Several studies compared microhabitat features of Henslow's Sparrow's territories to those of other grassland species. In New York, the Savannah Sparrow had the closest habitat requirements, but it tolerated nearby treelines and forest edges whereas the Henslow's Sparrow did not (Peterson 1983). In Pennsylvania, the Henslow's Sparrow preferred taller vegetation and was less tolerant of woody vegetation than the Grasshopper Sparrow (Hill and Diefenbach 2013). In Missouri, Winter (1999) compared habitat at nests of the Henslow's Sparrow and Dickcissel. Henslow's Sparrow nests had deeper litter (3.5 cm compared with 1.9 cm), shorter vegetation (42.0 cm compared with 46.1 cm), greater cover by litter (29.6% compared with 11.6%), less cover by forbs (17.9% compared with 26.0%), less woody plant coverage (1.5% compared with 5.2%), and less bare soil (0.4% compared with 4.8%). Henslow's Sparrow nests had a higher percentage of cover (90.3% compared with 67.7%) and were located closer to the ground (7.2 cm compared with 18.4 cm). Henslow's Sparrows never placed their nests in or immediately adjacent to woody vegetation. Dickcissels preferred forbs and shrubs as a nesting substrate. In Wisconsin, Wiens (1969) compared the microhabitats of the Henslow's Sparrow with those of the Vesper Sparrow, Savannah Sparrow, Grasshopper Sparrow, Bobolink, and Eastern and Western meadowlarks. Habitat of the Henslow's Sparrow was the most distinctive of the 7 species. It exhibited preference for either the highest or lowest value for each parameter. It selected the highest levels for grass-leaf narrowness, forb-leaf smallness, forb-stem straightness, total vertical vegetation density, and litter depth. It selected the lowest values for forb coverage, forb stem thinness, forb density, coverage of effective height of less than 5 cm, vegetation density 0-10 cm from the ground, and light intensity at 0-10 cm. Forbs were significantly taller and coverage by dead forbs was greater in Henslow's Sparrow territories than in territories of other species. The most distinctive feature was the density of the vegetation selected. Vertical density was greater in Henslow's Sparrow territories than in those of any other species, with low vegetation contributing the least to this density. There was little bare ground or area covered by low vegetation in territories. The Henslow's Sparrow spent more time in forbs than Savannah and Grasshopper sparrows despite having fewer forbs in its territories. Species arranged in the order of increasing habitat richness (vegetation density and height and litter coverage and depth) were Western

Meadowlark, Vesper Sparrow, Savannah Sparrow, Grasshopper Sparrow, Eastern Meadowlark, Bobolink, and Henslow's Sparrow.

Some studies concluded that the Henslow's Sparrow is adversely affected by edge; others found no edge effects. In Pennsylvania, density was highest in grasslands with small perimeter-to-area ratios of less than 0.141 km per ha, but it was detected in areas with ratios as high as 0.16 km per ha. It was less likely to occupy small grasslands, especially if they had complex shapes. Hill and Diefenbach (2014) concluded that it may avoid edges because lower densities occurred in small grasslands with large perimeter-to-area ratios. In Illinois, it was more inclined to nest in the interior of fields than within 50 m of a wooded area. In Missouri, nest success was lower less than 50 m from a shrubby edge, presumably because of mammalian predation (Herkert 2002; Winter and Faaborg 1999). In North Carolina, it was dispersed randomly or evenly in fields (Lynch and LeGrand 1985). In Ohio, mean distance of nests from woodlands was 161.1 m, but this was not compared with random sites (Graves et al. 2010). In Kentucky and Tennessee, it was 59% more abundant at points distant from a road than at points on roadsides. This may have been a result of the distribution of habitat. The mean percent land cover by old field was greater 600 m from roads and the mean percent land cover of forest was greater at roadside points. Sample sizes were small and Lituma and Buehler (2016) cautioned against drawing any conclusions about its road avoidance. In Kansas, 13.9% of singing males were within 100 m of woodland edge and 19.0% were within 100 m of savannah habitat. Grassland areas were used significantly more than other habitats. In Wisconsin, the mean distance from territory boundaries was 175.0 m from woods (range 90-240 m), 22.5 m from a fence line (range 5-50 m), and 40.0 m from a cultivated field (range 10-100 m). Territories appeared to be situated randomly from these features (Wiens 1969). There appears to be no evidence that the Henslow's Sparrow consistently avoids edge.

Most studies concluded that the Henslow's Sparrow is area sensitive, but it has been documented nesting in some very small patches. In Ontario, it is generally agreed that it requires grasslands at least 30 ha but that grasslands larger than 50 or even 100 ha may be required to maintain a viable population. Nonetheless, it has nested in much smaller fields in the province. A 3-ha field was occupied in 2 consecutive years near Brockville. Extensive searches for the Henslow's Sparrow were made in Ontario in those 2 years, including much larger patches, and this was the only record for it (Austen and Cadman 1993; Kraus 2015; Pearce et al. 2010). In Missouri, it was 1.8 times more abundant on prairies larger than 110 ha than on smaller prairies (Pruitt 1996). Another Missouri study determined that it was significantly affected by fragment size, but the extent to which patch size affected its density varied greatly among years. Vegetation characteristics were more important in determining its density. Nest success was not affected by patch size (Winter and Faaborg 1999). In New York, it occupied fields 36-100 ha (mean 66 ha). Occupied fields were significantly larger than the mean of 19 ha for unoccupied fields (Peterson 1983). Smith and Smith (1992) concluded that it required 30 ha in New York. In Illinois, grassland size appeared to be the most important factor influencing occupancy. It occurred in only 1 grassland smaller than 100 ha, but occasionally occurred within small patches (1 ha) of unburned prairie within a larger (120 ha) matrix of burned forest (Herkert 1994b). In the same study area, the Henslow's Sparrow occurred on 73% of transects with suitable habitat in grasslands larger than 100 ha, but on 0% of transects with suitable habitat in smaller patches. It rarely occurred in grasslands as small as 10 ha. The area at

which the probability of occurrence was 50% of the maximum was 55 ha (Herkert 1994a). Also in Illinois, Walk and Warner (1999) studied 9 grasslands 7-120 ha in size. It was not documented on the 3 smallest grasslands that were 7, 17, and 32 ha. It occurred in 1 of 4 years on patches 40 ha and 44 ha and occurred more frequently on larger patches. The minimum area requirement for the Henslow's Sparrow was estimated at 75 ha, the area when the frequency of occurrence was 50% of its maximum. Based on data from Maryland, Skipper (1998) concluded that it required a minimum of 28 ha of grassland in the east, but Ells (1995a) reported it nesting in a 6.9-ha field in Massachusetts. In Pennsylvania, Hill and Diefenbach (2014) determined that grassland area itself was insufficient to explain occupancy patterns, but it was less likely to occupy small grasslands with complex shapes. They detected it in grasslands as small as 12.9 ha. Occupied fields in Kansas averaged 29.7 ha (range 9.8-39.1 ha; Schulenberg et al. 1994). In Minnesota, 2 fields with a combined area of 23.1 ha were used in 15 years (Pruitt 1996). In Iowa, fields that supported it were 16-65 ha (Melde and Koford 1996). In Kentucky and Tennessee, almost all nests were in the largest fields. A few nests were in fields as small as 4 ha; all were within 10 km of larger fields (Giocomo et al. 2008). In Michigan, it nested regularly in a 12.1-ha field (Robins 1971a). Studies in Missouri, Kansas, and Ohio demonstrated that it can occur in small fragments (Winter 1999). In Ohio, 6 occupied fields averaged 12 ha and the smallest was 8 ha. Three occupied CRP grasslands averaged 13 ha (range 1-26 ha; Swanson 1996). In Missouri, it was absent in a 28-ha isolated prairie but present in a 16-ha fragment that was 1.6 km from a larger prairie where it was present. Although it may be sensitive to habitat fragmentation in some areas, nesting success does not appear to be affected by patch size. Density increased with the total area of grassland in the landscape and with decreasing distance among grassland patches (Herkert 2002). In most areas, including Ontario, the Henslow's Sparrow appears to be area sensitive. The minimum size of grassland it requires varies geographically, largely depending upon the regional abundance of grasslands and its own abundance. Where it is rare, it is most likely to occupy the best habitats and these are most likely to consist of the largest patches of habitat. It may occasionally occur in smaller than normal patches within a region, but populations in smaller patches are less likely to be sustainable and birds may exhibit lower site fidelity to small sites (Pearce et al. 2010; Pruitt 1996).

