced shrub density and shrub-dependent birds once deer densities exceeded 7.5 per km^2. In the west, cattle browsing in woodlands and riparian habitat has adverse effects on the Wilson's Warbler (Ammon and Gilbert 2020; Cardinal et al. 2012). In Ontario, the core breeding range of the Wilson's Warbler is north of the areas of high deer density and it is unlikely that any of its habitat is grazed by cattle. Numbers of this warbler have been demonstrated to decline significantly after herbicides that target deciduous species and promote growth of conifers are sprayed (Ammon and Gilbert 2020). In Alaska, it responded favourably to high infestations of spruce beetles. In areas of high tree mortality, the canopy was opened and shrub growth increased, thereby improving habitat (Matsuoka et al. 2001). The Wilson's Warbler may benefit from insect outbreaks, tree diseases, and blowdown.

In Oregon, Stephens et al. (2015) observed no clear pattern of increases or decreases over a period of 9 years following a forest fire. The Wilson's Warbler was unaffected by the severity of the fire.

Unusually adverse weather conditions during the breeding season can affect reproductive success. In Colorado, 19% of nests containing recently hatched young were deserted during a heavy snowstorm. In 1 year in the Sierra Nevada, a hailstorm destroyed all nests (Ammon and Gilbert 2020; Stewart et al. 1977).

Near Seattle, Marzluff et al. (2007) studied habitat use by the Wilson's Warbler in relation to predator density. It was rare where crows were abundant, but most common where chipmunks and squirrels were most abundant. It was rarely able to avoid habitat patches that supported predators. Its reproductive success was low, probably due to predation.

In Colorado, nest desertion rates were higher in areas used by recreational visitors. The Wilson's Warbler was particularly sensitive to desertion during incubation. In contrast, numerous California nests were within 1 m of recreational trails and none were deserted (Ammon and Gilbert 2020).

Price (2004) concluded that the Wilson's Warbler could disappear as a breeding species from southern Ontario if the average summer temperature increased by 2°C. It is a rare and infrequent breeder in the south, so this may not be a major limiting factor. DesGranges and Morneau (2010) observed that it appeared to be correlated with cooler and wetter summers in southern Quebec and concluded that it was very sensitive to climate change.

Status

Baillie and Harrington (1937) considered the Wilson's Warbler an uncommon summer resident in parts of Thunder Bay, Sudbury, and Cochrane districts, and probably throughout the more northern portions of the province. At that time, the only confirmed breeding records were from Sudbury and Lake Abitibi. The first atlas confirmed that its breeding range extended from the Sudbury area north to Hudson Bay, with isolated records in the southern portion of the Canadian Shield. These more southerly records may have been late migrants. It apparently bred sporadically as far south as the 20°C July isotherm. It was more common in the north than in the south (Helleiner in Cadman et al. 1987). Peck and James (1998a) reported a nest on Manitoulin Island which is the most southerly confirmed breeding record. James (1991) considered the Wilson's Warbler a common summer resident across the province south to Sudbury, with summer sight records south to Algonquin Park and Ottawa. Wilson and McRae (1993) concluded that it was a very common breeding bird in the Moosonee area.

The second atlas demonstrated that there had been no changes in the distribution of the Wilson's Warbler since the first atlas. The few records of breeding evidence south of the Sudbury area were once again considered late migrants. Its probability of observation increased significantly since the first atlas province-wide and in the Boreal Forest Region and Hudson Bay Lowland. It was uncertain if this represented a true increase in numbers and infilling of its range, or greater efforts to survey difficult-to-access habitats. It was most abundant in the Hudson Bay Lowland. It was approximately 3 times more abundant there than in the Boreal Forest Region. The shrub thicket habitat that it prefers is more abundant in the Hudson Bay Lowland (McLaren in Cadman et al. 2007).

Ammon and Gilbert (2020) reported that the Wilson's Warbler increased significantly in Canada at a rate of 6.6% per year 1966-96 according to the Breeding Bird Survey (BBS). The general trend over that time includes increases in the northwestern and northeastern regions and significant

decreases in Pacific coast populations. At the end of that period, there were declines in several eastern regions, continuing declines in western populations, and a decline in the entire North American population. By the end of the 20th century, the entire population was experiencing a decline of approximately 2% per year according to the BBS (Desrochers et al. 2012; Michaud et al. 2004). The BBS is not a reliable indication of trends in breeding populations of the Wilson's Warbler. Most of its range is in areas that are not covered by this survey. There are no BBS routes in the Hudson Bay Lowland where it is most abundant in Ontario. BBS results indicate that it increased at an annual rate of 0.574% in Canada and decreased at an annual rate of 1.31% in Ontario 1970-2021. Trends for 2011-21 were an annual increase of 0.297% in Canada and an annual decrease of 2.88% in Ontario. All results were of medium reliability except that the short-term trend for Ontario was of low reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

In California, a peak of adult wandering occurred in the latter half of June. First broods are complete by then so adult wandering probably occurs after breeding or attempted breeding when territoriality is waning (R.M. Stewart 1973). In California, adults undertook an altitudinal moult migration after breeding. For every 1,000-m increase in elevation, recaptured birds were 2.47 times more likely to display moult (Wiegardt et al. 2017). It is uncertain if eastern populations exhibit the same wandering tendency. If so, it would occur later in the season, possibly in late July or later.

Young are unable to fly a few hours to a day after fledging. Initially young remain in the underbrush 10-20 m apart. Young may return to the nest at night for several days after fledging in Colorado. Brood division occurs after the young leave the nest. The sexes may care for equal numbers of fledglings or the female may care for more young than the male. Late-season fledglings are attended by the female only. Young can fly strongly by age 13 days and make their first foraging attempts at age 16 days. Broods have been observed being fed 25 days after they leave the nest (Ammon and Gilbert 2020) and began to leave the territory at age 32 days in California (R.M. Stewart 1973). On 4 July near Rivière-du-Loup, Quebec, 11 recently fledged young were captured together in a mist net, suggesting that birds may travel through the understorey in groups (Alvo in Gauthier and Aubry 1996).

In Minnesota, Streby et al. (2011b) captured 30 Wilson's Warblers (7 adults and 23 juveniles) during 4 postbreeding seasons in clear-cuts 2-10 years old. Netting was also conducted during 1 breeding season and a single adult was captured. In clear-cuts 5-12 years old in Quebec, Major and Desrochers (2012) captured 15 Wilson's Warblers in 2 postbreeding seasons. In California, only 3.3% of juveniles were captured in mist nets situated more than 10 m from riparian woodland, the preferred habitat (Chase et al. 1997).

MIGRATION

The Wilson's Warbler migrates nocturnally either singly or in small groups of the same or different species. At daytime stopover sites, it is often seen singly but occasionally in the company of other species. One banded in Ontario at Mitchell's Bay was recovered in Texas, having travelled in a southwestern direction. Another banded at the mouth of the Humber River was recovered in Pennsylvania and had travelled due south (Ammon and Gilbert 2020; Brewer et al. 2018; Kelly et al. 2002a; Paxton et al. 2007, 2013; Ruiz-Sánchez et al. 2015).

Males arrive before females in the spring, and this has been confirmed for the eastern subspecies in Illinois and Ontario. At Prince Edward Point, the mean capture date of males (23.0 May) was 2.1 days earlier than for females (25.1 May), a significant difference (Francis and Cooke 1986; Graber et al. 1983). The interval between arrivals of the sexes of the western subspecies is highly variable, with greatest intervals where there is a long breeding season. Over 5 years in California, males arrived before females by 30, 21, 26, 12, and 6 days. In New Mexico, males arrived an average of 5 days earlier than females. In Arizona, males arrived 9.97 days earlier than females on average and in Alaska males preceded females by 5 and 8 days at 2 different sites (Benson et al. 2006; Otahal 1995; Paxton et al. 2007; Yong et al. 1998). In California, older males appeared to arrive before yearlings (R.M. Stewart 1973). In the west, warblers that bred at southern latitudes the previous year migrated earlier in spring than those that bred further north (Paxton et al. 2007). In New Mexico, the recapture rate in spring was significantly lower for males (5.2%) than for females. The stopover duration of the sexes combined was 2.52 days in spring (Yong et al. 1998). The authors predicted that males should migrate earlier in spring, have a lower capture rate, and have a higher fat deposition rate than females. It is advantageous for males to migrate earlier and faster in spring so they can establish territories in high-quality habitats. It is better for females to arrive later on the breeding grounds because this reduces the risks of adverse weather conditions, food resources are more plentiful, and males have established territories allowing females to assess the relative qualities of territories and males. In California, there were no differences in the stopover durations of the sexes in spring. Males remained on site an average of 4.4 days (range 1-13 days) and females remained on site an average of 3.4 days (range 1-9 days; Otahal 1995). In Arizona, the average spring stopover time was 2.5 days in 1 year and 4.2 days in the second year (Paxton et al. 2008). In Arizona, Hays et al. (2018) captured spring and autumn migrants and used plasma metabolite analyses to determine refueling rates and feather stable isotope analyses to determine origins of individuals. Birds breeding in Alaska to northern British Columbia migrated approximately 6,000 km compared with 2,000 km for those breeding in California. In spring, males arrived an average of 14.3 days before females and shorter-distance migrants also arrived earlier. Later-arriving migrants had higher fat scores and refueling rates, but migration distance and sex were unrelated to body condition, refueling rate, or length of stay. Minimum length of spring stopover was 1-31 days (median 1 day). Many male short-distance migrants stopped over in spring but most females from these areas did not. Many long-distance females stopped over in spring but most long-distance males did not.

In southern and central Ontario, most spring migrants are seen in the latter half of May. Average arrival is mid-May but some may arrive in the first week of May. Most have left by the end of May with a few remaining into early June (Black and Roy 2010; Curry 2006; Fleming 1907; Keast 1980; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008).

In autumn, there is no difference in the timing of migration by the sexes, but juveniles migrate earlier in most locations than adults. In Alaska, juveniles preceded adults by 6, 10, 11, and 13 days at 4 sites. Juveniles arrived 9 days earlier than adults in southwestern Idaho, and young started migration earlier than adults in Virginia and West Virginia. In New Mexico and South Dakota, there were no significant differences in the migration timing of the age classes. Juveniles initiate migration earlier because they do not have to moult, unlike the adults. The differential timing of migration may diminish southward because juveniles migrate slower, remaining longer at stopovers due to their

lower efficiency in foraging and because they may be relegated to inferior habitat. In New Mexico, the recapture rate for adults (7.6%) tended to be lower than for juveniles (9.7%), but not significantly. In autumn, adults had a significantly shorter stopover duration of 2.20 days compared with 2.42 days for juveniles. This suggested that juveniles migrated at a slower rate, and juveniles were in poorer condition than adults with lower fat scores and shorter, more rounded wings, thereby consuming more energy in flight. In Arizona, males tended to arrive later than females but the difference was not significant. Longer-distance migrants and males had higher refueling rates than shorter-distance migrants and females. Stopover durations were shorter in autumn than in spring (range 1-4 days, median 1 day; Benson et al. 2006; Dean et al. 2004; Otahal 1995; Stewart 1986).

Wilson and McRae (1993) observed Wilson's Warblers on 21 and 28 August at Shagamu that were probably autumn migrants. Average arrival in the southern Shield is mid-August, and all pass through by the end of September (Mills 1981; Tozer 2012). In the south, most pass through from late August to early September, with the earliest arrivals in early August. Most leave by the end of September with rare records to early November (Black and Roy 2010; Curry 2006; Fleming 1907; Keast 1980; LaForest 1993; Lancaster et al. 2004; Weir 2008). In the Hamilton area, 1 bird was observed from 26 December to 7 January where it frequented a small stream in a deeply incised valley. There was a severe storm with snow and freezing rain on the last day it was observed (Curry 2006).

During migration, the Wilson's Warbler continues to prefer shrubby areas, although it may occur in lesser numbers in forested areas (particularly those dominated by deciduous trees) and other areas where woody vegetation occurs. Other areas may include suburban habitats, farmsteads and rural residential areas, shrubby roadsides, and urban parks (Ammon and Gilbert 2020; Chapman 1907; Tyler in Bent 1953). In Algonquin Park, it is seen most frequently in dense thickets of willow or alder (MacLulich 1938; Tozer 2012). During spring migration on islands in the Gulf of Maine, it was significantly more abundant on an island dominated by deciduous shrubs and saplings than on a treed island. In autumn, it was significantly more abundant on the same island in 1 of 2 years (Suomala et al. 2010). During autumn migration in Pennsylvania, it was equally abundant in forest edges, shrub-sapling-stage forests, forest-agricultural edges, and suburban forests, but was absent in forest interior and pole-stage forests (Rodewald and Brittingham 2002). In Illinois, it was most abundant in shrub and forest edge habitat, especially in hawthorn meadows, and also occurred in willows. It occurred in lower numbers in bottomland and upland forests (Graber et al. 1983). Tyler (in Bent 1953) stated that the eastern subspecies was more likely to occur in dry habitats in autumn, such as oaks and pines growing on high ground.

The western subspecies appear to be even more reliant upon shrub habitat during migration. In the Yukon, it inhabits deciduous shrubs and trees such as balsam poplar and trembling aspen, and is most common in shrubby wetlands (Sinclair et al. 2003). In British Columbia, it frequents thickets and linear stands of shrubs and low trees at edges of lakes, beaver ponds, stream banks, sloughs, beaches, shoreline spits, airports, sewage lagoons, cleared fields, and hydro rights-of-way. In boreal forests, it occurs mostly in mixed woods and shrubby edges of willow, white birch, and alder in spring. In autumn, it occurs at edges of bogs and fens, in willow hedgerows, and wet areas where willows and other shrubs predominate. In British Columbia, it was significantly more abundant in riparian shrub areas than in forests in autumn. It was more abundant in riparian areas

in spring, but not significantly (Campbell et al. 2001; Wiebe and Martin 1998). During autumn migration in South Dakota, the Wilson's Warbler was more abundant in a 3.5-ha woodlot than in a contiguously forested riparian corridor (Dean et al. 2004).

Three studies in the southwest determined habitat preferences of migrating Wilson's Warblers. In New Mexico, it was more common in willows in spring than autumn but more common in willows than in any other habitat during both migration periods (Kelly et al. 2000). In New Mexico, capture rates differed among habitats in spring when 72% of all birds were captured in willows. In spring, the capture rate of females was highest in willow and saltcedar habitats. Males were more common in the other 4 habitat types: agricultural field–edge, cottonwood with a native understorey, cottonwood with a Russian olive understorey, and cottonwood with a saltcedar understorey. In autumn, there were significant differences in habitat usage by sex and age classes, although there was a more even distribution of birds among habitats. Overall capture rate was highest in agricultural field–edge, followed by cottonwood with a Russian olive understorey, and willows. The capture rate of adults was proportionally higher in willows and cottonwood with saltcedar and native understories than for juveniles. Juveniles were more abundant in agricultural field–edge, cottonwood with a Russian olive understorey, and saltcedar. Capture rates differed significantly among the habitats for the sexes, but these differences were small compared with the variation among age classes within a given habitat. The rate of mass gain varied among habitats, with birds in agricultural field–edge exhibiting the lowest rate of mass gain. Birds in this habitat tended to have longer stopovers (3.16 compared with 2.16 days). In spring, 88% of birds were recaptured in the same habitat compared with 53% in autumn; the difference between sexes was not significant. The seasonal shift in habitat preferences may have been due to changes in resource availability. It was more abundant in willows in spring because this plant supports more arthropods. Habitat switching was more frequent in autumn consistent with juveniles being forced to leave more productive willow habitat where they initially tried to settle (Yong et al. 1998). In Arizona, Paxton et al. (2008) studied movement patterns and habitat usage of spring migrants at a stopover site. The mean rate of movement was 61 m per hour (range 11-173 m) in 1 year and 102 m (range 11-720 m) in the next year. The rate of movement of yearlings was 55% greater than that of adults. The linear movement from sunrise to sunset decreased by 32% each successive day that a bird remained at the site. On average, birds moved 332 m (range 0-6,341 m) from their release point in the morning to their nocturnal roost. With time, movements became more aggregated within localized areas of use. All exploration by birds was restricted to small areas, primarily less than 2 km in diameter within the overall landscape, and they never left riparian habitat. The general location where a bird landed was critical in determining the resources available to it. If food resources are inadequate, the bird may depart rather than extend local exploration over several days. Initially, 84% of observations were in native vegetation when it was flowering, but numbers in native vegetation declined by 7% a day and only 24% of observations were in native vegetation once nonnative vegetation began flowering. As birds gained more information about the distribution of resources, they settled into a high-quality microsite. Flowering phenology strongly influenced the location of warblers such that additional exploration was required later in the season to locate sites dominated by nonnative shrubs.

Recapture data indicate that at least some birds use the same stopover sites in multiple years (Ammon and Gilbert 2020).

During migration, the Wilson's Warbler feeds mostly in shrubs and short deciduous trees, often in willows near water. During autumn migration at Prince Edward Point, foraging occurred 3-6.6 m from the ground. Overall, it has been reported feeding at heights of 0.5-7 m during migration. At Prince Edward Point, 35% of foraging was on outer leaves, 18% on inner branches, 12% on trunks, and 35% on sapling foliage. Foraging was not observed on twigs and inner leaves, outer branches, sapling branches, low shrubs, or on the ground or in the air (Ammon and Gilbert 2020; Keast 1980; Tyler in Bent 1953).

A study of 52 stomachs of the western subspecies revealed that 7% of the diet consisted of fruit pulp that was eaten predominantly during autumn migration in September and October. The Wilson's Warbler may also eat honeydew produced by scale insects. In the Yukon, aphid outbreaks occasionally attract large numbers of autumn migrants (Ammon and Gilbert 2020; Bent 1953; Sinclair et al. 2003).

During autumn migration in New Mexico, the Wilson's Warbler responded positively to food abundance. Its abundance was significantly correlated with abundance of hymenopterans, flies, and beetles captured in traps, but not with abundance of soft-winged bugs. Migrants passing through during peak migration times would be more likely to encounter depleted food resources and have more difficulty in refuelling than those migrating before or after the peak. Depletion of food resources could contribute to early passage of adults relative to juveniles and the use of inferior habitats by juveniles (Kelly et al. 2002b).

In Pennsylvania, an outbreak by the viburnum leaf beetle resulted in almost complete mortality of the southern arrowwood, which was formerly the third most abundant shrub species. After the infestation, the number of spring migrating Wilson's Warblers declined significantly (Smith and Hatch 2017).

During a dry year in Arizona, there were increased daily movements of birds and the minimum stopover time was twice as long as in a year with normal precipitation rates. Drought conditions may reduce arthropod abundance, requiring warblers to travel further daily to obtain sufficient food. It also takes longer to refuel when it is dry (Paxton et al. 2008). An unusually cold spring in Arizona appeared to lower the survival rate of migrants (Ammon and Gilbert 2020).

The Wilson's Warbler collides with tall structures such as television towers and hydro transmission towers during migration. Mortality associated with collisions does not appear to be unusually high. Seventy-eight were killed at the Lennox generating station chimneys 1972-82 (Ammon and Gilbert 2020; Graber et al. 1999; Leighton et al. 2002; Weir 2008).

Band recoveries suggest that domestic cats may cause significant mortality in migration stopover sites (Ammon and Gilbert 2020).

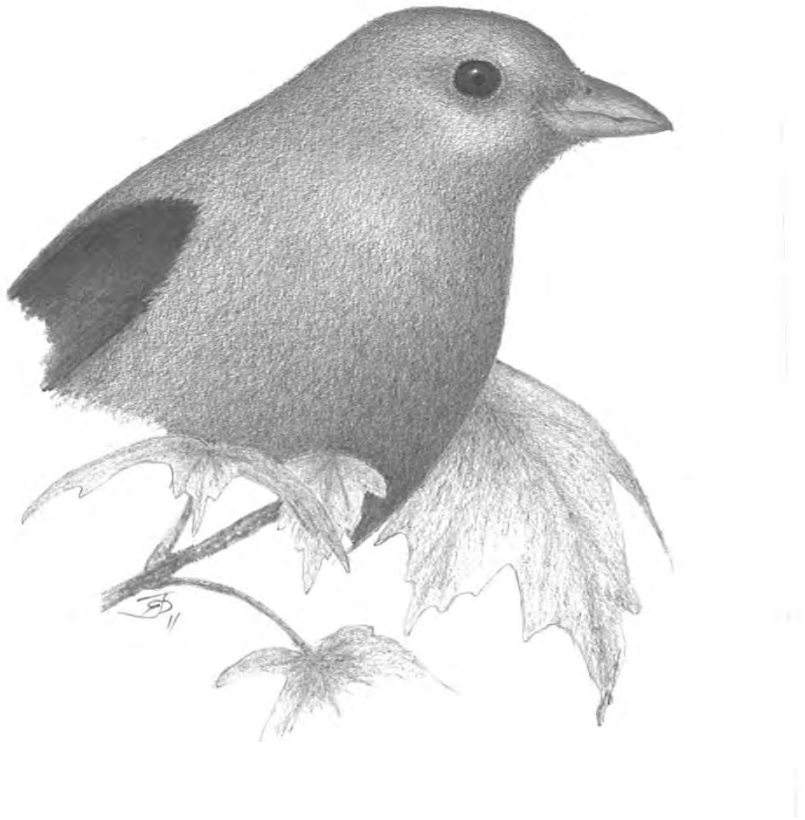
At Delta Marsh, Murphy-Klassen et al. (2005) analyzed the first date of spring arrival 1939- 2001. Arrival date was significantly correlated with temperature. The Wilson's Warbler arrived significantly earlier in the later years, which were associated with increasing temperatures. In New York, Zelt et

al. (2017) compared spring arrival dates, autumn departure dates, and length of the breeding season for 1888-1939 and 1967-2012. There was little climate change during the first period but significant warming occurred in the second period. The Wilson's Warbler arrived significantly earlier, departed significantly later, and had a significantly longer breeding season during the second period.

James (1991) considered the Wilson's Warbler a common migrant, but it is an uncommon migrant in Elgin County, Niagara Region, and Algonquin Park (Black and Roy 2010; Lancaster et al. 2004; Tozer 2012). At Long Point Bird Observatory, captures of the Wilson's Warbler decreased significantly at a rate of 3.2% per year 1961-88. Trends by period included: 1961-70, −5.9%; 1970-79, +9.1%; and 1979-88, −5.3%. It showed a similar but less marked response as the spruce budworm specialists, suggesting that it may be affected by outbreaks to some degree (Hussell et al. 1992).

Scarlet Tanager

Piranga olivacea

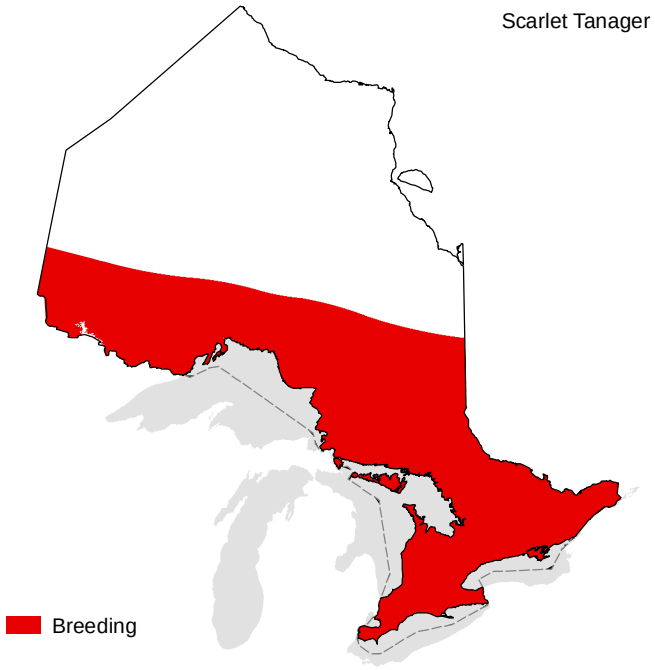


BREEDING SEASON

Habitat Requirements

Ontario Scarlet Tanager nests were near the edge of, or within, deciduous and mixed forests. It preferred deciduous forests. Equal numbers of nests were in closed-canopy woods and near open areas such as fields, roads, and water. Two nests were in a coniferous plantation near deciduous forest, one was in a spruce–sphagnum moss bog, and another was in an open sedge meadow (Peck and James 1987).

The Scarlet Tanager is sparsely distributed in the Boreal Forest Region of Ontario. Erskine (1977) considered it more characteristic of the transitional sugar maple–beech forests of eastern Canada. In the boreal forest, he reported it in pure poplar or white birch stands and poplar stands mixed with balsam fir. North of Lake Nipigon, it nested in tall poplar stands but not in those dominated by black spruce and balsam fir (Sanders 1970). In the Clay Belt, Welsh and Lougheed (1996) found it breeding in only 1 stand dominated by white spruce and balsam fir with minor inclusions of white cedar and



black spruce. The site was moderately rich in nutrients with wet soils. Venier et al. (2009) reported it in low densities in mature (60-223 years) mixed stands near Manitouwadge.

In jack pine stands near Gogama, the Scarlet Tanager was associated only with taller deciduous trees in mixed stands (James and Peck 1995a). In old-growth and mature white pine stands in the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region, it was never numerous because it was at the northern extent of its range. It was more abundant in old-growth stands, probably because of the higher proportion of deciduous growth (Kirk et al. 2012). In Algonquin Park, it was fairly common in maple stands but uncommon elsewhere (MacLulich 1938). Tozer (2012) concluded that it preferred mature hardwood stands with a small component of hemlock or white pine. It was infrequent in shelterwood cuts in Algonquin Park white pine stands (Kingsley and Nol 1999). Also in the park, Martin (1960) considered the Scarlet Tanager characteristic of deciduous forests but reported it in very low density in a black spruce–white cedar stand. It occurred in northern hardwoods, poplar–white birch stands, and balsam fir–spruce stands mixed with hardwoods. In hardwoods, it occurred at heights of 3-30 m, from the shrub layer to the top of the canopy. It ranged 12 m higher than any other species.

In Durham Region in the off-Shield portion of the Great Lakes–St. Lawrence Forest Region, the Scarlet Tanager occurred in open deciduous forests with standing water, a mature pine plantation with a remnant sugar maple–red oak forest, and mature sugar maple–oak and sugar maple–beech forests (Speirs and Orenstein 1975).

South of the Shield in Ontario, the Scarlet Tanager was positively correlated with the amount of forest 100 m from edge, woodlot size, the amount of forest cover within 2 km, and the amount of regional forest cover. Only the relationship with forest size was significant (Austen et al. 2001). It usually occurred only in larger woodlots in Elgin County (Lancaster et al. 2004).

Throughout its range, the Scarlet Tanager nests mostly in deciduous and mixed forests, particularly those containing hemlock or white pine. In many areas, it highly prefers oak stands over other deciduous species, but it commonly nests in sugar maple and beech forests. In more northern areas, it frequently nests in stands dominated by poplars or white birch, often mixed with spruce, hemlock, or balsam fir. In Virginia and Michigan, it preferred oak and mixed oak-pine stands. Highest densities in Quebec occur in red oak stands. In North Dakota, highest densities occurred in bur oak–green ash stands. It occurs in both upland and lowland stands, but is most prevalent in upland forests (Beals 1960; Bushman and Therres 1988; Faanes and Andrew 1983; Lanoue and Gauthier in

Gauthier and Aubry 1996; Létourneau in Robert et al. 2019; Mossman 1988; Mossman and Hoffman 1989; Mowbray 2020; Shugart and James 1973; Temple et al. 1979; Vega Rivera et al. 2003; Walley 1989b). Less frequently, it nests in other habitats such as extensive plantings of shade trees in suburban areas, parks, and cemeteries; strip-cuts and clear-cuts; pine and oak barrens; orchards; pastures invaded by red cedar; and coniferous plantations (Bielefeldt and Rosenfield 1994; Falardeau et al. 1999; Mossman et al. 1991; Mowbray 2020; Streby et al. 2011b; Tyler in Bent 1958).

Several studies examined habitat of the Scarlet Tanager at the landscape scale. In the eastern United States, 28% of its detections on Breeding Bird Survey (BBS) routes were in fragmented landscapes (Donovan and Flather 2002). Villard et al. (1992, 1995) determined that it acted as a metapopulation in the Ottawa area. They studied 70 woodlots within an area of 125 km^2. The total number of pairs within the study area remained constant over 2 years, but the individual woodlots that it occupied varied. Local extinctions and recolonizations occurred within woodlots, and this occurred in woodlots that were larger than those that consistently supported no tanagers. Its presence in a woodlot was dependent upon patch size, but patch isolation might also be an important factor in determining whether a woodlot is occupied. In Quebec, it occurs mostly in the southern portion of the province in regions where the forest is dominated by sugar maple. In more northern areas, it is associated with the few deciduous and mixed stands. It is mostly absent in the Boreal Forest Region and at elevations above 500 m (Lanoue and Gauthier in Gauthier and Aubry 1996; Létourneau in Robert et al. 2019). In Pennsylvania, it was associated with oak-hickory-maple stands. It occurred in large forest patches in less fragmented landscapes, with 40% forest cover rather than 15% (Keller and Yahner 2007). In North Dakota, it preferred landscapes that were 59-75% forested, with no areas having more than 75% forest cover. In New York, it preferred areas that were 81-100% forested (Cunningham and Johnson 2019).

Although the Scarlet Tanager appears to prefer mature forests, it nests in a wide range of successional stages. Mowbray (2020) concluded that it preferred tall deciduous trees in mature stands. DeGraaf and Chadwick (1987) determined that it occurred predominantly in sawtimber-size northern hardwoods and red maple stands, but it also occurred in other successional stages. Preferred stands had intermediate-sized trees and density and intermediate values of shrub density. In mesic forests in Wisconsin, it occurred predominantly in sawtimber-size stands (Hoffman 1989a). In Maryland, it occurred from early successional to mature stands, but was most abundant in mature stands (Bushman and Therres 1988). In northeastern upland hardwoods, Noon et al. (1979) reported it in 78% of mature undisturbed forests and 43% of disturbed and early successional forests. In northeastern poplar–white birch stands, Back (1979) reported it in sapling-pole-stage stands but not in seedling-stage or mature forests. In northeastern pine stands, it occurred in mature stands and was not documented in seedling- or pole-stage forests (Capen 1979). In Pennsylvania, Haney (1989) reported that it occurred in 100% of old-growth mixed forests, 86.8% of forests statewide, and 90.3% of forests in the Appalachian Plateau. He considered it to have a neutral old-growth affinity. In New Jersey old-field successional habitats, it was absent in 10- and 20-year-old fields and present in a 40-year-old field. Borders of the occupied field were heavily wooded with red maple, pin oak, and red cedar. The centre of the field supported dense shrub growth. This field was surrounded by forest on 3 sides (Suthers 1989); otherwise, the tanager would probably have been absent. In Vermont, Lent and Capen (1995) determined that some territories were exclusively in forest but a few included

areas of small clear-cuts. Overall, it tended to avoid clear-cuts and was associated with increasing successional age, few conifers, and few dead trees. In Minnesota, Streby et al. (2011b) found 2 nests in clear-cuts, with the youngest forest 7 years old.

Several studies examined microhabitat requirements of the Scarlet Tanager. In Virginia, it used hardwood stands more than their availability, tulip tree forests less than their availability, and mixed oak and black locust forests in proportion to their availability. Sites used for breeding had more trees larger than 46 cm diameter at breast height (DBH) and more trees characteristic of mature habitats, such as bitternut hickory, shagbark hickory, pignut hickory, mockernut hickory, red oak, white oak, chestnut oak, black oak, tulip tree, beech, and basswood. Forty-eight tree species occurred within radiotracked locations. Seventy percent of these were hickories, oaks, flowering dogwood, red elm, red maple, and tulip tree. The most abundant species in both breeding and postbreeding areas were hickories, red elm, and flowering dogwood. Pignut hickory was the only species found in breeding areas but not in postbreeding areas (Vega Rivera et al. 2003). In New Jersey, it was more abundant in oak-pine forests than hardwood swamps, but not significantly (Rich et al. 1994). In Maryland, it was negatively correlated with hemlock bottomland forests and was associated with upland hardwoods (Gates and Giffen 1991). In southern Ontario, it was positively correlated with total basal area (BA), forest age and type, and medium- to large-sized white pines. It was negatively correlated with the BA of coniferous species (Kirk et al. 2012). In Wisconsin, the Scarlet Tanager was most common in xeric stands. It appeared to prefer more pioneer woods, but only if they were sufficiently large (Bond 1957). In Vermont, it was associated with hophornbeam, sugar maple, beech, and red oak; moderate amounts of red maple; and limited cover by poplars (Lent and Capen 1988). In Maryland, its density was positively correlated with shrub diversity and negatively correlated with the abundance of pines (Lynch 1987). In New Hampshire and Maine, it was significantly associated with cover type and structure. It was associated predominantly with white pine and swamp hardwoods. The pine stands contained considerable inclusions of deciduous species, particularly in the 2-10-cm size class, so this may have explained its preference for these stands. It also occurred in white birch, northern hardwoods, balsam fir, and hemlock stands. It was absent in poplar and balsam fir–spruce stands. Its abundance was positively correlated with conifers 2-10 cm DBH and foliage volume of deciduous trees larger than 10 cm DBH. It was negatively correlated with canopy closure, deciduous trees larger than 10 cm DBH, foliage volume of trees 2-10 cm DBH, and foliage volume of conifers in all size classes (DeGraaf et al. 1998). In isolated Illinois woodlots, it was negatively correlated with shrubby vegetation (Blake and Karr 1987). In Indiana, it was affected by tree height, being most abundant in trees 16 m tall, less abundant in trees 20-24 m tall, and uncommon in trees 0-12 m tall. It was most abundant where tree densities were 400-600 trees per ha (Grundel and Pavlovic 2007a). Bushman and Therres (1988) reported that it tolerated a wide range of overstorey cover, but preferred a closed canopy. It also preferred a dense understorey and scant ground cover. In Virginia, BA of occupied areas averaged 11 m^2 per ha and the population increased with the BA of trees 19-35 cm DBH. In the mid-Atlantic states, it was positively correlated with slope and percent forest cover within 2 km. It was negatively correlated with the number of trees larger than 3 cm DBH, moisture gradient, and foliage density between 2 and 3 m (Robbins et al. 1989). In Connecticut, it was more abundant when hemlock was less dominant (Buchanan et al. 2016). In Vermont, its mean habitat variables were 30.8% ground cover by green vegetation, 10.0% ground cover by slash, 79.3%

canopy closure, 22.9 m canopy height, 11.7 m canopy depth, 17.3 m^2 per ha BA of deciduous species, 5.0 m^2 per ha BA of coniferous species, 14.1 cm DBH of deciduous species, and 17.3 cm DBH of coniferous species. It was associated with older deciduous stands with a moderately dense understorey. It was in the closed-canopy deciduous association. This guild occurred in beech–yellow birch–sugar maple stands with varying amounts of balsam fir, red spruce, and white pine (Thompson and Capen 1988). In Tennessee, it occurred in deciduous forests with dense canopies. It was significantly correlated with trees larger than 22.8 cm DBH (Anderson and Shugart 1974). In New Jersey, 68% of nests occurred in trees larger than 22.4 cm DBH. In Michigan, its probability of occurrence was greater than 94% in forested areas with a moderate density of large trees and low density of small trees. In Wisconsin, forest size, the openness of the canopy, and density of the shrub layer accounted for 77% of variation in its abundance. Where the Scarlet Tanager is sympatric with the Summer Tanager, the Scarlet Tanager prefers sites with significantly higher canopies, denser canopy cover, a greater variety of tree species, and a higher density of trees larger than 22.4 cm DBH. Where the 2 tanagers occur together, Scarlet Tanager territories have a higher percent canopy cover and more tree species than where the Summer Tanager is absent. In Missouri, 90% of Scarlet Tanager territories were on slopes (68% for Summer Tanagers). Where both species occurred on slopes, the Scarlet Tanager preferred steeper slopes (Mowbray 2020).

The Scarlet Tanager is occasionally classified as a forest-interior species, mostly by authors that did not specifically test where it nested in relation to edge (Askins et al. 1987; Freemark and Collins 1992). Studies that examined where it nests have found no evidence of edge avoidance. In Ontario, it commonly nests at or near forest edges and occasionally even in open habitats (Peck and James 1987). Streby et al. (2011b) reported it nesting in young clear-cuts. In New Hampshire, King et al. (1997) surveyed transects 50 m into clear-cuts, across the border between clear-cuts and forest, and 350 m into forest interior. Areas within 100 m of the clear-cut were classed as edge plots and those further from edge were classed as interior plots. There was no significant difference in the number of territories in edge and interior plots. The distribution of territories differed significantly from the distribution of simulated random territories but was not skewed toward either edge or interior. In Tennessee, Kroodsma (1984) studied the distribution of tanager territories in relation to edge created by a hydro corridor through the forest. There were 29 territories 0-268 m from edge and 6 268-488 m from edge. It did not exhibit any potential edge effect. In Alabama, it increased along a mountain road after it was daylighted (Bushman and Therres 1988). In Manitoba, Walley (1989b) reported a nest at the edge of an aspen forest and another at the edge of a 0.4-ha grassy opening in the forest.

With 1 exception, all studies concluded that the Scarlet Tanager is an area-sensitive species. The exception was in New Hampshire and Maine where DeGraaf et al. (1998) found that it was not correlated with woodlot size. This area is heavily forested, and it is likely that area sensitivity breaks down in landscapes dominated by forest cover. Other studies demonstrated that the amount of forest cover within 2 km can affect its abundance and the minimum size of forest that it will inhabit (Robbins et al. 1989). In the Ottawa area, the mean size of woodlots it occurred in was 18.8 ha (Villard et al. 1992). Because of the interrelationships among forest size, proximity to the nearest forest patch, and amount of forest in the landscape, this figure cannot be used as an estimate of the tanager's forest size requirements across Ontario. In the Canadian Shield and Niagara Escarpment where forest

cover is 80% or greater, it is likely that forests only need to be as large as a territory size to support it. In the extreme southwestern portion of the province where forest cover may be as low as 3% and woodlots are often isolated, it is probable that much larger forests are required to support the tanager than in the Ottawa area. Further research is required to determine the degree of its area sensitivity in different regions of the province. In Waterloo Region, Friesen et al. (1985) did not find it in 3-7-ha woodlots, but it was present in those 8-15 and 20-50 ha in size. Because of the complex relationships among forest size, isolation, and amount of regional forest cover, there are widely varying estimates of the minimum forest size that will support breeding Scarlet Tanagers. In the Appalachians, it has been predicted that it will occur in every size of forests in landscapes that are at least 50% forested. In areas that are 30% forested, patches as small as 10 ha may provide moderately suitable habitat (Vega Rivera et al. 2003). In New York, no tanagers were detected in forests smaller than 10 ha (Roberts and Norment 1999). In New Jersey, it was found only in woodlots larger than 3 ha, and 10-12 ha was considered the minimum to support a viable population (Mowbray 2020). In Wisconsin, Bond (1957) observed it in woodlots as small as 3.2 ha. It was least common in small woodlots and was 34% more common in larger woodlots. Its frequency of occurrence was 20.9% in forests 6.1-14.2 ha, 26.3% in forests 16.2-32.4 ha, and 28.6% in forests larger than 32.4 ha. Lynch (1987) also found that its probability of occurrence increased with forest size: 40% at 10 ha, 70% at 100 ha, 80% at 1,000 ha, and 90% at 3,200 ha. In Maryland, Robbins (1979) estimated that 100 ha were required to support a viable population and that 10 ha was the minimum size of forest it would occupy. In western Maryland, Bushman and Therres (1988) reported that its highest frequency of occurrence occurred in woodlots 38 ha and larger. It was documented in woodlots as small as 1-14 ha and 3-7 ha by other studies. It often breeds successfully in smaller woodlots, probably because the nest tends to be high in the canopy. In the mid-Atlantic states, the area of woodland where its probability of detection was highest was 3,200 ha and larger. Its probability of detection was reduced to 50% of the maximum at 12 ha. The 3 smallest woodlots in which it was documented were 2.1, 3.6, and 4.6 ha (Robbins et al. 1989). In Illinois, Blake and Karr (1987) inventoried isolated woodlots 1.8-600 ha. They found the Scarlet Tanager in forests 16 ha and larger. Askins et al. (1987) considered it area sensitive in Connecticut but did not provide any information on its forest size requirements. In Maryland and Delaware, its probability of detection increased significantly with increasing forest widths: 17% in 50-m wide forests, 20% in 100-m wide, 29% in 200-m wide, 39% in 300-m wide, and 87% in 800-m wide forests (Keller et al. 1993).

Ontario nests were in trees and saplings, with deciduous (12 species, 63.2% of nests) favoured over coniferous (5 species, 36.8% of nests) species. The species most frequently selected were maples (15 nests), hemlock (13 nests), beech (10 nests), birches (4 nests), oaks (4 nests), elms (4 nests), hawthorns (4 nests), pines (4 nests), and spruces (4 nests). The Scarlet Tanager selected mature trees more often than saplings for nesting. Nests were almost always on horizontal limbs out from the trunk, but 3 nests were at the trunk. Distances from the trunk were 0.6-6 m, mostly 1.5-3 m. Nests were usually at crotches or forks of the supporting limb or otherwise secured by upslanting branchlets. One nest was in a tangle of grapevines. Nests were 1.8-20 m from the ground, with most 4.3-9.8 m up. Nests were often concealed by overhanging branches and dense foliage (Peck and James 1987, 1998b). In Muskoka and Parry Sound districts, the Scarlet Tanager has nested in spruce, white pine, hemlock, yellow birch, and maple at heights of 4.9-12.2 m (Mills 1981).

Nests elsewhere are in saplings or trees, with deciduous species preferred over conifers. In Michigan, 50% of nests were in white oak and 35% were in black oak. Oaks are preferred in Maryland but it also nests in maples, hemlock, and tulip trees. Elsewhere, nests have been reported in bur oak, scarlet oak, beech, ash, apple, dogwood, and red cedar. Nests are usually among a cluster of leaves, often above an open area that is used by the male during courtship. Most are on a horizontal branch well out from the trunk with an unobstructed view of the ground and open flyways from adjacent trees. They are typically at a crotch or juncture of more than 2 smaller branches. Nests have been reported 1.5-21 m from the ground. Mean nest heights were 9.0 m in Michigan, 7.1 m in Tennessee, 7.8 m in Maryland, and 10.0 m in Vermont. Michigan nests averaged 2.8 m from the trunk and 1.9 m from the tip of the branch. The tanager selected mature trees as nest sites more frequently than saplings. Average nest-tree diameter in Michigan was 30 cm (Mowbray 2020; Tyler in Bent 1958; Walley 1989b).

The Scarlet Tanager is aggressively territorial, consequently seldom occurring in high densities. Males defend mating, nesting, and foraging areas. The foraging area is the largest but the nesting area is most vigorously defended. Once territories are established, territorial disputes and aggressive interactions decline abruptly. The breakdown of territoriality coincides with dispersal from the area, at least 2 weeks after the young fledge. It also countersings in response to Summer Tanager songs and the 2 species establish non-overlapping territories in areas of sympatry. Territory size varies with forest size, location, and vegetation type. Territory sizes were 0.8-2.4 ha in mixed hardwoods in Missouri and 2.5 ha in mixed oak woodlands in Wisconsin (Mowbray 2020). In New York, male territory sizes did not differ among forest-size classes in 2 years. Territory sizes were 6.7 and 7.6 ha in forests 10-50 ha, 6.13 and 7.19 ha in forests 50-150 ha, and 6.36 and 7.39 ha in forests larger than 1,000 ha (Roberts and Norment 1999). Vega Rivera et al. (2003) radiotracked Scarlet Tanagers in Virginia and determined that there were 2 groups of birds: those that kept the same home range during the breeding and postbreeding seasons and those that established different home ranges during the postfledging period. Some of the latter group moved back and forth between the breeding and postbreeding home ranges but most remained in the postbreeding home range. For the group that remained in the same area, average home range was 5.6 ha with a core area (where 50% of detections occurred) of 0.72 ha. For birds that switched home ranges during the season, the breeding season home range averaged 5.8 ha and the core area averaged 0.93 ha. Mean home range size of males that maintained a single home range was 6.7 ha with a core area of 0.95 ha. Results from 1 female were not included in the mean home range sizes because she moved over a large area and may not have been mated. Her home range size was 46.6 ha and her core area was 3.2 ha. In Pennsylvania, territory size of birds with red elderberry present was similar before (0.64 ha) and after (0.94 ha) the fruits ripened (Stutchbury et al. 2005a). In Quebec, territories were 0.9-1.2 ha in mature hemlock and sugar maple stands and 0.80-3.42 ha in forests of unidentified composition (Lanoue and Gauthier in Gauthier and Aubry 1996).

No information is available on natal philopatry. The only information on adult site fidelity is from Illinois where Robinson (1992) reported that 2 of 4 adults (50.0%) returned to the same territory in the following year.

Limiting Factors

Eggs have been found in Ontario nests from the last week of May to mid-July, with most present in the first half of June (Peck and James 1998b). In Algonquin Park, nests are under construction from late May to mid-June, eggs are present throughout June, nestlings occur from late June to mid-July, and dependent fledglings have been observed from late July to late August (Tozer 2012).

Males establish territories immediately upon arrival at the breeding area. Courtship and mating is completed within a week of the arrival of females and nest building begins immediately. The female selects the nest site, often above an opening that was used by the male during courtship. Most nests are built in 3-4 days (range 2-7 days). Egg laying begins within 2 days of nest completion and 1 egg is laid per day. Incubation is initiated when the last egg is laid. The incubation period is 12-14 days. The nestling period is 9-15 days, with most young leaving at age 9 or 10 days and others on days 11 or 12 (Klatt et al. 2008; Mowbray 2020; Prescott 1964; Tyler in Bent 1958).

A single brood is typically raised. Egg dates for Ontario are indicative of a single brood. Second broods have been reported but the incidence of this is unknown. It is probable that the Scarlet Tanager lays a replacement clutch if the first one fails, but this has not been confirmed. Clutches of 3-4 eggs were reported in Ontario (mode 4 eggs, mean 3.78 eggs). Clutches of 2-6 eggs have been reported elsewhere, with 4-egg clutches most common. Mean clutch sizes include 3.8 eggs in New York and Tennessee, 3.1 eggs in Maryland, 4.1 eggs in Michigan before 15 June (range 3-6 eggs) and 2.6 eggs for later nests with a range of 2-6 eggs (Klatt et al. 2008; Peck and James 1998b; Mowbray 2020; Tyler in Bent 1958).

Both sexes are capable of breeding when they are 1 year old but it is unknown what proportion of birds do. In Virginia, 1 female of unknown age was apparently unmated and 4 yearling males appeared to be unmated. Three of these moved considerable distances but the other remained within a fairly restricted range. In New York, many males in smaller forests were yearlings that were less likely to attract a female. In Pennsylvania, 3 of 9 unpaired males (33.3%) acquired a mate midway through the breeding season, probably due to females switching territories (Fraser and Stutchbury 2004; Mowbray 2020; Roberts and Norment 1999; Vega Rivera et al. 2003).

The Scarlet Tanager is presumed to be monogamous but females will mate with a second male if the first one disappears or dies. Pair bonds are usually retained through the breeding season until the young disperse. There are no records of members of a pair remating in a subsequent year, but limited information is available (Fraser and Stutchbury 2004; Mowbray 2020). Extra-pair copulations appear to be a common mating strategy. In Pennsylvania, 5 of 17 broods (29.4%) contained extra-pair young and 9 of 54 nestlings (16.7%) were the result of extra-pair copulations. Paired males left their territories an average of 0.2 time per hour and spent 4.7% of their time off-territory, presumably seeking extra-pair copulations. Pair members stay close together, possibly in an attempt to reduce the likelihood of cuckoldry. During nest building and egg laying, pairs spent an average of 33.1% of their time within 3 m of each other. This increased to 61% of the time during incubation (Fraser and Stutchbury 2004; Klatt et al. 2008). No evidence of intraspecific nest parasitism has been observed (Mowbray 2020).

Numerous studies described the foraging behaviour of the Scarlet Tanager. It forages on insects, other invertebrates, and fruit. It captures insects on the surface of leaves, flowers, fruit, and bark;

sallies from a perch to catch insects; and occasionally captures prey on the ground. It forages in trees and shrubs for a variety of fruits. It climbs vertically on tree trunks and probes for insects. In spring, it may follow plows to capture earthworms, grubs, ants, and ground beetles. On the ground, it walks through grass and dead leaves and occasionally probes for grubs and worms in lawns. It takes fruit by reaching and plucking or by hovering and plucking individual fruits; it also eats tender buds. It captures adult bees, wasps, and hornets by hawking. Occasionally, it visits bird feeders and it is possible that it eats nectar (Mowbray 2020; Tyler in Bent 1958). Most foraging occurs within forested habitat, but it may feed in open areas during cold, wet, spring weather. During such a period in New Hampshire and Vermont, tanagers left their typical forest habitat and appeared on lawns, in fields, and along roadsides. Hundreds were observed along highways on the gravel shoulders, adjacent mowed grass, and on guardrails. Elsewhere, they were reported hawking insects over a lake and falling into the water, too weak to return to shore; others landed on boats. They readily accepted food when it was offered to them. This foraging behaviour appeared to be a response to the reduced availability of aerial insects in its typical habitat as a result of the weather (Zumeta and Holmes 1978). Stutchbury et al. (2005a) reported it foraging on the fruits of red elderberry in Pennsylvania. It accounted for 45.3% of all bird visits to elderberries. During the fruiting period, males spent significantly more time (12.8%) within 25 m of elderberries than during the pre-fruiting period (4.0%). There was a strong but nonsignificant trend for males to shift their home ranges to include more elderberry plants during the fruiting period. One male travelled 300 m from his territory to an area of ripe elderberries. Most did not make long trips off their territory to find elderberries, but they spent more time near it when it was ripe. Many tanagers did not have elderberries in their territories. On Pelee Island, Nelson (1997) observed a Ruby-throated Hummingbird that darted at a Scarlet Tanager. The tanager lunged forward, grabbed it by the head, beat it to death against a log, and ate it. In Illinois, Gabbe et al. (2002) examined which tree species the tanager preferred to forage in. It greatly preferred cherrybark oak and shellbark hickory, followed by bitternut hickory, silver maple, sycamore, pin oak, shumard oak, and swamp chestnut oak. It greatly avoided foraging in overcup oak and sugar hackberry followed by sour gum, bald cypress, blue beech, Manitoba maple, green ash, pumpkin ash, red maple, and sweetgum. Three strongly preferred trees (shellbark and bitternut hickory and silver maple) were scarce. Some of the species that it avoided were abundant (pumpkin ash, sweetgum, overcup oak, and blue beech). Also in Illinois, Hartung and Brawn (2005) compared its foraging techniques in savannahs and woodlands. There were no significant differences in its tree species preferences or foraging heights. It foraged in black oak and white oak more than expected based on their availability and frequently in hickory. It foraged less frequently in red elm, black cherry, and hackberry. Sixty to 62% of foraging occurred at heights of 6-19 m, 23-31% above 16 m, and 9-15% at 5 m or lower in the 2 habitats. It searched for and captured prey by hanging, hovering, and gleaning, but 48% of total prey-attack manoeuvres were sallying and flycatching. Gleaning represented 20-40% of prey attacks. In Vermont, 85% of foraging occurred on leaves, 7% in the air, and 8% on twigs. Foraging techniques consisted of 50% gleaning, 42% aerial attacks, and 8% hanging (Lent and Capen 1995). In West Virginia, Maurer and Whitmore (1981) did not detect any differences in tanager foraging behaviour in a mature forest and one that was clear-cut 18 years previously. Hovering at leaves was the most frequently used technique. Foraging techniques in the young and mature forests, respectively, were: 74.3% and 67.7% hovering; 25.7% and 32.3% gleaning; 0% and 0% hawking; 17.1% and 12.9% proximal to the trunk; 82.9% and 87.1% distal to the trunk;

74.3% and 83.9% on leaves; 11.4% and 16.1% on branches; and 14.3% and 0% on trunks. There was a significant difference in the preferred trees for foraging: oaks in the young forest and beech in the mature forest. Foraging by species in the young and mature forests, respectively, consisted of 31.4% and 38.7% in maple; 34.3% and 6.5% in oak; 0% and 32.3% in beech; 17.1% and 12.9% in other species; and 14.3% and 9.7% in shrubs. It foraged mostly in the dense canopy layer 6.1-12.2 m above ground. This may have been why the rate of flycatching was lower than in some other studies. Three New Hampshire studies examined the foraging of the Scarlet Tanager. Holmes (1986) compared the foraging strategies of the sexes. Females foraged significantly higher than males (14.8 m compared with 11.7 m). The mean height of song perches (15.5 m) was significantly correlated with the mean foraging height of males. Foraging heights of both sexes were correlated with nest height, but not significantly. Both sexes were predominantly leaf hoverers. Frequency of foraging substrates and manoeuvres for males and females, respectively, were: leaf hovering, 34.9% and 34.6%; leaf gleaning, 28.9% and 28.4%; twig hovering, 0% and 0%; twig gleaning, 2.4% and 0%; branch hovering, 3.1% and 0%; branch gleaning, 8.4% and 4.9%; trunk hovering, 6.0% and 1.2%; trunk gleaning, 2.4% and 0%; hawking in air, 14.5% and 30.9%; and 0.6% and 0% on-ground foraging. The second-most common foraging strategy was gleaning for males and hawking for females. The frequency of foraging on different plant species for males and females, respectively, was: beech, 30.8% and 28.8%; sugar maple, 18.9% and 12.3%; yellow birch, 47.8% and 45.2%; white ash, 0.6% and 2.8%; conifers, 0% and 8.2%; other maples, 1.9% and 2.7%; viburnums, 0% and 0%; and forbs and ferns, 0% and 0%. Female foraging differed significantly from that of males for manoeuvres but not plant species. The amount of foraging in the distal half of trees was significantly less for males (29.3%) than for females (64.6%). Males foraged 70% in the proximal half of trees and took insects more often from bark than females. Females foraged most often in the distal portion of trees where most foliage and foliage-dwelling insects occurred. Male Scarlet Tanagers and Rose-breasted Grosbeaks were more similar to each other in their foraging behaviour than they were to their respective females. Females of these 2 species were more closely aligned with the Red-eyed and Philadelphia vireos in their foraging behaviour than they were to males of their own species. This was due to females of both species foraging higher in the canopy than average and more frequently in white ash than males. Males attacked prey on trunks and branches more often than females. Robinson and Holmes (1982) reported that 55.0% of prey attacks were on leaves and 20.2% were on bark, mostly in the canopy. Most of the available prey was adult and larval moths, adult flies, wasps, beetles, nymphal and adult leafhoppers and treehoppers, and spiders. Most of these occurred on leaf surfaces and not on twigs or small branches. Prey capture techniques included 54.5% hovering, 26.3% gleaning, 0.6% hanging, 0% flush-chasing, 18.3% hawking, and 0.3% other techniques which were mostly probing. The tanager often sat in the open inner branches of large canopy trees and searched outward for insects which were often actively flying wasps and beetles. Although it took some flying insects, it usually waited for insects to land before attacking them, especially large ichneumonid wasps. Holmes and Schultz (1988) studied its use of different species of trees for foraging. On beech, prey attacks were 28% on upper leaf surfaces, 72% on lower leaf surfaces, and 0% on petioles and twigs. On sugar maple, 29% of prey attacks were on upper leaf surfaces, 65% on lower leaf surfaces, 6% on petioles, and 0% on twigs. On yellow birch, 24% of prey attacks were on upper leaf surfaces, 67% on lower leaf surfaces, 0% on petioles, and 9% on twigs. Overall, 26% of prey attacks were on upper leaf surfaces, 68% on lower leaf surfaces, 1% on petioles, and 5% on twigs. On beech, 75% of prey-attack

manoeuvres were by hovering (81% on lower leaf surfaces), and 25% by gleaning (25% on lower leaf surfaces). On sugar maple, 67% of attacks were by hovering (75% on lower leaf surfaces) and 33% by gleaning (50% on lower leaf surfaces). On yellow birch, 78% of attacks were by hovering (75% on lower leaf surfaces) and 22% by gleaning (43% on lower leaf surfaces). On all tree species combined, 39% of attacks were by hovering (80% on lower leaf surfaces) and 61% by gleaning (61% on lower leaf surfaces). Caterpillars that were potentially available as prey occurred at low densities, were highly variable in their distribution among leaves, and differed significantly in abundance among tree species and canopy strata. Caterpillars of owlet, prominent, and geometer moths constituted 95% of lepidopterans on foliage of beech, 84% on sugar maple, and 73% on yellow birch. Most were on leaf blades and on the under-surface of leaves (75% on beech, 62% on sugar maple, and 73% on yellow birch). Prominents were found exclusively on leaves. Owlets and a large proportion of geometers also occurred on petioles and twigs. Twenty-nine percent of the caterpillars were free-living types on beech foliage, 42% on sugar maple, and 58% on yellow birch. Beech supported more caterpillars, mostly leaf miners and leaftiers which are smaller and taken less frequently by birds. Yellow birch had fewer caterpillars, but nearly two thirds were free-living types which are mostly larger and more active larvae. The tanager obtained more than 50% of its prey from foliage and foraged over the full vertical profile of the forest. Ten species of birds were studied and all differed significantly from each other in their use of foliage substrates and tree species. The Scarlet Tanager and 6 other species were considered lower-leaf specialists that predominantly hovered at leaf surfaces to capture prey. The tanager was the only species that attacked in proportion to prey abundance in all 3 tree species.

During the breeding season, the Scarlet Tanager is predominantly insectivorous, but eats a variety of fruits as they ripen later in the season. Nestlings are fed insects and berries. Insects consumed by adults include adult underwing, luna, and cecropia moths; caterpillars of owlet, prominent, geometer, leafroller, and gypsy moths; gall insects; weevils and metallic wood-boring, bark, click, and leaf beetles; crane flies; grasshoppers and locusts; bugs; and wasps. About 12% of the diet consists of fruits including those of juneberries, huckleberries, bayberries, sumacs, blackberries, mulberries, and cultivated cherries (Tyler in Bent 1958). In New Hampshire, emetic diet samples consisted of 7.7% caterpillars, 34.1% hymenopterans, 41.5% beetles, 4.9% flies, and 9.8% other items. Of food items that were observed being preyed upon, 63.1% were caterpillars, 5.2% were adult lepidopterans, 15.8% were beetles, and 15.8% were hymenopterans. The disparity between the results was probably because caterpillars were the most conspicuous prey for observers to see thereby inflating their importance in the diet (Robinson and Holmes 1982). In Michigan, the diet consisted of a variety of adult and larval insects, including hymenopterans (bees, wasps, hornets, ants, and sawflies), moths and butterflies, beetles, flies, cicadas, leafhoppers, spittle bugs, treehoppers, aphids, scale insects, termites, grasshoppers and locusts, dragonflies, dobsonflies, snails, earthworms, and spiders. It ate strawberries and chokeberries in addition to most of the fruits previously mentioned. In West Virginia, it shifted from a diet of predominantly caterpillars early in the summer to higher concentrations of beetles and orthopterans later in summer (Mowbray 2020). Birds foraging along roadsides during adverse spring weather ate mostly ants, beetles, earthworms, and midges indicating that most foraging occurred on the ground (Mowbray 2020; Zumeta and Holmes 1978). Royall (1988) observed a male in a tree crown that swooped down and captured a

large katydid that was flying about 3.7 m above the ground. Near Manitouwadge, Venier et al. (2009) observed no response by the tanager population to changing spruce budworm numbers. In New Hampshire, changes in tanager density among years appeared to be in response to numbers of saddled prominent caterpillars (Holmes and Sturges 1975).

The Scarlet Tanager is a common host of the Brown-headed Cowbird. The tanager accepts parasitic eggs and the cowbird often removes a tanager egg. In Michigan, the average clutch size was 3.7 eggs in unparasitized nests and 2.1 eggs in parasitized nests. In most cases, tanager eggs in parasitized nests are as likely to hatch and produce fledglings as those in unparasitized nests. In Illinois, where parasitism rates and intensity were high, 6 of 7 tanager families had at least 1 cowbird fledgling, only 2 had host fledglings. Parasitism does not appear to cause nest desertion or nesting failure. Parasitism rates vary considerably due to factors such as geography (with higher populations of cowbirds in the Midwest), size of the forest patch, and the degree of fragmentation of the landscape. In Ontario, 7 of 44 nests (15.9%) were parasitized. Parasitism rates reported elsewhere include 1 of 8 nests (12.5%) in Tennessee, 2 of 21 nests (9.5%) in Maryland, 7 of 22 nests (31.8%) in Pennsylvania, 3 of 4 nests (75%) and 16 of 18 nests (88.9%) in Illinois, 10 of 13 nests (76.3%) in Michigan, and 4 of 6 nests (66.7%) in New York (Hahn and Hatfield 1995; Mowbray 2020; Peck and James 1998b; Robinson 1992).

Habitat loss and fragmentation are the most significant limiting factors for the Scarlet Tanager. Fragmentation can lower forest size below the minimum threshold required to support it. Because its presence and abundance are correlated with the amount of forest cover within a landscape, even the loss of unoccupied forests may reduce its probability of occurrence in other forests. Forest fragmentation is considered one of the factors resulting in its decline in Quebec (Lanoue and Gauthier in Gauthier and Aubry 1996; Létourneau in Robert et al. 2019). Rosenberg et al. (1999) used Project Tanager results to determine the effects of forest fragmentation on the Scarlet Tanager. The 4 regions that were analyzed were the Northern Forest (all of Ontario except the Carolinian Zone), the Midwest (which included the Carolinian Zone of Ontario), the Northeast (New England south to North Carolina and Georgia), and the Atlantic Coast from Long Island to North Carolina. The proportions of sites with tanagers were 72% in the Northeast, 50% in the Midwest, 60% in the Atlantic Coast, and 57% in the Northern Forest. It was significantly affected by fragmentation (patch size, percent forest cover within a 10-km^2 block surrounding the site, and distance to the 2 nearest woodlots) in the Northeast, Midwest, and Atlantic Coast populations but not in the Northern Forest. Its probability of detection dropped below 50% at highly fragmented sites in the Midwest and Atlantic Coast. It was strongly negatively affected by edge in the Atlantic Coast and there was a weak effect of elevation in the Midwest. In the Northern Forest, only elevation significantly affected breeding probability, with it more likely to be detected at higher elevations. The cowbird was more likely to be found at fragmented locations and was less common at higher elevations. Avian predators were more common in the Northeast and in areas with more edge in the Atlantic Coast. Mammalian predators were more common at highly fragmented sites in the Northeast, Midwest, and Northern Forest. The response of the Scarlet Tanager to habitat fragmentation varied significantly geographically. The response to fragmentation by the cowbird and predators was opposite to that of the tanager. Results demonstrated that the Scarlet Tanager was negatively affected by fragmentation, with the greatest negative effects in the Midwest and Atlantic Coast

where forests are highly fragmented. It appears to be less sensitive to fragmentation in areas where the forest is largely intact, such as the Northern Forest. In Pennsylvania, Rodewald and Yahner (2001) examined the collective nesting success of the Eastern Wood-Pewee, Red-eyed Vireo, Wood Thrush, Ovenbird, and Scarlet Tanager at the landscape (314 ha), local (25 ha),and nest-patch (0.04 ha) scales. Daily nest survival was lower in landscapes disturbed by agriculture than those disturbed by silviculture for all species combined and canopy nesters (including the tanager) but not for ground or understorey nesters. Nest-patch microhabitat and distance to edge were not associated with nest success for any guild. Squirrels, American Crows, and cowbirds were more abundant in landscapes disturbed by agriculture. Chipmunks were equally abundant in landscapes disturbed by agriculture and forestry. Lower nest survival in lands disturbed by agriculture was best explained by greater abundance of some avian and mammalian predators, particularly squirrels. In New York, Roberts and Norment (1999) studied the effects of patch size and local-scale isolation on the reproductive success of the Scarlet Tanager. Pairing success, fledging success, and density varied significantly with forest area and were higher in larger patch sizes. Pairing success was greater than 75% in all occupied sites and was 100% in forests larger than 1,000 ha, a significant difference. Fledging success increased significantly with forest size. In 2 years, fledging success was 28% and 0% in woodlots 10-50 ha, 38% and 58% in woodlots 50-150 ha, and 80% and 75% in woodlands larger than 1,000 ha. Males breeding in forest patches with increased canopy cover and lower oak density had higher pairing success than those in patches with reduced canopy cover and higher oak density. This appears to be the only study that found that it did not prefer oaks. Those breeding in large forest patches with more surrounding forest cover had higher fledging success than those in small patches and less surrounding forest. The researchers could not determine if the fragmentation effects were due to patch size, isolation related to the amount of forest cover within 1 km, or interactions between these variables. Results also suggested that canopy cover, BA, and tree species richness affected nest success. Total BA and tree species richness were significantly higher in forests larger than 1,000 km than in smaller patches. The highly fragmented landscape of Illinois is considered a sink where more than 80% of nests are parasitized and the predation rate is 69-78% (Robinson 1992). In West Virginia, Farwell et al. (2019) studied the effects of shale gas infrastructure (access roads, pipelines, and well pads) on the Scarlet Tanager. It was more abundant distant from all types of facilities, but not significantly.

The effects of forest management on the Scarlet Tanager are variable. Most studies concluded that it tolerates a wide range of forest prescriptions and that harvesting has minimal effects. In the Boreal Forest Region of Ontario and Canada, there was no change in its abundance when 30%, 50%, or 70% of the tree cover was removed (Vanderwel et al. 2007, 2009). In Algonquin Park, Tozer et al. (2010) detected no effects from single-tree and group-selection harvesting. Jobes et al. (2004) found that it was significantly more abundant in sites that were selectively thinned 1-5 years previously than in sites that were unharvested or harvested 15-20 years previously. Near Sault Ste. Marie, it was equally abundant before and after selective harvesting; the BA did not change significantly (Holmes and Pitt 2007). South of the Canadian Shield in Ontario, Holmes et al. (2004) found no difference in its abundance in unharvested stands, those that were selectively thinned, and those where heavy diameter-limit cuts occurred. In Indiana, Robinson and Robinson (1994) observed no effects on the Scarlet Tanager due to selective logging that created openings 0.02-0.4 ha in area. In New York,

Webb et al. (1977) detected no changes in its relative abundance in forests where 0%, 25%, 50%, 75%, and 100% of the merchantable trees were removed. In Maryland, Bushman and Therres (1988) concluded that a wide range of forest management practices were acceptable. In Pennsylvania, it was more common in stands where snags were retained in improvement cuts than where snags were removed (Stribling et al. 1990). Also in Pennsylvania, it decreased by 32% when 1-ha blocks of aspen and mixed forest were clear-cut; the decline was nonsignificant (Yahner 2003). In New York, 2 of the woodlots studied by Roberts and Norment (1989) underwent a selective harvest that resulted in the removal of the largest trees. This resulted in an increase of male territory sizes and reduced pairing success in the harvested areas. In Michigan, sites that were selectively harvested supported Scarlet Tanagers prior to cutting but not afterwards in the same season or in the next year (Mowbray 2020). In Minnesota, harvesting reduced BA to 7-10 m^2 per ha and this had an adverse effect on the tanager (Hanowski et al. 2003).

The Scarlet Tanager may avoid housing. In Waterloo Region, the number of houses near a site significantly affected the number of breeding neotropical migrants with a significant decline in diversity and abundance as the level of development increased. Results were presented for the guild as a whole and not for individual species, but the Scarlet Tanager followed this pattern (Friesen et al. 1995). In North Carolina, Lumpkin and Pearson (2013) determined that it decreased significantly with the number of buildings within 200 m.

The Scarlet Tanager appears to be particularly vulnerable to extended periods of cold wet weather when it first arrives in spring. During a period of mean daily temperatures of 8-10°C and 1-12 mm of rain daily, numerous tanagers were found grounded along highways. The area affected included from southern Maine to eastern Vermont, including most of the northern half of New Hampshire. Of 485 birds observed along a small subsample of highways, the Scarlet Tanager represented 46.4% of live birds, 83.5% of dead birds, and 51.9% of all birds. The live tanagers were very sluggish, allowing close approach, and had difficulty flying, preferring to hop away. Breeding density at a study area in New Hampshire was half that of the previous year and nesting success appeared to be poor. Densities in the 2 subsequent years were half that of the 5 years prior to the cold spring and the lowest in 8 years of study. BBS results determined that it declined by 30% in New Hampshire and 50% in Maine in the year of the cold spring compared with previous seasons. It may be more affected than other species because of its greater dependence on large-sized insect prey. These are relatively rare in the environment and may be particularly depressed in abundance during cool wet weather. The tanager is also larger with greater metabolic needs (Zumeta and Holmes 1978). Mowbray (2020) reported that 27 were found dead after a thunder and hail storm in Louisiana. It may also be killed by vehicles while foraging along roadsides in adverse weather conditions.

In Pennsylvania and New Jersey over a 15-year period, hemlock declined from representing 56% of the total BA to 46% due to the hemlock woolly adelgid; the amount of deciduous understorey increased. The tanager increased in response to hemlock decline and exhibited the greatest increase in occupancy of all species (Toenies et al. 2018).

In a New York woodlot, Litwin and Smith (1992) attributed a 50% decline in the Scarlet Tanager to changes in forest succession. This occurred despite the forest becoming more consolidated and less isolated. Over the 30-year period, the species composition of the forest changed with almost

complete extirpation of elm, severe declines in beech, and increases in basswood, silver maple, sugar maple, red ash, and white ash. The canopy became more closed with a resulting decline in the shrub layer and hophornbeam, a midcanopy species. The decline was attributed to loss of vertical and horizontal heterogeneity and an overall decline in productivity associated with forest maturation.

In Georgia, Klaus et al. (2010) observed no effect of wildfires or controlled burns on the Scarlet Tanager. Even high-intensity fires that resulted in significantly less canopy cover had no effect.

Price (2004) predicted that the range of the Scarlet Tanager might contract in southern Ontario if the average summer temperature increased by 2°C. In New York, Kirchman and Van Keuren (2017) examined whether its range shifted in response to climate change over a 40-year period. It was associated with lower elevations of 500-650 m. There was no change in its range over time, but the range of many other species shifted upwards.

Status

McIlwraith (1894) stated that the Scarlet Tanager was restricted to the southern portion of the province and that it was not abundant anywhere. In Elgin County, it was considered common in 1891, moderately common in 1954, and uncommon in 2000 (Lancaster et al. 2004). Baillie and Harrington (1937) considered it fairly numerous in the southern half of the province. It bred north to at least Sault Ste. Marie and Algonquin Park and probably west to Lake of the Woods. The first atlas confirmed that it nested from the Lake of the Woods area east to Lake Abitibi southward through the remainder of the province. Its northern limit was delimited by the northern extent of the Great Lakes–St. Lawrence Forest Region with minor intrusions into the southern portion of the Boreal Forest Region. Gaps in its distribution were associated with the deforested area around Sudbury and areas of intensive agriculture in the southwest. Highest densities occurred in the southern Shield portion of the Great Lakes–St. Lawrence Forest Region from Kingston to Algonquin Park (Cadman in Cadman et al. 1987). James (1991) considered the Scarlet Tanager uncommon in the south and rare in the north to Sioux Lookout and Kapuskasing with sight records north to Moosonee.

The second atlas indicated that there had been no change in the Scarlet Tanager's range or probability of observation since the first atlas. It was most abundant in the southern portion of the Canadian Shield along the St. Lawrence River north to Ottawa and North Bay. High densities also occurred on the Bruce Peninsula and the heavily forested Norfolk Plain near Long Point. Density was low further to the north and in the intensively farmed areas of southwestern Ontario (McLaren in Cadman et al. 2007).

BBS data indicate that the Scarlet Tanager population has been stable since 1966, although changes in abundance occur within and between regions. Trends in abundance may be influenced by changes in habitat structure, variations in arthropod abundance, forest fragmentation, and source-sink dynamics. Long-term population trends may be misleading because BBS surveys often record unmated males in small woodlots and pairs in woodlots where they are unlikely to produce any young (Mowbray 2020). BBS results indicate annual decreases of 2.08% in Canada and 0.449% in Ontario 1970-2021. Trends for 2011-21 were annual increases of 0.741 in Canada and 0.522% in Ontario. All results were highly reliable except that the short-term trend for Ontario was of medium reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Most young walk from the nest when they fledge but some may fly as far as 15 m from the nest. The young are capable of short fluttery flight at age 10 days. Adults attend to the fledglings for 10-14 days after leaving the nest (Mowbray 2000). This author suggested that young remain in or near the natal territory until they fledge but studies conducted during the postfledging period indicate that many move to early successional habitat once they are independent. Tyler (in Bent 1958) reported that fledglings from 1 nest stayed in the area with the female for 26 days until 1 August. Another brood moved from the nest on the same date, travelled about 60 m down a valley and remained with the female until 15 August when all of them disappeared. In Virginia, 1 pair split the brood with each adult caring for 1 fledgling (Vega Rivera et al. 2003).

The 8-9-week postfledging period is important because the prebasic moult and premigratory fattening must be accomplished. The Scarlet Tanager has a gradual moult and does not lose its flight capability. Vega Rivera et al. (2003) radiotracked adults through the breeding and postfledging periods in Virginia. Eight males and a female did not change their home ranges during these periods. Even though they did not change areas, they shifted their core areas. Nine males and 2 females established postfledging home ranges more than 300 m from the breeding home range. Two males moved back and forth between their breeding and postfledging home ranges. One returned to the breeding home range 3 times and remained there until autumn migration. The other moved back and forth 4 times and remained in the postfledging home range until migration. The fact that some birds returned to the breeding home range suggests that it is important to maintain a presence, perhaps to retain control in subsequent breeding seasons. One female and 3 males established postfledging home ranges more than 3 km from the breeding home range. One of the males returned to his breeding home range in mid-September and disappeared 10 days later. During the postbreeding period, 3 males visited the same forest fragments 0.6-1.1 km from their breeding home range and 2 males moved to the same site 3.3 and 3.9 km from their breeding home ranges. Individuals moved as far as 11 km from the nesting territory, suggesting that they may have been scouting over an area of approximately 38,000 ha or even larger because some birds were not re-encountered. Eleven birds apparently left the area before the moult prior to 1 August. Early departure did not appear to represent the initiation of migration because 75% of birds remained after 1 August and did not depart until mid-September. Those that left did so in July prior to the moult, a condition unfavourable for migration. Television tower kills in Florida do not show evidence of migration until September. It may leave breeding home ranges prior to migration to find high-quality habitats with an abundant food source and low predator pressure. Rappole and Ballard (1987) captured a moulting female on 21 August in Georgia 100 km south of the nearest breeding population.

During the postfledging period, the Scarlet Tanager may continue to inhabit forests or move to early successional habitats such as clear-cuts. In Virginia, Vega Rivera et al. (2003) determined that its habitat did not change significantly between the breeding and postfledging periods at a macro level, remaining in forested habitat. There were some slight changes in vegetation composition between the 2 seasons. During the postfledging period, it used mixed oak and hardwood stands more than their availability, tulip tree forests less than their availability, and black locust in proportion to its availability. Results were similar in both periods except that mixed oak stands were used more

than their availability in the postfledging period and equal to their availability in the breeding season. Postfledging sites had more trees and higher BA (because of a higher density of trees 4-46 cm DBH), more snags, and more trees characteristic of early successional areas (red elm, hackberry, tree-of-heaven, black locust, sassafras, Manitoba maple, persimmon, and apple) than breeding sites. The 3 most abundant tree species in both breeding and postfledging sites were hickories, red elm, and flowering dogwood. Tree-of-heaven, sassafras, and red maple occurred only in postfledging sites.

Both adult and juvenile Scarlet Tanagers have been captured in clear-cuts during the postfledging period, often in high numbers, in Ohio, Pennsylvania, Minnesota, West Virginia, Virginia, and Missouri. It commonly uses early successional habitat throughout its range during the postfledging period. In Ohio, it seldom inhabited clear-cuts 10 years and older with a closed canopy and limited fruit. In Pennsylvania, it was significantly more abundant in clear-cuts than adjacent mature forests. There were no significant differences in coverage by shrubs, forbs, and grasses in the 2 habitats but the shrub species composition varied. Raspberries and cherries dominated the clear-cuts. Forests were dominated by beech and red maple seedlings and lacked raspberries. In Ohio, it preferred small (4.0-9.3 ha) to large (13.3-18.1 ha) clear-cuts. It was 4.5 times more abundant in small cuts. It may have preferred smaller cuts because they permitted increased access to both habitats. Tanagers were observed returning to the mature forests after foraging on fruit in the clear-cuts. Also in Ohio clear-cuts, it was positively correlated with canopy cover by vegetation taller than 4.5 m and negatively correlated with the density of shrubs 0.5-1.5 m tall (Marshall et al. 2003; Porneluzi et al. 2014; Stoleson 2013; Streby et al. 2011b; Vitz and Rodewald 2006, 2007).