Ontario nests were well hidden in and supported by clumps of tall vegetation that was often dead growth from previous years. Nest heights varied from being on the ground to 20 cm above ground (Peck and James 1987; Richardson 1933).

In Michigan, Hyde (1939) summarized 3 types of nest locations. Most nests were built at or near the bases of thick clumps of grass with the base of the nest 5-7.6 cm above ground. Dead grasses at the base of these clumps formed arched roofs over the nests. Some nests were 15-50 cm above ground and fastened to vertical stems of growing forbs and grasses. These nests were associated with advanced growth later in the season. They were usually deeply cupped and not arched over. Approximately 10% of nests were depressed into the ground and were either arched over by projecting earth or protected by dense vegetation. One nest was in a shallow, open saucer of grasses among young green vegetation that afforded no concealment. One nest was in a shrubby cinquefoil. A Kansas nest was 10.2 cm from the ground in a hollowed-out clump of little bluestem 37-39 cm tall. In many areas, nests are in clumps of little bluestem, but they have also been concealed in smooth brome, orchard grass, big bluestem, and Indian grass. Some nests are woven

into the supporting grasses; others are loosely attached. Nests are not reused and a new nest is built for each clutch (Guzy et al. 2002; Melde and Koford 1996; Reinking and Hendricks 1993; Robins 1971a; Schulenberg et al. 1994; Wiens 1969; Winter 1999).

The Henslow's Sparrow has often been described as being colonial or loosely colonial. Territories may be clumped together, but they may also be evenly or randomly distributed, and it may also nest solitarily. It is not a true colonial nester. There are 4 potential reasons why territories are sometimes clustered: the occupied area may have some microhabitat feature that makes the area more optimum than unoccupied areas; the presence of conspecifics may be a cue that it is a good breeding location; clumping of territories may provide enhanced protection from predators such as the Northern Harrier, with alarm notes being given when a sparrow detects a hawk; and having territories close to each other may facilitate extra-pair copulations. There is great variation in the stability of territories and their boundaries. In some areas, boundaries remain fairly constant throughout the season. In other areas, boundaries may be constantly shifting, even in response to human disturbance early in the season, and some males may occupy more than 1 territory in a season. In Michigan, 10 males had a single territory that remained stable over the season, 2 males had 2 successive territories, 2 males had 3 territories, and 4 males had 4 territories. Over the season, shifting of territories, disappearance of singing males, and colonization by new males were common. For males with 4 territories within a season, individual territories persisted for 28-30, 32-34, 22-23, and 34-35 days. In Maryland, some males remained on the same territory from early March until mid-August. Others began singing in early August in areas that were previously unoccupied. Usually singing in these areas lasted for only 3-4 days and then the territory was abandoned. During the nestling period, singing is greatly reduced but the territory is still defended. In Michigan, territories were not defended after mid-September although birds remained in the area for another month. These territories were distinct units separated by a buffer on all sides. The average distance between territories varied inversely with population. The distance between territories was 14 m in July when the population was at its peak and 131 m in September when the population was at its lowest. Thirteen of 22 territories (59.1%) in Pennsylvania overlapped. One territory in Oklahoma was about 1 ha. In Michigan, territories averaged 0.32 ha. Most territories were smallest there at the beginning of the season and increased the remainder of the year, but this was not true for all individuals. Mean territory size was 0.25 ha in the first half of May, 0.25-0.36 ha from May through July, and 0.65 ha in September. In Missouri CRP lands, there were no significant differences in territory sizes in warm-season native grasses and cool-season nonnative grasses. Mean territory sizes in native grasses over 2 years were 0.38 ha and 0.42 ha (range 0.03-1.11 ha) compared with 0.31 ha and 0.36 in nonnative grasses (range 0.01-1.25 ha). Territories averaged 0.18 ha on reclaimed surface mines in Pennsylvania. In Texas, 6 territories averaged 1.01 ha (range 0.15-1.91 ha). In Wisconsin, the average territory size was 0.61 ha (range 0.28-1.09 ha). Mean territory sizes changed with season there as well: 0.36 ha 5-9 May, 1.17 ha 15-25 May, 0.81 ha 28 May to 10 June, and 0.81 ha 14-25 June (Arnold and Garza 1998; Dornak 2010; Graber in Austin 1968; Herkert 1994b; Herkert et al. 2020b; Hyde 1939; Jaster et al. 2013; Lynch and LeGrand 1985; Pruitt 1996; Robins 1971a; Schulenberg et al. 1994; Skipper 1998; Wiens 1969).

Natal philopatry is low, although few nestlings and fledglings have been banded. In Michigan, 0 of 18 nestlings and 2 juveniles returned the following year. In Maryland, 0 of 36 fledglings returned;

0 of 9 juveniles returned in Missouri. In Ohio, 0 of 13 banded juveniles returned (Ingold et al. 2009; Jaster et al. 2013; Pruitt 1996; Skipper 1998).

Even in the core of its range where the Henslow's Sparrow is most abundant, adults exhibit low site fidelity. Throughout its range, birds may be present at a site for 1 to a few years and then disappear inexplicably. These same areas may be recolonized in subsequent years. In many areas, fields may be occupied for only 1 or 2 years. Based on BBS data, it returned to an entire route (30 km^2) in only 50% of years and was occasionally conspicuously absent from broader regions, with only 63% prevalence at a scale of 31,000 km^2. It was not consistently present (with prevalence greater than 75%) until the resolution was broadened to cover 126,000 km^2. It was concluded that the Henslow's Sparrow was nomadic in successive breeding seasons across multiple scales. It may not return to sites where it previously nested even if there have been no changes in habitat. Nomadism may be associated with the spatial and temporal patchiness of suitable breeding habitat and is a sound strategy given that habitat suitability is often ephemeral due to succession, mowing, and fire. Settling suitable habitat as it is encountered upon arrival in the breeding areas rather than homing is advantageous. It appears to track disturbance cycling across the landscape, moving among high-quality habitats characterized by patches that have been idle or only lightly disturbed for 2 or more years. At broader scales, it may respond to droughts, late springs, and regional variation in land use (Austen and Cadman 1993; Austen et al. 1995; Coffin and Pfannmuller 1988; Committee on the Status of Species at Risk in Ontario [COSSARO] 2011; Dornak 2010; Dornak et al. 2013; Hyde 1939; Pruitt 1996; Wiens 1969). In Maryland, 5 of 37 males (13.5%) and 0 of 14 females returned for an overall return rate of 5 of 51 adults (9.8%). Returning males settled an average of 93.4 m from the banding location (range 56-165 m; Skipper 1998). In Missouri, 5 of 32 males (15.6%) returned the following year and all occupied the same territory. One of 13 females (7.7%) returned to the same field (Jaster et al. 2013). In Ohio, 10 of 101 adults (9.9%) returned. All returns were by birds that had been banded in unmowed areas and all but 2 (80.0%) returned to unmowed areas. No birds banded on mowed areas returned to these areas when they were mowed again the following year. Two birds returned in 2 consecutive years and one returned in 4 consecutive years (Ingold et al. 2009). In Kansas, 0 of 13 adults returned even though the site still supported 37 pairs. Return rates of adults in other areas were: 1 of 5 (20.0%) in Minnesota, 0 of 24 in Michigan, 2 of 7 (28.6%) in Texas, and 0 of 17 in Missouri (Arnold and Garza 1988; Herkert et al. 2020b; Pruitt 1996).

Limiting Factors

Eggs have been reported in Ontario nests from the beginning of June until mid-August, with most present from the second week of June through the first week of July (Peck and James 1987). It takes 3-6 days to complete the nest. It is unknown whether egg laying starts as soon as the nest is complete. Eggs are laid at the rate of 1 a day and incubation begins with the laying of the last egg. The incubation period is 10-12 days. The nestling period is 9-10 days (Austen et al. 1995; Graber in Austin 1968; Herkert et al. 2020b; Hyde 1939; Robins 1971a; Winter 1999).

Egg dates suggest that the Henslow's Sparrow may raise 2 broods in Ontario, but this has not been confirmed. The extended egg-laying season with double peaks of activity suggest that 2 broods are raised in many, or most, other places. Two broods have been confirmed in Michigan and Kentucky. In Kentucky, 2 pairs successfully raised 3 broods. It is probable that 2 broods are raised in

most areas. Renesting is common if a clutch or brood is lost. In Michigan, a replacement nest was built 15 m from the first one 5-6 days after the original nest was destroyed. Clutches of 3-5 eggs have been reported in Ontario with most containing 4 eggs (mean 4.09 eggs). Clutches of 2-5 eggs have been reported elsewhere with 3-5 eggs the normal range and 4- and 5-egg clutches most common. In Kentucky and Tennessee, the mean clutch size was 3.8 eggs with a range in means in different years of 3.3-4.4 eggs. Other mean clutch sizes include 3.8 in Missouri, 4.06 in Indiana, 4.4 in Michigan, and 4.3 in Kentucky. In Kentucky and Tennessee, clutch size initially increased, peaked in mid-season, and then declined. In Missouri, clutch size tended to decrease with the season, but not significantly (Crimmins et al. 2016; Giocomo et al. 2008; Herkert et al. 2020b; Hyde 1939; Peck and James 1987; Reinking and Hendricks 1993; Robins 1971a; Skipper 1998; Winter 1999).

The age at first breeding is unknown, but it is likely that both sexes can breed in their first year. In Missouri CRP lands, only 19 of 54 males (35.2%) with territories were paired. There was no difference in pairing success in native and nonnative grasslands. No explanation was offered for the low pairing success. The sex ratio may have been male biased at this site, yearlings may have failed to attract a mate, possibly yearlings are not capable of reproducing, or habitat may have been suboptimal in areas where males remained unmated. The mating system is monogamous with no indication of polygyny. Extra-pair copulations were observed in Michigan and this may be a common mating strategy (Herkert et al. 2020b; Hyde 1939; Jaster et al. 2013; Wiens 1969).

In Wisconsin, the Henslow's Sparrow spent 93.6% of its foraging time in grass 11-15 cm tall and 6.4% of the time in grass 16-20 cm tall. It was not observed foraging in grass 0-10 cm tall or in the air, and it foraged in much deeper cover than other grassland species (Wiens 1969). In Michigan, about half the foraging trips by both sexes were outside the territorial boundaries. Males and females tended to forage in separate areas either within or outside the territory. Mean distances flown from the nest to forage were 30.8 m for males and 24.9 m for females. Each bird of a pair exhibited a strong directional bias in the area in which they foraged (Robins 1971b).

In Michigan, the primary food brought to day-old nestlings was smooth caterpillars, mostly owlet moths. These and soft abdomens of katydids, tree crickets, and grasshoppers were the chief items fed to young as old as 3 days. A greater variety of food items was fed to older nestlings, although orthopterans and caterpillars continued to dominate their diet. Young were also fed willow sawflies, spiders (including garden orbweavers), fireflies, and crickets. The food provided to young consisted of 80% orthopterans and caterpillars (Hyde 1939). In Michigan, the prey most commonly fed to nestlings consisted of caterpillars, primarily of snout moths, and scarab beetle larvae. These were provided to young on 44% of feeding trips. Other important prey included orthopterans (17%), leafhoppers (5%), and assassin bugs (5%). The latter 2 food items were small and probably formed an important part of the unidentified small insects that comprised 21% of the sample. Other invertebrate prey of lesser importance in nestlings' diet included cutworms, crickets, preying mantises, click beetles, fireflies, wasps, lacewings, dragonflies, spiders, and harvestmen. Smooth brome florets were fed on 2 days at 1 nest to nestlings 1 and 2 days old. Small insects and larvae were often brought several at a time and were the major food items fed to 1- and 2-day-old nestlings at all nests. Orthopterans were important foods over the entire nestling period, but most were fed to young in the 3 days prior to fledging. The wings of moths, hind legs of crickets and

grasshoppers, and forelegs of mantids were usually removed before they were fed to young. There were large differences in prey taken at various nests suggesting that adults were selecting prey based upon their availability, but there was no difference in the prey selected by the sexes at individual nests (Robins 1971b). In Illinois, food brought to nestlings consisted of 38.5% caterpillars, 30.7% orthopterans, 15.4% beetles, 7.7% hymenopterans, and 7.7% spiders (Herkert et al. 2020b).

In Michigan, 1 adult was observed eating a large katydid. Seventeen stomachs contained 82% animal food and 18% vegetable matter by volume. From April to September, animal food comprised 85-100% of the diet, except for 1 juvenile that had eaten only 10% animal food. Two stomachs collected in October contained only 9% and 15% animal matter. Orthopterans comprised 36.5% of the entire diet and more than 50% of the August and September diet; 17% of these were crickets and 8.2% were short-horned grasshoppers. Beetles comprised 19.3% of the diet and were found in all but 1 stomach. These included 6.5% weevils. Leaf beetles constituted 5.4% of the diet from April to September, mostly taken from leaves of goldenrods and evening-primrose. The Henslow's Sparrow also ate click beetles and ground beetles. From May to October, bugs comprised 12.2% of the diet, including milkweed bugs, stink bugs, and bug eggs. Lepidopterans comprised only 3.3% of the adult diet, fly remains or eggs were found in only 4 stomachs, and small amounts of hymenopterans, insect eggs, spiders, neuropterans, myriapods, and snails were found in stomachs. Grass seeds constituted 6.2% of the diet, about a third of the vegetation consumed. Grass seeds it ate included those of paspalum, foxtails, crabgrass, corn, and cutgrasses. Other seeds it ate were those of ragweed, smartweeds, sedges, beaked-rush, fox sedge, sheep sorrel, and violets (Hyde 1939). Judd (1901) analyzed 4 stomachs collected in summer and they contained beetles, owlet moth caterpillars, grasshoppers, bugs, and blackberries. The beetles consisted of ground, leaf, and click beetles, and weevils. Bugs were represented by soldier bugs and assassin bugs. Three collected in January in Texas had eaten a spider, grass fragments, and seeds of plants in the aster family.