In Virginia, Vega Rivera et al. (2003) determined the home range sizes of Scarlet Tanagers during the postfledging period. For those that remained in the breeding season home range, there was no difference in the size of their home ranges during the breeding (5.6 ha) and postfledging (5.4 ha) periods, or in their core areas (0.72 and 0.62 ha), respectively. For birds that established a distant postfledging home range, these were significantly larger (34.5 ha) than breeding (5.8 ha) home ranges. Core areas were also larger during the postfledging period (5.8 ha compared with 0.93 ha). For 2 birds that moved back and forth between their breeding and postfledging home ranges, sizes were significantly larger during the postfledging period. Their home ranges were 2.6 and 2.7 ha in the breeding season compared with 9.3 and 23.6 ha in the postfledging period. Core areas were 0.67 and 0.46 ha in the breeding season and 4.9 and 11.7 ha in the postfledging period.

In Ohio clear-cuts, numbers of the Scarlet Tanager peaked in mid-July then quickly decreased. Its capture rate was positively correlated with fruit abundance, predominantly raspberries. Its capture rate was 2.5 times greater in nets with more than 600 fruits within the net belt than in nets with less than 100 fruits. Eighty-one percent of captured birds had fruit stains on their bills. As the fruit declined within the clear-cuts, so did the tanager (Vitz and Rodewald 2007). Vitz and Rodewald (2012) used feather isotopes to determine the diet of the Scarlet Tanager during the postfledging period. They found no evidence that it adopted a strongly frugivorous diet at this time. Although it has been confirmed eating fruit, results indicated that the diet consisted mostly of arthropods.

MIGRATION

The Scarlet Tanager is a long-distance neotropical migrant that winters in northwest South America. It may migrate singly or in small loose flocks with other neotropical migrants such as vireos, thrushes, and warblers. Most migration occurs at night (Mowbray 2020; Tyler in Bent 1958). In Ohio along the southern shore of Lake Erie, it made spring morning flights about an hour after sunrise. These were oriented west to northwest along the coastline, with no birds crossing Lake Erie. The purpose of these flights was possibly to compensate for the drifting effects of winds experienced during the night, with winds almost exclusively from the west. The principal direction of nocturnal flight was north or northeast (Tuck et al. 2018).

Timing of spring migration appears to be related to foliage development, as this influences food availability, territory establishment, mating, and courtship on the breeding grounds (Mowbray 2020). Consequently, climate change has the potential to alter the timing of migration. From 1967 to 2011 in New York, the trend was toward earlier arrival and later departures but this was not significant (Zelt et al. 2017). In Massachusetts, there was no change in the mean arrival date 1851-1973 and 1988-2007 (Ellwood et al. 2010). Males arrive in spring a few days to a week before females (Mowbray 2020; Weir 2008). At Long Point, the mean capture date for males was significantly earlier than for females. Mean capture dates were 11.2 May for adult males, 15.8 May for yearling males, 22.1 May for males of unknown age, and 20.0 May for adult females (Stewart et al. 2002). In southern Ontario, most arrive in early to mid-May with the earliest migrants appearing in mid- to late April (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008). In the southern Shield, migration begins around the second week of May and continues until the end of the month (Mills 1981; Tozer 2012).

There appears to be no temporal segregation of the sex and age classes during autumn migration. Departures from the breeding grounds may begin in mid- to late August, but most birds do not leave until mid- to late September (Mowbray 2020). In the southern Shield, tanagers start migrating south in August with most gone by mid-September but a few remain into early October (Mills 1981; Tozer 2012). In the south, migrants arrive in mid-August and depart in late September, with some remaining until mid-October or rarely early November (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008).

During migration, the Scarlet Tanager is associated mostly with forested areas with tall trees, but it also occurs in more open habitats such as savannahs and woodlands, parks, and gardens (Mowbray 2020). During spring migration in Indiana, it was most abundant in trees 20-23 m tall (Grundel and Pavlovic 2007a). In Pennsylvania, it was associated with larger forests in spring but occurred in all sizes of forests in autumn (Keller and Yahner 2007). During spring migration in Wisconsin and Minnesota, it occurred in upland forests dominated by oaks or oaks mixed with sugar maple, beech, and red elm. It was absent in floodplain forests dominated by Manitoba maple, green ash, and white elm (Kirsch et al. 2013). During spring migration in Ohio, it was more common in mature upland than mature riparian forests, but not significantly (Rodewald and Matthews 2005). During spring migration in Pennsylvania, it was significantly more abundant in forested than shrubby habitat (Smith and Hatch 2008). In Pennsylvania, Smith and Hatch (2017) studied the effects of southern arrowwood loss on spring migrating tanagers. This shrub was defoliated and killed by

the viburnum leaf beetle, resulting in a significant decline of this shrub. Tanager captures declined by 45%, but this was not significant. There were insufficient data to determine if its body mass declined. Rodewald and Brittingham (2002, 2004) compared tanager usage of different habitats during autumn migration in Pennsylvania. Highest abundance occurred in forest-agricultural edges. Usage of forest interior, suburban forests, pole-stage forests, and shrub–sapling-stage forests was similar and significantly lower than for forest edges.

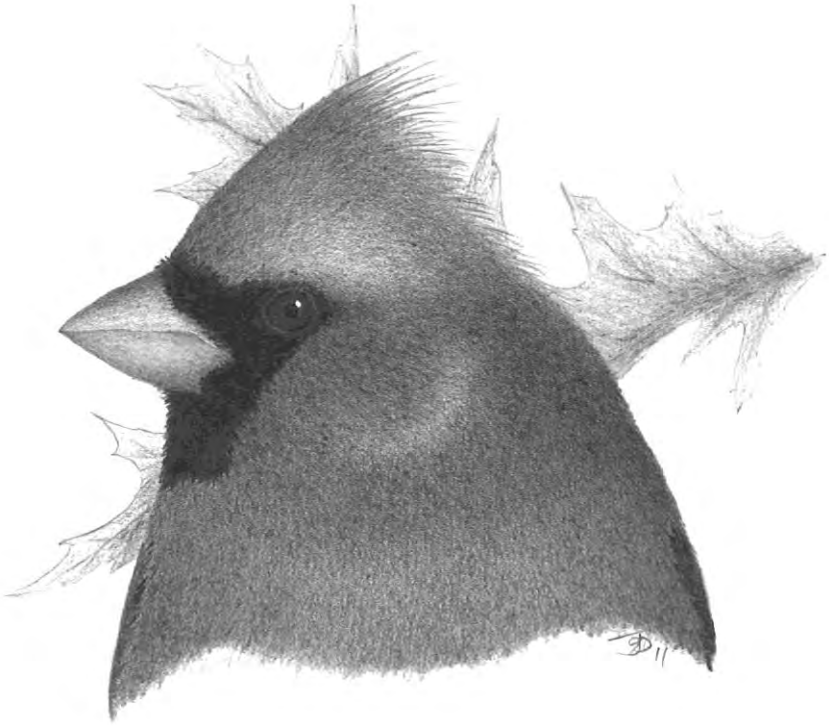
The Scarlet Tanager may eat a higher proportion of fruit during autumn migration (Mowbray 2020). In Ontario, it has eaten the fruits of wild raisin, mountain-ash, and honeysuckles (Mills 1981; Tozer 2012).

During migration, the Scarlet Tanager is frequently killed at buildings, communication towers, and other tall structures. In the United States, it is 18.5 times more likely to strike a high-rise than the average for birds. It was not among the top 20 species most likely to be killed for all building types combined, 1-3-storey residences, or low-rises. Thirteen were killed at the Lennox generating station chimneys near Kingston 1972-82 (Loss et al. 2014; Mowbray 2020; Weir 2008).

James (1991) considered the Scarlet Tanager an uncommon migrant in Ontario. Captures at Long Point Bird Observatory decreased nonsignificantly at a rate of 1.4% per year 1961-88. Annual trends by periods were: +15.3% 1961-70; –10.2% 1970-79; and –11.5% 1979-88 (Hussell et al. 1992).

Northern Cardinal

Cardinalis cardinalis

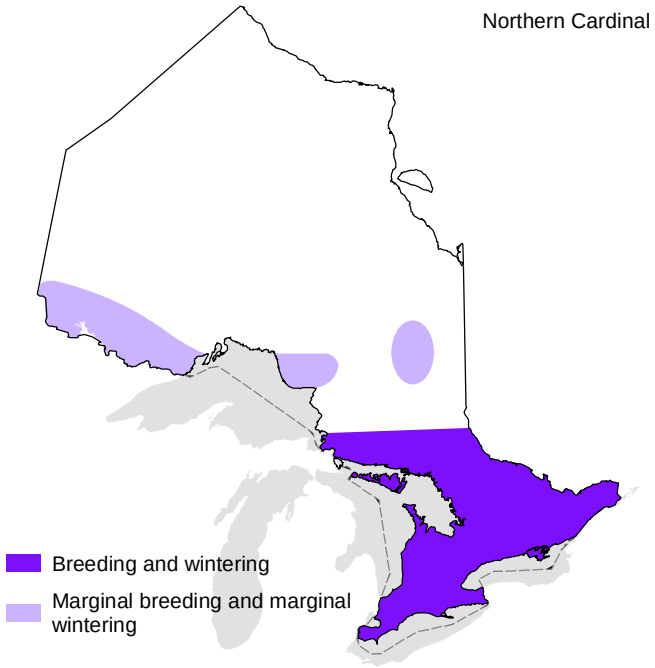


BREEDING SEASON

Habitat Requirements

Ontario Northern Cardinal nests were in urban gardens, parks, golf courses, and nurseries (38.9% of nests); in open deciduous, mixed, and coniferous woodlands, at either their edges or in clearings (35.9% of nests); in rural fields and pastures overgrown with hawthorns or other shrubs or saplings, in parks, in fencerows, and in orchards (24.9% of nests); and in a sand-dune area (0.3% of nests). An unspecified number of nests were in or near marshes and wooded swamps (Peck and James 1987).

South of the Canadian Shield in the Great Lakes–St. Lawrence Forest Region, Weir (2008) reported that the cardinal was most abundant in villages, towns, and cities, but also occurred in more natural habitats north to the edge of the Shield. In Durham Region, Speirs and Orenstein (1975) found it in only 1 of 11 forested plots that they surveyed: an open-canopy deciduous forest with a rank growth of ferns and raspberries. Dow (1969a, 1969b, 1994) studied the cardinal near Elmira when it was still uncommon and becoming established in the area. Its only vegetational requirement was an adequate amount of woody cover that was suitable for nesting. It was



associated only with woodlots and was not detected in hedgerows. The woodlots were mostly dominated by sugar maple–beech but it also used lowland white cedar stands with alders, willows, and many dead elms. It also favoured woods and swamp edges containing considerable white birch and poplar. Home ranges were 62.4% wooded. Average characteristics of home ranges were 18% forbs, 55% graminoids 0.25-0.8 m tall, 1% graminoids 0.8-2 m tall, 10% woody plant cover less than 0.25 m tall, 18% deciduous leaf coverage, 6% coniferous foliage cover, 20% dead wood, 4% rocks, 5% water, and 12% marsh. Only 2 of 10 home ranges contained vegetation taller than 18.3 m. It selected song perches for their conspicuousness rather than their height and often selected dead elms as perches. It had difficulty perching on the flexible tops of white cedars and did not stay in them long. Population density was significantly correlated with distance to the nearest river or bottomland.

In the Carolinian Forest Region, the cardinal was common on the University of Western campus and adjacent riparian woods along the Thames River (Lemon 1969; Scott and Lemon 1996). Dodds and Otis (2009) reported it in fairly high density in wooded areas dominated by ash at Point Pelee.

In southern Ontario south of the Shield, abundance of the cardinal was significantly negatively correlated with forest cover more than 100 m from edge, the amount of forest cover within 2 km, and the amount of regional forest cover. It was negatively correlated with woodlot size, but not significantly (Austen et al. 2001). In a sparse and pioneering population at Elmira, 54% of males were in woodlots larger than 10 ha, 1% were in woodlots smaller than 2 ha, 7% in woodlots 1-20 ha, and 5% in extensive forests (Dow 1969a). It may select moderately sized woodlots first, with more extensive use of smaller woodlots and hedgerows once the population grows.

The Northern Cardinal nests in a wide variety of habitats that support woody vegetation. Highest densities occur in urban areas where there is a proliferation of shrubs, especially nonnative species such as honeysuckles and buckthorns. It occurs in areas dominated by shrubs and saplings, but is common in ornamental plantings in lawns and forest edges and gaps. It nests in hedgerows, deciduous scrub, small woodlots, urban parks and open spaces, shrubby borders of agricultural fields, riparian forests, regenerating clear-cuts and burns, marsh edges, grasslands supporting shrubs, successional fields, orchards, pine and oak barrens, conifer plantations, reclaimed mines, and savannahs. It tends to avoid open habitats without woody cover and extensive forests, although it will nest at their edges and in gaps and much less frequently in forest interior. Outside urban areas, it prefers sites with dense shrubs or tangles of vines over shrubs or saplings. Some authors reported

it as being ubiquitous, being present in all habitat types they studied (Austin 1968; Bielefeldt and Rosenfield 1994; Bond 1957; Bowen et al. 2007; Conner et al. 1983; Conover et al. 2009; Dow 1969a; Fitch 1958; Ford et al. 2001; Gentry et al. 2006; Graber and Graber 1963; Halkin et al. 2021; Hurst and Bourland 1996; Kerr 1968; Leston 2006; Margeneau et al. 2019; Michaud in Robert et al. 2019; Mossman 1988; Mossman and Hoffman 1989; Mossman et al. 1991; Paquin in Gauthier and Aubry 1996; Schneider and Miller 2004; Suthers 1988; Walk et al. 2011).

Some studies examined cardinal habitat at the landscape level. In the eastern United States, 58% of detections of the cardinal on Breeding Bird Survey (BBS) routes were in fragmented landscapes (Donovan and Flather 2002). In Quebec, highest densities occurred in the deciduous forest regions of the southwest in regions dominated by sugar maple–bitternut hickory and sugar maple–basswood. It rarely occurred at elevations above 200 m (Michaud in Robert et al. 2019). In Illinois, densest populations occurred in urban habitats, possibly due to the presence of feeders (Walk et al. 2011). In Ohio it was significantly more abundant in urban than rural forests, being 1.67 times more abundant in urban areas in the summer and 5 times more abundant in the winter. It may be more abundant in urban areas because of the warmer winter temperatures, presence of feeders, and abundant nest sites in ornamental trees and shrubs (Leston 2006). In Alabama, it was less likely to abandon areas surrounded by development sites with high shrub density and ground cover (McClure et al. 2013a). In South Dakota, it was significantly more abundant in contiguous riparian forests than in small isolated woodlots (Gentry et al. 2006). In South Carolina, it was significantly more abundant in oak-hickory woodlots surrounded by field and scrub habitats than those surrounded by closed-canopy forests (Kilgo et al. 1997). In New York, it preferred landscapes that were 42-71% forested (Cunningham and Johnson 2019).

Numerous studies determined microhabitat preferences of the cardinal. In Michigan, those nesting near Cooper's Hawks' nests sang from similar heights (2.46 m near hawk nests and 2.83 m where hawks were absent). Perches were significantly less exposed at hawk nests (Duncan and Bednekoff 2006). In Tennessee, 20% of cardinals occurred in narrowly wooded stream edges that represented only 3.6% of the available habitat and 41.2% occurred in hedgerows that were 12.5% of available habitat, indicating that these were preferred sites. Home ranges contained 37% forbs 0.8-2.0 m tall, 55% woody plants less than 0.25 m tall, 54% coverage by deciduous leaves, 2% conifer coverage, 8% dead wood, 1% rock, 1% standing water, and less than 1% marsh (Dow 1969a). In Texas, it was positively correlated with the number of shrub species and stems, foliage density 1 and 3 m above ground, and the percent coverage by pines 5-16 cm diameter at breast height (DBH). It was negatively correlated with vegetation height, percent canopy closure, foliage density 12-15 m above ground, the number of tree stems 17-32 cm DBH, and percent coverage of pines 17-32 cm DBH. It was common in clear-cuts and often occurred in mature forests where there were openings in the canopy with a subcanopy of shrubs. It preferred some tall live or dead trees for singing perches (Conner et al. 1983). In South Carolina, the cardinal occurred significantly more often in forest gaps 0.13, 0.26, and 0.50 ha in size than in the adjacent forest in all seasons. During the breeding and postbreeding seasons, it was significantly more abundant in gaps than edge habitat between gaps and forests. In autumn, it was equally abundant in gaps and edges and almost absent in forest. Gap interiors were densely vegetated and supported early fruiting shrubs such as sumac and blackberry. Poison ivy and hawthorn were common at gap edges. It did not shift its habitat use in response to

seasonal fruit availability (Bowen et al. 2007). Moorman et al. (2012) determined that usage of forest gaps was not driven by changes in arthropod abundance. Cardinals were attracted to forest gaps by the vegetation structure rather than the abundance of fruit or arthropods. In Mississippi, it was more abundant in agricultural fields with borders retained around them, and more abundant in 10-m-wide borders than those 30 m or wider. It appeared to benefit mostly from borders near wooded edges and used the borders for foraging (Conover et al. 2009). In Chicago, its abundance was positively correlated with the amount of coverage by honeysuckle and declined with tree density and distance to edge. Management that completely removed invasive shrubs could be detrimental (Schneider and Miller 2014). In the mid-Atlantic states, it was positively correlated with foliage density 2-3 m from the ground and canopy height. It was negatively correlated with the amount of forest cover within 2 km (Robbins et al. 1989). In North Carolina, it was negatively correlated with canopy cover (Lumpkin and Pearson 2013). In Maryland, it was positively correlated with herbaceous cover and negatively correlated with shrub density (Lynch 1987). In Tennessee, the cardinal inhabited areas with dense subcanopy vegetation with open canopies on flat slopes. These were mostly recently abandoned farmlands. It selected areas with a high biomass of trees 8.5-22.8 cm DBH (Anderson and Shugart 1974). In Iowa riparian stands, it was positively correlated with horizontal and vertical patchiness of habitat, grasses and forbs, and snags 3-9 m tall (Stauffer and Best 1980). In Wisconsin, it occurred in more pioneer woods and was most common in xeric stands. It was very rare in more climax stands (Bond 1957). On reclaimed mines in West Virginia, it was most abundant in shrublands with retained trees followed by remnant forest patches, grasslands, and intact forests (Margeneau et al. 2019). On strip mines in Illinois, it was most abundant in late shrub communities where the oldest trees were 37 years old, followed by upland maple-oak forests and early shrub communities where the oldest trees were 10 years old (Karr 1968). In Texas, cardinal nests were in open habitats with few trees and high coverage by grasses. Mean nest-site characteristics were 6.32 m of canopy directly above (range 2.07-22.64 m), 5.02 m to the nearest rock 20 m or longer or log 7.5 cm or more in diameter, 1.81 m to nearest understorey tree 7.5 cm or greater in DBH (range 0-14.1 m), 4.64 trees 7.5 cm or greater in DBH within 10 m (range 0-60), 13.61 understorey trees 7.5 cm or greater in DBH and 2 or more m in height within 30 m (range 0-51), 14.37 cm litter depth within 1 m (range 0-55 cm), 28.62% grass cover within 2 m (range 0-94%), 2.26% bare ground within 2 m (range 0-38%), 3.89% woody debris within 2 m (range 0-34%), 3.66% coverage by rocks within 2 m (range 0-50%), 16.78% herbaceous cover within 2 m (range 0-98%), and 1.00 m to the nearest canopy opening greater than 3 m in diameter (range 0-5.78m; Sperry et al. 2012). In Texas, better-quality territories had fewer trees and more understorey vegetation. The mean characteristics of 27 territories were 0.60 m^2 per m^3 foliage density 0-3 m from the ground, 0.27 m^2 per m^3 foliage density at ground level, 0.13 m^2 per m^3 foliage density 1 m from the ground, 0.12 m^2 per m^3 foliage density 2 m from the ground, 0.08 m^2 per m^3 foliage density 3 m from the ground, 0.04 m^2 per m^3 foliage density 7-13 m and 13-20 m from the ground, 0.20 m^2 per m^3 foliage density above 20 m from the ground, 26.85% canopy closure, 13.41 m vegetation height, 3.12 tree species, 7.47 trees smaller than 6 cm DBH, 8.21 m^2 per ha basal area, 8.37 shrub species, 29.96 shrub stems, 42.91% ground cover, and 3.78 grams of arthropod biomass. Mean characteristics within 8 m of 30 nest sites were 0.28 m^2 per m^3 foliage density at ground level, 0.23 m^2 per m^3 foliage density 1 m above ground, 0.32 m^2 per m^3 foliage density 2 m above ground, 0.15 m^2 per m^3 foliage density 3 m above ground, 0.02 m^2 per m^3 foliage density 7-13 and 13-20 m above ground, 0.29 m^2 per m^3 foliage density more than 20 m

above ground, 11.98 m vegetation height at the nest, 7.43 m^2 per ha basal area, 2.88 m nest-plant height, 45.09% horizontal concealment of the nest, and 64.57% vertical concealment of the nest (Conner et al. 1986).

Most researchers concur that the Northern Cardinal is an edge species, although it may nest in gaps in forest interior (Bowen et al. 2014). In Tennessee, it was most abundant within 30 m of edge, declining significantly to 22% of the edge density 120 m from edge. Nonetheless, it occurred in low density as far as 458 m from edge (Kroodsma 1984). In Missouri, it preferred to nest within 20 m of edge and avoided areas more distant from edge. Only 1 nest was further than 40 m from edge (Woodward et al. 2001). In New Jersey, Suthers (1988) reported that it preferred to feed in shrubs on edges.

The cardinal is not usually considered an area-sensitive species. It commonly nests in very small patches and urban areas with scattered woody cover. In some areas, populations are so dense that large patches are frequented as often as small patches. In certain areas, larger wooded areas may be preferred. In Connecticut, its abundance was significantly negatively correlated with forest size (Askins et al. 1987). In Virginia, it was more abundant in woodlots 4-24 ha in size than in blocks of contiguous forest larger than 50 ha (McShea and Rappole 1997). In red maple swamps in Rhode Island, it was most abundant in stands less than 1 ha in area, but not significantly (Golet et al. 2001). In riparian forests of differing widths in Maryland and Delaware, it was one of the most abundant species. There was no difference in its probability of detection in forests 50 m wide and those 800 m wide (Keller et al. 1993). In Illinois, its abundance was significantly correlated with patch size of isolated woodlots, but only in 1 of 2 years (Blake and Karr 1987). In South Dakota, it was significantly more abundant in large riparian forested corridors than in small isolated woodlots (Gentry et al. 2006). It is possible that some small isolated woodlots are deficient in key habitat features such as invertebrates or shrubs and saplings.

Ontario nests were in living deciduous trees, shrubs, and vines (63.3% of nests), and in living coniferous trees and shrubs (35.2% of nests). The most frequently used species were hawthorns (57 nests), cedars (55), spruces (41), grapevines (27), and honeysuckles (12). Only 1.5% of nests were in dead or dying trees or shrubs. In residential areas, the cardinal often used hedges and small ornamental trees and shrubs as nest sites and several were very close to buildings. In other habitats, it often nested in shrubby tangles and vine-covered trees and shrubs. Unusual nest sites included 2 in upturned tree roots (1 over water), 1 on top of a fence in a shrub, 1 in a roll of fence in raspberries, 1 in a climbing rose on a lattice, 1 in vines on a cottage wall beneath the eaves, and 1 in a tree in a greenhouse. Most nests were in crotches, with some on horizontal branches. They were either against the main trunk or more frequently 0.6-1.5 m from it. Most nests were located from the centre to near the top of the shrub or tree. Nests were 0.5-4.9 m from the ground with most 1.2-2.1 m up (Peck and James 1987). Peck and James (1998b) reported an exceptionally high nest 22 m from the ground in a white pine. All 8 nests that Dow (1969b) found near Elmira were in white cedars, which represented only 17.5% of trees within the home ranges. Conifers provided the best cover early in the season. Nests averaged 1.64 m from the ground (range 1.2-2.7 m).

The cardinal typically nests in shrubs and tree saplings, often in thick tangles of vines. The few that are in larger trees are often among dense foliage of vines but they may be concealed in trees

without vines. It uses a wide variety of tree and shrub species for nesting. In Michigan, 334 nests were found in 53 species of shrubs and trees: 21% in hawthorns, 19% in dogwoods, 9% in honeysuckles, and 8% in wild grape. Coniferous species it nested in included red cedar, white cedar, white spruce, pines, and hemlock. Of 121 Ohio nests, 65% were in honeysuckles or multiflora rose and 7% were in red cedar. Of 140 Indiana nests, 34% were in white elm, 21% in hawthorn, 15% in sugar maple, and 13% in red cedar. The remainder were in wild grape, dogwood, black locust, honeysuckle, Manitoba maple, elderberry, and rose. In Wisconsin, it nested mostly in honeysuckle shrubs and under the leafy canopy of wild grape growing over shrubs or lower tree branches. In Tennessee, it nested in young conifers of many species, privet hedges, rose and honeysuckle vines, various shrubs, blackberry thickets, and saplings of hackberry, elm, hawthorn, and locust. Individuals exhibit no preference for species and may nest in 2-3 different species within a single breeding season. In Iowa, 50% of nests were in shrubs, 20% were in deciduous saplings, 20% were in deciduous trees, 10% were in coniferous trees, and 0% were in forbs or grasses. It has nested on the side of a house, on a feeding shelf outside a second-storey window, among upturned tree roots, inside a chicken coop, in a bale of wire in an open-ended shed, and in a woven-wire sparrow trap on a beam in an outbuilding. The nest is usually in a fork of twigs or small branches or among mats of vine stems. It is wedged into position and not attached to the substrate. Nests are usually very well concealed in a tangle of vegetation. Most nests were 1-2.5 m from the ground, but a few very high nests have been reported. In Tennessee, nests were 0.5-8.5 m from the ground, averaging 1.28 m up before 15 May and 2.0 m later in the season. This did not include an unusually high nest found in a beech tree, but the height of the nest was not specified. Another Tennessee study reported nests 0.76-3.66 m from the ground, with most 1.2-1.5 m up. In Ohio, 2,962 nests ranged from 0.5 to 20 m above ground (mean height 2.87 m). Only 5% of nests were more than 7 m up. Mean nest height in Texas was 1.58 m. Ohio nests were 0.5-18 m from the ground and the mean height in Oklahoma was 1.8 m with a range of 0.38-4.6 m (Austin 1968; Brackbill 1950a; Conner et al. 1986; Halkin et al. 2021; Kearns and Rodewald 2017; Laskey 1944; Stauffer and Best 1980; Stoklosa et al. 2014). The cardinal rarely uses old nests. One used the lower part of a nest that remained from the previous season as the foundation for a new nest (Halkin et al. 2021; Hawksley and McCormack 1951; Laskey 1944).

Males chase all male intruders and some females out of the territory, and females chase out intruding females. Both sexes frequently intrude on other territories, so chases are common. Territorial defence begins in early spring (January to March) and ceases in late summer or autumn. Guarding and defence of the nest against predators are weak and usually ineffective (Breitwisch et al. 1999; Dow 1969b; Halkin et al. 2021; Laskey 1944; Lemon 1968; Nealen and Breitwisch 1997). In dense populations, the home range and territory coincide. In a pioneering population at Elmira, most cardinals did not have neighbours and had very large home ranges (Dow 1969a). Territory boundaries tend to be similar year to year even if they are occupied by different individuals (Halkin et al. 2021). In Texas, territory size was correlated with vegetation height and negatively correlated with foliage density 0-3 m from the ground and at the ground, and the number of shrubs. Territories were larger in areas with mature trees and smaller where only shrubby vegetation was present. A threshold amount of understorey foliage was required in territories (Conner et al. 1986). At Elmira, home ranges averaged 18.81 ha (range 10.97-23.34 ha). In denser populations at Melbourne and

Simcoe, home ranges averaged 4 ha. In dense populations in Tennessee, home ranges and territories coincided and averaged 1.18 ha (range 0.51-2.32 ha). In Ontario, a 4-ha woodlot was never found to support more than 1 pair. In Tennessee, as many as 6 pairs inhabited 1.2-ha woodlots (Dow 1969a). The Ontario study was completed more than 50 years ago when the cardinal was much less common. Territories and home ranges may continue to be large on the periphery of its range, but are probably more typical of other locations where it is more abundant in the province. In Ohio, territories were 0.3-2 ha with larger territories occurring in rural landscapes. A Missouri territory that encompassed 2 residential yards was 0.28 ha. Two Illinois territories were 0.13 and 0.18 ha. Territory sizes may have been underestimated because few observations were made. In Texas, territories were 0.2-0.9 ha and home ranges were 0.8-1.5 ha. Territory sizes of 1.4-1.6 ha have been reported in Arizona; mean territory size in Texas was 0.64 ha; 193 territories in Indiana, Ohio, Tennessee, and Arizona were 0.21-2.60 ha (means 0.93-1.50 ha); Kansas territories averaged 1.3 ha (Brewer 1955; Conner et al. 1986; Dow 1969a; Fitch 1958; Halkin et al. 2021; Hawksley and McCormack 1951; Humbird and Neudorf 2008; Paquin in Gauthier and Aubry 1996; Shustack and Rodewald 2011).

Most yearlings nest close to their natal area, but a few disperse further and these birds appear to be largely responsible for range extensions. In southern Ontario, 26 yearling males first nested an average of 1.55 km (range 0.2-5.3 km) from their natal territories. Yearling females nested 2.61 km (range 0.35-5.3 km) from their natal territory. Males from last broods dispersed further than those from earlier broods. Males from last broods that fledged before late July dispersed further than those from last broods that fledged after late July (Halkin et al. 2021). In Tennessee, 2 yearling males nested 0.8 and 1.6 km from their natal territories, and 1 yearling female first nested 4.0 km from her natal territory (Laskey 1944).

Adult site fidelity is very high, with most birds remaining in the same territory their entire life, or moving only short distances. At London, 65% of breeding birds returned in the following year (Scott 1967). In Ohio, 143 of 241 males (59.3%) and 105 of 184 females (57.1%) returned in a subsequent year (Shustack and Rodewald 2011). Of 1,621 birds in Tennessee, none were found more than 6.4 km from the banding site. Birds were highly sedentary, travelling only a few kilometres in their lifetime (Laskey 1944). Beddell (1963) analyzed banding recoveries and found that most birds were recovered within 8 km of the banding site, although some long-distance movements occurred. Adults of both sexes usually occupy territories with the same or very similar boundaries year to year, but may shift between non-overlapping territories in successive years. In Ontario, yearling birds were more likely to shift territories than adults, possibly because they may be forced to nest in suboptimal habitat in their first year. Of 13 yearling males, 8 (61.5%) remained in the same territory, 4 (30.8%) moved to an adjacent territory, and 1 (7.7%) moved 1.6 km. Of 7 yearling females, 4 (57.1%) remained in the same territory, 1 (14.3%) moved to an adjacent territory, and 2 (28.6%) moved further than 400 m (Halkin et al. 2021). In Kansas, the apparent survival rate was 40% for males and 36% for females; the overall rate of return and survival was 38% (Verheijen et al. 2017).

Dow and Scott (1971) analyzed banding returns for 1,486 cardinals recovered prior to 1962. Only 153 (10.3%) were recovered outside the 10-minute block where they were banded. The mean distance moved by all birds was 77.1 km. The longest distance was 893.2 km almost due east from northern Illinois to central Pennsylvania. One adult flew 523.0 km from New Jersey to New

Hampshire in 71 days. Nine other cardinals dispersed more than 320 km and 14 more moved further than 160 km. Two moved east from southern Michigan to southwestern Ontario, and 12 moved within southwestern Ontario. There was no apparent pattern to the direction of dispersal. More distant dispersal occurred in the first year of life but dispersal by older birds continued throughout their lives. Females decreased dispersal distances with age and were more sedentary than males. The number of cardinals dispersing represented less than 0.004% of birds, but many additional individuals must make shorter movements. Adults tended to disperse greater distances than juveniles. There was no evidence that birds on the periphery of the range dispersed further than those in the centre of the range.

Limiting Factors

Eggs have been reported in Ontario nests from the second week of April until mid-August, with most present from mid-May through the first week of June (Peck and James 1987). At London, the laying period lasted approximately 120 days from mid-April until mid-August (Scott et al. 1987).

Courtship occurs soon after the initiation of song very early in spring, typically in February in Ontario. In Ohio, nesting activity began earlier in urban than rural areas. Older males establish territories before yearlings. Nest-site visiting and displays with nesting material may occur 5-16 days before the initiation of construction of the first nest. Nests are built in 2-9 days. During adverse weather, it may take 3-4 weeks to complete a nest. Egg laying begins 1-8 days after nest completion with the interval shortening as the season progresses; 1 egg is laid per day. The egg-laying period extends into August throughout the cardinal's range and into September in more southern areas. One clutch was still being incubated in mid-October in West Virginia. Incubation begins with the laying of the last egg. At London, the mean incubation period was 12.2 days. Incubation periods of 11-13 days have been documented in Ontario and elsewhere. Brooding of the nestlings by the female is almost continuous for the first 3 days. The nestling period is 7-13 days but most commonly 9-10 days if the nest is undisturbed (Austin 1968; Halkin et al. 2021; Hawksley and McCormack 1951; Koenig and Stahl 2007; Laskey 1944; Peck and James 1987; Potter 1989; Scott and Lemon 1996; Shustack and Rodewald 2011).

In Ontario, the cardinal often successfully rears 2 broods. At London, all second broods fledged from clutches that were initiated when the rate of cowbird parasitism had begun to decline in early July. A median of 28 days elapsed between fledging and laying of the first egg of the next clutch. There is an early report of a pair successfully rearing 4 broods in a season at Toronto (Austin 1968; Peck and James 1998b; Scott and Lemon 1996). Double broods are common throughout the cardinal's range, but 3 or even 4 broods may be attempted. Three successful broods have been reported in Quebec and Tennessee, with Tennessee birds attempting a fourth brood unsuccessfully in 2 consecutive years. In Ohio, birds that initiated nests in early April made 4 nesting attempts. Those initiating nesting in late May made only a single attempt. In Kentucky, the mean number of nests initiated by 17 pairs was 2.94. When a single young fledges, the second nest is initiated about 12 days later. If 2 or more young fledge, the second nest is delayed to an average of 19.2 days after fledging (Halkin et al 2021; Laskey 1944; Pacquin in Gauthier and Aubry 1996; Ritchison et al. 1994; Shustack and Rodewald 2011). The cardinal is a frequent renester if early nests fail. It may attempt as many as 8 clutches within a season. In Ohio, 29.7% of females renested after an unsuccessful

attempt, similar to the 30.1% that attempted another brood after a successful nest (Halkin et al. 2021; Shustack and Rodewald 2011; Stoklosa et al. 2014). At London, 84 females that renested after failure laid their first egg in the replacement nest an average of 5.53 days after the loss (range 3-16 days). Renesting intervals were longest and most variable in April and May and shorter later on. Prior to 17 May when the interval length was most variable, the time between nests was dictated by temperature. Only 27.3% of intervals were within 6 days during below-average temperatures; 85.7% of warm-weather intervals were within 6 days. The stage at which failure occurred had no effect on the renesting interval. It cannot physically renest within a period shorter than 4 days because it takes that long for the egg to develop. When shorter intervals occur, the first egg of the second clutch would probably have been the last egg of the previous clutch (Scott et al. 1987). In Ontario, clutches of 2-5 eggs have been documented (mode and mean, 3 eggs). Single clutches of 6 and 8 eggs were reported (Peck and James 1998b), but it is likely these were laid by more than 1 female. Elsewhere, clutches of 1-5 eggs have been reported. The mean clutch size in Kansas was 3.31 eggs. Single-egg clutches may be a result of partial predation. Three-egg clutches are the most abundant in most populations (Austin 1968; Halkin et al. 2021; Laskey 1944; Rice 1969; Scott and Lemon 1996).

Both sexes are capable of breeding in their first year (Halkin et al. 2021). Yearling males have difficulty establishing a territory because adults defend the same area year to year. At London, 3 yearling males eventually acquired territories after they became vacant. Three others acquired territories of inferior quality with little vegetation. They did not return the next year. Three yearling males did not attract a mate, although females occasionally visited their territories. Unmated females also occurred. These trespass into territories in an attempt to mate with the male, even if he is already mated (Lemon 1968).

The mating system is monogamous (Halkin et al. 2021). Male bigamy is rare with only 3 cases confirmed. Two occurred in London where unmated females persistently trespassed into males' territories, resulting in mating and bigamy by the male. Neither case was successful because the male tended to them less. The females eventually disappeared, although one did build a nest (Lemon 1968). Another case of bigamy occurred in Ohio. The male occupied one of the largest territories in the study area. The mate of the neighbouring female disappeared and the bigamous male further expanded his territory to include hers. The nests of the 2 females were 60 m apart and out of sight of each other. The male fed the primary female but not the secondary female. He fed the nestlings at both nests at approximately the same rate. The incidence of bigamy at 2 locations was less than 5% and more likely less than 1% (Bretwisch et al. 1999). Monogamous pairs may remain mated for several years (Laskey 1944) and some pairs remain on their territories year round. In Ohio, 2 of 10 pairs (20.0%) divorced between seasons and 2 of 21 pairs (9.5%) divorced within seasons. Upon divorce or death, mates are replaced by unmated individuals or neighbours that have also lost their mates. New pairs form during the breeding season or even in autumn (Halkin et al. 2021; Ritchison et al. 1994).

Extra-pair copulations may be a common mating strategy, although the incidence of extra-pair fertilizations in cardinal populations appears to be lower than for most passerine species. Both sexes occasionally leave their territories during the breeding season, with females moving as far as 75 m and males as far as 100 m (Halkin et al. 2021). Males guard females in an effort to reduce the

incidence of extra-pair copulations. Pairs spend more time together during the female's fertile period, with males in close contact with fertile females 72.8% of the time during initial nesting attempts. Attentiveness may decline with subsequent nestings. In Kentucky, 5 of 37 nestlings (13.5%) were extra-pair young; they were present in 3 of 19 broods (15.8%). Males benefit from extra-pair copulations by increasing their reproductive success at the expense of other males. Males contribute significantly to the care of nestlings and their assistance may be essential. They may gain more from parental efforts than by pursuing extra-pair fertilizations, which may explain the low incidence of this mating strategy. Female cardinals have more opportunities to assess the quality of males than females of migratory species, so extra-pair fertilizations may be less likely to be beneficial to them (Ritchison et al. 1994). Nonetheless, females have been observed soliciting extra-pair copulations on neighbouring territories (Halkin et al. 2021). In Texas, all females made extra-territorial forays to either forage or seek extra-pair copulations. Supplemental food was supplied on some territories. If females left territories to forage, those with supplemental food should leave less frequently than those without supplemental food. Females with supplemental food spent significantly more time off their territory than those without supplemental food. Results supported the hypothesis that the extra food allowed females to spend more time off their territories, possibly in search of extra-pair copulations (Humbird and Neudorf 2008).