The Henslow's Sparrow is an infrequent host of the Brown-headed Cowbird. This is because the nests are so well concealed and the cowbird appears to prefer to target woodland and shrubland species. In Missouri, no nests were lost due to parasitism, and both species fledged from parasitized nests. Sparrow clutch size was reduced by 0.9 egg as a result of parasitism. The number of young fledged per successful nests was 3.6 for unparasitized nests and 2.0 for parasitized nests. In Ontario, 1 of 12 nests (8.3%) was parasitized. Parasitism rates from other areas include 1 of 113 nests (0.9%) in Kentucky and Tennessee, 0 of 21 nests in Indiana, 1 of 1 nest in Kansas, 0 of 11 nests in Pennsylvania, 3 of 56 nests (5.3%) in Missouri, 1 of 135 nests (0.7%) in Indiana, 2 of 24 nests (8.3%) in Oklahoma, and 2 of 3 nests (66.7%) in Kansas (Crimmins et al. 2016; Galligan et al. 2006; Giocomo et al. 2008; Herkert et al. 2020b; Hill and Diefenbach 2013; Peck and James 1987; Rivers et al. 2010; Winter 1999; Zimmerman 1989).

Habitat loss and degradation are the greatest limiting factor for the Henslow's Sparrow. It is an early successional species with exacting microhabitat requirements. It is adversely affected if habitat is directly lost, if too much woody growth invades its habitat, or if disturbance results in loss of litter and dense standing dead vegetation. Historically, its habitat was maintained by wildfires, light grazing by bison, and periodic outbreaks by the Rocky Mountain grasshopper. Most native prairies have since been plowed under, there are essentially no wild herds of bison left, the Rocky Mountain

grasshopper is extinct, and fire is typically suppressed (Wells 2007). The Henslow's Sparrow now relies mostly on nonnative habitats for nesting, particularly in Ontario. It is dependent on human management such as prescribed burns, mowing, and grazing by livestock. This management is typically directed toward optimizing profit for humans and any benefits that may accrue to the Henslow's Sparrow are incidental. Where grasslands are managed for wildlife, waterfowl or upland game birds are typically the target species so any benefits to the Henslow's Sparrow are incidental (Pruitt 1996).

Forest clearing to create agricultural land enabled the Henslow's Sparrow to colonize Ontario, but agricultural practices are now the main cause of habitat loss. The losses are due mostly to conversion of pastures and unimproved hayfields to row crops and hayfields dominated by alfalfa. Many poorly drained fields were drained and converted to cropland. In Ontario, there has been a gradual loss of both summer fallow and pasture, with the area available in 1976 only half that of 1951. In 2006, there were 315,000 ha of summer fallow, natural pasture, and improved pasture in Ontario, a decline of 14% since 1996 and 61% since 1976. In Elgin County, low wet meadow habitat is almost gone; there are fewer marshes in Middlesex; there has been a decline in old fields in Oxford, Haldimand, and Norfolk; in Niagara, there are fewer uncultivated fields; there has been a loss of grassy fields and fallow land in Wellington; and successional changes have occurred in former fields in Northumberland. In 1937, there was a colony in Holland Marsh that persisted for about a decade until it was converted to market gardening. Early hay crops consisted of a mixture of grasses, clovers, and a small proportion of alfalfa. These were cut later in the season and often yielded only a single cut or a maximum of 2. Most hayfields are now planted to alfalfa which grows faster. It is cut much earlier in the season than traditional hayfields and 2 or 3 cuts are routinely made each year. In Ontario, habitat loss may also occur due to urbanization, but the effects of this are small compared with agricultural losses. Throughout its range, loss of habitat due to agricultural practices is the most significant limiting factor (Austen 1994; Austen and Cadman 1993; Austen et al. 1994, 1995; COSSARO 2011; Devitt 1967; Heagy 2011; Herkert et al. 2020b; Knapton 1984a; Lancaster et al. 2004; Pearce et al. 2010; Pruitt 1996; Swanson 1996).

Habitat may be lost due to natural succession or tree planting. In 1998, mowing and brush clearing was undertaken at Ostrander Point in Prince Edward County and this area attracted Henslow's Sparrows the next 2 years (Pearce et al. 2010). The site that was formerly occupied at Luther Marsh was planted to conifers and became unsuitable habitat by the early 1970s (personal observation). Many Ontario fields that it formerly bred in have succeeded to shrubland and forest and are no longer occupied (Austen et al. 1999). In Pennsylvania, Hill and Diefenbach (2014) conducted vegetation and breeding bird surveys on reclaimed mine sites 9 years apart. During this time, the amount of woody vegetation increased by 2.5 times and grass height and cover decreased. The Henslow's Sparrow decreased 49% between sampling periods. Surface mine habitats are ephemeral habitat for the Henslow's Sparrow unless regular maintenance occurs to arrest succession. In North Carolina pocosins that had been clear-cut and replanted to pines, habitat became unsuitable once the pines attained a height of 2.4-3.0 m (Lynch and LeGrand 1985).

Loss of grassland habitat has resulted in habitat fragmentation. There are fewer grasslands large enough to support Henslow's Sparrows. Smaller grassland patches have the potential to increase

predation and parasitism rates, but there are no real data to support or refute this. Because of its very specific habitat requirements and its requirement for large patches, only a very small proportion of Ontario agricultural grassland habitat is suitable. Remaining prairies are too small and fragmented to support populations. Assessments of former breeding sites since 1980 in 2002 and 2007-08 found that much of the former habitat now appears unsuitable due to changes in agriculture, conversion to shrublands, and development. Nonetheless, large areas of apparently suitable habitat remain in Grey, Prince Edward, Lennox-Addington, and Frontenac counties. The fact that these are unoccupied suggests that other factors may be affecting the Henslow's Sparrow, such as loss of wintering habitat, mortality between breeding seasons, local population losses due to small numbers of individuals, natural population fluctuations, or low site fidelity. The loss of wintering habitat is a real limiting factor to the Henslow's Sparrow. Perhaps the main reason for apparently suitable habitat remaining unoccupied in Ontario is the fact that this province is at the extreme northern extent of its range. When species decline as a whole, they may contract from the periphery of their range and breed only in their core range. It is also declining in states adjacent to Ontario so there is less likely to be recruitment from other areas (Austen 1994; Austen and Cadman 1993; Austen et al. 1995; Heagy 2011; Pearce et al. 2010; Pruitt 1996).