Intraspecific nest parasitism is a rare breeding strategy. In Oklahoma, 3 of 93 nestlings (3.2%) were not related to the female tending the nest, indicating that egg dumping had occurred (Halkin et al. 2021). Peck and James (1998b) reported 2 nests with clutches of 6 and 8 eggs. The abnormally high clutch sizes may have been a result of intraspecific nest parasitism.

The bill of the cardinal is highly adapted for extracting seeds by crushing or cutting shells. At Elmira, foraging sites underwent strong seasonal changes. Early in the breeding season, most foraging occurred on the ground in freshly cultivated fields, old grassy meadows, or in leaf litter in forests. As the season progressed, foraging sites shifted with the availability of food. It consumed tree buds just before leafout. When the canopy was fully developed, it foraged among the leaves for insects. Individuals tended to exploit whatever was available in their territory. It foraged in coniferous foliage 1.9% of the time, less than its availability (Dow 1969b). It actively moves along branches to search the foliage for insects and takes fruit from trees, shrubs, and vines. It pecks grapes with its bill, removing the pulp and seeds and discarding the skin. It has been observed catching termites in flight. One captured large goldfish in an outdoor pool (Halkin et al. 2021). In Florida, it fed on the nectar of 2 plants. It picked off the blossoms, consumed the nectar in them, and discarded them, dropping them to the ground (Russell 1951; Wible 1974). It occasionally drinks from sapsucker wells in maple trees (Austin 1968).

The red colour of the cardinal results from ingestion of carotenoid pigments obtained from the diet and may signal the quality of individuals. Fruits and insects are high in carotenoids; seeds have low carotenoid concentrations. The relationship between plumage brightness and condition is most pronounced in rural birds. In urban areas, carotenoid-rich foods from anthropogenic sources and invasive shrubs are more available to birds over a wide range of conditions. Males with brighter plumage have higher reproductive success and territories with greater vegetation density (Halkin et al. 2021; T.M. Jones et al. 2010). Plumage brightness of the adults affected the rate at which they fed

their nestlings. Male feeding rates were unaffected by the brightness of their breast plumage but the underwing brightness of females was positively correlated with the number of feedings per nestling per hour. Females mated to bright males fed their nestlings less than those mated to duller males. Females mated to bright males may increase their reproductive success by decreasing their provisioning effort while preparing physiologically for the next nesting. The underwing colour of a female appears to be an indicator of quality that may be maintained by sexual selection (Linville et al. 1998).

The male plays an important role in reproductive success. He feeds the female during incubation both on and off the nest. This allows her to be more attentive and potentially reduces the incubation period and increases nest success. Males feed the nestlings at a higher rate than females. Only males maintain their feeding rate per nestling as brood size increases and increase their feeding effort as the nestlings age. When males disappeared or were removed, there was no significant difference in the number of nests that failed. Females increased their feeding rates to compensate for the males′ absence. Males also care for the first brood if females initiate another nest. The rate of feeding by adults is unrelated to their age or experience (Filliater and Breitwisch 1997; Halkin et al. 2021; Laskey 1944; Linville et al. 1998; Ritchison et al. 1994).

Nestlings are highly insectivorous, with 94.75% of their diet consisting of animal food; 5.25% of the diet is vegetable matter. Two nestlings had eaten cicadas, caterpillars, grasshoppers, and spiders. Four others had consumed 17.25% cicadas, 20% grasshoppers, 21.25% caterpillars, and 23.25% beetles. Young have been fed dragonflies, mulberry seeds, horse flies, snails, and grass seeds (McAtee 1908). Young at 1 nest were fed goldfish (Halkin et al. 2021).

Adult cardinals feed on a mix of animal and vegetable foods, with animal foods predominating in the early portion of the breeding season. Late in the breeding season and during the postfledging period, fruits become important in the diet. The winter diet is comprised of 88% vegetable matter. This proportion is probably higher in more northern areas that are snow-covered for most of the winter. In the northeast, the main vegetable foods include fruits and seeds of wild grape, smartweeds, dogwoods, sedges, mulberries, sumacs, vervains, tulip tree, corn, and oats. In the southeast, it also consumes foxtails, blackberries, and panic grasses. It eats seeds of croton, hackberries, bush-clovers, and blazing-stars (Halkin et al. 2021). In spring in Ontario, it has been documented feeding on sugar maple sap icicles (Simpson 2025). Stutchbury et al. (2005a) studied its frugivory on red elderberry in Pennsylvania. The cardinal was one of the most abundant species, occurring on 71% of surveys but was rarely observed foraging on elderberries. It foraged on elderberries at 5.9% of sites and made only 1.9% of all bird visits to elderberries. Other authors have reported it feeding on cicadas and fruits of mulberries, hollies, and red cedar (Dow 1969b; Holt 1916; Petrides 1942; Royall 1995). Beal et al. (1916) reported that the diet of the cardinal in the southeastern United States consisted of 29% animal and 71% vegetable matter. The dominant animal foods were caterpillars, beetles, grasshoppers, and true bugs. The beetles were predominantly weevils but it also ate click and leaf beetles. The vegetable food was mostly weed seeds but also wild fruit and grain. When eating fruit, it typically eats only the seeds and rejects the pulp. Wild grape is a favourite, but it also eats seeds of dogwoods, blackberries, hackberries, greenbriers, cherries, blueberries, elderberries, pokeweed, and juneberries, and fruits of prickly-pear cactus, sumacs, holly, hawthorns,

and mulberries. Weed seeds comprised more than 33% of the diet with smartweeds most important. It also ate seeds of foxtails, crabgrass, dodder, dock, sow thistles, plantains, tumbleweed, lamb's-quarters, chickweeds, beggarticks, partridge pea, and buttonweed. McAtee (1908) analyzed the contents of 408 stomachs from 20 states, the District of Columbia, and Ontario, but a high proportion of samples were from Texas. The diet consisted of 28.99% animal and 71.1% vegetable matter. Animal food reached its maximum of 78.4% of the diet in May; the minimum was 4.9% in January. The plant material consisted of 36.38% weed and other seeds, 24.17% wild fruit (of which usually only the seeds were eaten), 8.73% grain, and 1.73% miscellaneous material. Of the weed seeds, smartweeds were most important at 5.57% followed by foxtails at 3.21%. Other seeds it commonly consumed included those of barnyard grass, crabgrass, goose grass, sedges, blue and white vervain, and ragweeds. It ate fewer seeds of dodders, vetches, docks, sow thistles, sunflowers, violets, geraniums, stargrass, corn, gromwell, spiderwort, lamb's-quarters, chickweeds, beggarticks, and clovers. Grapes were the most important wild fruit, representing 17% of the diet from November to April. Dogwood fruits, mostly those of rough-leaved and flowering dogwood, were next in importance, representing 3.97% of the annual diet. Other fruits comprised 8.3% of the diet, mostly blackberries and raspberries, but also mulberries and hackberries. Less-frequently consumed fruits included those of greenbriers, solomon's-seal, chokecherry, sweet cherry, apple seeds, blueberries, spicebush, pokeweed, prickly-pear cactus, poison ivy, elderberries, roses, juneberries, hollies, red cedar, and hawthorns. Corn was the most important grain, comprising 7.1% of the diet. Most was eaten in winter and was waste grain. Wheat, oats, sorghum, and rice comprised the other 1.62% of grains in the diet. Miscellaneous vegetation included acorns, hickory nuts, maple samaras, tulip tree seeds, galls, and buds. The animal food included millipedes, centipedes, insects, spiders, clams, and snails. It has been reported eating a mouse. Insects were most important, comprising 26.25% of the 18.99% animal food. Beetles represented 10.48% of the diet with weevils most important at 3.26%. Other beetles that it consumed were scarab, june, metallic wood-boring, click, long-horned, leaf, darkling, and blister beetles. Grasshoppers constituted 6.43% of the diet, but it also ate crickets and katydid eggs. Butterflies and moths represented 5.1% of the annual diet but 26.71% of the May diet. These were mostly caterpillars but it ate some adults. Bugs comprised 3.72% of the diet, including cicadas, leafhoppers, jumping plant-lice, treehoppers, scale insects, stink bugs, assassin bugs, and chinch bugs. Hymenopterans represented about 1% of the diet, mostly wasps, but ants and sawflies were also eaten. It rarely ate flies and mayflies. Snails were commonly consumed, 1 slug was eaten, and 1 bird had eaten several small clams that it must have obtained from water.

Two studies compared the feeding ecology and seed preferences of the cardinal with other species. In an aviary experiment, Browning et al. (1981) provided seeds of round-headed bush-clover, blazing-star, and 2 types of sunflowers to the cardinal. The cardinal selected sunflower seeds and ate few bush-clover and blazing-star seeds. It gained 1% of its weight daily when feeding on sunflower seeds and lost 12-13% of its weight when feeding on the other 2 species. Bush-clover was of the lowest nutritional quality and least preferred; sunflowers were the highest quality. In North Carolina, Pulliam and Enders (1971) compared the feeding ecology of the cardinal, Field Sparrow, Dark-eyed Junco, White-throated Sparrow, and Song Sparrow. Vegetable matter comprised 100% of the cardinal's January diet, dropping to a low of 40% in July and increasing to 90% from October to March. This pattern was similar for all species. The mean size of seeds it consumed was 3.1 mm.

Almost all foods larger than 3.5 mm were soft fruits; smaller seeds were hard grains, achenes, and nutlets. The main habitats it used were dominated by crabgrass, broomsedge, or shrubs. Cardinal habitat use overlapped 51% with the Field Sparrow, 73% with the junco, 65% with the Song Sparrow, and 72% with the White-throated Sparrow. Seed-site use overlapped 100% with the Field Sparrow, 98% with the junco, 99% with the Song Sparrow, and 100% with the White-throated Sparrow. Twenty-three percent of cardinal feeding observations were of birds perched on plants, 9% on bare ground, and 68% standing on the ground feeding from a standing plant. The cardinal spent the most time (34%) in forests of the species and ate the most fruit (32%) thereby reducing competition. The authors concluded that these species were limited by the food supply, with the presence of any species reducing the total number of individuals of any other species that a site could support.

The cardinal is one of the Brown-headed Cowbird's more common hosts. Despite this, parasitism has a low effect on the reproductive success of the cardinal, and reproductive success of cowbirds in cardinal nests is very low. The cardinal is an acceptor of cowbird eggs (Rothstein 1975). Its primary defence is nest abandonment. Using data from the Ontario Nest Records Scheme (ONRS), Graham (1988) determined that 52% of parasitized nests were abandoned compared with 4% of unparasitized nests, a significant difference. Egg acceptance rates were 25% before the peak of clutch initiation and 52% later. Cowbird eggs are occasionally buried in cardinal nests, but this is probably due to parasitism occurring before the nest is complete. McLaren et al. (2006) also used ONRS data to conclude that there had been no change in frequency or intensity of cardinal nest parasitism in response to population changes of the cowbird. At London, cardinals rarely deserted parasitized nests unless there was obvious interference by the cowbird. Cowbirds began parasitizing nests there in late April, about a week after cardinals initiated nesting, with peak parasitism rates reaching 100% at the end of that month. There was a decline in the rate of parasitism in May and June that was likely due to cowbirds selecting alternative hosts. The incidence of parasitism declined rapidly in July, dropping to 0% by August. This was a result of the reduction in reproductive activity of the cowbird. Seventy-five percent of parasitized nests lost an egg compared with 12.5% of unparasitized nests. This was attributed to cowbird removal of eggs. Reduction of clutch size appeared to be the only negative impact of parasitism on the cardinal. Hatching and fledging success rates for cardinals were similar in parasitized and unparasitized nests. In contrast, very few cowbirds survived in cardinal nests and many that did fledge died a few days after leaving the nest (Scott 1963, 1977; Scott and Lemon 1996). Eckerle and Breitwisch (1997) reported similar results in Ohio, with the timing of parasitism similar and the only cost to cardinals being egg removal by cowbirds. They concluded that the lack of rejection behaviour by the cardinal may be due to the low costs of parasitism. Stoklosa et al. (2014) studied parasitism on the cardinal in Ohio in relation to distance to forest edge. Early in the nesting season, the risk of parasitism was lower in nests further from edge but the opposite was true later in the season. Cowbirds may spend more time searching for prey in forests later in the season as arthropod abundance increases and move further into forests to seek alternative host species. Peck and James (1998b) reported that 72 of 358 nests (20.1%) were parasitized in Ontario. At London, 72 of 85 nests (89.7%) were parasitized 1960-69 (Scott 1977). From 1955 to 1968, about 230 of more than 700 nests (about 33%) were parasitized (Scott and Lemon 1996). Parasitism rates in other areas include 6 of 231 nests (2.6%) in Georgia (Kilgo and Moorman 2003), 139 of 347 nests (40.1%) and 55 of 115 nests (47.8%) in Ohio (Eckerle and Breitwisch 1997;

Stoklosa et al. 2014), 10 of 15 nests (66.7%) in Kansas (Rivers et al. 2010), 1 of 7 nests (14.3%) in New York (Hahn and Hatfield 1995), and 13 of 39 nests (33.3%) in Illinois (Chapa-Vargas and Robinson 2013).

Habitat loss is not a limiting factor for the cardinal. Forest fragmentation and urbanization have created considerable habitat for it. Modern subdivisions are considerably less likely to provide suitable habitat due to the high density of houses and small yards with limited planting of shrubs.

Several studies examined whether urban areas and forest edges, 2 preferred habitats, are ecological traps, enticing cardinals to nest where reproductive success is likely to be low. In Ohio, Leston (2006) reported no significant differences in productivity and return rates of adults in urban and rural forests. The cardinal strongly selected for exotic shrubs as nest sites and urban forests with lower canopy heights where these shrubs were common. Even though nests in exotic shrubs were more than 2 times likely to fail as those in native trees and shrubs, overall productivity in urban forests was similar to that of rural forests. It was concluded that there was no evidence that urban forests acted as ecological traps. In Missouri, Woodward et al. (2001) observed no difference in nest success in relation to distance from edge and concluded that edge did not act as an ecological trap. In Illinois, Chapa-Vargas and Robinson (2013) determined that nest success decreased slightly but nonsignificantly as the amount of agricultural habitat within 500 m of the nest increased. They concluded that the landscape was saturated with predators and that nesting success did not increase with increasing proportions of natural habitat. In Indiana, Ford et al. (2001) compared parasitism and nest survival rates in a 1.1-km forested floodplain corridor and an 87%-forested landscape. There was no difference in the parasitism rates in the 2 habitats. Cardinals in the forested landscape produced 2 times as many fledglings per nesting attempt than those in the riparian corridor. In Ohio, Shustack and Rodewald (2011) found no differences in productivity of birds nesting in rural and urban areas and there was no particular advantage or disadvantage to nesting earlier in the season. In Missouri, Peak et al. (2004) studied cardinal nest success in narrow (55-95 m) and wide (400-530 m) riparian forests. The habitat, edge, timing of nesting, and nest site had limited effects on nest success. Even wide corridors were insufficient to increase nest success in agricultural landscapes saturated with predators.

In Texas, Conner et al. (1986) examined characteristics of successful and unsuccessful territories. Territories with successful nests had higher foliage density 2 m above ground throughout the territory than those with unsuccessful nests. Fledging success and the number of young in nests were positively associated with arthropod biomass, which in turn was correlated with foliage density 0-3 m from the ground, percent ground cover, and shrub species diversity. Arthropod biomass was negatively correlated with the number of trees, basal area, and tree height. There was no correlation between nest height and nest success.

Several studies examined cardinal nesting in relation to predator populations. In Ohio, first nests of cardinals were located in areas of high activity of avian predators and cowbirds, significantly higher than in random locations. Second nests were not associated with high levels of activities of these species. Nest survival decreased when both avian and mammalian predator activity was high but increased over the season when only mammalian predator activity was high. There was little evidence that cardinals used predator activity as information to select nest sites. Other cues such as

nesting habitat, food resources, and social information may be more important in nest placement and habitat selection (Kearns and Rodewald 2017). Also in Ohio, Malpass et al. (2017) determined the effects of bird feeders on nest predation of the cardinal. Neighbourhoods with at least 15 feeders had 2.7 times more American Crows and 3.2 times more cowbirds than those with 3 or fewer feeders. Nest survival of the cardinal was not related either to the number of feeders or predators. In Texas, cardinal nest survival was negatively correlated with rat snake activity, which was low in the early and late nesting season and peaked mid-season. Snakes were found in areas with more habitat structure than cardinals. Nest-site attributes had little influence on nest survival, which was related predominantly to snake activity (Sperry et al. 2012).

McAtee (1908) reported that the cardinal was highly sensitive to disturbance and would abandon unfinished nests and even full clutches if disturbed. It is quite possible that it is now more habituated to human activity. Smith-Castro and Rodewald (2010) studied its response to human disturbance along recreational trails in Ohio. When approached directly, 67% of females flushed from nests compared with 11% when a human passed by on a trail. Birds with nests closer to the ground had a greater tendency to flush. Birds did not appear to habituate to humans, with those closer to trails having an increased tendency to flush. There was no association between nest survival and the tendency of a female to flush. Human disturbance related to trail use had only short-term effects with no effects on nest survival. Battle et al. (2016) conducted a similar study in urban and rural areas in Virginia. The average flight initiation distance was 8.5 m in urban habitats and 13 m in rural habitats. Although the difference was not significant, birds in urban habitats may have been more habituated to human activity. Baldassarre et al. (2024) reported almost identical results in New York. The average flight initiation distance was 8 m in urban habitats and 17.5 m in rural habitats. In Virginia, McShea and Rappole (1997) determined that birds more than 50 m away from the observer sang more frequently than closer birds. In the late 19th and early 20th century, the cardinal was a common household pet. In some areas, great numbers were captured and sold into captivity. Many were also killed for the millinery trade (McAtee 1908).

Forest harvesting tends to have either no or positive effects on the cardinal. In small clear-cuts in Pennsylvania aspen and oak stands, there were no significant differences in its abundance before and after cutting (Yahner 2003). In southern Ontario deciduous woodlots, there were no significant differences in its abundance in uncut stands, those that were selectively thinned, and those where heavy diameter-limit cuts were made (Holmes et al. 2004).

Drought may end the nesting season prematurely by reducing the availability of insect prey (Halkin et al. 2021).

In Tennessee, the cardinal responded favourably to fire in pine-oak forests. It occurred more frequently only after high severity burns that resulted in more than 60% mortality of the canopy and loss of most of the understorey (Rose and Simons 2016).

In Delaware, density of the cardinal was similar in areas with low, moderate, and high white-tailed deer populations. Shrub-nesting species combined were consistently found with greater species richness and abundance at low deer densities (Tymkiv et al. 2012).

In West Virginia, Farwell et al. (2019) investigated the effects of shale gas infrastructure (access roads, pipelines, and well pads) in a large contiguous forest. There was no significant difference in the cardinal's abundance near or distant from any of these facilities.

Near Missouri lead mines, the probability of a female fledging a young decreased from 60% to 48% in areas with elevated lead concentrations in soil. Most nest failures were due to predation, suggesting that lead affected birds' behaviour and activity at the nest or affected nest-site quality (Thompson et al. 2024).

In North Carolina, the abundance of the cardinal increased with increasing temperatures (Lumpkin and Pearson 2013). Price (2004) predicted that its range in southern Ontario might expand if the average summer temperature increased by 2°C.

Status

The Northern Cardinal is a recent addition to the avifauna of Ontario. Its range expansion into the province was part of a larger range extension that was probably prompted by increased habitat availability as a result of forest fragmentation and urbanization coupled with provision of bird feeders and amelioration of winter temperatures. Fairly uniform peripheral expansion of its range occurred prior to 1943, with a smaller amount of dispersal by birds in the centre of its range and a high amount in the northwest. From 1943-52, there was a decrease in its dispersal in the west and an increase in the east 1953-62. The decrease in dispersal in the west was roughly equivalent to the increase in the east. Juveniles exhibit a marked increase in dispersal after their first year. Dispersal and pioneering occurs in the early years of life, but not all in the first year. In Elmira, 64% of territorial males were yearlings compared with 11% in Tennessee, indicating a high proportion of pioneering by yearlings in Ontario at a time when Elmira was near the northern extent of its range. In comparison, 28% of territorial males at London were yearlings in an area where populations had been established longer. Dispersal occurs both before and after the breeding season from December to April and August to December, by juveniles and adults respectively. Dispersing cardinals tend to follow river systems and settle close to them. Others pioneer in cities near feeders in winter and remain to breed. It appears as though there has been a loosely cyclical pattern of expansion and retraction whereby birds move up waterways to establish local populations only to be extirpated by severe winter weather (Austin 1968; Dow 1994; Dow and Scott 1971; Halkin et al. 2021).

The first record of the cardinal in Ontario occurred at Chatham in 1849. Breeding was first confirmed at Point Pelee in 1901 with subsequent early breeding records at Chatham in 1909, London in 1915, Brantford in 1919, Toronto in 1922, Orillia and Port Hope in 1938, Owen Sound in 1942, Meaford in 1943, and Tweed in 1953 (Baillie 1967; Dow 1994). McIlwraith (1894) considered it a casual visitor along the southwest border. There were a few reports from Port Rowan and Dunnville where it purportedly nested in conifers. In Elgin County, it was accidental in 1891, a common resident in 1954, and a common and widespread resident in 2000 (Lancaster et al. 2004). The first Hamilton record was in 1894 and the first for Guelph was in 1898. It is now an abundant and ubiquitous permanent resident in these areas (Curry 2006). Fleming (1907) considered it accidental in Ontario and concluded that it probably occurred only in winter. Baillie and Harrington (1937) concluded that the cardinal was fairly common in southern Ontario north to at least Simcoe County

and east to Ottawa, with accidental occurrences in Algoma and Parry Sound districts. Its known breeding range was confined to the area south and west of Toronto. In Niagara Region in 1936, it was slowly extending its range from the west but was still rare in the eastern portion of the region. There were no records from the Niagara Falls area but it was fairly common along the Lake Erie shoreline in the western portion of the region (Sheppard et al. 1936). There appears to have been a large increase in its range in Ontario in 1938 so that by 1965-67 the northern extent of its breeding range was a line from Goderich to Port Hope. Its distribution was influenced by lake-effect snowfall with heavy snowfall producing the main limiting factor by diminishing food availability (Dow 1994). It was first seen in Northumberland County in the late 1930s and at Presqu'ile in 1957, where it is now a permanent resident (LaForest 1993). The first record for the Kingston area was in 1951 but it was not confirmed as a breeder until 1968. It is now a fairly common to common permanent resident there (Weir 2008). The first record for Muskoka and Parry Sound districts was in 1954 where it is still uncommon (Mills 1981). The first atlas revealed that the cardinal nested in most squares south of the Canadian Shield, with more records in eastern Ontario and the Ottawa area than previously reported. There were scattered records on Manitoulin Island, where breeding was confirmed, in the southern Shield, and in northern Algoma District. Evidence of possible breeding was obtained near Thunder Bay and Marathon (McNicholl in Cadman et al. 1987). James (1991) considered the cardinal a common permanent resident south of the Shield; rare north to Manitoulin Island and North Bay; and an occasional straggler north to Rainy River, Thunder Bay, and Kirkland Lake.

The second atlas indicated that there had been no significant change in the cardinal's range since the first atlas. The population appeared to continue to grow, particularly south of the Shield in the Great Lakes–St. Lawrence Forest Region. Its probability of observation increased significantly there, particularly in southeastern Ontario and along the southern edge of the Shield. It also occurred in more squares in the southern Shield and on Manitoulin Island. There were additional records from the north near Atikokan, Cochrane, and Kenora, which represented significant northward movement. It was most abundant along the north shore of Lake Erie and southwestern Lake Ontario northeast to Toronto. An area of higher density also occurred in the urban portion of Ottawa (McLaren in Cadman et al. 2007).

In Ontario, BBS data indicated that the cardinal increased at an annual rate of 3.2% 1983-2013, the 24th highest rate of all Ontario birds (Cadman et al. 2016). It appears to have increased in much of its range in addition to expanding its range. BBS results indicate that it increased at annual rates of 3.66% in Canada and 3.09% in Ontario 1970-2021. The trends 2011-21 were annual increases of 4.72% in Canada and 3.74% in Ontario. Results were highly reliable for the long-term Canadian and short-term Ontario trends; the other results were of medium reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Young are unable to fly when they leave the nest, or can fly weakly, and are capable of strong flight when they are 19 days old. At 1 nest, young travelled 18 m from the nest across a yard to a privet shrub where they remained overnight. Birds in urban yards tend to remain close to the nest for several days. For the first 11 days after fledging, young rarely move from the branches where they are perched. From 12-20 days after fledging, they move more, occasionally leaving the natal territory

but still receiving most of their food from the parents. In southern Ontario, young were fed an average of 32 days after fledging with an average of 39.2 days in Ohio. Complete independence may not be attained until the young have been out of the nest for 56-59 days. Prior to the female initiating another brood, the earlier brood is split between the adults. Once the female starts the next nest, the male cares for all the fledglings. The male feeds them until the next brood hatches, and the first brood leaves the natal territory about this time. The last brood of the season is attended to by both adults and tends to remain on the natal territory longer than earlier broods and is fed for longer (Austin 1968; Halkin et al. 2021; Laskey 1944; Van Tyne 1951).

Ausprey and Rodewald (2013) studied the movement patterns and habitat use of cardinal fledglings in Ohio. The mean 95% home range of 20 fledglings was 2.33 ha (range 0.92-6.75 ha); the mean 50% kernel home range was 0.48 ha (range 0.21-4.6 ha); and the minimum 95% convex polygon was 0.93 ha (range 0.18-2.74 ha). Young dispersed from the natal territory an average of 47 days after fledging (range 35-55 days). The distance from the nest on the breakpoint day was 23.1-51.3 m. The natal-range size was correlated with fledglings' distance to forest edge, with birds near edges having smaller ranges. Distance from the nest to the range was negatively correlated with the extent of urbanization in the surrounding landscape and percent cover by honeysuckle at the nest. Thirteen of 20 fledglings (65.0%) dispersed from the natal territory. Birds that dispersed locally did so within their natal forest but others made extended movements to other forest fragments or into the surrounding landscape matrix. Birds leaving the natal forest dispersed significantly further (median 594 m, range 349-985 m) than locally dispersing birds (median 171 m, range 93-569 m). Of birds that dispersed, 11 went to a single dispersal area, 1 moved to 2 sites, and 1 moved to 3 sites. Six birds that dispersed made exploratory movements into their future home range before dispersing. Birds in forests with higher densities of conspecifics dispersed later than those in forests with low density. The extent of movement was inversely related to preferred habitat attributes, with less movement from sites with extensive honeysuckle cover or those in heavily urbanized landscapes. Proximity of forest edge, which often supports dense vegetation, contributed to the size of the eventual home range. Cover of honeysuckle increases with urbanization, so fledglings at urban sites likely had more protective cover from this shrub and moved less. Movements appeared to be related to habitat but the timing of movement was associated with density which may have been a social cue indicating habitat quality. In this study, most birds dispersed near their natal ranges or did not disperse within the life of the transmitters. It is probable that stationary fledglings dispersed later. Other studies determined that juveniles generally move no more than 100 m and many remain within a few kilometres of the natal area.

Fledgling position in the canopy was influenced by the presence of honeysuckles. The average height of fledglings' perches was 4.1 m. Fledglings in honeysuckle were significantly lower (2.1 m) than those in other substrates. Fledgling age and position were not significantly related. Microhabitats used by fledglings differed significantly from random. Selected areas had 1.7 times more honeysuckle cover and 1.3 times more saplings than random areas. Areas used by fledglings had significantly more surrounding vegetation than nest sites. Fledglings selected areas with 2.2 times more shrub coverage than occurred at nests (Ausprey and Rodewald 2011).

In Ohio, Ausprey and Rodewald (2011) studied fledgling survivorship along a rural to urban gradient and how the presence of Amur honeysuckle influenced survival. Cardinal density was 1.7 times higher in urban forests than rural forests during the breeding season and 4.0 times higher in the postfledging period. Mortality of fledglings was greatest in the 3 days following fledging. Their survival rate increased as the number of saplings 3-8 cm DBH increased and the number of small (8-23 cm DBH) and medium-sized (23-28 cm DBH) trees decreased. The survivorship on days 1-3 increased from 73% to 95% as the number of saplings increased from 0-46. Survival increased as the landscape became more urban, and was 59% higher in the most urban areas than the most rural areas. Survival tended to be higher in urban areas in the first 3 days when mortality was highest. Fledglings were more likely to survive as the structural complexity of forests increased, and urban forests were denser due to the presence of honeysuckle. Survivorship was not related to the extent of urbanization but rather to the structural complexity of the vegetation, whether or not it was honeysuckle. Although urban areas tend to have higher predator densities, presence of outdoor pet food, refuse, bird feeders, and other food sources may weaken the link between predator populations and bird depredation rates. In this area, urban forests appeared to act as source populations for the cardinal.

Limited information is available on the diet of fledglings but they probably eat mostly insects. They have been fed cicadas, grasshoppers, snails, weevils and other beetles, caterpillars, and blackberry seeds. Young at a feeder ate bird seeds, elderberries, suet, bread, and cheese. Adults at the same feeder ate all these items plus canary seed, corn, nut meats, and sunflowers. Fruit becomes important in the adult diet during the postbreeding moult. In Ohio, the adult diet consisted of 58% fruit, 18% unidentified, 16% insects, and 8% seeds (Halkin et al. 2021; McAtee 1908; Nice 1927; Van Tyne 1951).

Flocks of cardinals begin to assemble after the autumn moult. These start as family groups and enlarge as birds from adjoining territories join. Flocks may remain intact until early spring when individuals begin to establish territories. Other birds remain in their territories year round and briefly join these flocks as they pass through the territory (Halkin et al. 2021; Laskey 1944).

MIGRATION

The Northern Cardinal is usually considered a permanent resident that exhibits no evidence of migration. Many birds remain on their breeding territories in the winter and essentially for their lifetime once they reach breeding age. Reports of migration are often dismissed as representing juvenile dispersal (Halkin et al. 2021).

There is some evidence that at least a proportion of the population undertakes migratory movements. Brewer et al. (2018) reported that northern populations are partly migratory. Dow (1994) reported that there appeared to be a well-defined movement through Long Point in late April and early May at a time when most birds were breeding. This suggested that dispersal was more than casual random movement away from natal areas. Austin (1968) reported that there was a decided trend of movement north and northeast in late summer and autumn that might account for many northern winter records and for its northward spread. In Illinois, Graber and Graber (1963) reported that there appeared to be a southward shift of the population in midwinter. In 1957, populations in the northern and central portions of the state were lower in January than in June and

the southern population was 2.1 times higher in January than in June. Fitch (1958) also noted seasonal fluctuations in populations in Kansas. It suddenly became more abundant in late autumn of each year. Even larger numbers sometimes occurred in late winter when the weather was severe and the ground was covered by snow.

WINTER

Some cardinals of both sexes remain on their breeding territories all winter. Others join loose flocks that form in September and disband in February once mating activity resumes. Flocks often consist mostly of juveniles but some adults occur, usually with the sexes equally represented. There is a possibility that adults in flocks may be migrants. The number of birds in flocks remains fairly constant but flock membership frequently changes. Flocks tend to move over the landscape, with individuals dropping out as a similar number join. Individuals may move 500-900 m and change flocks and rarely remain with the same flock if it travels further than 1.6 km. Birds that remain on their territories join flocks temporarily as they move through. Flocks are often associated with American Tree Sparrows, Dark-eyed Juncos, Song Sparrows, and American Goldfinches (Dunn and Tessaglia-Hymes 1999; Halkin et al. 2021; Laskey 1944; Lemon 1969; Shustack and Rodewald 2011).

The cardinal typically occurs where the average minimum January temperature is above –15°C. River valleys strongly influence its distribution, with highest densities along major river systems (Root 1988). Smith (2003) analyzed Winter Bird-Population Study data for southern Ontario and determined that the cardinal was most abundant in urban natural areas. Densities per km^2 were 28 in commercial and residential areas dominated by buildings and pavement, 24.3 in urban public spaces smaller than 10 ha, 16.4 in urban public spaces larger than 10 ha, 7 in urban natural areas with water, 1.9 in rural forests, 1 in rural farmlands, and 0 in cropland.

In Illinois, the cardinal was more likely to visit open field habitats in winter than in spring (Graber and Graber 1963). In Arkansas, Kentucky, and Mississippi, Evans et al. (2015) studied its response to buffers of grasses and forbs around fields of corn or soybean stubble. It was more abundant in fields with than without buffers and in fields with buffers less than 23 m in width than wider buffers, but these relationships were not significant. Doherty and Grubb (2000) examined its use of isolated woodlots 0.05-6.01 ha in Ohio during winter. It was less likely to be present as woodlots became more isolated but its density decreased with increased connectiveness. Its density increased with increased coverage by swamps but highest densities occurred in beech–sugar maple woodlots. In Texas, the winter population increased with shrub density and soil moisture. It was most abundant in riverine forests, with a density of 692 per km^2. Densities in other habitats included 148 in oak woodlands, 114 in brushland with 2 layers, 106 in dense brushland, 67 in open brushland, 47 in grass-forb prairie, and 2 in scrubby grassland (Halkin et al. 2020).

The cardinal may have a large home range in winter. In Tennessee, birds frequently moved to a site 1.2 km away to feed on hackberry and sunflower seeds (Laskey 1944). In Kansas, winter home ranges averaged 4.9 ha for 49 males and 9.3 ha for 31 females. This excluded movements of about 800 m by 1 male and 2 females (Fitch 1958). In Kentucky, winter ranges averaged 19.9 ha for males, 23.1 ha for females, and 21.2 ha overall. Daily home ranges averaged 1.17 ha (range 0.32-3.38 ha). Home ranges overlapped with conspecifics by as much as 3.36 ha. Over the course of a winter, an

individual may move back and forth between feeding stations as far as 2.1 km apart and as far as 4.5 km in 1 direction (Halkin et al. 2021; Paquin in Gauthier and Aubry 1996).

In winter, the cardinal prefers to feed on the ground or in short vegetation under woody cover (Dunn and Tessaglia-Hymes 1999). The winter diet consists mainly of seeds. In Ontario, it has eaten seeds of giant ragweed and riverbank grape (Dance 1986, Dance et al. 2012). It rarely feeds on tree seeds, including those of tulip tree. In Florida, it fed on attached pine cones in the mid- to upper canopy. It rarely visits pine forests and typically feeds on the ground. It walked or hopped along branches or made short flights within trees to visit cones. This was the first documentation of it eating pine seeds (McNair 1997). Searles (1989) reported a male and female cardinal feeding on a Black-capped Chickadee carcass.

The cardinal is a common visitor to bird feeders and is common at feeders all winter. Feeders in rural areas are visited less frequently than those in urban areas, but flock sizes tend to be larger in rural areas (Dunn and Tessaglia-Hymes 1999). Stanbeck and Powell (2010) studied its feeder preference based on distance from cover, presence and absence of Cooper's Hawks, and type of seeds provided. They installed feeders 1.5 and 15 m from dense vegetation cover, provided sunflower seeds in some feeders and mixed seeds in others, and played Cooper's Hawk calls. Prior to playing the calls, the cardinal visited feeders with sunflowers significantly more than those with mixed seeds, and significantly more visits were made to feeders closer to cover. Exposure to Cooper's Hawk calls resulted in a dramatic and significant shift in feeder use. On playback days, instead of preferring the higher-quality seed in the exposed feeder, it had a significant preference for the lower-quality seed in the safer location. On days when no hawk calls were played, 67% of visits were to the exposed feeder when it contained sunflowers compared with 36% of visits on playback days. Horn et al. (2014) provided tube, hopper, and platform feeders to participants in Canada and the United States. The cardinal preferred platform feeders over the other 2 types. In North Carolina, Millican et al. (2012) provided feeders with safflower or sunflower seeds. Both sexes visited the sunflower feeders significantly more often than the safflower feeders and both preferred sunflowers when no conspecifics were present at a feeder. Females avoided all conspecifics when visiting feeders regardless of which feeder was occupied. They visited the safflower feeder significantly more frequently than the sunflower feeder when it was occupied. Females were particularly adverse to visiting feeders that were occupied by males. Males avoided feeders occupied by other males, visiting safflower feeders significantly more often when the sunflower feeder was occupied by another male. Males preferentially visited feeders occupied by females even when they contained the less preferred food. The landing of a new bird usually resulted in the departure of the first bird. Other authors noted that males are often aggressive toward females in winter. Females do not exhibit aggression to males at any time of the year (Laskey 1944; Lemon 1968).

Horn et al. (2014) and Johansen et al. (2014) provided 10 types of seeds to participants in Canada and the United States, who made 54,017 observations of feeding cardinals. The cardinal preferred black oil sunflowers over all other seeds. In 93% of observations, it selected seeds with a hull, 46% of the time it selected seeds with greater fibre content, and 27% of the time, it selected seeds with more protein content. The cardinal is one of few species that readily eats safflower seeds at feeders, and sunflowers are a staple. Preferred seeds were those of striped and black oil sunflowers, hulled

sunflowers, mixed seeds, and safflowers. Black oil sunflowers were preferred over all other seeds. It also eats millet, canary seed, whole and cracked corn, wheat, peanuts in any form, pet food, peanut butter mixes, bird puddings, fresh fruit, baked goods, canola, and water (Dunn and Tessaglia-Hymes 1999). Austin (1968) reported it eating raisins, pieces of apple, and bread at feeders.

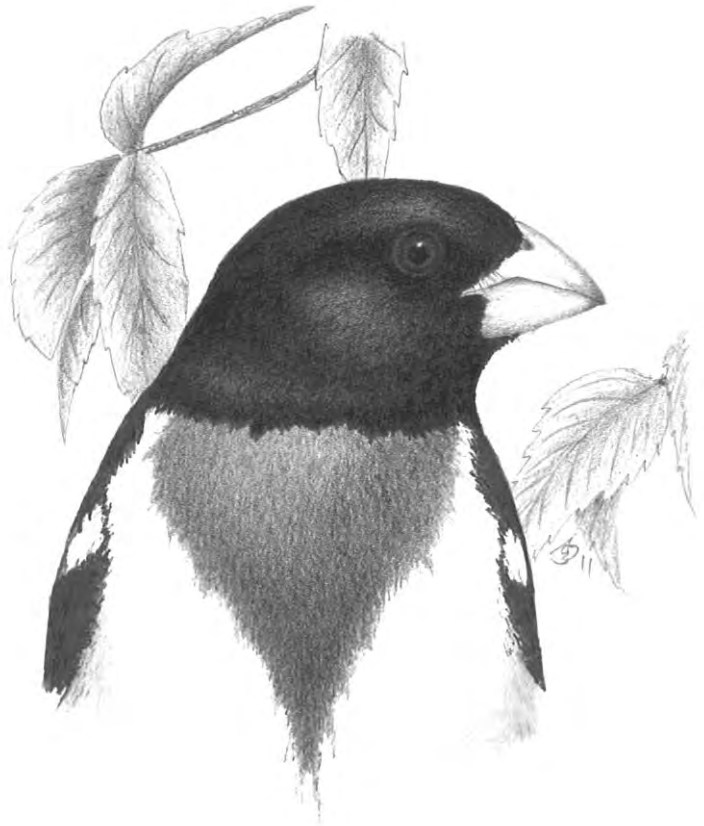
Severe winter weather is probably the most important factor limiting the northern range expansion of the cardinal. After a severe winter storm in Illinois, its density declined significantly in bottomland and upland forests. A slight population decline occurred in urban residential areas. The effects of the storm may have been lessened by the presence of feeders and ornamental plantings. Some cardinal carcasses were found and it was believed that most of the population decline was due to mortality (Graber and Graber 1979).

Loss et al. (2014) determined that the cardinal was 27.5 times more likely to strike a 1-3 storey residence than average. It was among the top 20 species striking residences but not among those most likely to strike low-rises or high-rises. Although building strikes by the cardinal may occur at any time of the year, they are most prevalent when visiting winter bird feeders.

The winter population of the cardinal has increased in Ontario and elsewhere. This is due to a combination of habitat modifications by humans that are beneficial to the cardinal, and to winter bird feeding (Halkin et al. 2021). Cardinals may range into northern Ontario well north of the breeding range, particularly in November. This may be the mechanism of northward expansion of the breeding range, facilitated by warmer temperatures and bird feeders (Ratcliffe et al. 2021). Freedman and Riley (1980) analyzed Christmas Bird Count (CBC) data for southern Ontario 1929-77. Numbers increased greatly over this time. Bedell (1963) summarized CBC data for Ontario for 1938-60. Numbers reported ranged from 3 to 127 seen per 100 party-hours. The lowest count was in 1938 and the highest was in 1948. The cardinal was first recorded on the Hamilton CBC in 1930 and has been observed every year since. Numbers continue to climb consistently (Curry 2006). CBC data indicate that it increased in Ontario at annual rates of 3.25% 1970-2021 and 1.70% 2009-21 (National Audubon Society 2022).

Rose-breasted Grosbeak

Pheucticus ludovicianus



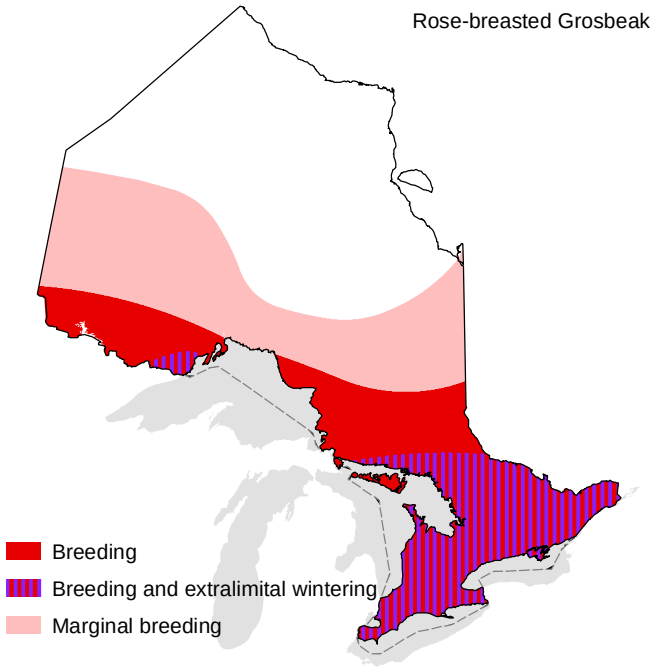
BREEDING SEASON

Habitat Requirements

In Ontario, 69.2% of Rose-breasted Grosbeak nests were in woodlands, including 31.5% in deciduous, 24.3% in mixed, 0.9% in coniferous, and 12.5% in unspecified stands. Of the remaining nests, 25.2% were in shrubby areas and overgrown fields and pastures; 2.5% were in shrubby road and railway rights-of-way; 2.5% were in gardens, parks, and cottage areas; 0.3% were in sand dune areas; and 0.3% were on rock outcrops. Woodlands that it used most frequently open second growth rather than mature dense stands. Many nests were at shrubby edges and clearings or near paths and shorelines, suggesting that it preferred to nest near open areas. It exhibited no preference for moisture regime, nesting in dry habitats as well as moist woods, swamps, willow swales, and bogs (Peck and James 1987).

In the Clay Belt of the Boreal Forest Region, Welsh and Lougheed (1996) found the Rose-breasted Grosbeak in a trembling aspen stand that was wet and nutrient-rich. Near Hearst, Welsh

and Fillman (1980) reported it in 9-, 13-, and 17-year-old clear-cuts in upland mixed forests. All were characterized by dense coverage by mountain maple and beaked hazel 2-5 m tall. North of Lake Nipigon, Sanders (1970) reported it in overmature trembling aspen stands. Near Manitouwadge, Venier et al. (2009) reported it in boreal mixedwood forests. It was most abundant in stands 24-36 years old, followed by those 1-21 years old and 60-223 years old.



In Quetico Park in the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region, the Rose-breasted Grosbeak was most abundant in stands 112-370 years old, uncommon in stands 1-23 years old, and absent in stands 67-72 years old (Apfelbaum and Haney 1985). In jack pine stands near Gogama, it was associated only with the deciduous elements of mixed forests. It was present in more open parts of mixed forests that were more than 20 years old (James and Peck 1995a). It was absent in pure jack pine stands near Parry Sound. It occurred at low densities in open jack pine stands mixed with trembling aspen, white birch, sugar maple, white pine, and white spruce (James 1979a). It occurred predominantly in second-growth deciduous forests in Parry Sound and Muskoka districts (Mills 1981). In Algonquin Park, it was fairly common in deciduous woods, particularly at edges of openings (MacLulich 1938). Martin (1960) reported it in the park in hardwoods and poplar–white birch stands mixed with balsam fir, spruce, and hardwoods. Kingsley and Nol (1999) studied it in shelterwood cuts in white pine stands in Algonquin Park. It was associated with dense deciduous cover in the canopy and subcanopy. It was equally abundant in stands with no recent history of cutting and those 2-16 years old. Kirk et al. (2012) examined its presence in old-growth and mature white pine stands in the Shield portion of the Great Lakes–St. Lawrence Forest Region. It occurred in low numbers in both age classes of forest but tended to be more abundant in mature than old-growth stands. In Muskoka District and Haliburton County, singing posts were associated with deciduous woods with a dense understorey. Nest sites had low canopy volume and very high shrub cover, typical of stands of immature trees. Its preference for high tree density and extensive shrub cover resulted in it inhabiting areas where large trees had been removed and the understorey had been allowed to develop. Cottage lots that have been cleared and allowed to succeed naturally to the immature tree stage create suitable breeding habitat (Clark et al. 1983).

In the off-Shield portion of the Great Lakes–St. Lawrence Forest Region, Burke and Nol (2000) studied the Rose-breasted Grosbeak in 40 woodlots ranging in size from 11.75 to 2,353 ha. They also surveyed it in 2 continuous forests in the Shield. All woodlots were older than 40 years in agricultural or suburban settings, and were deciduous closed-canopy forests dominated by sugar maple and

beech with hophornbeam, white ash, and white pine. Woodlands were classified as small with an average size of 93 ha (range 11.75-365 ha) with a core area of habitat greater than 100 m from forest edge of 7.8 ha, large with an average size of 849 ha (range 81-2,353 ha) with a core area of 121 ha, and continuous forest (the 2 Shield sites). Daily nest mortality rates were highest in small woodlots and declined with forest size, with nests in large woodlots less vulnerable to predation than expected. Woodlot size was the most important factor affecting reproductive success with the amount of forest cover within a 10-km radius in fragmented landscapes having no significant effect. There was no difference in success rates in large and continuous forests. Nests within 100 m of forest edge were depredated at a significantly higher rate than those further from edge. In small woodlots, the number of fledglings produced per nest was one half to two thirds that produced in large and continuous forests. Friesen et al. (1999a) studied the Rose-breasted Grosbeak in 41 woodlots in the Region of Waterloo that were dominated by sugar maple, beech, and white ash. Twenty-six were classified as small (3-14 ha) and 15 were large (26-140 ha). All but 1 forest were smaller than 50 ha. Their edge categories were 0-5 m from edge, 5-25 m, 25-50 m, 50-100 m, and more than 100 m. They found no significant difference in nest success related to forest size or distance from edge. The lack of size effect may have reflected the small range of available woodlot sizes. Nest success tended to be higher along the forest edge than 100 m or more from edge, but the study woodlots may have consisted entirely of edge. A high percentage of nests within 5 m of edge succeeded, suggesting that this area may not be as hazardous for nesting birds as often thought. Results of these 2 studies demonstrate that woodlot size and edge effects on nest survival may differ even within the same general area. Nest success may be related to other factors such as the types of predators present, habitat quality, and food abundance. In Durham Region, the Rose-breasted Grosbeak nested in open deciduous woods with an abundance of shrubs and saplings, a black spruce bog surrounded by a red maple–poplar swamp, in sugar maple–oak and beech–sugar maple woodlots, and in an old beech stand. Speirs and Orenstein (1975) considered it typical of mid-forest succession where it was most abundant, but it also occurred in other stages of succession.

L.A. Smith et al. (2007) studied nest-site selection by the Rose-breasted Grosbeak in the Carolinian Forest Region. The 23 woodlots they surveyed were upland deciduous forests 15-270 ha in area. Three types of forest management treatments were surveyed: those with no recent history of harvesting and those harvested by standard selective thinning and heavy diameter-limit cuts. Nest-site microhabitat was characterized by an open canopy and subcanopy, with deciduous saplings selected for nesting more often than tall trees. There was no significant difference in the coverage by seedlings (15%) and regenerative cover 0.5-1.3 m tall (32%) at nest sites and random areas. There was a tendency for the coverage of regenerative cover to be higher at nest sites. It selected nest sites with significantly more sapling cover (41%) in heavy cuts than in standard cuts (21%) and reference sites (24%). Canopy closure was significantly lower in all treatments at the nest (37%) than at random sites. Nest sites had a significantly lower basal area (BA) than random sites (18 compared with 23 m^2 per ha). Nests were significantly lower in heavy cuts (4.38 m) than in standard cuts (11.0 m) and reference sites (8.46 m). Nests were more concealed in heavy (74%) and standard (73%) cuts than reference sites (65%). Nest sites differed across treatments. In selective cuts and reference stands, nests were often in areas with less canopy cover, more sapling cover, and lower BA, and there was a tendency for more regenerative cover than at random sites. Heavy cuts had

denser regeneration and sapling layers and more open canopies. In these woodlots, it nested lower and had more concealed nests. It consistently selected nest sites with reduced BA, a tendency for more regenerative cover, more sapling cover, and less canopy cover than random sites, and this preference became stronger in heavy cuts. In the Hamilton area, McIlwraith (1894) reported that the Rose-breasted Grosbeak preferred to nest along wooded banks of streams. Dodds and Otis (2009) found it in 2 stands containing a high proportion of ash trees in Point Pelee. In 1 plot, ash represented 18% of the canopy cover with trees with an average diameter at breast height (DBH) of 26.5 cm. In the other plot, ash averaged 41.1 cm DBH and represented 38% of the canopy cover.

Two Ontario studies examined Rose-breasted Grosbeak habitat at the landscape level. Nol et al. (2005) studied the effects of large woodlots that were potential source areas on the probability of smaller woodlots supporting it. They considered large woodlots with more than 90 ha of core area more than 100 m from edge as putative source habitats and small woodlots as putative sinks. Large forests averaged 283 ha of core area compared with 7.5 ha for small woodlots. The odds of a small woodlot being occupied was not affected by regional forest cover, although the range of forest cover was low, or by the number of nearby large forests. The odds of a woodlot being occupied increased significantly as the distance to the nearest large woodland decreased. Occupancy was approximately 30% in small woodlots 2.5 km from a large woodland, 24% at 5 km, 20% at 10 km, 15% at 15 km, and 10% at 20 km. This study underscored the importance of maintaining large forests in the landscape. Retention of small woodlots is also important. These act as a reservoir for excess individuals if catastrophic events result in vacancies in source woodlands. Even sink woodlots produce some fledglings that contribute to the population. Austen et al. (2001) determined that its abundance was positively correlated with the amount of forest cover further than 100 m from edge and negatively correlated with woodlot size, forest cover within 2 km, and regional forest cover. All these relationships were nonsignificant.

Other studies examined the habitat of the Rose-breasted Grosbeak at the landscape level. Cunningham and Johnson (2019) determined that it occurred in areas having 65-75% tree cover in North Dakota, with no areas having greater than 75% tree cover. In New York, it occurred in areas with 61-80% tree cover. In Quebec, it nests in regions dominated by deciduous and mixed forests, being most common in the sugar maple–dominated landscape and, to a lesser extent, in the balsam fir–yellow birch landscape. It is uncommon in the balsam fir–white birch landscape. In extensively forested landscapes, it was associated with natural openings such as clearings and edges of watercourses and water bodies, beaver ponds, and old burns (Pelletier and Dauphin in Gauthier and Aubry 1996; Toussaint in Robert et al. 2019). In Saskatchewan, it was randomly distributed among fragmented and forested landscapes, but was more common in large forest fragments or areas with high forest cover within 5 km. Its abundance was significantly correlated with forest size and amount of local forest cover (Hobson and Bayne 2000). In Pennsylvania, Rodewald and Yahner (2001) combined data for all species and determined that daily nest survival was higher in forests disturbed only by silviculture than those disturbed by agriculture. Agricultural landscapes probably supported a greater abundance of avian and mammalian predators.

Although almost all information on the habitat of the Rose-breasted Grosbeak is related to forests, it also nests in dense shrubby old fields and regenerating clear-cuts and burns that are

essentially devoid of trees. In Quebec, it nests in strip-cuts with dense deciduous regeneration but not in conifer-dominated regrowth. It also nests on shrubby hydro corridors. In New Jersey, it was absent in 10- and 20-year-old fields but present in a 40-year-old field. The borders of this field were treed but the centre was dominated by dense shrubs and saplings. It was considered a shrub species that preferred edges. An occupied clear-cut in Minnesota had average characteristics of 2.1 m shrub height, low shrub patchiness, 398 cm per m^2 BA of shrubs, moderate shrub density, 3.4 m^2 per ha tree BA, 73 trees per ha with DBH greater than 7.6 cm, 3.6 m^2 per ha dead tree BA, and 70 trees per ha with a DBH greater than 7.6 cm (Falardeau et al. 1999; Hoffman 1989a; Keller et al. 2003; Niemi and Hanowski 1984a, 1984b; Yahner et al. 2002).

The Rose-breasted Grosbeak prefers deciduous woods but also occurs in mixed-wood stands, with it declining as the proportion of conifers increases. It inhabits both upland and lowland forests and shrubby ecotones at edges of woods at streams, ponds, marshes, roads, or pastures. It commonly uses second-growth woodlands but may occur in all ages of forests. It also breeds in well-vegetated suburban areas, parks, gardens, and orchards. In the southern portion of its range, it breeds mostly in mountain deciduous forests. In the north, it occurs in stands of poplars or white birch mixed with conifers. It also occurs in oak savannahs and some conifer forests dominated by pines, tamarack, white cedar, or spruces. Many occupied forests support shrubs that produce berries later in the season, such as highbush cranberry, blueberries, chokecherry, honeysuckles, mountain-ash, cloudberry, and raspberry. In extensive forests, it is often associated with openings such as beaver ponds, muskegs, swamps, stream sides, dry hillsides, and utility corridors (Austin 1968; Campbell et al. 2001; Capen 1979; Dawson 1979; Mossman et al. 1991; Wyatt and Francis 2020).

Some information is available on the microhabitat requirements of the Rose-breasted Grosbeak. Essentially all researchers concur that shrubs or saplings are an important component of its habitat. In New Hampshire, it declined in abundance when the forest changed from one characterized by a dense closed canopy with an open subcanopy and a dense low shrub layer to one with a more open and patchy canopy, a denser and taller shrub and subcanopy layer, and a more sparse low shrub layer (Holmes and Sherry 2001). In Vermont, Thompson et al. (1988) concluded that it was associated with deciduous forests with a dense understorey. Average habitat characteristics included 35.4% ground cover by green vegetation, 8.0% ground cover by slash, 83.0% canopy closure, 21.5 m canopy height, 11.4 m canopy depth, 17.8 m^2 per ha BA of deciduous species, 3.3 m^2 per ha BA of coniferous species, 11.3 cm DBH for deciduous trees, and 11.9 cm DBH for coniferous trees. In Iowa, it was positively correlated with sapling richness and vertical patchiness and stratification of vegetation (Stauffer and Best 1980). In Wisconsin upland forests, it preferred an open canopy with moderate growths of saplings and shrubs (Mossman and Hoffman 1989).

Other studies examined the preference of the Rose-breasted Grosbeak for stand types and age of forests. In the Boreal Forest Region, Erskine (1977) considered it typical of aspen or white birch stands. It also occurred in stands dominated by balsam fir, usually mixed with aspen or birch. In northeastern northern hardwoods, it was equally abundant in mature undisturbed habitats and disturbed and early successional habitats (Noon et al. 1979). In northeastern poplar–white birch stands, it occurred in all ages of stands from the seedling stage in young burns to mature forests (Back 1979). In Alberta boreal forests dominated by poplars, it was significantly more abundant in

forests 23-26 years old than in mature and old-growth stands. It was positively correlated with the density of aspens (Schieck et al. 1995). In northeastern mixed-wood forests, Temple et al. (1979) considered it a late seral species, but not one of mature forests. It was associated with increasing abundance of sugar maple and yellow birch. In Saskatchewan, it was more common than expected in trembling aspen stands and used mixed and white spruce stands according to their availability (Hobson and Bayne 2000). In the Prairie Provinces, it occurred in mixed and deciduous forests and was absent in black spruce and species-poor jack pine stands. It was associated with fairly dry stands that were moderately rich in nutrients (Kirk et al. 1996). In Pennsylvania, it occurred in 36.4% of old-growth mixed forests, 63.9% of forests statewide, and 83.5% of forests in the Appalachian Plateau. Haney (1999) considered it to have a negative old-growth affinity. In the same state, it was the sixth most abundant species in clear-cuts 3-6 years old (Dessecker and Yahner 1987). In Vermont, it was associated with beech and sugar maple with high numbers of aspen and white birch. It was negatively correlated with red maple. It was correlated with increasing successional age, increasing amounts of conifers, and a moderate number of dead trees (Lent and Capen 1995). In Wisconsin, it was associated mostly with xeric stands where it was abundant. It was an insignificant component of the avifauna in more mesic stands, if it was present at all. In many of the more mesic stands where it occurred, the terrain was steep and it occurred at the higher points. It was more likely to occur in early and mid-successional than late successional stands, being most abundant in the pioneer 60% of the seral gradient. It was most common in pioneer stands where sturdy oak saplings and thick oak branches and twigs were available for the bulky nests (Bond 1957). In New Hampshire and Maine, it was most abundant in poplar and white birch followed by, in decreasing order of abundance, northern hardwoods, white pine stands, spruce–balsam fir stands, swamp hardwoods, balsam fir stands, and hemlock stands. It was positively correlated with canopy closure, percent ground cover, and deciduous trees 2-10 cm DBH. It was negatively correlated with coniferous trees 2-10 cm DBH (DeGraaf et al. 1998). In North Dakota, it was most common in late seral stages of deciduous forests. It preferred semiopen mesophytic stands and was more than 3 times as abundant in lowland forests than upland bur oak stands (Faanes and Andrew 1983).

Most authors concur that the Rose-breasted Grosbeak is not area sensitive (Bond 1957; Golet et al. 2001; Stauffer and Best 1980; Wyatt and Francis 2020). There is no evidence that it is area sensitive in Ontario. In Missouri, Hayden et al. (1985) considered it area sensitive, but at a level of significance of 0.25 rather than 0.05. They observed it in woodlots as small as 2.2 ha and it reached 100% occurrence in forests 42.2-53.6 ha. They reported that it occurred in woodlots as small as 1.2 ha in New Jersey. In North Dakota, Grant and Berkey (1999) considered it area sensitive because its probability of occurrence increased with forest size. Nonetheless, the probability of occurrence was 20% in 1-ha woodlots and 50% probability of occurrence was achieved in woodlots 8-20 ha. In the mid-Atlantic states, Robbins et al. (1989) concluded that its abundance was positively correlated with forest area. Its probability of occurrence reached its maximum in woodlands larger than 3,000 ha but the probability of occurrence was not reduced to 50% until woodlots were 1.0 ha in size. The minimum size of woodlots that it was detected in at least twice was 11.3, 24.1, and 123.0 ha. They sampled woodlots as small as 0.2 ha. In this area, the Rose-breasted Grosbeak is at the extreme southeastern corner of its range and often confined to mountainous areas, so results are not typical of the core of its range.

Ontario nests were elevated in a wide variety of living trees, shrubs, and vines. Small or sapling trees were preferred over large trees. Deciduous trees, shrubs, and vines (30 species, 87.1% of nests) were greatly favoured over coniferous trees (6 species, 12.9% of nests). The most commonly used species were hawthorns (77 nests), maples (74 nests), cherries (21 nests), beech (21 nests), birches (16 nests), and spruces (13 nests). Nests were usually in the upper half of the nest species and more often near than distant from the trunk. Nests were 0.2-6 m from the trunk, with most 1.2-2.4 m from it. Most (64.8%) nests were in upright crotches rather than on horizontal branches at forks (35.2%). Nests were 0.8-16.8 m from the ground, with most 1.8-3.7 m up (Peck and James (1987). Near Rutherglen, 2 nests were in white birches 12.2 and 15.2 m from the ground. Most nests were 1.2-6.1 m from the ground. Other nest-tree species included white spruce, balsam fir, red maple, and white pine. One nest north of Toronto was 1.5 m up in a hemlock on the edge of an overgrown pasture (Austin 1968). Nests in Muskoka and Parry Sound districts were 11-15.2 m from the ground in a variety of deciduous species plus hemlock and spruce (Mills 1981). In Waterloo Region and Wellington County, 76% of nests were in deciduous saplings, shrubs, and vines. They were typically in forest openings with a more open canopy and subcanopy than random sites (Wyatt and Francis 2020). The average height of 50 nests at London was 6 m. These included one that was 2 m up in a dogwood, another 2.5 m up in a blue beech on the upper surface of a branch overhanging a pond, and a third 2.5 m up on a horizontal branch of a Manitoba maple (Scott 1998). Friesen et al. (1999c) reported that 3 nests found the previous year in Waterloo survived the winter. One was repaired and reused.

Of 47 Iowa nests, 21% were in shrubs, 6% were in deciduous saplings, and 72% were in deciduous trees (Stauffer and Best 1980). In British Columbia, 13 of 15 nests (86.7%) were in deciduous trees, mostly in trembling aspen and willows; the others were in deciduous shrubs. The Rose-breasted Grosbeak selected small or sapling trees more often than large trees. Nests were in forks or crotches of upright stems, closer to the top than the bottom of the tree, and usually closer to the trunk than away from it. Nests were 1.2-9.1 m from the ground, with most 2.2-4 m up (Campbell et al. 2001). Nests have been reported in apple trees, small elms, Osage orange hedges, hawthorns, pear, Manitoba maple, chokecherry, hophornbeam, and alders (Austin 1968; Rothstein 1973b).

The Rose-breasted Grosbeak defends its territory mostly by singing. Male-male interactions are most common, followed by male-female and female-female interactions. Agonistic behaviour is much less frequent after egg-laying starts. Breeding pairs are intolerant of conspecifics. Territories seldom overlap and trespassing rarely occurs (Ivor 1944; Wyatt and Francis 2020). Limited information is available on territory size. New York territories averaged 0.77 ha (range 0.34-1.3 ha; Wyatt and Francis 2020). Pelletier and Dauphin (in Gauthier and Aubry 1996) reported territory sizes of 0.8-1.2 ha in Quebec.

No information is available on natal philopatry except that 0 of 81 juveniles returned in New York (Yunick 1996b). Limited information is available on adult site fidelity. In Massachusetts, 9 of 27 adult males (33.3%) and 2 of 20 females (10.0%) returned in a subsequent year. One bird returned in 5 years (Smith 1966). In New Jersey, 7 of 94 yearling birds (7.4%) returned (Suthers 1988). Two of 6 adults (33.3%) returned the next year in New Hampshire (Whittle 1938). In New York, Yunick (1996b)

banded at 2 stations: 1 in spring only and the other year-round. At the spring-only sampling area, 24 of 81 adult males (29.6%), 7 of 26 yearling males (26.9%), a total of 31 of 107 males (29.0%), 14 of 104 adult females (13.5%), and 45 of 211 adults (21.3%) returned. At the year-round sampling area, 25 of 130 adult males (19.2%), 5 of 47 yearling males (10.6%), 30 of 177 males (16.9%), 17 of 120 adult females (14.2%), and 47 of 297 adults (15.8%) returned. Males were more likely to return than females at the spring-only site but there was no difference at the year-round site. The lower return at the spring-only site may have been due to territorial males excluding others from the vicinity of the nests. Results suggested that adult males may have been more site faithful than yearling males, but some birds may have been migrants.

Limiting Factors

Eggs have been found in Ontario nests from the second week of May until the third week of July, with most present in the first half of June (Peck and James 1987). In Algonquin Park, nests are under construction from mid-May to late June, eggs are present late May to early July, nestlings are present early June to late July, and dependent fledglings have been seen mid-June to mid-August (Tozer 2012).

Some birds may be paired when they arrive on the breeding grounds, but pairing usually occurs shortly after arrival. Territorial males are initially aggressive toward females on their territories, but after 1-2 days, the male follows the female or vice versa. The earliest males to arrive stay to breed while migrants continue to move through for several weeks afterwards. In southwestern Ontario, mean nest initiation dates were 18-19 May. Nests take 2-5 days to build and the female may begin laying eggs a day before the nest is complete. One egg is laid per day. Incubation appears to start before the clutch is complete, possibly with the laying of the second egg. The incubation period for Ontario nests was 11-14 days, consistent with reports from elsewhere. The nestling period varies from 9 to 17 days, but is mostly 10-12 days (Austin 1968; Ivor 1944; Peck and James 1998b; Smith et al. 2006; Scott 1998; Wyatt and Francis 2020).

The Rose-breasted Grosbeak rarely attempts to raise 2 broods. Ontario egg dates indicate that single broods are typical, although there are reports of second broods. Two semicaptive pairs at Erindale successfully reared 2 broods and a pair in Michigan attempted 2 broods. These appear to be the only confirmed double broods for the species, although double-brooding has been suspected in other cases, including in Ontario. In all confirmed cases, the second nest was initiated shortly before the young in the first nest fledged. Second nests were 12-35 m from the first nests (Ivor 1944; Peck and James 1998b; Rothstein 1973b). Smith et al. (2006) monitored 213 nests in southwestern Ontario and observed no cases of double-brooding. They observed only 1 renesting attempt after nest failure. The replacement nest was 30 m from the original nest, but was subsequently abandoned. This may be the only confirmed case of renesting (Wyatt and Francis 2020). Clutches of 2-5 eggs have been reported in Ontario, with 3- and 4-egg clutches most common; average clutch size was 3.44 eggs (Peck and James 1987). In southwestern Ontario, there were no differences in clutch sizes in uncut forests and those thinned selectively or heavily at 2.56, 2.71, and 3.02 eggs, respectively (Smith et al. 2006). Across its range, the clutch size is typically 3-5 eggs, with 4-egg clutches most frequent (Austin 1968; Wyatt and Francis 2020).

Both sexes are capable of breeding when they are 1 year old. Yearling males arrive later than older males and may not be successful in obtaining a territory or attracting a mate. Unmated birds remain solitary throughout the breeding season. Once a bird breeds, it is presumed to do so each year thereafter. The Rose-breasted Grosbeak is apparently monogamous, with no cases of polygyny reported (Wyatt and Francis 2020).

The Rose-breasted Grosbeak usually forages at all canopy levels at the periphery of foliage and branches where the leaf cover is densest. Foraging in the understorey is more common later in summer when understorey fruits are available. It occasionally gleans from the ground. When feeding on flowers, it cuts and discards the petals and eats the base containing the ovaries and seeds (Wyatt and Francis 2020). In Vermont, 95% of foraging occurred in foliage and 5% in the air. Sixty-four percent of foraging was by gleaning, 31% by aerial manoeuvres, and 5% by hanging (Lent and Capen 1995). It has been observed eating elm seeds, often hanging head-downward in the manner of a chickadee. It may also open the long seed pods of catalpa to obtain the seeds (Austin 1968). Hartung and Brown (2005) studied the foraging behaviour of the Rose-breasted Grosbeak in open-canopied savannahs and closed-canopy woodlands in Illinois. There were no differences in its foraging methods in the 2 habitats, and it selected tree species according to their availability. Foraging occurred in black and white oaks, hickory, black cherry, black locust, hackberry, and several miscellaneous species. It preferred to forage in the lower canopy levels (0-5 and 6-10 m from ground) rather than at heights of 11-15 m and higher. The 2 lower layers were used more than expected, but not significantly. In closed-canopy woodlands, it exhibited a strong preference for the subcanopy and appeared to avoid the upper canopy level. Foraging manoeuvres in savannahs were 56% gleaning, 36% hovering, 5% sallying, and 3% flycatching. In woodlands, they were 46% gleaning, 38% hovering, 5% sallying, and 4% flycatching. Robinson and Holmes (1982) described its foraging behaviour in New Hampshire. Of attacks on arthropods, 75.9% were on leaves and 16.4% were on bark. Foraging techniques included 55.8% gleaning, 36.7% hovering, 3.5% flush-chasing, 2.4% hawking, and 1.5% hanging. They considered it a variable-distance searcher that ate medium- to large-sized insects such as caterpillars. It searched near and far substrates, hopping along branches while carefully peering under leaves. It occasionally gleaned insects from upper leaf surfaces. As it approached the distal end of a branch, it stopped and searched foliage as far as 1-2 m away. It was highly variable in its foraging behaviour, occasionally searching the leaf litter on the ground, hunting along tree trunks, or moving among the foliage. Other species that were most similar in their searching behaviour differed in their microhabitat use. In New Hampshire, Holmes and Schultz (1988) examined its foraging in relation to food availability. It foraged more on upper and lower leaf surfaces than expected and less than expected on petioles and twigs. The differences were significant on yellow birch but not on sugar maple or beech. On all species combined, 61% of foraging was by gleaning (61% on lower-leaf surfaces) and 39% by hovering (80% on lower-leaf surfaces). Free-living types of caterpillars, which are most available as prey, constituted 29% of caterpillars on beech foliage, 42% on sugar maple, and 58% on yellow birch. Beech supported more caterpillars, but most were leafminers and leaftiers which are small and seldom taken by birds. Yellow birch had fewer caterpillars, but most were free-living types that were larger and more active. The Rose-breasted Grosbeak foraged preferentially in yellow birch. It infrequently foraged on twigs and petioles, but did so more in yellow birch than other tree species. It changed foraging tactics in

different tree species, hovering less often in beech. Ten bird species foraged predominantly on caterpillars in this area and all but the Black-throated Blue Warbler foraged throughout the height of the vegetation. All 10 species differed significantly from each other in their use of the foliage substrates. In New Hampshire, Holmes (1986) compared the foraging behaviours of male and female Rose-breasted Grosbeaks. Females foraged significantly higher (average 12.9 m) than males (10.8 m). There was a positive but nonsignificant relationship between female foraging height and nest height. Male foraging height was significantly correlated with song-perch height. Both sexes foraged over almost the entire vertical profile of the forest, and both mostly gleaned on leaf surfaces. There were significant differences in their use of tree species for foraging. Males foraged with equal frequency on beech, sugar maple, and yellow birch. Females foraged more often on yellow birch and appeared to avoid beech. Male foraging tactics were most similar to those of male Scarlet Tanagers. This was due to females of the 2 species foraging higher in the canopy and more frequently in white ash than males. Males of the 2 species attacked prey on trunks and branches more often than females. Birds foraged more near the centre of their activity areas: song perches for males and nests for females.

In southwestern Ontario, adults fed nestlings soft-bodied insects heavily coated with saliva. They were fed more and larger insects as they aged and were fed insects almost exclusively except for a small amount of tree leaves (Ivor 1944). The stomachs of 4 nestlings contained 78% animal and 22% vegetable matter. The animal food included 20% caterpillars (including those of sphinx moths), 25% beetles (weevils and metallic wood-boring, click, and leaf beetles), and wasps. Adults were observed feeding nestlings Colorado potato beetles and caterpillars that were mostly leafrollers (McAtee 1908). Austin (1968) reported that young were fed elderberries, insect larvae, various seeds, butterflies and moths, flies, crickets and grasshoppers, beetles, and spiders.

Insects are important in the adults' diet during the breeding season, but the Rose-breasted Grosbeak is almost entirely frugivorous during late summer and autumn migration (Wyatt and Francis 2020). Favourite foods of semicaptive birds in southwestern Ontario included mealworms, raw peanuts, and sunflower seeds (Ivor 1944). In New Hampshire, 16 emetic samples revealed a diet consisting of 15.6% caterpillars, 1.3% adult lepidopterans, 11.7% hymenopterans, 62.3% beetles, 6.5% flies, and 2.6% spiders. The diet determined by field observations consisted of 82.9% caterpillars, 7.3% beetles, and 7.3% hymenopterans (Robinson and Holmes 1982). Austin (1968) reported that it ate blossoms of hickory and beech trees, white ash buds, and European mountain-ash fruit. Stutchbury et al. (2005a) reported that it was the second-most common visitor to red elderberry after the Scarlet Tanager. Beal (1897a) reported that the Rose-breasted Grosbeak was one of few birds that attacks the Colorado potato beetle. Its vegetable food consisted of buds and blossoms of forest trees and seeds, but it also consumed peas from gardens. McAtee (1908) analyzed the contents of 176 stomachs. The diet consisted of 52% animal matter and 48% vegetable matter, with consumption of animal prey peaking at 74.25% in June at the height of the breeding season. The animal food consisted almost entirely of insects: 36% beetles, 6.43% hymenopterans, 3.82% caterpillars, 2.38% scale insects, and 3.33% miscellaneous invertebrates. The beetles included weevils, fireflies, and ground, lady, metallic wood-boring, click, long-horned, scarab, dung, and leaf beetles. Leaf beetles were the most commonly consumed beetles, especially the Colorado potato beetle. The hymenopterans included parasitic wasps, sawfly larvae, ants, and bees. In addition to

scale insects, other bugs it ate included stink bugs, treehoppers, and aphids. Grasshoppers constituted only 0.2% of the diet. It rarely ate spiders and their egg sacs, flies, and snails. The vegetable food consisted of 19.3% wild fruit, 15.74% weed seeds, 5.09% grain, 1.37% garden peas, and 6.5% other material including small quantities of cultivated fruit, buds, and tree flowers. Common and red elderberries were the most frequently consumed fruits with blackberries and raspberries second in preference. Other fruits it commonly ate included those of mulberries, juneberries, pin and black cherries, chokecherries, rough-leaved and flowering dogwoods, wintergreen, hawthorns, strawberries, pokeweed, juniper, and sour gum. It eats more weed seeds in August and September than in other months. Seeds of smartweeds are most selected with amaranths next in importance. It also eats seeds of foxtails and other grasses, nightshades, sedges, common and giant ragweed, vervain, docks, milkweeds, sunflowers, jewelweeds, bloodroot, and sycamore. Some ate plant galls for the vegetable matter. The grain consumed included corn, wheat, and oats, which was mostly waste grain but some grain may be taken from the plants and fed to nestlings. It has eaten buds of beech, cherry, pear, wild plum, silver and red maple, Manitoba maple, and elm. It cuts off buds close to the twig, eats the soft pip, and drops the shell. It probably eats tree flowers more than buds and has eaten flowers of hickory, elm, walnut, and oak. Near Manitouwadge, its abundance did not change in response to a spruce budworm outbreak (Venier et al. 2009).

Friedman (1929) considered the Rose-breasted Grosbeak a fairly common host of the Brown-headed Cowbird and Austin (1968) repeated this assertion. More recent information indicates that it is an infrequent host, probably because both sexes incubate and the nest is seldom left unattended (Friesen et al. 1999a; Wyatt and Francis 2020). This grosbeak is an acceptor of cowbird eggs (Rothstein 1975), but parasitism has minimal effects on it. In southwestern Ontario, there was no significant difference in the number of young fledged from parasitized and unparasitized nests. Only 2 of 138 nests (1.5%) failed due to parasitism. The grosbeak is also a poor host, fledging few cowbirds. In this study, only 3 of 16 parasitized nests (18.75%) produced a cowbird fledgling, contributing only 4 cowbirds to the population (Smith et al. 2006). Peck and James (1998b) reported that 28 of 367 Ontario nests (7.6%) were parasitized. Habitat conditions may affect the rate of parasitism. In eastern Ontario, Burke and Nol (2000) reported that 0% of nests were parasitized in small and continuous forests compared with 7.4% in large forests. In Waterloo Region, Friesen et al. (1999a) reported an overall parasitism rate of 10%: 18% in small woodlots and 5% in large woodlots. In southwestern Ontario, parasitized nests were significantly lower (2.9 m compared with 4.3 m) and had significantly more vegetation 0.5-1.3 m tall (57.9% compared with 34.9%) than unparasitized nests. All parasitized nests were in woodlots that had been heavily cut; none occurred in uncut or selectively harvested woodlots. Sixteen of 138 nests (11.6%) were parasitized (L.A. Smith et al. 2006, 2007). Parasitism rates reported from elsewhere include 3 of 42 nests (7.1%) in Quebec (Pelletier and Dauphin in Gauthier and Aubry 1996), 0 of 18 nests in British Columbia (Campbell et al. 2001), 1 of 15 nests (6.7%) in New York (Hahn and Hatfield 1995), 0 of 13 nests in Minnesota (Hanski et al. 1996), 1 of 5 nests (20.0%) in Wisconsin (Brittingham and Temple 1996), 0 of 2 nests in Indiana (Robinson 1992), 0 of 3 nests in Illinois, and 0 of 18 nests in Iowa (Wyatt and Francis 2020).