Prescribed burns are a common management technique used to arrest natural succession. If the fire is intense enough, it will kill shrubs and saplings that have become established. It also removes the litter layer and dead standing vegetation which usually makes the habitat unsuitable for the Henslow's Sparrow immediately after burning. At 1 Kansas site, it was absent at 4 sites where it had nested the previous year. This was because April burning removed the standing dead grass and litter. Rotational burning occurred every 3-4 years at this site and this activity appeared to be favourable for the Henslow's Sparrow (Schulenberg et al. 1994). On another Kansas prairie, it did not occur in areas that were burned in the spring. Over 2 years, 89 and 105 territories were mutually exclusive of burned areas. The most obvious difference between burned and unburned areas was the complete lack of litter and standing dead vegetation in burned areas. Areas that are never burned quickly become invaded with shrubs, so a 3-4-year rotational cycle of burning was recommended, with each tract being at least 30 ha in area. In Missouri, it occurred only on idle or lightly grazed, unburned prairie (Zimmerman 1988, 1989). In tallgrass prairies in Kansas, burns occurred in spring at frequencies of 1, 2, or 4 years. It was nearly absent in the year of the burn. More frequent burning was preferred there. In areas that had not been burned in 1-3 years, it was less abundant in areas burned every 4 years than those burned annually. Areas burned at shorter intervals had higher grass densities (Powell 2008). Also in Kansas, 96% of occupied areas had been burned 2 or 3 years previously. One occupied site was burned 4 years previously and no areas that had been burned in the same year were occupied. Burned sites reached the highest total vegetation cover and density in late spring rather than in summer, and this may have been important in establishing territories (Cully and Michaels 2000). At an Indiana site, burning every 3-5 years was necessary to manage succession. Densities usually peaked 1 year postburn. Some nested successfully during the same year following a spring burn, but density was lower in these areas (Crimmins et al. 2016). At another Indiana site, densities were highest 2 and 3 years after burning and declined in the fourth year. It preferred smaller fields in years 2 and 3, but larger fields in the first and fourth years postburn. Large grasslands may contain patches that did not burn and the effects

of shrub regrowth may be greater in smaller grasslands. A fire frequency of every 3 years would be beneficial for this population (Keating et al. 2023). In Illinois, burning had a significant effect and the Henslow's Sparrow was never encountered in a recently burned area. Densities in areas 2 years postburn were less than half of those 3 or more years postburn (Herkert 1994b). In Oklahoma, all nests were in areas that had not experienced spring burning (Reinking and Hendricks 1993). Periodic rotational burning is beneficial. This arrests succession and results in denser, more vigorous grass growth. In most cases, the habitat is unsuitable the year of the burn except for wet areas where not all litter and standing dead vegetation is burned. Many areas in the Midwest where prescribed burning occurs are devoid of Henslow's Sparrow because the frequency of burning is too high, preventing development of litter and dead vegetation layers. The optimum frequency of burning varies geographically and depends upon the soils, moisture regime, characteristics of the grassland, and how soon litter accumulates. In the case of small grasslands, the entire area is likely to be unsuitable habitat in the year of the burn (Herkert 2002; Pruitt 1996).

The Henslow's Sparrow avoids recently mowed areas. The frequency of mowing that occurs in privately managed hayfields severely limits or eliminates nesting. In Illinois, mowed areas were not completely avoided but densities in mowed areas were 90% less than those in unmowed areas. At a Kansas site, only areas that were not hayed the previous year were occupied. On reclaimed mines in Indiana, 252 Henslow's Sparrows were detected at point counts and many more were observed away from count areas; 0 occurred in hayed grasslands. It may use fields planted to switchgrass used in the production of biofuels. Due to the typical harvest regimes, these fields are likely to act as ecological traps, with a very small probability of any young being produced. CRP lands in Illinois and other states have been beneficial because these are typically planted to grasses and left idle for a 10-year period. Population gains as a result of CRP lands have not been sufficient to overcome losses. The CRP is a 10-year contract so much of this land may revert to agriculture. For lands remaining in the program, there may be a need to control succession for them to continue to provide habitat. Mowing is the preferred method of eliminating woody vegetation because the litter layer and standing dead vegetation typically recover faster. In Missouri, grasslands managed by mowing had almost 2 times as many Henslow's Sparrows as those managed by fire. In New York, maintenance mowing in mid-August allowed it to raise 2 broods while still leaving enough time for regrowth to provide dead vegetation for the next year. Even delaying mowing until mid-July may enable it to raise a single brood and at some sites this is done every other year. In Minnesota, it was recommended that a few small (0.4 ha or smaller) portions of a site be mowed, with 10% or less of the entire site being mowed. This slowed woody encroachment while maintaining enough area with standing dead vegetation, litter, and singing perches (Bajema et al. 2001; Cully and Michaels 2000; Hands et al. 1989b; Heagy 2011; Herkert 1994b, 1997, 2002; Knapton 1984a; Pruitt 1996; Robertson et al. 2012; Swanson 1996). Wolcott et al. (2023) recommended that grassland management be deferred until August to protect both nests and fledglings.

The Henslow's Sparrow avoids grazed areas unless the intensity of grazing is very low. It is absent in areas subjected to moderate or heavy grazing. The level of grazing pressure required for a reasonable economic return is not compatible with this sparrow. In 1 year of a 4-year study in Michigan, it was much more abundant in fields that were lightly grazed than in ungrazed meadows. Of more than 500 sightings of the Henslow's Sparrow in Indiana reclaimed mines, none occurred in

grazed areas. In addition to modifying the habitat so that vegetation is too short or sparse, cattle may trample or lay on nests. In Kansas, it was absent at a site until grazing had been halted for 2 years. It nested successfully in Missouri and New York in pastures grazed by cattle from mid-May to mid-October. Grass height averaged 30.4 cm or more in Missouri and 61 cm in New York. Light grazing after the nesting season may successfully inhibit succession while maintaining habitat and avoiding nest destruction by cattle (Bajema et al. 2001; Hands et al. 1989b; Herkert 2002; Hyde 1939; Ingold et al. 2009; Peterson 1983; Pruitt 1996; Swanson 1996).

Local populations may fluctuate with spring precipitation rates. In Illinois, population fluctuations were associated with the total amount of precipitation received January through April. Abundance tended to increase in years when the spring precipitation was greater than in the previous year and decline when spring precipitation declined (Herkert et al. 2020b). Zuckerberg et al. (2018) determined that its abundance was positively correlated with the amount of precipitation received in the previous summer and the amount of rain from June to August in the current breeding season. These studies suggest that the Henslow's Sparrow may be vulnerable to climate change.

Human disturbance is potentially a limiting factor. Vehicle traffic during a single night in a field caused boundaries of 2 of 6 territories to shift. Disturbance by birders and photographers has been considered a risk in Massachusetts and Ontario (Pruitt 1996). Hands et al. (1989b) recommended that human access to nesting fields should be prohibited to prevent disturbance.

Herkert (2002) offered management recommendations for the Henslow's Sparrow: provide 30 ha or more of contiguous grassland or a complex of smaller areas close together; create large grassy areas near small prairie fragments; remove woody vegetation within and along edges of grasslands to discourage predators; implement a rotational disturbance regime and never burn, mow, or otherwise disturb an entire site within a single year; conduct management treatments before birds arrive or after the young fledge; provide dense and moderately tall (higher than 30 cm) grassy vegetation; remove woody vegetation when it becomes taller than grass or herbaceous vegetation; use prescribed burns on a rotational basis to remove woody cover, and do this in early spring or late autumn; and create restoration areas that are larger than 50 ha and preferably larger than 100 ha.

Status

The Henslow's Sparrow was first reported in Ontario in 1898 at 3 locations: near Sarnia, at Lake St. Clair, and in Leeds County near Lansdowne where a nest was found. It was not seen in the latter region for another 52 years. It was later found breeding in the tallgrass prairies of Walpole Island. Some authors speculated that it always nested in the province; others assumed that the 1890s records represented the initial colonization. It seems most likely that the Henslow's Sparrow was not historically part of Ontario's avifauna and that it colonized the province as it shifted its range eastward and northward in response to forest clearing. It did not become established until 1881 in Michigan, 1894 in Ohio, 1880 in Minnesota, 1870 in Wisconsin, and 1887 in inland New York. It seems unlikely that it would have been present in Ontario much before its presence was confirmed. By the early 1900s, it was breeding regularly in Essex and Lambton counties and nested at Lake Joseph in Muskoka District in 1902. A large colony occurred at Long Point in 1927, it was fairly common in the London area by 1931 and one of the more common birds in the Rondeau area at this time. The late

1920s and the 1930s appear to have been the peak years for it (Austen and Cadman 1993; Austen et al. 1994, 1995; Heagy 2011; Hyde 1939; Knapton 1984a, 1984b; Weir 2008). Baillie and Harrington (1937) considered the Henslow's Sparrow a local summer resident in extreme southern Ontario, where it bred only south and west of York Region. Sarnia and Bradford appeared to mark its northern limit but it was fairly common in certain locations. The population and its range continued to increase through until the 1960s after which it began to decline. By 1966, its range had expanded northeastward to Ottawa and Morrisburg. It peaked in abundance in Niagara Region 1947-52 but remained uncommon until 1965. It may have nested on Manitoulin Island in 1952 and probably bred in the Vermilion Bay area in Kenora District in 1975 and 1976. The first breeding season record in the Hamilton area was in 1929 and it was encountered in 12 of 20 years 1931-50. During the 1930s and early 1940s, there was a colony in a large abandoned field that was subsequently developed. From the 1930s to 1970s, various small colonies were discovered. These only lasted for a few years before disappearing, only to have another small colony appear elsewhere. The last breeding record there was in 1981. In the mid-1960s, it was common in old fields and hayfields in Durham Region, but these sites are no longer extant. Results at Hamilton are typical of the entire province. Numbers probably peaked in the 1950s and 1960s and were followed by a precipitous decline in the 1970s and 1980s. The range contracted from the southwestern agricultural landscape, more northern areas, and the eastern part of the former breeding range. Large colonies were presented at Tiny Marsh with as many as 43 seen in 1978; this colony was last occupied in 1980. Colonies at Barrie, Holland Marsh, Luther Marsh, and in Chatham-Kent, Lambton, Middlesex, Haldimand, and Norfolk counties were abandoned. In Elgin County, isolated colonies numbering as high as 12 birds were reported annually in the 1930s and 1950s but there have been no breeding records there for over 3 decades (Austen and Cadman 1993; Austen et al. 1994; Brewer 1977; Curry 2006; Devitt 1967; Heagy 2011; Knapton 1984a, 1984b; Lancaster et al. 2004; Speirs and Orenstein 1967). During the first atlas, the Henslow's Sparrow was documented in only 38 squares, not all of which were occupied in each year of the atlas. Only 1 colony larger than 10 pairs was found. It was considered unlikely that the provincial population exceeded 50 pairs. Most records were concentrated in the Kingston area and, to a lesser extent, in Wellington and Dufferin counties in the general vicinity of Luther Marsh (Knapton in Cadman et al. 1987). In 1983, the known population was 25-29 individuals at 13 sites; in 1982, only 6 individuals were detected and 17 were found at 7 sites in 1981 (Austen 1994; Austen and Cadman 1993; Austen et al. 1994, 1995; Knapton 1984a). James (1991) considered the Henslow's Sparrow a rare to locally uncommon summer resident in the south north to Bruce County and Kingston.

Numbers continued to decline after the first atlas. A concerted effort to find the Henslow's Sparrow in 1992 and 1993 found only a single singing male each year, both at the same location. In 1988-90, searches for it were made in Grey, Wellington, and Dufferin counties and totals of 2, 1, and 0 were detected in those 3 years. In 1989, a site with 10 territories was located in Haldimand-Norfolk, but it was abandoned during the breeding season. By the early 1990s, it was concluded that the province supported fewer than 10 pairs. Nonetheless, several singing males were found in 1999 and 2000 at a site in Prince Edward County that was managed for Henslow's Sparrows in 1998. At least 7 singing males were found in Halton Region in 2000 (Austen 1994; Austen et al. 1994, 1995; Knapton 1993; Pearce et al. 2010). The second atlas demonstrated an 86% decline in its probability of

observation since the first atlas. It was documented in only 9 squares in the province and probable breeding evidence was attained in only 3 squares. These included 2 birds in Chatham-Kent, a singing male that remained at least a week in Grey County, and as many as 4 birds in Halton Region in 2001. It was absent in the Kingston and Luther Marsh areas. Three of the 4 records from the Carolinian Forest Region were in native tallgrass prairie remnants or restorations. It was concluded that breeding pairs, if present at all, are likely to be very few in any given year. The species is difficult to detect and its habitat is often not checked by birders, so it is easily overlooked (Tuininga in Cadman et al. 2007). From 2000-09, the Henslow's Sparrow was reported from only 16 sites, including those documented in the atlas. Most records were of single males singing on a single day with no subsequent occurrence in either the same or following years. The most recent record of a pair is the 2005 Chatham-Kent observation reported in the atlas. The population in recent years has barely been above 0 and there is no evidence that any young have been produced in several decades. The Natural Heritage Information Centre in Ontario has 73 element occurrences. Sixteen are considered extirpated and 51 are historical. Only 6 were documented in the past 20 years and none are ranked as high-quality occurrences (COSSARO 2011).

Prior to European settlement, the Henslow's Sparrow was probably restricted to the prairies and the Atlantic coast. It nested in native tallgrass and mixed-grass prairies in the west and low wet meadows with tall grasses. Along the Atlantic coast, it probably nested on the drier edges of salt marshes, habitat it continues to occupy. Within the eastern forest, it probably nested in prairies, savannahs, and openings created by forest fires and First Nations. It nests in cranberry bogs in New Jersey and Michigan and these habitats would have been available historically. With the arrival of Europeans, its habitat was altered drastically. Massive amounts of habitat were lost in the west as prairies were converted to agricultural land. This was partially compensated for by deforestation in the east which allowed it to colonize exotic grasslands, pastures, and old fields north and east of its original range. It began to nest in a variety of anthropogenic habitats, including CRP lands, hayfields, abandoned fields, meadow marshes, reclaimed mine surfaces, capped landfills, sphagnum bogs mined for peat, lightly grazed pastures, military training areas, and very young conifer plantations. In North Carolina, it nested in pocosins that had been clear-cut and planted with pines 0.6-2.4 m tall. Pocosins are wetlands on poorly drained fine sandy or sandy loam soils that have a seasonally high water table at or near the surface. The pattern throughout the east was similar to what occurred in Ontario: colonization in the 1880s to 1900s, growth in populations until the mid-19th century, followed by a significant decline due predominantly to habitat loss. BBS data indicates that it declined at an annual rate of 8.7% continentally 1966-2004. Its decline is the steepest of any North American grassland songbird. It is now extirpated as a breeding species in North Dakota, Texas, Quebec, most of New Jersey and Delaware, most of Virginia, and part of West Virginia. Prior to 1900, it was abundant in Illinois and among the most numerous prairie species in some areas of the state. Populations declined by as much as 94% between 1958 and 1979. This was attributed to a 65-75% decrease in grassland habitat and a 75% decline in its density in the remaining grassland. The CRP has partially slowed the decline in some areas but has not fully compensated for losses elsewhere. Many of these lands will probably be converted back to agricultural uses once the 10-year contracts expire. In Ohio, Pennsylvania, and some other states, reclaimed surface mines are providing large tracts of habitat for the Henslow's Sparrow. Unless active management is undertaken, these areas

remain suitable for only a few years due to natural succession (Askins et al. 2007; Graber in Austin 1968; Herkert 1994a, 1994b; Herkert et al. 2020b; Hyde 1939; McCracken 2005; Melde and Koford 1996; Lynch and LeGrand 1985; Pearce et al. 2010; Pruitt 1996; Swanson 1996; Wells 2007).