The greatest limiting factor for the Rose-breasted Grosbeak may be its low reproductive output. This is due to its rarely renesting or raising second broods. Reproductive success is further diminished in landscapes fragmented by agriculture or development where predators are more

abundant. In southern Ontario, only populations in large contiguous forest appear to be self-sustaining (Wyatt and Francis 2020). In southeastern Ontario, Burke and Nol (2000) determined that productivity levels in large forests (average 849 ha) and continuous forests were above maintenance levels and acting as sources. Those in small forests (average 93 ha) were sinks but close to maintenance levels. This was determined under the assumptions that most birds renested after nest failure and that most raised 2 broods. Subsequent research indicates that these assumptions are rarely met. If the Rose-breasted Grosbeak is not double-brooded in their study area, large forests would function as sinks and continuous forests would be close to maintenance levels, with 1.3 nests required for maintenance. Populations remained constant over a 4-year period, suggesting a source-sink metapopulation. Fragmentation in that area probably has not proceeded to the extent that the woodlots investigated are too isolated on a landscape scale to prevent colonization from source populations. This grosbeak is not area sensitive and does not preferentially select territories in large woodlots. Consequently, a large proportion of the population may breed in sink habitats that are incapable of sustaining the population. In their study area, only 1% of forests were larger than 200 ha and 82% had no core area, so the majority of the habitats were sinks. Loss of large forested tracts would probably result in dramatic population declines. Sink habitats are still important because they produce some young and may function as sources in some years. In Waterloo Region, populations were sinks with 0.98 fledgling produced per female and 1.2 required for a viable population (Friesen et al. 1999a). In southwestern Ontario, only 75 of 193 nests (38.9%) produced fledglings. Losses of 19-24% of the population were estimated due to low productivity (L.A. Smith et al. 2007). Similar productivity was reported by Hanski et al. (1996) in Minnesota, where 38% of nests were successful. Canopy cover was the only variable that affected nest success, which was unrelated to distance from forest edge, nest height, or nest concealment.

In Waterloo Region, Friesen et al. (1995) studied the effects of residential housing on the Rose-breasted Grosbeak. They surveyed small (3-4 ha), medium-sized (8-15 ha), and large (20-50 ha) woodlots with 0, 1-3, 8-15, and more than 25 houses within 100 m. Its frequency of occurrence increased with increasing forest size, but was still as high as 57% in small woodlots. Its frequency of occurrence tended to decline with increasing numbers of houses, but not significantly.

Numerous studies examined the effects of forest management on the Rose-breasted Grosbeak. With a few exceptions, most of these considered only how its abundance was affected but some Ontario studies examined its effects on nesting success. Results are highly variable, depending on the forest management technique. Forest management has been variously described as having no effect, being detrimental, or highly beneficial. In Algonquin Park, it exhibited no response to typical and intensive group-selection cuts (Tozer et al. 2010). Jobes et al. (2004) reported no differences in its abundance in the park in uncut stands and those logged 5 or 15-20 years previously. In partial cuts in the Boreal Forest Region of Ontario, Vanderwel et al. (2007) reported that it declined by 25% when 50% of trees were removed, by 50% when 60% of trees were removed, and by 75% when 80% of trees were removed. In the same area, it was less abundant in early regenerating clear-cuts than early regenerating burns, more abundant in mid-successional clear-cuts than burns, more abundant in early regenerating cuts than mature forests, and less abundant in mid-successional cuts than mature forests. All relationships were nonsignificant (Zimmerling et al. 2017). In southern Ontario, there was no difference in its abundance in stands that were selectively thinned and those that were

heavily thinned by diameter-limit cuts (Holmes et al. 2004). In southwestern Ontario, the Rose-breasted Grosbeak tended to be more common in heavily cut woodlots than in selectively cut or uncut woodlots. In heavily cut woodlots, it nested lower and had more concealed nests. This appeared to be maladaptive, with these nests having lower nest success. L.A. Smith et al. (2006, 2007) considered heavily cut woodlots ecological traps, attracting more birds most of which failed in their reproductive attempt. Approximately 94% of the cuts in some regions of Ontario are heavy diameter-limit cuts, and this could be contributing to its decline. Wyatt and Francis (2020) concluded that forest maturation may reduce nesting opportunities and that it is often found in higher densities in postharvest forests. In Quebec, it may occur in strip-cuts 5 years after harvesting. Reforestation and maturation of second-growth forests may limit breeding opportunities (Pelletier and Dauphin in Gauthier and Aubry 1996; Toussaint in Robert et al. 2019). In New York clear-cuts, the Rose-breasted Grosbeak reached its highest abundance 7-10 years after cutting and declined slowly throughout mid- and late succession (Keller et al. 2003). In the same state, it represented 1.86% of birds in uncut forests, 1.50% when 25% of harvestable trees were removed, 1.68% when 50% of trees were removed, 3.11% when 75% were removed, and 4.70% when 100% were removed. It tended to increase with increasing intensity of logging (Webb et al. 1977). In Pennsylvania, it was equally abundant pre- and postcutting of clear-cuts in aspen and mixed oak stands but densities tended to be higher in cuts (Yahner 1993, 2003). In the same state, there was no difference in its abundance in stand improvement cuts whether snags were retained or harvested (Stribling et al. 1990). In Minnesota, it responded positively to tree removal when basal area was reduced to 7-10 m^2 per ha (Hanowski et al. 2002). In Saskatchewan, Cumming and Diamond (2002) studied the Rose-breasted Grosbeak in 4 age-classes of forest: mature (50-60 years old), rotation age (80-90 years), old (100-110 years), and very old (more than 140 years). It was absent in mature and rotation age forests and occurred in 20-49% of old stands and less than 20% of very old stands. It was significantly more abundant in post-rotation-age stands and was therefore likely to decline if older stands disappeared from the landscape. They recommended that some stands 120 or more years old should be maintained. In Alberta, it colonized deciduous stands when 75-100% of trees were retained. It experienced no other increases, decreases, extirpations, or colonization in any other forest type or level of tree retention (Harrison et al. 2009). In Alberta, Tittler et al. (2001) studied the effects of retaining some residual trees in clear-cuts in aspen-spruce–jack pine forests. There was no significant difference in its abundance in control and treatment plots prior to cutting, but it was significantly more abundant in control than treatment plots after cutting. Tree retention in cut-blocks did not affect its abundance. In the Yukon, Sinclair et al. (2003) reported that its primary habitat was being rapidly lost due to clear-cutting of mixed white spruce and balsam poplar stands.

In West Virginia, the Rose-breasted Grosbeak exhibited no response to well pads, access roads, or pipelines (Farwell et al. 2019). In Alberta and the Northwest Territories, it was significantly more abundant along seismic lines and pipelines than in forest interior adjacent to these facilities. It was significantly less abundant within 50 m of well pads than in forest interior. It was significantly more abundant at quiet well pads than at noisy compressor stations (Bayne et al. 2008, 2016).

In Pennsylvania and New Jersey over 15 years, hemlock declined from representing 56% of the total basal area to 46% due to the hemlock woolly adelgid; the amount of woody understorey

increased. The Rose-breasted Grosbeak responded positively to hemlock decline, probably due to the increase in the shrub and sapling layer (Toenies et al. 2018).

DesGranges et al. (1987) studied the response of the Rose-breasted Grosbeak to die-backs of sugar maple. Healthy stands had 35% more foliage and 57% more insects than die-back stands. It was 20% less abundant in die-back stands.

Blake et al. (1992) examined the effects of drought on the Rose-breasted Grosbeak in Wisconsin and Michigan. It was negatively affected by wet Mays and positively by dry Junes.

In Minnesota, Hanowski et al. (1996) concluded that very low frequency electromagnetic fields associated with a transmission line had no measurable effect on the Rose-breasted Grosbeak.

The Rose-breasted Grosbeak is a popular cage bird in its wintering range and habitat loss may be occurring there as well (Wyatt and Francis 2020). Males were formerly highly prized as ornaments for ladies' hats and abundant numbers were shot (Beal 1897a).

Price (2004) predicted that the breeding range of the Rose-breasted Grosbeak might contract in southern Ontario if the average summer temperature increased by 2°C.

Status

The range of the Rose-breasted Grosbeak appears to have increased in southern Ontario from a restricted area along the southern border to the southern half of the province, but this may be a result of better coverage by observers. Range expansions and contractions are likely related to changes in habitat, particularly clearing of forests followed by increased availability of edge and second-growth habitat, as well as its adaptation to suburban habitats (Wyatt and Francis 2020). McIlwraith (1894) reported that it bred regularly along the southern border. In Elgin County, it was a common resident in 1891 and 1954; by 2000, it was uncommon but widespread (Lancaster et al. 2004). In the Kingston area, it has been reported since the mid-19th century (Weir 2008). Sheppard et al. (1936) reported that it was observed only during migration in Niagara Region where it was a rare migrant in the Niagara Falls area. It was suspected that some birds might have remained to breed in the more secluded portions of the region. Baillie and Harrington (1937) considered it fairly common throughout southern Ontario, breeding north to the transcontinental railway and probably west to Lake of the Woods. The first atlas demonstrated that its range included all the Carolinian and Great Lakes–St. Lawrence forest regions with some intrusions into the Boreal Forest Region north to Red Lake, Sioux Lookout, and Lake Abitibi. There was 1 record from the Hudson Bay Lowland near Moosonee. It was widespread south of the Boreal Forest Region except in Essex County which has very limited forest cover. It was concluded that the historical range was probably the same, with early observers overlooking it. Highest abundance appeared to occur along the southern edge of the Canadian Shield from Owen Sound to Kingston (Eagles in Cadman et al. 1987). James (1991) considered the Rose-breasted Grosbeak common in the south, uncommon in the north to Sioux Lookout and Cochrane, rare north to Pickle Lake and Moosonee, and a vagrant at Winisk.

The second atlas demonstrated that there had been no significant change in the distribution of the Rose-breasted Grosbeak since the first atlas. It was a little more widespread in the extreme southern Boreal Forest Region, particularly at the latitude of Lake Nipigon. It was observed in some

new blocks in the Boreal Forest Region but was apparently absent in some previously occupied blocks. It disappeared from many squares on Manitoulin Island and in Algoma District, but was present in many more squares in Essex County. Its probability of observation declined significantly province-wide and in the Carolinian and Great Lakes–St. Lawrence forest regions. It was most abundant in southern Ontario from Algonquin Park south to Lake Simcoe, Peterborough, and Kingston east to Pembroke and Cornwall. It was also abundant on the Bruce Peninsula and the Norfolk Sand Plain. It was least abundant in extreme southwestern Ontario, Toronto, and Manitoulin Island (Wyatt in Cadman et al. 2007).

Wyatt and Francis (2020) noted that the Breeding Bird Survey (BBS) for the United States showed no change for the Rose-breasted Grosbeak for 1966-2000, but that this masked a significant increase 1966-79 and a significant decrease 1980-2000. In Canada, there was a significant increase of 7.3% per year 1966-79 and a significant decrease of 4.4% per year 1980-2000, with a net decrease of 2.1% per year 1966-2000. L.A. Smith et al. (2007) reported that the Ontario population decreased at a rate of 2% per year 1966-2004. Moore et al. (2010) reported that BBS data indicated that it decreased in North America at a rate of 0.8% per year 1968-2005, 1.9% in Canada, and 2.3% in Ontario. BBS results indicate that it decreased at annual rates of 0.284% in Canada and 1.05% in Ontario 1970-2021. The trends 2011-21 were annual increases of 0.199% in Canada and 0.0793% in Ontario. All results were highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Fledglings are incapable of flight when they leave the nest. Semicaptive birds at Erindale could fly when they were 12 days old. Young in southwestern Ontario were incapable of flight 2-5 days after leaving the nest and moved only short distances from it. After the first week, they began to forage for themselves and were capable of short flights. Fledglings became increasingly mobile as they aged and moved significantly higher up into the canopy. Those 0-5 days out of the nest occurred at heights similar to or lower than nests, typically less than 5 m from the ground, but within a week were usually more than 10 m up. They also moved further from the nest as they aged. Fledglings 0-5 days out of the nest averaged 48.5 m from the nest. By 6-11 days, they were 136.3 m from the nest and they were 228.1m from it 12-18 days out of the nest. Fledglings were usually independent 18 days after leaving the nest, at the age of 28-30 days. The Erindale young started feeding themselves when they were 28 days old and the adults stopped feeding them when they were 30 days old (Ivor 1944; Moore et al. 2010). Austin (1968) reported that young could not fly well until they were 20 days old. Family groups remain together until autumn migration (Wyatt and Francis 2020).

Both adults and young inhabited clear-cuts 1-10 years old in Pennsylvania, Minnesota, Virginia, and West Virginia. In Pennsylvania, the Rose-breasted Grosbeak was not netted in mature forests adjacent to clear-cuts. In Minnesota, adults nested in clear-cuts as young as 7 years old, so these birds may simply have remained in the breeding area during the postfledging period. In other areas, birds may have moved from forests to clear-cuts after the young were independent (Marshall et al. 2003; Stoleson 2013; Streby et al. 2011b). In Michigan, it was much more abundant during the postfledging period in mature riparian than mature upland forests. Both forest types had a similar overstorey, but riparian woodlots had a shrubby understorey of alders and honeysuckles (Akresh et al. 2009).

Nest sites tended to have more understorey cover than random locations in southwestern Ontario. There was no difference in the shrub cover of nests and fledgling locations 0-5 days out of the nest. Of those that survived a week out of the nest, 17 of 28 (60.7%) moved to a different forest treatment than where the nest was located. Treatments included uncut forests and those thinned by selective harvesting and heavy diameter-limit cuts. The mean age of dispersal was 14.2 days postfledging (range 7-21 days). Six of 17 fledglings (35.3%) crossed open gaps to a different forest fragment, with a median gap distance of 20 m (range 20-50 m; Moore et al. 2010).

McAtee (1908) reported that fledglings ate as much as 85% plant material, but did not elaborate further. It is most likely that this was predominantly fruit.

Moore et al. (2010) determined that there were no significant differences in daily nest survival or fledgling survival in 3 forest management treatments: unharvested woodlots and selectively thinned and heavy diameter-limit cuts. Twenty-six of 42 fledglings (61.7%) survived the 3-week fledgling period. Eighty-six percent of deaths occurred in the first week after leaving the nest, mostly in the first 5 days. Fledgling survival to independence was similar between years and sexes. The recruitment rate per female per season was 0.22 and 0.37 for the best- and worst-case scenarios, with predation by mammals and birds the most significant cause of mortality. Fledglings became less vulnerable to predation as they aged because they became more mobile and begged less. Young fledglings appeared to rely primarily on camouflage, often remaining perfectly still until approached within 1 m. Adults actively defended fledglings and gave alarm calls when potential predators approached. Older fledglings moved vertically into denser and elevated vegetation layers, probably limiting the suite of predators that they were vulnerable to. Forest management appeared to have little effect on fledgling survival even though the forest treatments varied significantly for a suite of vegetational parameters. Low regional forest cover rather than selective logging is likely contributing to population declines of the Rose-breasted Grosbeak.

MIGRATION

The Rose-breasted Grosbeak is a medium- to long-distance migrant that winters in Central and South America. Ontario birds have been recovered in Honduras, El Salvador, Guatemala, Columbia, Venezuela, and southern Mexico after travelling as far as 3,790 km. Although there are few recoveries, there appear to be no differences in the distance travelled by the sexes. Autumn migration is more protracted than spring migration. It migrates nocturnally; during the day it may be seen singly, in pairs, or in loose conspecific flocks. It may also occur in mixed flocks, particularly with warblers in late summer and autumn (Brewer et al. 2018; Collier 1989; Francis and Cooke 1990; Tozer 2012; Wyatt and Francis 2020).

Weir (2008) reported that the sexes arrived simultaneously in spring at Kingston. At Prince Edward Point, the earliest and latest arrival dates were 1 and 13 May for males and 5 and 12 May for females. The mean arrival date of 17.1 May for males was significantly earlier than the mean arrival date of 18.2 May for females. In every year, the mean arrival date of males was earlier, although the difference was slight in some years. Older birds also returned earlier than yearlings. Average arrival was 15.5 May for older males and 18.1 May for yearling males. Early females appeared to include a higher percentage of adults than later arrivals. There was a significant tendency for brighter males to arrive earlier but there was considerable variation in arrival dates of birds with similar brightness.

If few yearling males obtain territories, there is little advantage in arriving early. The earlier arrival of brighter yearling males suggests that they may be more likely to obtain territories (Francis and Cooke 1990). At Long Point, mean capture dates were 9.7 May for older males, 13.1 May for yearling males, and 10.0 May for females of unknown age. Older males arrived significantly earlier than yearling males (Stewart et al. 2002). Wyatt and Francis (2020) reported that 50% of birds arrived at each location in spring within a 6-14 day period. They reported median capture dates at Long Point of 11 May for adult males, 13 May for yearling males, and 14 May for females. In New York, older males showed a strong tendency to arrive earlier than yearling males. This tendency was most pronounced among older returning males that had previously bred in the area (Yunick 1996b).

Some studies examined whether climate change affected migration timing of the Rose-breasted Grosbeak. In New York, Zelt et al. (2017) compared its spring arrival and autumn departure dates in 1888-1939 to 1967-2012. It arrived slightly earlier and left slightly later in the later period, but not significantly. In Massachusetts, the mean arrival date was 9 May 1851-1973 and 6 May 1988-2007, a significant difference. Arrival times were less responsive to temperature than to the flowering periods of plants (Ellwood et al. 2010).

In southern Ontario, average arrival is in the first week of May and the earliest migrants arrive in mid-April. The peak of migration is in the second and third weeks of May and migrants leave by the end of May (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008). In the southern Shield, the Rose-breasted Grosbeak typically arrives in the second week of May with the earliest records in late April (Mills 1981; Tozer 2012).

In the southern Shield, birds are migrating by at least the second week of August, with sightings well into September and the latest observations in late September or very early October (Mills 1981; Tozer 2012). In the south, migration begins in early to mid-August with numbers increasing later in the month. Most depart in late September or early October, with late records to December and early January (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008). At Long Point, there was no difference in the timing of autumn migration of the sex or age classes, with 50% of birds passing through within a 10-20-day period. The median capture date was 20 September for adult males, 15 September for juvenile males, 13 September for adult females, and 15 September for juvenile females. The middle 50% of birds passed through between 8 and 21 September, with 90% occurring between 18 August and 27 September (Wyatt and Francis 2020).

The Rose-breasted Grosbeak uses a variety of habitats during migration, mostly forested and shrubby areas, especially where there is an abundance of fruit. These include upland and lowland deciduous and mixed forests, treed islands, shrubby margins of forests and wetlands, and shrub thickets. In Mississippi after trans-Gulf migration, it used mostly shrub thickets less than 5 m tall, but also pine forests and shrubby dune ridges (Campbell et al. 2001; Wyatt and Francis 2020). In Wisconsin and Minnesota, spring migrants were significantly more abundant in upland than riparian forests. Upland forests were dominated by sugar maple or oaks. Riparian forests were characterized by silver maple, green ash, and white elm (Kirsch et al. 2013). It was also significantly more abundant in upland than riparian forests during spring migration in Pennsylvania. Upland forests had 74% canopy closure compared with 83% for riparian forests and 39% shrub coverage compared with 19% in riparian forests (Rodewald and Matthews 2005). During spring migration in Pennsylvania, it

was significantly more abundant in shrubby habitats than in forests (Smith and Hatch 2006). During autumn migration in Pennsylvania, Rodewald and Brittingham (2002, 2004) determined that there were no significant differences in its abundance in forest interior, forest edges, forest-agricultural edges, suburban forests, pole-stage forests, and shrub-sapling-stage forests.

The earliest spring migrants often visit bird feeders where they prefer black oil sunflowers. Autumn migrants and postfledging-period birds may also eat sunflowers at feeders and feed them to their fledglings (Lancaster et al. 2004; Tozer 2012). In early spring, the Rose-breasted Grosbeak may visit hummingbird feeders to drink sugar water (personal observation). During spring migration, it eats leaf buds of ash and presumably other tree species (Fitch 1958). During autumn migration in Muskoka and Parry Sound districts, small groups eat elderberries and fruits of hophornbeam (Mills 1981).

The Rose-breasted Grosbeak commonly strikes television towers, lighthouses, and other structures during migration. During 1960-2000, 152 were killed in spring and 104 in autumn at the Long Point lighthouse (Wyatt and Francis 2020). From 1972 to 1982, 45 were killed at the Lennox generating station chimneys; 14 were killed on a single night on 6 September (Weir 2008). Loss et al. (2014) determined that it was 24.1 times more likely to strike a low-rise building than average and 16.2 times more likely to strike a high-rise. It was not among the top 20 species overall or for striking 1-3-storey residences.

James (1991) considered the Rose-breasted Grosbeak a common migrant in Ontario. Hussell et al. (1992) reported a significant decline of 2.4% per year at Long Point Bird Observatory (LPBO) 1961-88. Annual trends by period were: 1961-70, –2.0%; 1970-79, –4.9%; and 1979-88, –4.6%. LPBO data for 1961-97 indicated a marginally significant decline of about 1% per year in spring but a similar increase in autumn (Wyatt and Francis 2020).

WINTER

James (1991) reported that the Rose-breasted Grosbeak was an occasional rare winter resident in the south north to Sudbury and at Thunder Bay. One overwintered successfully in the Kingston area at a feeder, and there are winter records from Elgin County and Niagara Region (Black and Roy 2010; Lancaster et al. 2004; Weir 2008).

Blue Grosbeak

Passerina caerulea

BREEDING SEASON

Habitat Requirements

In Ontario, the Blue Grosbeak has been observed during the breeding season in open anthropogenic habitats. These include a grove of roadside trees, on wires above a grassy field, in common reed in a ditch along a road, and in semiopen shrubby and woodland habitat. It probably bred somewhere within these areas, but this was not confirmed (Woodliffe 2022).

The Blue Grosbeak's habitat requirements are very similar to those of the Indigo Bunting. The Blue Grosbeak nests in old fields, forest edges, transmission-line corridors, open areas with slash left after logging, hedgerows, stream edges, deserts, mesquite savannahs, saltcedar stands, multi-aged southern pine forests, and roadsides. It also nests in orchards, shrubbery around houses and gardens, and sunflower patches. In the west, it requires dense vegetation near water and nests in shrubs along watercourses, ditches, and canals. In the east, presence of water may not be essential and it prefers upland areas to lowlands. It tends to avoid treed and shrub swamps and forest interior. Its general habitat structure is characterized by dense ground cover, low to moderate shrub density, few trees, and an open canopy (Austin 1968; Lowther and Ingold 2020; Stabler 1959; Taber in Austin 1968). In Arkansas, it was a typical species of early tree succession areas, but was not numerous. It was absent in burned and unburned broomsedge fields and treed plots. It occurred in clonal persimmon plots in the early tree phase with 17% cover, 301 trees per ha, a stem density of 796 per ha, and sparse ground cover (Shugart and James 1973). In Utah, Arizona, and Nevada, its average habitat characteristics were 24.5% canopy cover, 28.8% shrub density, 27.6 trees 7.6-15.2 cm diameter at breast height in a 0.04-ha circle, and 35.6% ground cover (Whitmore 1977). In Arizona, it nested in a 20-ha riparian stand of cottonwood and willow with a patchy understorey of saltcedar, cattails, and bulrushes (Rosenberg et al. 1982).

In the Atlantic states, the nest is usually in a low shrub or vine in a thicket. Where it is more common, nests are often in fruit trees or cultivated plants around houses (McAtee 1908). In Colorado, the first nest of a pair was 76 cm from the ground and was attached to sumac and wolfberry. The nest for the second brood was 17 m away, 97 cm from the ground in a sparse clump of skunkbush sumac (Stabler 1959). In California, nests along ditches were fastened to 2-3 upright shoots at heights of 15 cm to 1.5 m. Some nests were in dense patches of small willow saplings. Occasionally, nests were in peach orchards 2.4-3.7 m from the ground. One nest was 6 m up in a willow at the end of a horizontal branch overhanging a ditch full of water. Another was 4.6 m up in a poplar in a residential yard (Taber in Austin 1968). Four other California nests were all in young black willows along the edge of a tidal bay 0.9-2.1 m from the ground (Bleitz 1956). In the east, the Blue Grosbeak usually nests in a shrub or small tree 0.9-2.4 m from the ground, but it also nests in tall herbaceous species and vines. In Virginia, it preferred to nest in second-growth saplings such as oaks and locusts and these seemed to be their natural nesting sites. Species that it has nested in

include grapevines, pines, alders, sweetgum, mulberries, blackberries, oaks, pear, cherries, willows, locusts, red maple, and a variety of ornamental shrubs. Most nests are 1-2 m from the ground but one was 7.6 m up in an oak. Nests may be as low as 15 cm from the ground (Austin 1968).

The Blue Grosbeak vigorously defends a territory against intruding conspecifics but tolerates other species. In Georgia, 1 pair had a territory of 6.2 ha during nest building and incubation but defended only 5.3 ha during the nestling stage (Odum and Kuenzler 1955). In another area in Georgia, territories averaged 1.2 ha. Territories averaged 5.2 ha in Alabama with a range of 0.8-8.73 ha (Lowther and Ingold 2020).

No information is available on natal philopatry or adult site fidelity.

Limiting Factors

No information appears to be available on how long it takes to build a nest and how much time elapses between nest completion and egg laying. Eggs are laid at the rate of 1 a day. Hatching takes place over 2 days, so it is probable that incubation begins before the clutch is complete. The incubation period is 11-13 days and the nestling period is 9-13 days (Austin 1968; Lowther and Ingold 2020; Stabler 1959).

The Blue Grosbeak commonly raises 2 broods in the south but only one in the northern portion of its range. In Colorado, 1 pair raised 2 broods in nests 17 m apart. The second clutch was completed about a month after the first clutch was completed. Clutches of 2-5 eggs have been reported. Most clutches contain 4 eggs; 2- and 5-egg clutches are rare (Austin 1968; Lowther and Ingold 2020; McAtee 1908; Stabler 1959; Taber in Austin 1968).

The age at first breeding is unknown but it is probable that yearlings are capable of breeding. The Blue Grosbeak is probably monogamous but no detailed studies have been done on this aspect of its breeding biology. Extra-pair copulations are a significant component of its mating system. In Alabama, 29 of 55 nestlings (52.7%) were extra-pair and 14 of 20 broods (70%) contained extra-pair young (Lowther and Ingold 2020).

In Tennessee, 1 pair foraged by one or both birds flying to a weed-top perch and sitting motionless for a few seconds. Then they either made low short flights and hovered over or adjacent to the herbaceous vegetation, plucking insects from leaves or stems, or flew to the ground and hopped among the grasses until they made a capture. The male often followed the female from place to place as she hunted and accompanied her when she returned with an insect even if he had

not made a kill himself (Alsop 1979). It is possible that the male was guarding the female against extra-pair copulations rather than participating in foraging. In Arizona, the Blue Grosbeak foraged by hovering and gleaning from foliage (Rosenberg et al. 1982). It spends considerable amounts of time foraging on the ground, often in and around plowed fields and pastures. On the ground, it searches one spot thoroughly before hopping to another location. It may also perch on roadside wires to hover and glean on vegetation, or flycatch from the ground and shrubs (Austin 1968; Lowther and Ingold 2020).

Males exhibit no strong tendency to feed nestlings. In Tennessee, Blue Grosbeaks fed their nestlings preying mantises almost exclusively. All mantids delivered to young were very large, in excess of 75 mm. The females removed the head and wings from all carcasses and all or most of the legs before delivering them to the nest. Young were fed 96% mantids with the only other food being grasshoppers. Grasshoppers were the most common large insects in the fields where the birds were hunting, ranging in size from 20 to 50 mm. The mantids' large size (mostly 75-100 mm but some larger) in addition to their slow movements and their tendency to remain motionless when approached probably made them desirable prey (Alsop 1979). McAtee (1908) reported that nestlings and recently fledged young ate 99.08% animal food and 0.92% vegetable matter. The animal food consisted of 74.1% grasshoppers, 10.7% caterpillars, 10% snails, and a single each of weevil, long-horned beetle, robber fly, and bristle fly. The vegetation consisted of blackberry remains and seeds of crabgrass, yellow foxtail, green foxtail, wild rice, dropseed grass, and smartweed. Lowther and Ingold (2020) stated that nestlings ate mostly orthopterans, especially short-horned grasshoppers. They are also fed owlet moth caterpillars, especially those of the small mocis moth.

In Arizona, 9 adults had consumed 48% cicadas and 52% grasshoppers by volume and 50% cicadas and 50% grasshoppers by frequency. Most prey was 21-30 mm long. Young fledged in July when cicadas were most abundant (Rosenberg et al. 1982). McAtee (1908) analyzed the contents of 51 stomachs collected from April to September. The diet consisted of 67.6% animal matter and 32.4% vegetable matter. The animal matter was mostly insects (65.7% of the entire diet) plus some snails and spiders. Grasshoppers were the most important animal food, comprising 27.2% of the diet, especially short-horned grasshoppers and crickets. Thirty-two of the 51 Blue Grosbeaks had eaten nothing else. Caterpillars and adult moths formed 9.77% of the diet, including caterpillars of the white-lined sphinx moth which constituted 40% of the May diet in Texas, and many other sphinx moths. Beetles were also important in the diet. June beetles comprised the entire diet of some birds. It also ate dung beetles, 7.18% weevils, leaf beetles, metallic wood-boring beetles, click beetles, and long-horned beetles; it rarely consumed ground beetles. It ate leaf-footed bugs, stink bugs, treehoppers, and cicadas. It rarely ate flies (including robber flies), wasps, ants, sawfly larvae, snails, and spiders. Vegetation it consumed included 14.25% grain, 18.05% weed seeds, 0.06% fruit, and 0.04% miscellaneous. Wild blackberries were the only fruit that it consumed. Seeds were the preferred vegetable food, but it did not eat a great variety. They were mostly foxtails and bindweeds. One bird fed largely on the seeds of wild rice. It did not specifically seek grain and only 1 bird had eaten grain exclusively. Lowther and Ingold (2020) reported that it also ate seeds of panic grasses, dropseeds, oats, corn, and alfalfa.

The Blue Grosbeak is a common host of the Brown-headed Cowbird. It sometimes ejects cowbird eggs and may bury them in the nest. The cowbird usually removes a grosbeak egg from the nest. All 7 nests found at 1 California site were parasitized. Five cowbirds and only 2 grosbeaks fledged from these nests. Zero of 6 nests were parasitized at another California site. Other parasitism rates include 3 of 5 nests (60%) in Arizona, 20 of 33 nests (60.6%) and 4 of 5 nests (80%) in Oklahoma, and 4 of 17 nests (23.5%) in South Carolina. One cowbird and 1 grosbeak fledged from 1 nest. Four of each species fledged from 6 nests that contained 13 grosbeak and 14 cowbird eggs (Bleitz 1956; Lowther and Ingold 2020).

Habitat loss does not appear to be a significant limiting factor for the Blue Grosbeak. It is expected to benefit from abandonment of agricultural land (Lowther and Ingold 2020). The current trend is to convert shrubby land to agricultural fields or other land uses, so the amount of suitable habitat for it may be decreasing in Ontario.

The Blue Grosbeak is widespread but scarce throughout its range. This may be due to competition with the Indigo Bunting and other species in the same genus (Lowther and Ingold 2020).

The Blue Grosbeak commonly nests along roads and is occasionally killed by vehicles (Lowther and Ingold 2020).

Status

James (1991) considered the Blue Grosbeak an occasional rare straggler in the south to Lake Nipissing. It was a vagrant in the north at Vermilion Bay and Rossport. It was first reported in the province in 1913 and there were at least 11 records in the decade before 1991. At that time, there was no evidence of breeding in the province.

The first indication that the Blue Grosbeak might breed in Ontario was in 1995. A pair was observed west of Blenheim along the Lake Erie shoreline. They were observed mate feeding, copulating, and carrying nesting material. Both sexes were observed carrying food but did not always go to a specific spot, so nesting was not positively confirmed. The male remained in the area until early September. He returned in 1996 and stayed for several weeks, but no females were present (Woodliffe 2022).

Breeding evidence for the Blue Grosbeak was obtained in 4 atlas squares in 2024: 3 in Essex County and 1 in Middlesex-Elgin. One pair was seen near Leamington and a pair with at least 1 fledgling was observed in Windsor. The latter record is the first confirmation of breeding in the province (Bumelis 2024), although no nests have been found yet.

Ontario is well north of the Blue Grosbeak's normal breeding range. Its range is extending northward with strays found in spring and autumn into Connecticut, Massachusetts, and Wisconsin. It has recently been confirmed nesting in New York. The Breeding Bird Survey indicates an annual increase of 1.0% 1966-2006. During this period, there was significant positive growth at the periphery of its range in Illinois, Maryland, and Colorado and also in its core range in Kentucky, Tennessee, and California (Lowther and Ingold 2020).

POSTFLEDGING PERIOD

When fledglings become independent, they leave the adults and assemble in small flocks composed of a few families. The adults join them later with the young from their second broods. Shortly afterwards, in early September, they depart southward on their autumn migration (Austin 1968).

During the postfledging period, juveniles and adults move to grain fields, roadside weed patches, and rice fields to forage. Favourite foods at this time include cultivated and wild oats and cultivated rice when it is in the milk stage (Austin 1968; Taber in Austin 1968).

An immature male banded in September in Alabama was recaptured in the same location the following August (Lowther and Ingold 2020). This suggests that there is some site fidelity to postfledging habitat.

Domestic cats are a known threat to Blue Grosbeak fledglings (Lowther and Ingold 2020).

MIGRATION

The Blue Grosbeak is a nocturnal migrant that occasionally strikes television towers. It arrives in the Gulf Coast states in the first week of April and migration continues through the second week of May. During spring migration, individuals may occur far north of the breeding range. Spring overshoots occur mostly in April and May. Males arrive in spring ahead of females and form feeding flocks before the females arrive (Austin 1968; Lowther and Ingold 2020). In South Dakota, autumn migration extends from mid-August to mid-September, but may continue through October in other areas (Lowther and Ingold 2020).

Spring migration habitat is similar to the breeding habitat. Autumn migrants gather in habitats similar to those used during the postfledging period. These include grasslands, rice fields, and grain fields (Lowther and Ingold 2020).

Most Ontario migration records are of spring overshoots. These occur mostly in May, but spring birds have been detected from 18 April to 7 June (Burrell and Charlton 2015; Cranford 2010). Spring birds are seen predominantly in the south, particularly in Essex County, but they may occur anywhere in the south and have been documented in Algonquin Park, Sault Ste. Marie, and Thunder Bay District (Cranford 2013).

Beginning in the late 1990s, 2-4 records of the Blue Grosbeak were documented annually in Ontario and accepted by the Ontario Bird Records Committee. It is likely that additional birds were observed but not reported to the committee. By 2021, 112 records had been accepted, including 48 in the southern portion of the province in the previous 20 years. At this time, it was concluded that there was no longer a need to report Blue Grosbeaks observed in the south (Riley et al. 2021). Nonetheless, it is not a regular migrant in Ontario. Most birds are spring overshoots and almost none of these breed or exhibit normal migration patterns.

Indigo Bunting

Passerina cyanea

BREEDING SEASON

Habitat Requirements

In Ontario, 52.7% of Indigo Bunting nests were in open woodlots or in wooded areas at clearings, edges, roads, paths, and shorelines; 28.0% were in shrubby fields and pastures, fencerows, savannahs, and orchards; 15.1% were on road and railway rights-of-way; 3.2% were in residential gardens; and 1.1% were in a cottage area of a provincial park. It preferred deciduous stands (21 nests) to mixed (12 nests) and coniferous (2 nests) stands. Only 3 nests were reported in closed woods. Almost all nest sites had dense undergrowths of saplings or shrubs, herbaceous species, or vines (Peck and James 1987).

In Algonquin Park, the Indigo Bunting preferred shrubby areas such as recently logged areas (MacLulich 1938). Martin (1960) found that it was common in plots bordering woods but did not

record it in forests. In Muskoka and Parry Sound districts, it nested in brushy pastures, along hydro corridors, and at edges of woods, streams, and ponds (Mills 1981).

In the Great Lakes–St. Lawrence Forest Region south of the Canadian Shield in Durham Region, the Indigo Bunting nested in a black spruce bog surrounded by a red maple–poplar swamp, an open wet forest with rank growth of ferns and raspberries, and in beech–sugar maple, sugar maple, and beech woodlots (Speirs and Orenstein 1975).

In the Carolinian Forest Region, the Indigo Bunting favoured shrubby hillsides in Niagara Region and was partial to nesting in raspberry bushes (Sheppard et al. 1936). In Elgin County, it usually nests in woodland edges or shrubby pastures, but occasionally in rural residential yards that contain suitable stands of trees and shrubs (Lancaster et al. 2004). At Point Pelee, it nested in 2 wooded areas where ash represented 18% and 38% of the crown cover. Average diameter at breast height (DBH) of ash trees in these stands were 26.5 and 41.1 cm (Dodds and Otis 2009).

In Ontario south of the Shield, abundance of the Indigo Bunting was negatively correlated with the amount of forest 100 m from edge, forest size, the amount of forest cover within 2 km, and the amount of regional forest cover. These relationships were not significant at the 0.05 level but the relationship with core area of forest interior was significant at the 0.10 level (Austen et al. 2001).