The Henslow's Sparrow was designated threatened nationally in 1984 and its status was upgraded to endangered in 1993. In Ontario, it was designated threatened in 1986 and endangered in 1994 (Austen 1994; Austen and Cadman 1993; Austen et al. 1995).

Four recovery strategies have been prepared for the Henslow's Sparrow, with the objectives becoming more pessimistic with time. In 1995, the recovery objectives were to prevent a further decline and establish a stable or increasing breeding population of 500 adults distributed across Ontario in 50 colonies with a minimum of 10 birds in a colony (Austen et al. 1995). In 2006, the short-term objective for the next 5 years was to create large patches of suitable secure grassland habitat at 3 locations in Ontario. The long-term objective was to increase the population to a stable annual minimum population of 50 breeding pairs among at least 3 geographically distinct nesting areas over the next 20 years (Pearce et al. 2006). In 2010, the objective over the next 5 years was to establish and secure at least 1 large patch (larger than 50 ha) of suitable grassland habitat and achieve at least 1 stable population of 5-10 pairs (Pearce et al. 2010). In 2015, no objectives for recovery were stated but suggestions for habitat regulations under Ontario's *Endangered Species Act* were recommended in the event that the species was found breeding (Kraus 2015).

POSTFLEDGING PERIOD

In Missouri during the dependent stage, all fledglings remained within 100 m of the nest for the first 2 weeks after fledging. Average movement between daily locations was 36 m. At the onset of the independent period (16-23 days postfledging, median 19 days), fledglings moved an average of 236 m from the nest with an average of 90 m between daily locations. Fledglings used an area of 1.5 ha, considerably larger than the 0.29-ha territory. Areas used during the dependent period had a lower percent cover of woody vegetation than random sites. During the independent period, fledglings used areas with shorter grass and lower percent cover of woody vegetation than occurred in random sites. Areas used during the independent period had a higher percent cover of forbs and lower percent cover of litter than areas used during the dependent period. Habitat characteristics at the territory scale (100-m radius) influenced fledgling survival. Survival decreased as shrub cover increased and as the season progressed. Survival was higher 2 and 3 years after burning than 1 year after burning (Young et al. 2019).

It appears as though adults remain in the breeding area until autumn migration. In August in Michigan, juveniles made minor movements into adjacent habitat. Some were observed in weedy vegetation along a railway right-of-way that ran between 2 breeding areas, but the adults remained in the breeding habitat (Hyde 1939).

MIGRATION

The Henslow's Sparrow is believed to migrate singly or in small groups at night over a period of 1-2 weeks (Pearce et al. 2010). Rivers may function as major migration corridors and Lake Ontario may act as a barrier to migration (Hyde 1939).

Males tend to arrive in spring earlier than females, but the interval between the sexes' arrival has not been determined in Ontario (Knapton 1984a). Spring migrants arrive in southwestern Ontario from mid-April to mid-May and arrive in the breeding areas in late April and early May (Austen et al. 1995; Black and Roy 2010; Curry 2006; Devitt 1967; Heagy 2011; LaForest 1993; Lancaster et al. 2004; Weir 2008).

The Henslow's Sparrow leaves Ontario during September or early October and probably winters along the Gulf Coast of the United States. Birds may remain on the breeding grounds until autumn departure, but autumn migrants have been seen in late July. It has been seen as late as mid-October. One seen at Luther Marsh on 8 October was in a field where breeding did not occur (personal observation), but 1 at Millgrove on 7 October appeared to be still on territory (Austen et al. 1995; Curry 2006; Devitt 1967; Heagy 2011; Hyde 1939; LaForest 1993; Weir 2008).

During migration, the Henslow's Sparrow occurs mostly in grasslands and wet meadows but may also occur in hedgerows, in small copses of trees, and forest edges. In Iowa, the first spring arrivals were in shrubs at edges of wooded areas, later moving out into prairie. A group of 3 that appeared to have just arrived in Michigan were seen around a small puddle in a heavily grazed field that offered no cover (Herkert et al. 2020b; Hyde 1939; Pearce et al. 2010). An autumn migrant at Luther Marsh was observed in a moist field dominated by reed canary grass and several at Conestogo Lake were in a 160-ha field dominated by timothy, quack grass, and orchard grass (personal observation).

Suitable habitat for migrants has decreased significantly but it is unknown if this is causing adverse effects. The Henslow's Sparrow occasionally strikes buildings, communication and television towers, and other tall structures during migration, particularly in autumn. It may also be vulnerable to adverse weather during migration. Thirty-two were killed in an April storm in Indiana in 1960 (Herkert et al. 2020b; Pruitt 1996).

James (1991) considered the Henslow's Sparrow a rare migrant and this is confirmed in all books on regional populations. At least 20 were seen at Conestogo Lake on 27 September 1973. It bred there that year so it is uncertain if these were migrants or had nested or been raised on site (personal observation). There are fewer autumn than spring records because it tends to be silent at this time. It is still found during migration almost every year, but numbers are declining. Numbers reported in the entire province during migration from 1986 to 1993 were 17, 17, 18, 0, 3, 5, 7, and 8 (Austen 1994; COSSARO 2011).

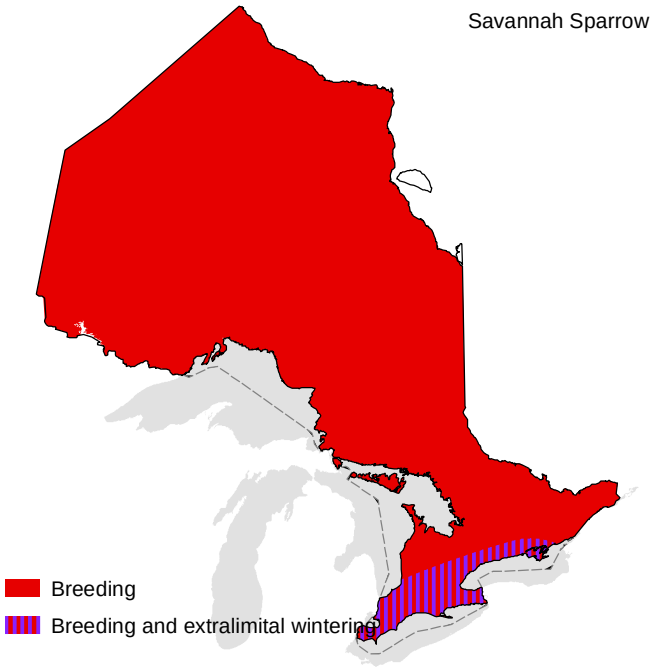
Savannah Sparrow

Passerculus sandwichensis

BREEDING SEASON

Habitat Requirements

In southern Ontario, the Savannah Sparrow nested in grassy fields, hay and clover fields, and occasionally grain fields (50.4% of southern nests); in open and overgrown pastures (34.5%); in other grassy areas such as playing fields, campgrounds, airfields, lawns, young conifer plantations, and orchards (4.3%); on grassy dunes, river banks, floodplains, and shorelines (3.6%); on roadsides, embankments, and in fencerows (3.2%); on mine tailings and in lumberyards (2.9%); on blueberry barrens (0.4%); in heath bogs (0.4%); and on a rocky island near a tern colony (0.4%). In northern Ontario, nesting occurred in sedge and grass marshes (44.6% of nests), on sedge-lichen tundra (25.0%), in bogs and fens (23.2%), and in salt marshes (7.1%). It nested in both wet and dry habitats that were open with sufficient growths of grasses, sedges, or forbs to provide nest sites and concealment (Peck and James 1987).