The Indigo Bunting is an early successional species associated with shrubby thickets and forest edges. It nests in both dry and damp areas but tends to avoid very wet areas. Highest densities often occur in shrubby and weedy habitat between forests and fields. It commonly nests at edges of forests, in fields regenerating 6-30 years after cultivation is abandoned, gaps in forest canopies created by tree falls or insect infestations, young clear-cuts and burns, shrubby roadsides, shrubby areas along streams, railway and hydro line rights-of-way, hedgerows, oak savannahs, brushy prairies, shrubby swamps, along irrigation ditches, and borders of agricultural fields. It seldom nests in conifer plantations except in the southern portion of its range, in treed swamps, and grazed pastures and rarely nests in corn and soybean fields. It avoids urban and suburban areas, intensively grazed and cultivated areas, closed-canopy forests with limited woody undergrowth, and hayfields (Alterman et al. 2005; Baily 1954; Bielefeldt and Rosenfield 1994; Carey 1982; Carey and Nolan 1979; Cox et al. 2012; Davis and Mack 1995; Faanes and Andrew 1983; Fitch 1958; Graber and Graber 1963; Hoffman 1989a; Keller et al. 2003; Kopachena and Crist 2000; Lehnen and Rodewald 2009a; Lent and Capen 1995; Morgan 1976; Mossman 1988; Mossman and Hoffman 1989; Mossman et al. 1991;

Novak et al. 2016; Payne 2020; Payne and Payne 1993; Shugart and James 1973; Taber and Johnston in Austin 1968; Taylor and Taylor 1979; Westneat 1989; Yahner 2003; Yahner et al. 2002). Although it nests in sites dominated by saplings, it is more numerous in shrubby areas (Payne 2020). In addition to areas with low woody vegetation, males require tall perches for singing posts. These are often at the top of a tall tree, particularly if the top is dead, but males often sing from utility wires along roadsides. Perches are usually adjacent to edges between wooded and open habitats (Davis and Mack 1995; Kopachena and Crist 2000; Payne 2020).

Some studies examined the habitat requirements of the Indigo Bunting at the landscape scale. In the eastern United States, 57% of detections of the Indigo Bunting on Breeding Bird Survey (BBS) routes were in fragmented habitats (Donovan and Flather 2002). In Quebec, it inhabits the deciduous forest zone where forests are dominated by sugar maple–bitternut hickory or sugar maple–basswood communities. Forests in this region are fragmented and there is much edge habitat. The demarcation between areas of high and low probability of observation is clear and corresponds to the transition between deciduous and mixed forests (Barden in Robert et al. 2019; Labonté and Dauphin in Gauthier and Aubry 1996). In North Dakota, it inhabited landscapes that were 42-75% forested; no areas were more than 75% forested (Cunningham and Johnson 2019). In Indiana, Ford et al. (2001) studied the Indigo Bunting in a forested landscape and an agricultural corridor. They found more nests in the corridor landscape. It was the only species they studied that had better nest survival rates and a higher number of fledglings per nest attempt in the agricultural landscape. In Pennsylvania, it was equally abundant in landscapes with 40% and 15% forest cover (Keller and Yahner 2007). In North Carolina, it was negatively correlated with elevation and the amount of canopy cover at the 200-m scale, and residential development at the 1,000-m scale. It required a disturbed landscape but was adverse to development (Gilbert and Ferguson 2019).

Some studies suggested that the Indigo Bunting requires water in the vicinity of its territory. In Utah, all nests reported by Whitmore (1975) were along streams or irrigation areas. In Texas, it was associated with water, with 94% of territories containing water. Thirty percent of territories were associated with livestock ponds, 58% with permanent creeks, and 12% with intermittent creeks (Kopachena and Crist 2000). Nonetheless, it has nested in a wide variety of upland sites lacking any water (Taber and Johnston in Austin 1968). There is no evidence that presence of water is essential in Ontario.

The Indigo Bunting highly prefers deciduous stands and its probability of occurrence declines with increasing coverage by conifers. It prefers young stands to mature stands and open-canopy stands with an undergrowth of deciduous shrubs and saplings to closed-canopy forests. In the southeastern United States, it nests in pine and pine-hardwood stands in early successional areas where it is abundant in both middle-aged and young shrubby stands (Conner et al. 1983). In Texas, it was most often associated with low-elevation mesic woodlands and uniform early successional growth typical of moist bottomlands that had been cleared. It occurred predominantly along edges created by clearing forests for pastures and hayfields. In Kansas, it was more abundant in young forests than in cropland, old fields, or mature hardwood forests (Kopachena and Crist 2000). In northeastern upland hardwoods, it was detected in 15% of plots in mature undisturbed forests compared with 47% of disturbed and successional stands (Noon et al. 1979). In northeastern poplar–

white birch stands, Back (1979) reported it in 3-year-old burns and sapling-pole-stage stands, but not in more mature stands. In deciduous woodlots in Illinois, it was positively correlated with the density of shrubs (Blake and Karr 1987). In Pennsylvania, Haney (1999) reported it in 9.1% of old-growth forests, 94.6% of woodlots statewide, and 93.1% of forests in the Appalachian Plateau. In North Carolina, it was negatively correlated with the percent coverage of forest canopy (Lumpkin and Pearson 2013). In bottomland hardwoods in South Carolina, it occurred only in early successional stands dominated by black willow, alders, and other shrubs (Buffington et al. 1997). In Wisconsin upland forests, it was a species of more open xeric woods and was 5 times more abundant in the most xeric continuum than the most mesic continuum. It occurred in 3 other woodlots where there were occasional openings in the canopy due to fallen trees (Bond 1957).

Considerable information is available on the microhabitat preferences of the Indigo Bunting. In Indiana, Carey and Nolan (1979) observed differences in habitat where it occurred at high and low densities in old fields. Low-density areas had been out of cultivation for 25-30 years and were characterized by dense stands of deciduous trees mostly more than 7 m tall with large eroded areas with little ground cover. High-density areas had been cut over or cultivated 3-5 years previously and some were mowed during the study. The vegetation was a lush cover of forbs and grasses with scattered blackberries, roses, and small saplings. In Utah, it was associated mostly with hedgerows among alfalfa fields. Habitat within 0.04 ha around male song perches consisted of 0.5 species of trees, 3.24 shrub density, 14-76 cm canopy height, 67.1% ground cover, 0.09 tree 7.6-15.2 and 15.2-22.9 cm diameter at breast height (DBH), 0.14 tree 22.9-38.1 cm DBH, and 0.29 tree larger than 38.1 cm DBH (Whitmore 1975). In Texas pine forests, it was positively associated with increasing percentage of sapling pines and negatively with increasing density of pole-sized trees, foliage at 7-15 m, the number of tree species, and percent canopy closure. It tolerated tall vegetation as long as it was sparse and patchy. It was not negatively affected by the absence of tall trees (Conner et al. 1983). Conover et al. (2009) studied its response to borders between wooded field margins and row-crop fields. It occurred in low density in fields with no borders, had highest density in fields with 10-m borders, and moderate density in fields with borders 30 m or more wide. In borders, the Indigo Bunting represented 8% of all birds and was fifth in abundance. In Texas, Kopachena and Crist (2000) sampled a diameter of 229 m around song perches, an area of 4.1 ha. Mean habitat characteristics included 2.91 isolated trees, 5.67 tree stands, tree stand size 9,119 m^2, size of largest open area 14,004 m^2, size of largest stand of trees 14,706 m^2, and 228.7 m of edge around the largest stand of trees. The area consisted of 48.9% open habitat, 16.1% early second growth, 16.4% late second growth, and 16.0% mature forest. Perches frequently occurred on or near edges of extensive woodlands. Perches occurred at lower elevations and were mostly on level ground; they were on lower slopes when they were on a slope. In Pennsylvania, nest sites had higher densities of woody stems than random sites (Schill and Yahner 2009). In Texas, it occurred more often in sites with low canopy cover and nested in areas with greater concealment than random sites. Nest concealment at 1.5-2.0 m above ground where most nests were placed was important in influencing nest success, with nest concealment greater around successful sites (Novak et al. 2016). The Indigo Bunting was largely a hedgerow species in the mid-Atlantic states. It was positively correlated with slope, percent ground cover, and the amount of forest cover within 2 km. It was negatively correlated with foliage density 0.3-1.0 m from the ground and the number of dead trees larger than 3 cm DBH (Robbins et al. 1989).

In Iowa, it nested mostly in woody vegetation. All nests with woody support were surrounded by dense forb growth. It was positively correlated with saplings, grasses, forbs, vines, horizontal patchiness of vegetation, and vertical stratification of vegetation. It was negatively correlated with deciduous trees. Dense herbaceous cover was a prerequisite for nesting (Stauffer and Best 1980). In Vermont, it was associated with clear-cuts, dense understorey, and deciduous vegetation. Its mean habitat values were 86.6% ground cover by green vegetation, 10.8% ground cover by slash, 13.9% canopy closure, canopy height 2.9 m, 0.0 m^2 BA of trees, 0.5 cm DBH of deciduous trees, 0 conifer, and 0 snag (Thompson and Capen 1988).

In Arkansas, nests in areas with shorter shrubs and trees and with few large trees were more likely to be successful. Increased cover by vines was also an indicator of nest success. Nests lower to the ground with increased cover of shrubs 0.5-1.0 m tall were more likely to be successful. Nests in areas with more vegetation were more successful; grapevines often provided excellent cover (Alterman et al. 2005). In Missouri, higher nests were less likely to be depredated than lower nests. Few other microhabitat variables were important in defining predation rates (Burhans et al. 2002).

The Indigo Bunting is an edge species. Bond (1957) agreed with this assessment but also observed it well within upland forests even where there was no reduction in forest cover. In Missouri, 60% of nests were within 20 m of edge, significantly more than the 45% of habitat at this distance from edge; 25% were 21-40 m from edge, similar to availability; and 15% were more than 40 m from edge, less than availability. It selected areas within 20 m of edge and avoided areas more than 40 m from edge. Predation rates were significantly lower within 20 m of edge indicating that edge habitat was not acting as an ecological trap (Woodward et al. 2001).

The Indigo Bunting is not an area-sensitive species. Studies on its area-sensitivity have been conducted in woodlands rather than shrublands. The fact that it commonly nests in hedgerows indicates that it is not area sensitive. In Illinois, it was positively correlated with woodlot size in 1 year but forest size had no effect in another year (Blake and Karr 1987). In Pennsylvania, it was equally abundant in woodlots less than 2 ha, 6-20 ha, 40-150 ha, and larger than 1,500 ha (Keller and Yahner 2007). There was no difference in its probability of detection in riparian woodlots 50-800 m in width in Maryland and Delaware (Keller et al. 1993). In the mid-Atlantic states, it was negatively correlated with woodlot size (Robbins et al. 1989).

Indigo Buntings have been documented roosting in dense raspberry bushes during the breeding season (Payne 2020).

Ontario nests were in shrubs, trees (mostly saplings), herbaceous plants, and vines. Deciduous shrubs, trees, and vines were greatly preferred (27 species, 97.2% of nests) over coniferous shrubs and trees (4 species, 2.8% of nests); 11 nests were in nonwoody species. Sixty-five nests were in raspberry bushes, 12 were in maples, 8 were in hazels, 7 were in hawthorns, 5 were in dogwoods, 5 were in elms, 4 were in apple trees, and 6 were in ferns. Most were in upright forks with fewer supported between vertical stalks and canes. Three were at the ends of boughs saddled on a branch or woven around a sapling trunk. Many, and especially those in raspberries, were near the top of the shrubs, well hidden just below the uppermost leaves. Nests were 0.2-6 m from the ground, with most 0.6-1 m up (Peck and James 1987). Mills (1981) reported a nest in alders in Muskoka or Parry Sound district.

In other areas, choice of the nest plant appears to be determined by the canopy cover over the nest and rigidity and branching form of the plant. The most frequently used species have forking stems that support the nest below a continuous layer of leaves. Later nests are often in forbs with rigid stems such as goldenrods, stinging nettle, thistles, milkweeds, giant ragweed, great burdock, joe-pye-weed, cow parsnip, and purple loosestrife. In Michigan, nests were found in more than 40 plant species but 50% of nests were in black raspberry and gray dogwood. Other species it has nested in include multiflora rose, staghorn sumac, red cedar, common juniper, bracken fern, Allegheny blackberry, spreading dogbane, bedstraws, poison ivy, prickly-ash, oaks, greenbrier, wild grape, Virginia creeper, mountain laurel, spicebush, spotted knapweed, garlic mustard, autumn olive, privet, barberry, buttonbush, hackberry, sweetgum, Jerusalem artichoke, hophornbeam, gooseberry, and black walnut. Of 41 Iowa nests, 42% were in forbs, 39% in shrubs, and 20% in deciduous saplings. Most nests are 0.3-1.0 m from the ground with less than 10% 10 m or higher in trees. There are no reports of nests being reused (Baily 1954; Morgan 1976; Payne 2020; Phillips 1951; Stauffer and Best 1980; Taber and Johnston in Austin 1968).

In Kansas, males with nests in cornfields sang from a roadside utility wire, with each claiming about 10 m of wire. The closest neighbouring territory on a wire was 40 m (Davis and Mack 1995). In Michigan, territories averaged 1.4 ha (range 0.4-8 ha). The smallest were along shrubby and weedy edges of woods and in old fields. The largest were in shrub swamps (Payne 2020). A territory in Kansas was 1.1 ha. The distance between pairs of 32 singing males averaged 153.6 m (range 33.5-396 m; Fitch 1958).

Natal philopatry rates are low, with most birds banded as nestlings nesting far from the natal site. Of more than 2,600 nestlings in Michigan, 138 (about 5.3%) returned to breed as yearlings or adults. Two nestlings were recovered as adults in the breeding season 52 km and 350 km from the natal area. Of more than 150 returning nestlings in Michigan, fewer than 10% bred within 1-2 km of the natal site (Payne 2020; Payne and Payne 1993). Of 155 young in Ohio, only 2 (1.3%) were recovered as adults and only 1 (0.6%) returned to its natal area (Lehnen and Rodewald 2009b).

It appears as though most surviving adults return to the same area to breed in subsequent years. In Indiana, 50% of females returned (Carey 1982). Return rates of males were 62% in fields with high-density populations and 28% in low-density fields. In high-density fields, 67.3% of males were adults; 73.5% of the males in low-density fields were yearlings (Carey and Nolan 1979). In Ohio, 82 of 280 adults (29.3%) were recovered in a subsequent year and 81 (98.8% of returning birds) returned to the same site (Lehnen and Rodewald 2009b). At 2 sites in Michigan, 42.4% and 62.1% of males returned in a subsequent year. Ninety-six percent of adult males and 71% of yearling males returned to the same territory. Females were significantly more likely to disperse to a new territory in a subsequent season than males. The return of her mate was the best predictor of whether a female would settle at the same territory or disperse, with most dispersal related to changes in males. The Indigo Bunting breeds in local groups of territories with several neighbours within 200 m. Social familiarity with song within the group may be a reason for males to return to their previous site. The greater incidence of dispersal by females may be because they are unlikely to benefit from prior familiarity of other females (Payne 2020; Payne and Payne 1993).

Limiting Factors

Eggs have been found in Ontario nests from the last week of May until the third week of August, with most present in the last 3 weeks of June. A nestling in pinfeathers on 4 September indicated an even later egg date (Peck and James 1987, 1998b). In Algonquin Park, nest construction occurs from late May to late June, eggs are present from early June to late July, nestlings are present from late June to late July, and dependent fledglings have been seen from early July to early September (Tozer 2012).

Females settle on males' territories 1-2 days after they arrive. The pair spends 0-6 days in selecting a nest site (mean 3.4 days). The first nest of the season takes 4-10 days to build, but later nests are built in as little as 2 days. The first egg is usually laid the day after the nest is complete, but as many as 3 days may elapse before egg-laying begins. In Indiana, the time spent from nest-site searching to laying of the first egg varied from 5-34 days (average 15.8 days). Longer periods were associated with early nesting yearling females and abundance of cowbirds. When cowbirds were abundant, nesting was delayed to avoid the peak laying period of the parasite. Eggs are laid on consecutive days. Incubation begins with the laying of the last egg. The incubation period in 2 Ontario nests was 12 days. Incubation periods of 12-13 days are typical, occasionally 11 days in summer and 14 days during cool weather. The nestling period is typically 9-12 days but may be as short as 8 days if the young are disturbed and as long as 14 days during cold weather (Carey 1982; Morgan 1976; Payne 2020; Peck and James 1987; Taber and Johnston in Austin 1968).

The Indigo Bunting typically raises 2 broods, rarely 3. Females nest repeatedly after both failed and successful nestings. In Michigan, 56.5% of females fledged 1 brood, 12.8% fledged 2, and 0.1% fledged 3 broods. These proportions were considered minima because females may breed elsewhere in the same season. Clutches of 2-6 eggs were reported in Ontario, with only a single 6-egg clutch found. Three eggs was the most common clutch size (average 3.31 eggs). The clutch size is typically 3-4 eggs, less often 1-2 eggs; single-egg clutches are usually abandoned. Smaller clutches may have had an egg removed by a cowbird. Larger clutches are more common later in the season (Payne 2020; Peck and James 1998b; Phillips 1951; Taber and Johnston in Austin 1968).

Both sexes are capable of breeding when they are 1 year old. Yearling females breed regularly and nest repeatedly during the season. About half of yearling males breed and almost all older males breed. In Michigan, 55% of yearling and 90% of adult males were mated and 49% and 85% nested respectively. Yearling males have lower reproductive success than adults. Yearlings that are unsuccessful in attracting a mate sometimes move to a new territory. Yearling males with blue plumage have better reproductive success than brown yearlings. Matching songs of neighbouring males raised the breeding success of browner males by 50% to equal that of blue males that did not song-match. Song-matching by blue yearling males increased their success to equal that of adult males (Payne 1982, 2020).

Carey and Nolan (1979) defined 4 types of mating systems for the Indigo Bunting in Indiana: polygyny, when a male was mated simultaneously to 2 or more females; season-long monogamy, when a male mated with a single female for the entire season; successive monogamy, when a male mated with 2 or more females but with no overlap in the period of association; and short-term monogamy, when a male was mated to a single female for less than the entire breeding season. Of

141 males, 10% were polygynists, 28% were season-long monogamists, 11% were successive monogamists, 37% were short-term monogamists, and 13% were unmated. The percentage of birds that were polygynists was significantly higher than expected. The proportion of polygynists changed annually from 3% to 15%, with no apparent reason for the changes. Eighty-five percent of males that were polygynous, season-long monogamists, and successive monogamists were adults. Yearlings predominated in the short-term monogamy (58% of males) and unmated (95%) categories. Polygynous males were the most productive and short-term monogamists were the least productive. Females mated to polygynous males were as productive as those mated to long-term monogamists and much more productive than those mated to other monogamous types of males. Females settled first in territories of polygynists and last in territories of short-term monogamists. In Michigan, 15% of males were polygynous. Most polygynous males had 2 mates but 2 had 3 mates and 1 had 4 mates. Of yearling polygynists, 84.2% matched a neighbour's song. The rate of polygyny was similar for adult and yearling males, and song-matching did not influence the rate of polygyny for adult males (Payne 1982). In Michigan, polygyny was associated with a decrease in male parental care (Westneat 1988a). Pairs usually remain together for the breeding season. Less often, the female disperses to another territory and mates with another male. Some females nest with 3 different mates within a season. Females are more likely to move to another territory when they are successful than unsuccessful in their first nesting attempt. Some take their fledglings with them and mate with another male after the brood is independent. Occasionally pairs move together and renest as far as 1 km from the original territory (Payne 2020). When both members of a pair return in a subsequent year, the proportion of them that remate is significantly higher than expected. At 2 Michigan sites, 50.7% and 49.0% of returning pairs reunited. Rematings may be due to a mutual attraction by both sexes to a common breeding site or to active mate selection. Sixteen Michigan pairs bred together for 3 or more years, including 2 pairs for 4 years and 1 pair for 5 years (Payne 2020; Payne and Payne 1993).

Extra-pair copulations are a common mating strategy. Nesting in neighbourhoods of 8-14 males facilitates extra-pair copulations. Both sexes spend considerable time foraying off their territories. Although some of this time may be spent foraging, most appears to be used to solicit extra-pair copulations, typically within 200 m of the home territory. Females solicit extra-pair copulations on their male's territory and those of other males, and may be forced by intruding males. Most off-territory forays occur when females are fertile. In Kentucky, 36 of 88 nestlings (40.9%) were extra-pair; 29.0% of Michigan broods had at least 1 extra-pair young. In another study, 41.5% of young were not matched genetically with the putative father, but all matched with the female. In 3 broods, all young were extra-pair. One study found that yearlings were less likely to be cuckolded than adults; another study found the opposite. Yearlings achieve fewer extra-pair copulations than adults (Carter et al. 2018; Payne 2020; Payne and Payne 1989, 1993; Payne and Westneat 1988).

Intraspecific nest parasitism is rare and occurs in less than 1% of nests. Single 6-egg clutches have been reported in Ontario and Michigan and these suggest laying by 2 females (Payne 2020).

The Indigo Bunting feeds on the ground on fallen seeds, takes grass seeds from plants, and forages in low shrubs, herbaceous species, and trees from ground level to a height of 15 m. It takes seeds from standing grasses and forbs, shuffling along the stem to the seed head. It gleans insects

and spiders from leaves while perching on small branches or moving through the canopy. It feeds on dandelion seeds in lawns, in cornfields on the pollen in the tassels, and in soybean fields on small insects. In summer, it feeds in open wetlands on reed canary grass seeds, with males from several territories visiting without conflict. It takes seeds from the surface of the ground without scratching with its feet. Upon arrival in spring, it feeds on twigs and leaves of flowering deciduous trees and also on leaf buds, young leaves, and pollen of trees. During autumn migration, it feeds in the tops of shrubs and trees and more often on the seeds of standing grasses and forbs. It is an opportunistic feeder, eating small seeds, insects, and berries as they become available (Payne 2020).

In Michigan, only 1.5% of males fed the nestlings in their first 4 days and all were adult males. Overall, 20.6% of males fed nestlings at least once; 18.8% of Kentucky males fed young. No polygynous males fed young. Nestlings are fed spiders, bees, mayflies, butterflies, moths, caterpillars, and harvestmen (Morgan 1976; Ritchison and Little 2014; Taber and Johnston in Austin 1968; Westneat 1988a, 1988b).

During the breeding season, adults eat small spiders and insects and occasionally berries and seeds. The predominant insects consumed include grasshoppers, caterpillars, bugs, and beetles. Aphids and cicadas are the main bugs consumed. Beetles that it eats include weevils, click beetles, and locust borers. Grass and forb seeds that it eats include those of thistles, dandelions, goldenrods, big bluestem, oats, common reed grass, Johnson grass, vetches, clovers, asters, and sorghum. Berries that it consumes include strawberries, blueberries, blackberries, and mulberries. The Indigo Bunting has eaten dog biscuits, cankerworms during an outbreak in an orchard, and mosquitoes. During autumn migration, the diet consists mostly of grass seeds (Holt 1918; Payne 2020; Taber and Johnston in Austin 1968).

The Indigo Bunting is a common host of the Brown-headed Cowbird. It deserts all nests when the cowbird egg is laid prior to bunting eggs, but otherwise accepts eggs. The proportion of parasitized nests decreases as the season advances. More than half of bunting nests are initiated after the peak of cowbird laying. In Michigan, 23% of May nests were parasitized, 26% were parasitized in June, 9% were parasitized in July, and 0% were parasitized in August. Parasitized nests fledge about 1.5 fewer young than unparasitized nests. Nests with 1 cowbird nestling are more likely to fledge buntings than those with 2 cowbird nestlings, and parasitized nests are more likely to be depredated. Nests with less tree canopy, more tall snags nearby, and closer to trees are more likely to be parasitized. In Ontario, 51 of 193 nests (26.4%) were parasitized. Parasitism rates reported in Indiana include 5 of 7 nests (71.4%), 53 of 126 nests (42.1%), and 22 of 63 nests (34.3%). In the latter study, the parasitism rates before and after 15 June were 46.3% and 13.6% respectively. Other parasitism rates include 6 of 14 nests (42.9%) in Ohio, 3 of 82 nests (3.7%) in Arkansas, 13 of 55 nests (23.6%) in river floodplains and 142 of 295 nests (48.1%) in old fields in Missouri, 18 of 109 nests (16.5%) in Georgia and South Carolina, 3 of 15 nests (20.0%) in Texas, 411 of 1,725 nests (19.5%) in Michigan, 8 of 10 nests (80.0%) in Wisconsin, 18 of 60 nests (30.0%) in West Virginia, 12 of 68 nests (17.6%) in Mississippi, and 6 of 30 nests (20.0%) in Quebec (Alterman et al. 2005; Brittingham and Temple 1996; Burhans et al. 2010; Carey 1982; Chapa-Vargas and Robinson 2013; Hackemack et al. 2016; Kilgo and Moorman 2003; Labonté and Dauphin in Gauthier and Aubry 1996; Morgan 1976; Novak et al. 2016; Payne 2020; Peck and James 1998b; Phillips 1951).

The Indigo Bunting benefitted from early deforestation and forest fragmentation, but the amount of suitable habitat is declining. Habitat loss is occurring due to hedgerow removal, roadside maintenance, natural succession of old fields, urbanization, and planting coniferous plantations (Hanberry and Thompson 2019; Labonté and Dauphin in Gauthier and Aubry 1996; Taber and Johnston in Austin 1968).

Forest management improves habitat for the Indigo Bunting. In Pennsylvania hardwoods, it was absent in uncut forests and increased significantly immediately after clear-cutting (Yahner 1993, 2003). In Pennsylvania bottomland hardwoods, it was absent prior to clear-cutting; 2 years after cutting it represented 70% of all birds present. At least 1 growing season was required for establishment of early successional grasses and forbs (Harrison and Kilgo 2004). In New York clear-cuts, it was in a guild of species that was most abundant 5-7 years after clear-cutting and that declined significantly thereafter to become almost absent 24-25 years after cutting (Keller et al. 2003). It also benefits from partial harvests. Vanderwel et al. (2007) reported that it increased by 50% when 10% of trees were removed from boreal forests, including in Ontario. In southwestern Ontario, Holmes et al. (2004) did not find it in woodlots with no recent history of harvesting. It and the cowbird were the best indicators of heavy diameter-limit cuts. In New York upland forests, it was absent in uncut woods and occurred in low abundance in stands where 25-75% of merchantable trees had been removed (Webb et al. 1977). In Indiana, it was significantly more abundant 2-4 years after creating openings of 0.02-0.4 ha in a 2,000-ha forest (Robinson and Robinson 1999). In stand improvement cuts in Pennsylvania, it was more abundant in snag-retention treatments. These had significantly greater woody plant material 0-1.5 m above ground (Stribling et al. 1999).

The Indigo Bunting appears to avoid housing. In Waterloo Region, neotropical migrants consistently decreased in diversity and abundance as the number of houses within 100 m of forest edge increased, regardless of woodlot size (Friesen et al. 1995). In Chicago, it was strongly negatively correlated with distance to edge and the amount of coverage by urban development (Schneider and Miller 2014). In North Carolina, it was negatively correlated with the number of buildings within 200 m (Lumpkin and Pearson 2013).

Fires within forests tend to be beneficial, with the Indigo Bunting responding positively to fire in the Great Smokey Mountains (Rose and Simons 2016). In Georgia, it was associated with high-intensity burns that resulted in 20-50% canopy mortality and severe to total midstorey mortality. It was most abundant 3-6 years after fire when there was decreased canopy cover and an increase in shrub density (Klaus et al. 2010).

In Delaware, the Indigo Bunting was equally abundant in areas with low, moderate, and high populations of deer (Tymkiw et al. 2013).

In West Virginia, the Indigo Bunting was significantly more abundant adjacent to shale gas infrastructure (roads, pipelines, and well pads), particularly linear features, than distant from these features. As the forest was fragmented, its population expanded to follow the new construction and concentrated near pipelines and access roads (Farwell et al. 2019).

Near Missouri lead mines, the probability of a female fledging a young decreased from 57% to 23% in areas with elevated lead concentrations in the soil. Most nest failures were due to predation,

suggesting that lead affected birds' behaviour and activity at the nest, or affected nest-site quality (Thompson et al. 2024).

In North Carolina, the Indigo Bunting was negatively correlated with the average daily mean temperature, suggesting that it may be sensitive to climate change (Lumpkin and Pearson 2013).

Status

The Indigo Bunting is much more common now than it was prior to European settlement. It would have been confined to openings and edges in the extensive forest cover, such as wetland borders, areas cleared by First Nations, savannahs, burns, and alvars. The opening of the eastern forests coupled with tree planting and fire suppression in the west allowed it to greatly expand its range and population (Wells 1958). Baillie and Harrington (1937) considered it fairly common and well distributed north to Lake Nipissing and Ottawa, breeding throughout this range but more common along the southern edge of the province. They concluded that it probably bred at Sioux Lookout, Thunder Bay, and in the Sudbury area. The first atlas confirmed that it nested from the southern border throughout the Great Lakes–St. Lawrence Forest Region, with minor intrusions into the extreme south of the Boreal Forest Region. It was scarce in Nipissing and Parry Sound districts except in disturbed areas. Highest densities occurred in southwestern Ontario and in Rainy River District (Rising in Cadman et al. 1987). James (1991) considered it common in the south and rare in the north to Red Lake, Nipigon, and Timmins.

The second atlas revealed no significant change in the distribution of the Indigo Bunting. Overall, the population was stable, but its probability of observation declined significantly south of the Canadian Shield. The decline may have been due to agricultural intensification. It was most abundant in the Carolinian Forest Region and along the southern edge of the Shield (McLaren in Cadman et al. 2007).

The range and population of the Indigo Bunting increased throughout most of the 20th century, but the Breeding Bird Survey (BBS) indicated a decline in the last quarter of the century (Payne 2020). BBS results indicate that it increased at annual rates of 0.466% in Canada and 0.588% in Ontario 1970-2021. The trends 2011-21 were annual decreases of 1.41% in Canada and 2.1% in Ontario. All results were highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Fledglings perch a few metres from the nest for the first few hours after leaving the nest and are capable of flying upward into a tree within hours of leaving the nest. Sometimes they return to the nest to roost at night, especially if they left the nest before they were 10 days old. Brood division may occur, with each adult responsible for particular individuals. A maximum of 50% of males feed the fledglings; polygynous males rarely provide care to fledglings. Males that do not feed usually follow the female and fledglings, but some remain on their territory and mate with another female. Young reach independence 14-25 days after fledging. Once they are independent, juveniles often flock together, with or without adults (Payne 2020; Westneat 1988a, 1988b).

Both adult and juvenile Indigo Buntings commonly occur in clear-cuts in hardwood stands during the postfledging period, but little is known of its use of other habitat types. In Pennsylvania, it was common in clear-cuts and absent in adjacent mature forests. In Missouri clear-cuts, it was

most abundant the second year after cutting and was significantly less abundant 7-15 years postharvest. In West Virginia clear-cuts, adult captures were correlated with vertical complexity of vegetation, herbaceous ground cover, and arthropod richness and biomass. The herbaceous ground cover was probably a source of seeds. Juveniles were positively correlated with caterpillars and negatively with basal area, vertical vegetation complexity, understorey stem density, herbaceous ground cover, and arthropod richness and biomass (Marshall et al. 2003; McDermott and Wood 2010; Porneluzi et al. 2014; Stoleson 2013; Streby et al. 2011b; Vitz and Rodewald 2005).

MIGRATION

The Indigo Bunting is a complete migrant, wintering from Florida to northern South America. It is a nocturnal migrant that may continue to fly after daylight. During autumn migration in Louisiana, it made northeastern morning flights, probably to account for wind drift during the nocturnal migration. It is solitary during nocturnal flights but may occur in flocks during the daytime. In Mississippi during spring migration, birds stopped over for an average of 2.8 and 3.5 days in 2 years. In New Jersey, the mean autumn stopover duration was 10.1 days (maximum 29 days). In Ontario, birds fly directly to the breeding areas, so spring flocks are rarely seen (Brewer et al. 2018; Curry 2006; Kuenzi et al. 1991; Payne 2020; Seewagen and Newhouse 2018; Yaukey 2010).

In New York, Zelt et al. (2017) compared Indigo Bunting arrival and departure dates for 1898-1939 and 1967-2012. There was little climate change in the first period and significant warming in the second. It arrived significantly earlier in the later period but there was no difference in its autumn departure date. Ellwood et al. (2010) did a similar study in Massachusetts for 1851-1973 and 1988-2007 and observed no response to increasing temperatures. In Indiana, older males arrived 19-21 days earlier in spring than yearling males and 15-18 days earlier than females (Carey and Nolan 1979). In Michigan, there was no difference in the mean arrival time of adult and yearling males but the first arrivals were adults (Payne 1982). In Missouri, adult males arrived earlier than yearling males and females, but adult males with less blue colour and yearlings with more blue arrived at the same time (Quay 1987). At Long Point, mean capture dates were 18.6 May for adult males, 17.5 May for yearling males and 18.5 May for males of unknown age. Although adult males arrived a bit later, the difference was not significant (Stewart et al. 2002).

In southern Ontario, most Indigo Buntings arrive in mid-May, the peak of migration is in the last 2 weeks of May, and the earliest migrants occur in late April. One was observed at a feeder in late March in Elgin County (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008). Average arrival in the southern Shield is mid- to late May (Mills 1981; Tozer 2012).

In the southern Shield, autumn migration begins in mid-August and all birds are gone by late September (Mills 1981; Tozer 2012). In the south, the main departure is in mid- to late September with stragglers to mid-October; one was reported on a Christmas Bird Count (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008).

The Indigo Bunting is occasionally a late autumn vagrant to northern Ontario north of the normal breeding range. There are 20 records of birds in the north from 20 September to 24 November. All 3 November records were of birds at feeders that had probably been artificially induced to linger. Almost all were associated with human-influenced areas such as weedy or

disturbed areas in towns, feeders in towns, or campgrounds in provincial parks. Three were found at natural sites: 2 on shorelines and 1 on an island (Wormington 1986).

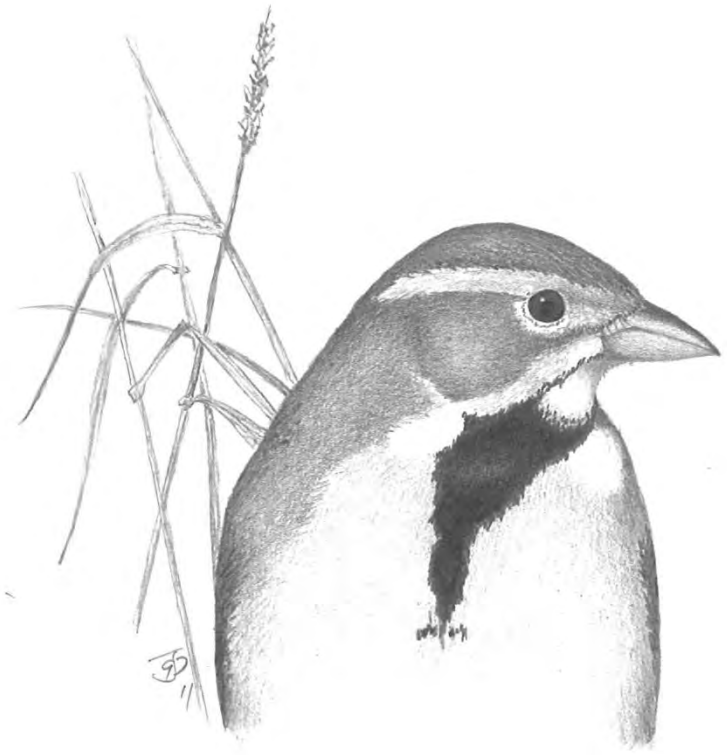
During migration, the Indigo Bunting inhabits open grasslands, shrubs, leafy trees, and tall standing grasses with seeds (Payne 2020). During spring migration in Pennsylvania, Smith and Hatch (2008) observed it significantly more often in shrubs than in forest. During autumn migration in Pennsylvania, it confined its habitat use to shrub-sapling-stage forests and forest-agricultural edges. It was not detected in older or suburban forests or in forest-interior habitat (Rodewald and Brittingham 2004).

The Indigo Bunting is occasionally killed at communication towers and other tall structures during migration. Three were killed at the Lennox generating station chimneys 1972-82 (Payne 2020; Weir 2008).

James (1991) considered the Indigo Bunting an uncommon migrant and an autumn wanderer north to Winisk and Moosonee.

Dickcissel

Spiza americana



BREEDING SEASON

Habitat Requirements

Peck and James (1987) reported that 1 Ontario Dickcissel nest was in a timothy field and another was in a shrubby farm field. During an invasion in 1988, most nests were in old or abandoned fields of grasses, forbs, and shrubs; 1 was in a hayfield (Peck and James 1998b). During the 2017 invasion, breeding birds were reported in grasslands, hayfields, and sites where tallgrass prairie habitat restoration had taken place. All were open areas dominated by grasses with some shrubs, taller forbs, or overhead wires that provided singing perches (Woodliffe 2018).

The Dickcissel is an obligate grassland species that nests in tallgrass prairies, old fields and meadows, hayfields, reclaimed surface mines planted to grasses, lightly grazed pastures, weedy field borders, roadsides, fencerows and hedgerows, Conservation Reserve Program lands, and grassed waterways. It occasionally nests in no-till row crops, shrubby areas, and marshes. Old fields, meadows, and hayfields are highly preferred over tallgrass prairie, its historical habitat. These are occupied first and birds tend to colonize prairies only after old fields are at carrying capacity. The

more heterogeneous vegetation structure in old fields provides better nesting habitat than prairies and supports a higher density and more polygynous males. Predation rates may be higher in old fields because these may have a higher density of predators. It prefers hayfields that contain alfalfa to those dominated by grasses. Habitats that contain forbs are superior. The forbs increase vegetation structure, provide nest sites and cover for nests, and are used as singing perches. When grasslands are sprayed to kill weeds, density of the Dickcissel declines significantly. Perches are an essential component of the habitat. Ideal nesting habitat may be unoccupied if there are no suitable singing perches. Tall forbs, shrubs, fence posts, and overhead wires along roads are suitable perches (Askins et al. 2007; Dechant et al. 2002k; Finck 1984; Fitch 1958; Fretwell 1977; Fretwell and Calver 1969; Graber and Graber 1963; Graves et al. 2010; Gross in Austin 1968; Harmeson 1974; K.L. Mitchell et al. 2012; Mulvihill 1988; Patterson and Best 1996; Swanson 1996; Temple 2020; Walk et al. 2010; Winter 1999; Zimmerman 1971, 1982, 1984; Zimmerman and Finck 1989).

At the landscape level, the Dickcissel is negatively affected by urbanization. McLaughlin et al. (2014) found that it did not avoid grasslands embedded in urban landscapes, but its density declined significantly with the intensity of surrounding urban areas. In Illinois at the 400-m scale, it was positively associated with agricultural land (Glass and Eichholz 2023).

The Dickcissel occurs in a wide range of habitats, but prefers areas with tall (25-150 cm) and dense (90-100%) cover, greater than 50% forb coverage, and more than 10 elevated song perches per ha. Occupied areas in Wisconsin had less than 1% woody cover, 74% herbaceous cover, 17% litter cover, 9% bare ground, 63 cm maximum vegetation height, 19 cm vegetation height-density, and 5-8 cm litter depth. Mean nest-site characteristics in Iowa were similar to those of the Red-winged Blackbird: 67 cm vertical cover, 98 cm height of live vegetation, 48% grass cover, 54% forb cover, and 94% total cover. Vegetation within territories and at nest sites is either taller or denser than unoccupied areas. Nest sites with taller vegetation, greater visual obstruction, greater coverage by grasses, and smaller amounts of bare soil have higher nest success. When Dickcissel densities are high, all but the least suitable vegetation is included within territories. At low densities, only optimum habitats are occupied. It is positively correlated with grass cover, litter cover and depth, and vegetation height and density. It is strongly negatively correlated with bare ground. Although shrubs and small trees may be used as nest sites and perches, all studies except one in Ohio determined that it was negatively correlated with coverage by woody vegetation (Chapman et al. 2004; Dechant et al. 2002k; Graves et al. 2010; Hatchett et al. 2013; McLaughlin et al. 2014; Monroe

et al. 2019; Patterson and Best 1996; Powell et al. 2008; Rotenberry and Wiens 1980; Swanson 1996; Winter 1999; Zimmerman 1971).

The Dickcissel does not avoid grassland edges adjacent to cropland or roads, with nests reported as close as 3 m to a cropland edge (Lituma and Buehler 2016). It appears to avoid edges with treed habitats, with the median distance of nests 400 m from a wooded edge in Illinois compared with 100 m for cropland edges (Walk et al. 2010). Proximity to wooded areas appears to reduce habitat suitability (Temple 2020). It may also avoid edges in urban landscapes where its occurrence was negatively correlated with the edge-to-interior ratio (McLaughlin et al. 2014).

Most studies concluded that the Dickcissel is not area sensitive and not significantly affected by habitat fragmentation (Dechant et al. 2002k; Herkert 1994a; McLaughlin et al. 2014; Swanson 1996). It has nested in grasslands as small as 1 ha and in strip habitats such as roadsides, fencerows, and grassed waterways. In Illinois, it nested in grassed waterways 7-28 m wide rather than hedgerows 1-3 m wide (Dechant et al. 2002k). Some studies found relationships between its abundance and patch size. In Kentucky and Tennessee, Giocomo et al. (2008) found most nests in fields larger than 150 ha. Temple (2020) reported that it preferred fields larger than 10 ha and had denser populations in larger fields. In Missouri, its density was unaffected by patch size but its nesting success decreased with decreasing patch size. Nest success may vary by the type of predators present, possibly explaining why patch size does not affect nesting success in some areas (Winter and Faaborg 1999). Zuckerberg et al. (2018) found that the direct and indirect effects of temperature and precipitation on nesting success were moderated by grassland patch size. The positive effects of precipitation in the previous year were strongest in small patches but had little effect in large patches. Warm temperatures reduced nesting success in small patches but increased nesting success in large patches.

In Ontario, 23 nests were elevated and 2 were on the ground. Elevated nests were in 5 species of forbs and 6 species of deciduous trees and shrubs. One ground nest was at the base of a forb and the other was concealed among timothy stalks. Nests were 0.08-1 m above ground, with most 0.3-0.6 m up (Peck and James 1998b). Coady (2007) reported a 2005 nest in Bronte Provincial Park that was 0.96 m above ground in a 2-m-tall hawthorn.

Typically 75% or more of nests are elevated. Early nests may be in grasses when forbs are still short and below the grasses. Deciduous shrubs and saplings are often used as nest sites. Nests are in a crotch or clump of the supporting vegetation but not tied to it in any manner. They are surrounded by green vegetation and well shaded (average 96%) with overhead vegetation. In Oklahoma, 36.2% of elevated nests were in white elm, 7.4% in Osage orange, 6.3% in hackberry, 4.2% in evening-primrose, 3.2% in mulberry, 2.1% in plum, and 1.1% in each of dogwood, coralberry, juniper, blackberry, heath aster, fleabane, sunflower, giant ragweed, and thistle. In Illinois, it highly selected old field aster for nesting, but nesting success was lower in asters than in dead vegetation. It has also nested in greenbrier, alfalfa, rose, green milkweed, grama grass, smooth brome, willow, wild crabapple, oak, cherry, and apple. Nests have been reported as high as 4.3 m from the ground but most are less than 1 m up. Replacement nests tend to be higher above ground in vegetation with greater average height, visual obstruction, and forb coverage, and somewhat lower grass coverage. Vegetation at random sites exhibited the same trends. Nests are only used once but may

be built on top of an old nest (Dechant et al. 2002k; Fretwell 1977; Gross in Austin 1968; Harmeson 1974; Overmire 1962; Patterson and Best 1996; Temple 2020; Walk et al. 2004).

The male defends a territory that includes the nest site and foraging area; females are not aggressive. Males abandon their territories toward the end of the breeding season, often before their mates have finished nesting. Males may make distant flights, possibly to scout for better habitat. In Kansas prairies, which are suboptimal habitat, males were on their territories significantly less than old-field males, spending more time in distant flights. Old-field males spent more time in territorial displays and less time in distant flights. Territory size is affected by habitat quality, density of Dickcissels, and mating status. Territories in suboptimal habitat are significantly larger than those in optimal habitat. Territory size decreases with increasing density. In Kansas, the minimum territory size that could support a pair was 0.36 ha but smaller territories have been reported elsewhere. This minimum territory size limited the density that could be reached. Unmated males have significantly smaller territories than mated males, but there is no difference in territory sizes of monogamous and polygynous males regardless of how many mates they have. In Kansas, mean territory sizes were 0.72 ha for unmated males, 0.85 ha for monogamous males, and 0.95 ha for polygynous males. Overall mean territory sizes in 2 years were 0.50 and 0.71 ha (maximum 0.98 ha). In Illinois, territories ranged from 0.16 to 0.95 ha for mated males. In tallgrass prairies, territories averaged 1.4 ha in Iowa and 1.5 ha in Oklahoma. Overall, territories are typically 0.3-1.1 ha with extremes of 0.15-1.5 ha. Territory sizes tend to decline with the season (Dechant et al. 2002k; Finck 1984; Fitch 1958; Harmeson 1974; Schartz and Zimmerman 1971; Temple 2020; Verheijen et al. 2019; Zimmerman 1966, 1971).

No information is available on natal philopatry, but it is probably extremely low or nonexistent.

Males exhibit site fidelity in the core of the range but there is considerably less fidelity to peripheral and sporadically occupied areas. These sites are typically not inhabited in subsequent years even if conditions have not changed (Temple 2020). In Kansas, an average of 49% of territorial males returned in the next year; no females returned. Sixty-nine percent of returning males switched territories. Those that switched spent an average of 7.5 weeks on their territories, significantly less than for males that remained on their previous territories (10.3 weeks). Fidelity to the territory of the previous year was related to the number of mates that they attracted and perhaps to the number of young that they produced (Zimmerman and Finck 1989). Also in Kansas, 16 of 197 males (8.1%) and 1 of 146 females (0.7%) returned (Verheijen et al. 2017). In Illinois, 5 of 25 females (20.0%) were resighted the next year. Two that emigrated following nest failure were seen the following year 1.1 and 5 km from their previous nests (Walk et al. 2004).

Limiting Factors

Eggs have been found in Ontario nests from the first week of June until the last week of July, mostly in mid-July. The female builds the nest in 2-4 days and begins laying 1-2 days later. Eggs are laid on consecutive days. The incubation period at 4 Ontario nests was 9-10 days, shorter than reported elsewhere, suggesting that incubation began before the clutch was complete. Incubation is 11.5-13 days elsewhere with an average of 12.0 days in Kansas. The nestling period is 7-10 days, mostly 9-10 days (Gross in Austin 1968; Harmeson 1974; Peck and James 1998b; Temple 2020; Winter 1999; Zimmerman 1971, 1983).

The Dickcissel is typically single-brooded, consistent with its long-term care of fledglings. At least 2 cases of double broods have been reported. It has been speculated that early breeders in the southern portion of the range may move northward to nest again later in the season, but this has not been confirmed. Replacement nests may be common. Almost all females that remained at an Illinois site continued to nest until they fledged young. After nest failure, 62% of females emigrated, 36% renested, and 2% ceased nesting. Emigrants were detected 13-32 km away and some may have renested at distant locations. Dispersal distances from initial to subsequent nests in the same area were 22-806 m (mean 222 m). First eggs were laid in replacement nests an average of 8.5 days after nest loss (range 4-15 days). At another site, 85.7% of females that lost their nests in good habitat renested. Only 17% of those in low-quality habitat renested (Harmeson 1974; Temple 2020; Walk et al. 2004). Clutches of 3-5 eggs have been reported in Ontario (average 3.83 eggs); 4 eggs was the most common clutch size. Elsewhere, clutches of 3-6 eggs have been reported, with most clutches containing 4 eggs. In some cases, clutch size is smallest early in the season when food resources are scarce. In other areas, clutch size decreases regularly as the season progresses. Clutch size was about 0.75 eggs smaller in replacement than first clutches in Illinois, but subsequent nests fledged as many young because nesting success was higher. Two 7-egg clutches have been reported and at least 1 of these (0.3% of nests) was a result of intraspecific nest parasitism. Similarly, a 9-egg clutch must have been due to more than 1 female laying in the same nest (Giocomo et al. 2008; Gross in Austin 1968; Harmeson 1974; Peck and James 1998b; Peer 2010; Temple 2020; Walk et al. 2004).

Both sexes are capable of breeding as yearlings but some males are unsuccessful in attracting a mate; all females breed. Unmated yearling males are common and these birds tend to have the lowest-quality territories. Unmated males may retain their territories for less than 2 weeks and these represent 13.6-33.3% of the male population. Vegetation in bachelors' territories is shorter, less dense, and covers less of the area than territories of mated males. Females may be attracted to a bachelor's territory but do not remain long if the habitat is inferior (Fretwell 1977; Schwartz and Zimmerman 1971; Temple 2020; Zimmerman 1966; Zimmerman and Finck 1989).

The Dickcissel is commonly polygynous in the core of its range and considerably less so at its periphery. In Kansas, males in prairies were all monogamous; more than 50% of males in old fields were polygynous. The female-to-male sex ratio was higher in old fields. Females selected habitats with greater vegetation structure and vegetation volume. Polygyny is adaptive for females because it allows them all to nest and select higher-quality habitats. Females mated to polygynous males also have higher reproductive success. Most polygynous males are bigamists but a few have 3 mates. Some males had as many as 8 mates in a season. The nests of females mated to a polygynous male are asynchronous, with an average of 8.8 days between the laying of the first egg by the first and second females. The male is highly attentive to the female until she starts brooding, thereby precluding him from attracting another mate at that time (Finck 1984; Fretwell 1977; Fretwell and Calver 1969; Harmeson 1974; Schultz and Zimmerman 1971; Zimmerman 1966, 1971; Zimmerman and Finck 1989).

The Dickcissel forages for arthropods on the ground in dense foliage of grasses, forbs, and low shrubs. It takes seeds from the ground and ripe seed heads. In Kansas, it spent most of its time foraging in forbs where arthropods were most abundant, lesser time in grass where insects were

38% less abundant, and the least amount of time in wheat where insects were 53% less abundant than in forbs. In wheat fields, it fed on wheat rather than insects (Schwartz and Zimmerman 1971; Temple 2020).

In the core of the range, males rarely feed nestlings, usually only later in the season after territoriality declines or during droughts or other periods when food is scarce and the nestlings are at risk of starving. Provisioning rates are significantly higher when the male helps. Male provisioning may be more common at the periphery of the range where there are fewer opportunities for attracting additional mates (Finck 1984; Maddox and Bollinger 2000; K.L. Mitchell et al. 2012; Schwartz and Zimmerman 1971). Nestlings are preferentially fed grasshoppers, with the nestling diet consisting of 86% and 91% orthopterans in 2 years. The Dickcissel ate caterpillars according to their availability and spiders, beetles, flies, bugs, and hymenopterans less than their availability (K.L. Mitchell et al. 2012). In Illinois, the nestling diet was highly selective for orthopterans, and caterpillars were eaten more than their availability. Beetles and hymenopterans were consumed less than their availability (Temple 2020). One brood was fed garden orbweavers (Judd 1901).

During the breeding season, adults feed on orthopterans, lepidopterans, termites, flies, hymenopterans, and spiders. They also eat seeds of grasses, willows, smartweeds, and pinks. During migration and winter, the diet consists almost entirely of grass seeds (Temple 2020). At 1 Kansas site, the Dickcissel fed extensively on grasshoppers, profitable prey because of their large size (Schwartz and Zimmerman 1971). Thirty-three Illinois birds ate 68% vegetable and 32% animal matter. The vegetation included 32% waste wheat and oats and 36% weed seeds, especially those of foxtails, smartweeds, and knotweeds with lesser amounts of chickweeds. Orthopterans comprised 28% of the diet: 26% short-horned grasshoppers and 2% crickets. Birds also ate cankerworms in an infected orchard (Gross in Austin 1968). Judd (1901) analyzed the contents of 152 stomachs collected during the breeding season. The diet consisted of 70% animal and 30% vegetable matter. Insect food included 41% orthopterans, 15% beetles, 8% lepidopterans, 2% hymenopterans, and 1% flies and bugs. From June to August, 50% of the diet consisted of short-horned and long-horned grasshoppers and crickets. Two percent of the diet consisted of spiders and a few small snails. The vegetable matter consisted of seeds of millet, foxtails, panic grasses, and oats. Wiens and Rotenberry (1979) reported the Oklahoma diet over 3 years to consist of 2%, 22%, and 1% beetles; 30%, 6%, and 32% orthopterans; and 32%, 33%, and 2% lepidopterans. In 2 years, short-horned grasshoppers were most important in the diet; beetles (mostly weevils) were most important in the third year. Caterpillars contributed a third of the diet biomass in 2 years and odonates comprised a similar amount in the other year. Seeds, largely of grasses, consistently constituted 25-33% of the diet. It also consumed bees, ground and long-horned beetles, assassin and jewel bugs, flies, and spiders.

The Dickcissel is a common host of the Brown-headed Cowbird. It usually accepts parasitic eggs but may occasionally abandon heavily parasitized nests. Nest survival is not reduced by parasitism, but the clutch size is reduced due to egg removal by cowbirds. In the core of its range, parasitism rates are very high and nest loss may be considerable. In the periphery of its range, parasitism rates are low and the effects of parasitism are negligible. In Kansas, the Dickcissel was the preferred host because it nested later into the season than other hosts and can raise as many as 5 cowbird fledglings. In Kansas, nests had lower parasitism rates in annually burned and ungrazed pastures

than in pastures managed with patch-burn grazing. Parasitism rates appear to be higher when nests are closer to woody vegetation, in nests placed higher in vegetation, in lower density Dickcissel populations, and in populations nesting with Red-winged Blackbirds because of the blackbirds' effective mobbing of cowbirds. Parasitism rates of 0-92% have been reported. At the periphery of the range, parasitism rates tend to be 0-5% or a maximum of 10%. In the core of the Dickcissel range, which corresponds to the highest cowbird densities, parasitism rates are 31-33% in old-field habitats and 50-70% in prairies, with a maximum of 92%. In Ontario, 1 of 25 nests (4.0%) was parasitized (Burhans et al. 2010; Dechant et al. 2002k; Fretwell 1977; Galligan et al. 2006; Giocomo et al. 2008; Jensen and Cully 2005; Monroe et al. 2019; Overmire 1962; Patterson and Best 1996; Peck and James 1998b; Peer et al. 2000; Rivers et al. 2010; Temple 2020; Verheijen et al. 2022; Walk et al. 2010; Winter 1999; Zimmerman 1983).

The most significant limiting factor for the Dickcissel is control programs in South America where it is considered an agricultural pest. It is hunted and eaten throughout its winter range. In Venezuela, it is killed illegally by spraying roosts with lethal organochlorine and organophosphate pesticides. Some roosts support 10-30% of the global population. Its decline in North America has been attributed mostly to winter control (Temple 2020).

Only about 4% of tallgrass prairie remains, the Dickcissel's original habitat. It has adapted well to anthropogenic habitats such as pastures, hayfields, and old fields, but these are also disappearing due to conversion to row crops. Fields planted to switch grass for agrofuel production have the potential to support it, but these are managed to maximize biomass and homogeneity of the vegetation, typically making them unsuitable (Askins et al. 2007; Robertson et al. 2012; Temple 2020; Walk et al. 2010).

Hay mowing is a significant source of mortality. This is exacerbated by the recent tendency to plant monocultures of alfalfa which are mowed earlier and more frequently than traditional clover-timothy fields. Mowing may retard natural succession and maintain habitat but annual mowing and mowing during the breeding season results in very high mortality. Low productivity and low annual return rates are associated with mowed alfalfa fields, suggesting that these are population sinks. In Arkansas, all nests were destroyed in fields mowed 26-31 May but the effects of haying 17-26 June were trivial. In Iowa, all birds left fields after mowing and did not recolonize them until the vegetation was 20 cm tall. Densities in unmowed fields increased after other fields were mowed. In Illinois tallgrass prairies, it preferred areas that were mowed in July every 2-3 years. In Iowa, it increased in monotypic reed canary grass when blocks less than 2 ha were mowed to 10 cm then disked. This resulted in an increase in litter and forb cover and arthropod biomass and abundance (Benson et al. 2013; Dechant et al. 2002k; Frawley and Best 1991; Gross in Austin 1968; Luscier and Thompson 2009; Patterson and Best 1996; Swanson 1996; Temple 2020). Wolcott et al. (2023) recommended that grassland management be deferred until August to protect both nests and fledglings.

Burning is a common management practice to prevent woody growth in grasslands. Fire also eliminates accumulated litter and standing dead vegetation. The Dickcissel largely avoids habitats in the year that they are burned, but it may be common the next year (Askins et al. 2007; Dechant et al. 2002k; K.L. Mitchell et al. 2012; Powell et al. 2008; Verheijen et al. 2019). In Illinois, it responded

positively to prescribed burns in undisturbed grasslands. Nest density and survival also increased with forb coverage (Glass and Eichholz 2023).

Light to moderate grazing may provide suitable habitat by controlling woody growth and making grasslands more heterogeneous. Heavy grazing is detrimental, resulting in vegetation that is too short and sparse. It may also make nests more susceptible to predation and parasitism (Dechant et al. 2002k; Kim et al. 2008; Renken and Dinsmore 1987; Swanson 1996; Verheijen et al. 2019).

The Dickcissel is strongly affected by drought. Densities decline significantly in the core of the range during drought, with birds often moving to the periphery of the range. During droughts, food is scarce with some nestlings starving and brood sizes being smaller (Kim et al. 2008; Patterson and Best 1996; Suedkamp Wells et al. 2008; Temple 2020; Verheijen et al. 2019).

In Texas, Hatchett et al. (2013) reported that wind farms had no effects on the Dickcissel. Proximity to a wind turbine did not affect nest density, nest-site characteristics, or nest success.

Price (2004) predicted that the Dickcissel's breeding range might expand in southern Ontario if the average summer temperature increased by 2°C.

Status

Historically, the Dickcissel was probably confined to the tallgrass prairies in the central portion of the continent. It spread north and east following extensive deforestation and conversion of land to pastures and hayfields. A disjunct population nested along the Atlantic coast from the early 1800s, but declined and disappeared by 1900, when the breeding range was probably similar to historical conditions. It began to reappear in the east in the 1920s and its range gradually extended northward and eastward from the prairies. Even in the core of its range, populations fluctuate markedly in response to precipitation, being abundant in years of normal precipitation and uncommon during droughts. At the periphery of its range, it is a sporadic breeder, often common in some years and completely absent in other years. Invasions into peripheral areas are often associated with droughts in the core of the range (Fretwell 1977; Gross 1956; Hurley and Franks 1976; Temple 2020).

Ontario is at the periphery of the Dickcissel's range. It is absent or rare in most years but there are occasional invasions to southern Ontario when it may be locally rare or uncommon (James 1991). Breeding was first documented at Point Pelee in 1884 where it was present in all suitable habitat as far as 4.8 km into the mainland (Saunders 1885). Baillie and Harrington (1937) considered it a very rare breeder in the extreme southwest, but with rare records east to Ottawa. Only 2 breeding records were obtained during the first atlas (Eagles in Cadman et al. 1987). An invasion occurred in 1988, with more than 30 nests documented at Point Pelee, Pelee Island, Wheatley, Sarnia, Port Colborne, and Richmond Hill. This occurred during a drought year on the prairies, with breeding evidence obtained as far north as Manitoulin Island and Rainy River District (Austen et al. 1994; Coady 2007; Peck and James 1998b). Breeding evidence was also obtained in 1989, 1990, 1992, and 2000 before the second atlas. During the second atlas, breeding evidence was obtained in 11 squares in southwestern Ontario, mostly in Essex and Chatham-Kent, with at least 43 individuals reported in 2005 (Read and Sutherland in Cadman et al. 2007). From 2010 to 2017, there was a noticeable increase north and northeast of its core range and the area it occupied increased significantly by

2017. In that year, it was reported in 21 Ontario municipalities from Rainy River to Algoma in the north, to Prince Edward County in the east, and most municipalities southwest of there. A total of 410 birds were reported at 129 sites. The invasion did not appear to be drought related and was probably a result of a general range expansion (Woodliffe 2018).

Breeding Bird Survey (BBS) data indicate that the Dickcissel declined steeply by more than 30% 1966-78. Its population has been stable since 1976 at approximately 66% of its 1966 population (Temple 2020). BBS results indicate that it increased at annual rates of 0.892% in Canada and 0.0748% in Ontario 1970-2021. Trends for 2011-21 were annual increases of 2.02% in Canada and 0.789% in Ontario. All results were of low reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Fledglings 1-3 days out of the nest selected areas that were more concealed with denser vegetation than random sites, but vegetation at nest sites was denser. Those 4-11 days out of the nest used even denser vegetation that was comparable to nest sites. Survival rates were positively correlated with vegetation density at the nest site and during the first 3 days out of the nest, but not for older fledglings. Most mortality occurs within a week of leaving the nest. In Nebraska and Iowa over 2 years, fledglings moved an average of 3.7 m and 6.5 m from the nest in the first day, 93.1 m and 123.2 m by day 7, and 141.8 m and 355.3 m by day 15. The maximum distances moved were 401 m and 1,060 m. In Illinois, fledglings remained within 50 m of the nest for the first 6 days and moved out to 150 m by day 27. In Missouri, daily movements by juveniles were fairly constant, increasing at a slow rate until 28 days postfledging. Large movements of more than 600 m started then with the longest movements of 1.8-2.4 km occurring 32-38 days after fledging. The mean time when fledglings first moved more than 300 m was 17.7 days. Three weeks after fledging, average daily movements were 172.6 m. Young have been found as far as 1.6 km from the nest 10 days after fledging. The average home range size of fledglings was 48.8 ha. Home ranges were larger when vegetation was shorter and less variable and were nearly 2 times larger in a drought year (Berkeley et al. 2007; Jones et al. 2017; Suedkamp Wells et al. 2007, 2008; Temple 2020).

Fledglings gradually move from dense grass and forb cover to more open habitats such as corn and soybean fields and wetlands. Grasslands were used at a rate (64%) more than their availability. Crop fields (34%) and wetlands (2%) were used less than their availability. Fledglings that left the natal fields were still being fed by adults, so it is uncertain whether they were selecting habitat or simply following the adults (Berkeley et al. 2007).

Females are largely responsible for feeding the fledglings, although a few males assist. They are fed mostly caterpillars and grasshoppers. Fledglings may be dependent on adults for as long as 4 weeks after fledging. One female fed a juvenile 43 days after it fledged. Soon after independence, juveniles join postbreeding flocks of adults and form premigratory flocks that may consist of several hundred birds in the core of the range (Berkeley et al. 2007; Gross in Austin 1968; Suedkamp Wells et al. 2008; Temple 2020; Walk et al. 2004; Wilhelm 1994).

MIGRATION

During migration, the Dickcissel inhabits large open fields and wetlands where there are abundant seeds to feed on, especially sorghum, rice, and grasses. Flocks often visit grain fields to feed. Nocturnal roosts may be in open fields, bare croplands, marshes, dense stands of grasses, and along

weedy margins of drainage ditches. In late autumn and winter, it may visit bird feeders where it commonly associates with the House Sparrow (Blomme 1989; Gross in Austin 1968; Temple 2020).

The Dickcissel is a rare migrant in Ontario that occasionally wanders north to Thunder Bay and Fort Albany. Some birds remain in the south until early winter (James 1991).

SCIENTIFIC NAMES OF SPECIES MENTIONED IN THE TEXT

Acorn *Quercus*
Adelgid *Adelgid*
    balsam woolly *A. piceae*
    hemlock woolly *A. tsugae*
Admiral, red *Vanessa atalanta*
Agalinis *Agalinis*
Alcid ALCIDAE
Alder *Alnus*
    black *A. glutinosa*
    green *A. alnobetula*
    grey *A. incana*
Alderfly SIALIDAE
Alewife *Alosa pseudoharengus*
Alfalfa *Medicago sativa*
Algae ALGAE
    green CHLOROPHYTA
Almond *Prunus amygdalus*
Alyssum *Lobularia*
    sweet *L. maritima*
Amaranth *Amaranthus*
    redroot *A. retroflexus*
Amphibian AMPHIBIA
Amphipod AMPHIPODA
Anemone *Anemonoides*
    wood *A. quinquefolia*
Animal ANIMALIA
Annelid ANNELIDA
Anole *Anolis*
    brown *A. sagrei*
Ant FORMICIDAE
    carpenter *Camponotus*
    fire *Solenipsis invicta*
Ant-lion MYRMELEONTIDAE
Anthracnose *Apiognomonia*
    sycamore *A. veneta*
Aphid APHIDAE
    birch *Euceraphis*
    woolly ERIOSOMATINAE
Apple *Malus pumila*
Apricot *Prunus armeniaca*
Arachnid ARACHNIDA
Arbutus *Epigaea*
    trailing *E. repens*
Armyworm NOCTUIDAE
Arrow-grass *Triglochin*
    common *T. maritima*
Arrowhead *Sagittaria*
    broad-leaved *S. latifolia*
Arrowwood *Viburnum*
    northern *V. recognitum*
    southern *V. dentatum*
Arthropod ARTHROPODA
Artichoke *Cynara*
Artichoke, Jerusalem *Helianthus tuberosus*
Arum, arrow *Peltandra*
    green arrow *P. virginica*
Ash *Fraxinus*
    black *F. nigra*
    green *F. pennsylvanica*
    pumpkin *F. profunda*
    white *F. americana*
Asparagus *Asparagus officinale*
Aspen *Populus*
    large-toothed *P. grandidentata*
    trembling *P. tremuloides*
Aster ASTERACEAE
    heath *Symphyotrichum pilosum*
    large-leaved *Eurybia macrophylla*
    old field PORTERIANI
    Pringle's *Symphyotrichum pilosum* var. *pringlei*
Avens, mountain *Dryas integrifolia*

Bacteria BACTERIA
Baldcypress *Taxodium distichum*
Balm, horse *Collinsonia*
Banana *Musa*
Barberry *Berberis*
    Japanese *B. thunbergii*
Barley *Hordeum vulgare*
Basswood *Tilia americana*
Bat CHIROPTERA
    hoary *Lasiurus cinereus*
    little brown *Myotis lucifugus*
    red *Lasiurus borealis*

Bayberry *Myrica pensylvanica*
Beaked-rush *Rhynchospora*
Bean FABACEAE
Bear *Ursus*
    polar *U. maritimus*
Bearberry *Arctostaphylos uva-ursi*
Bearberry, alpine *Arctous alpina*
Beaver *Castor canadensis*
Bedstraw RUBIACEAE
Bee APOIDEA
    bumble *Bombus*
    carpenter XYLOCOPINAE
    honey *Apis*
    sweat HALICTIDAE
Beech *Fagus grandifolia*
Beech, blue *Carpinus carolinus*
Beet *Beta vulgaris*
Beetle COLEOPTERA
    Asian longhorned *Anoplophora glabripennis*
    bark SCOLYTINAE
    bean leaf *Certoma trifurcata*
    bess PASSALLIDAE
    black margined loosestrife *Galerucella calmariensis*
    blister MELIDAE
    brown leaf *Phyllobius oblongus*
    carrion SILPHIDAE
    cedar *Sandalus niger*
    checkered CLERIDAE
    click ELATERIDAE
    clown HISTERIDAE
    Colorado potato *Leptinotarsa decemlineator*
    crawling water HALIPLIDAE
    darkling TENEBRIONIDAE
    dung SCARABAEINAE
    eastern larch *Dendroctnus simplex*
    ebony THYREOCORIDAE
    elm leaf *Xanthogaleruca luteola*
    flat bark CUCUJIDAE
    flea ALTICINI
    glowworm PHENGODIDAE
    ground CARABIDAE
    Japanese *Popillia japonica*
    June MELOLONTHINAE
    lady COCCINELLIDAE
    leaf CHRYSOMELIDAE
    long-horned CERAMBYCIDAE
    marsh SCIRTIDAE
    metallic wood-boring BUPRESTIDAE
    minute brown scavenger LATHRIDIIDAE
    mountain pine *Dendroctonus ponderosae*
    picnic NITIDULIDAE
    pill BYRRHIDAE
    potato *Leptinotarsa*
    predaceous diving DYTISCIDAE
    rainbow scarab *Phanaeus vindex*
    rose chafer CETONIINI
    rove STAPHYLINIDAE
    scarab SCARABAEIDAE
    skin DERMESTIDAE
    soldier CANTHARIDAE
    spruce *Dendroctonus rufipennis*
    stag LUCANIDAE
    tiger CICINDELIDAE
    tumbling flower MORDELLIDAE
    viburnum leaf *Pyrrhalta viburni*
    water-scavenger HYDROPHILIDAE
    whirligig GYRINIDAE
    willow flea *Crepidodera aurata*
Beggartick *Bidens*
    nodding *B. cenua*
Bellwort *Uvularia*
    perfoliate *U. perfoliata*
Bentgrass *Agrostis*
    creeping *A. stolonifera*
Bergamot *Monarda*
    wild *M. fistulosa*
Bilberry *Vaccinium*
    bog *V. uliginosa*
Bindweed CONVOLVULACEAE
    black *Fallopia convolvulus*
    field *Convolvulus arvensis*
Birch *Betula*
    bog *B. nana*
    dwarf *B. glandulosa*
    gray *B. populifolia*
    river *B. nigra*
    silver *B. pendula*
    swamp *B. pumila*

sweet *B. lenta*
white *B. papyrifera*
yellow *B. lutea*
Bishop's cap *Mitella*
naked *M. nuda*
Bison *Bison bison*
Bittern *Botaurus*
Least *B. exilis*
Bittersweet *Celastrus*
American *C. scandens*
Asiatic *C. orbiculatus*
Blackberry *Rubus*
Allegheny *R. allegheniensis*
Bladdernut *Staphylea trifolia*
Blanketflower *Gaillardia*
Blazing-star *Liatris*
Blight, chestnut *Cryphonectria parasitica*
Bloodroot *Sanguinaria canadensis*
Blueberry *Vaccinium*
highbush *V. corymbosum*
lowbush *V. angustifolium*
velvetleaf *V. myrtilloides*
Bluebird *Sialia*
Mountain *S. curricoides*
Bluegrass *Poa*
annual *P. annua*
Canada *P. compressa*
Kentucky *P. pratensis*
Bluejoint *Calamagrostis*
Canada *C. canadensis*
Bluestem POACEAE
big *Andropogon gerardii*
little *Schizachyrium scoparium*
Boatman, water CORIXIDAE
Bobcat *Lynx rufus*
Bogbean *Menyanthes trifoliata*
Bog-rush *Schoenus*
Boneset *Eupatorium*
Borage BORAGINACEAE
Borer, currant-tip *Psenocerus supernotatus*
Borer, emerald ash *Agrilus planipennis*
Borer, European corn *Ostrinia nubialis*
Borer, European oak *Agrilus sulcocollis*
Borer, locust *Megacyllene robiniae*
Borer, sugar maple *Glycobius speciosus*
Bristletail THYSANURA
Brome *Bromus*
downy *B. tectorum*
smooth *B. inermis*
Broom *Cytisus*
Scotch *C. scoparius*
Broomsedge *Andropogon*
Virginia *A. virginicus*
Bti *Bacillus thuringiensis israelensis*
Buckeye *Aesculus*
Ohio *A. glabra*
Buckthorn *Rhamnus*
common *R. cathartica*
glossy *R. frangula*
Buckwheat *Fagopyrum sagittatum*
Buckwheat, false climbing *Fallopia scandens*
Budworm TORTRICIDAE
black-headed *Acleris variana*
jack pine *Choristoneura pinus*
spruce *Choristoneura fumiferana*
western spruce *Choristoneura occidentalis*
Buffalo-berry *Shepherdia canadensis*
Bufflehead *Bucephala albeola*
Bug HEMIPTERA
ambush PHYMATINAE
ash-gray leaf PIESMATIDAE
assassin REDUVIIDAE
box elder *Boisea*
chinch BLISSIDAE
damsel NABIDAE
ebony THYREOCORIDAE
harlequin *Murgantia histrionica*
jewel SCUTELLERIDAE
lace TINGIDAE
leaf PHYLLIDAE
leaf-footed COREIDAE
mealy PSEUDOCOCCIDAE
milkweed LYGAEINAE
plant MIRIDAE
seed LYGAEIDAE
shield ACANTHOSOMATIDAE
shore SALDIDAE
soldier *Podisus maculiventris*

- soft-winged HOMOPTERA
- spittle CERCOPIDAE
- squash *Anasa*
- stink PENTATOMIDAE
- stilt BERYTIDAE
- swallow *Oeciacus vicarius*
- tarnished plant *Lygus lincolnaris*
- true HEMIPTERA

Bugleweed *Lycopus*
Bugloss *Echium*
- viper's *E. vulgare*

Bulrush CYPERACEAE
- American three-square *Schoenoplectus americana*
- dark green *Scirpus atrovirens*
- hard-stemmed *Schoenoplectus acutus*
- red *Blysmus rufus*
- river *Schoenoplectus fluviatilus*
- saltmarsh *Bolboschoenus maritimus*
- soft-stemmed *Schoenoplectus tabenaemontani*
- tufted *Trichophorum cespitosum*

Bumble Bee *Bombus*
- arctic *B. polaris*

Bunchberry *Cornus canadensis*
Burdock *Arctium*
- lesser *A. minus*

Burnet *Sanguisorba*
- Canadian *S. canadensis*

Bur-reed *Sparganium*
- big *S. eurycarpum*

Bush, beauty *Kolkwitzia amabilis*
Bush, creosote *Larrea tridentata*
Bush-clover *Lespedeza*
- round-headed *L. capitata*

Butter-and-eggs *Linaria vulgaris*
Buttercup *Ranunculus*
Butterfly LEPIDOPTERA
- admiral, red *Vanessa atalanta*
- black swallowtail *Papilo polyxenes*
- brush-footed NYMPHALIDAE
- cabbage white *Pieris rapae*
- copper LYCAENINAE
- gossamer-winged LYCAENIDAE
- hackberry emperor *Asterocampa celtis*
- lady *Vanessa*
- monarch *Danaus plexippus*
- mourning cloak *Nymphalis antiopa*
- sulphur PIERIDAE
- swallowtail PAPILIONIDAE
- white PIERIDAE

Butternut *Juglans cinerea*
Buttonbush *Cephalanthus occidentalis*
Buttonweed *Diodia virginiana*

Cabbage *Brassica oleracea*
Cabbage, skunk *Symplocarpus foeditus*
Cactus CACTACEAE
- prickly-pear *Opuntia*

Caddisfly TRICOPTERA
- giant casemaker PHRYGANEIDAE
- long-horned LEPTOCERIDAE
- net-spinning HYDROPSYCHIDAE

Calla *Calla*
- wild *C. palustris*

Campion *Silene*
Cane, switch *Arundinaria tecta*
Canker, beech bark *Neonectria faginata*
Cankerworm GEOMETRIDAE
- fall *Alsophila pometaria*
- spring *Paleacrita vernata*

Canola *Brassica campestris*
Caragana *Caragana*
Caribou *Rangifer tarandus*
Carnation *Dianthus caryophyllus*
Carp *Cyprinus carpio*
Carrot, *Daucus*
- wild *D. carota*

Cat FELIDAE
- domestic *Felis catus*

Catalpa *Catalpa*
Catchfly *Silene*
Caterpillar LEPIDOPTERA
- cherry sphynx *Sphinx drupiferatum*
- eastern tent *Malacosoma americanum*
- forest tent *Malacosoma disstria*
- geometer GEOMETRIDAE
- hackberry emperor *Asterocampa celtis*
- owlet NOCTUIDAE
- rosy maple moth *Dryocampa*

- saddled prominent *Heterocampa guttivitta*
- spring cankerworm *Paleacrita vernata*
- tent *Malacosoma*
- winter moth *Operophtera brumata*

Catnip *Nepeta cataria*
Cattail *Typha*
- broad-leaved *T. latifolia*
- hybrid *T.* x *glauca*
- narrow-leaved *T. angustifolia*

Cattle *Bos taurus*
Cedar CUPRESSIDAE
- Atlantic white *Chamaecyparis thyoides*
- red *Juniperus virginiana*
- white *Thuja occidentalis*

Centipede CHILOPODA
Cestode CESTODA
Chafer, shining leaf RUTELINAE
Cherry *Prunus*
- black *P. serotina*
- pin *P. pensylvanica*
- sand *P. pumila*
- sweet *P. avium*

Chestnut, American *Castanea dentata*
Chestnut, horse *Aesculus hippocastanum*
Chickadee *Poecile*
- Carolina *P. carolinensis*

Chicken *Gallus gallus*
Chicory *Cicorium intybus*
Chickweed CARYOPHYLLACEAE
- common *Stellaria media*
- mouse-ear *Cerastium*

Chipmunk SCIURIDAE
- eastern *Tamias striatus*

Chokeberry *Aronia*
Chokecherry *Prunus virginianus*
Cicada CICADIDAE
- 17-year *Magicicada septendecim*

Cicely, sweet *Osmorhiza*
Cinquefoil POTENTILLEAE
- creeping *Potentilla reptans*
- marsh *Comarum palustre*
- shrubby *Dasiphora*
- silvery *Potentilla argentea*
- sulphur *Potentilla recta*

Clam PELECYPODA
- Venus VENERIDAE

Clematis *Clematis*
Cloudberry *Rubus chamaemorus*
Clover FABACEAE
- bur *Medicago polymorpha*
- hop *Trifolium aureum*
- low hop *Trifolium campestre*