In the Hudson Bay Lowland, the Savannah Sparrow is most abundant along the James and Hudson bay coasts from the Moosonee area to York Factory. Highest numbers occurred in dwarf willow and birch at edges of barrens. It also occurred in the long grass of coastal barrens, occasionally in open grass or scrub areas behind the first rows of spruce, and among willows and alders at the Attawapiskat River. It was scarce or absent in deep alder thickets. Occasionally it occurred in isolated patches of spruce, but never within the main spruce forest. It was especially common at a marsh at Beacon Point in mid-July and appeared to nest in Moosonee (Manning 1952). On the Twin Islands in James Bay, it nested in dense dwarf birch and avoided the shoreline (Manning 1981). Wilson and McRae (1993) concluded that it was the most abundant nesting passerine at all the coastal stations they examined. At Moosonee, it was most abundant in extensive grassy areas such as the airport, but a few nested in a tamarack fen. There are extensive areas of bogs and fens in the southern portion of the Hudson Bay Lowland that may also support populations of the Savannah Sparrow.

Erskine (1977) considered the Savannah Sparrow characteristic of open bogs and fens with low (10-20 cm) ericaceous shrubs, sedges, and a few herbaceous species in the Boreal Forest Region. It also inhabits wetter sedge meadow bogs. It may nest in unvegetated areas in addition to natural grasslands, sand barrens, and abandoned farmland. Nesting may occur in burns or clear-cuts, but only if a ground cover of grass is present. Because it avoids forested habitat, it is associated with the tundra-forest and alpine-forest ecotones. In the Clay Belt, it was the most common sparrow around farms, lakesides, and river banks. It also nested in bogs and fens and clearings about buildings (Smith 1957). In the Clay Belt, it nested in a wet nutrient-poor stand dominated by Labrador tea, leatherleaf, and sphagnum moss (Welsh and Lougheed 1996). Near Hearst, it nested in a 3-year-old clear-cut in lowland coniferous forest (Welsh and Fillman 1980). Near Pickle Lake, it occurred regularly in large open bogs (James 1980). Between Pickle Lake and Little Sachigo Lake, highest densities were in tundra followed by heath, mixed scrub, and coniferous scrub. It was absent in deciduous scrub and all forested habitats (McLaren and McLaren 1981). Along the northeastern shore of Lake Superior, it was common in clearings around settlements and occurred in an open graminoid bog (Baillie and Hope 1943).

In Parry Sound and Muskoka Districts, the Savannah Sparrow was common where there were extensive fields and meadows (Mills 1981). In Algonquin Park, it avoided forested habitat and was restricted to grassy openings near settlements and areas cleared for log landings (MacLulich 1938). Tozer (2012) reported that most of the population in the park now breeds in sedge meadows within

large bogs and marshes. Lesser numbers breed in remnant openings such as large human-made clearings and old fields such as an old airport, former sawmill site, and farms. Small numbers probably nested in natural meadows and dry grass or sedge marshes before logging started in the 1830s. Logging resulted in marshes created by dams, large clearings, burned areas, and farm fields that provided additional habitat.

South of the Shield, the Savannah Sparrow is abundant in agricultural landscapes. Curry (2006) stated that it was found in every field in the countryside, whether cultivated or pasture. Speirs and Orenstein (1967, 1975) reported it nesting in old fields, hayfields, a very young red pine plantation where most of the trees were shorter than 0.9 m and overtopped by old-field herbaceous vegetation, and in an old-field community with scattered apple trees and hawthorns. It is abundant in hayfields, meadows, and pastures with sparse or no weedy vegetation. It occasionally nests in agricultural fields planted to row crops, but at much lower densities. At Luther Marsh, it nests within extensive bog and fen habitats (Sandilands 1984).

The Savannah Sparrow nests in a variety of open habitats throughout its range. From the Boreal Forest Region southward, it nests in habitats dominated by grasses or occasionally sedges, often with varying amounts of herbaceous species. It avoids areas with dense woody vegetation, but scattered shrubs or saplings may be included in the territory to provide singing perches. The most typical habitats consist of native grasslands, hayfields, pastures that are not excessively grazed, and old fields. Large bogs and fens may provide suitable habitat and it may inhabit cordgrass marshes on coastlines. Above the treeline, alpine meadows and tundra provide suitable high-elevation habitat. Dwarf willow and birch communities are optimal habitat in tundra regions.

In Newfoundland, the Savannah Sparrow is abundant in meadows and also occurs near tops of hills and mountains. In central Labrador, it nests in sedge bogs (Baird in Austin 1968). It is a common breeder on sand dunes on the Atlantic coast of Canada and the northeastern United States. On the mainland of Nova Scotia, it nested on beaches and dunes stabilized by dense growths of beach grass and seaside pea, with clumps of myrtle, crowberry, and American cranberry and scattered small spruce that it used as singing perches (Welsh 1975). The Ipswich Sparrow, a subspecies of the Savannah Sparrow, nests on sand dunes on Sable Island in Nova Scotia. The entire island is devoid of trees (Ross 1980). In New Brunswick on Kent Island, it nests in a grassy 10.7-ha field dominated by creeping bentgrass and red fescue (Williams 1987), with timothy, bluegrasses, reed canary grass, and some alfalfa (Nocera et al. 2007b). In Quebec, it is particularly abundant in the south in hayfields, pastures, and meadows, and in the upper drier portions of marshes, particularly those dominated by cordgrass. Its distribution in the south corresponds with open habitat found mainly in agricultural areas, near rivers and streams, and along the coast in meadows and grassy dunes. It may also frequent roadsides and transmission-line corridors. In the north, it inhabits peatlands, sedge meadows, and shrubby areas (Bonneau in Gauthier and Aubry 1996). Baird (in Austin 1968) reported that it nested on Anticosti Island in bogs, along the coast, and in drier areas surrounding muskeg. In Carleton, Quebec, 1 pair nested in a small (0.68 ha) park in the centre of the town in an area of mowed grass. Northeast of Quebec City along the St. Lawrence River, it nested in ecotones between abandoned fields and highly productive tidal marshes. The saltwater marshes were dominated by cordgrass that was regularly flooded by tides and the upland habitat consisted of old-field meadow

dominated by nonnative species such as creeping bentgrass, red fescue, timothy, and Canadian burnet. The meadows were used for nesting and the marshes provided productive foraging habitat at low tide. Habitat was patchy so most territories contained 2 or more habitats (Bédard and LaPointe 1984a; LaPointe and Bédard 1986). In California, the Savannah Sparrow nests in meadows adjacent to saltwater cordgrass marshes (Fernández-Juricic et al. 2009; Powell and Collier 1998). At Le Pérouse Bay in Manitoba, it was common in areas dominated by short-fruit willow mostly less than 0.5 m tall with a maximum height of 1 m, and a mix of hoary willow and tea-leaved willow taller than 3 m (Weatherhead 1979). Near Churchill, it is abundant in large sedge meadows near the treeline and in wet tundra (Jehl 2004; Jehl and Smith 1970). Near Winnipeg, it nested along grassy hydro transmission corridors that were a minimum of 30 m wide and at least 500 m long. It also nested in grassy rights-of-way along a provincial highway (Leston and Koper 2017). Although it occasionally nests in bogs and fens (Kirk et al. 1996), it is almost exclusively a grassland species in the Prairie Provinces and the Great Plains. It nests in native grasslands, including tallgrass prairies, mixed-grass prairies, and, in the southwest, desert grasslands. Native vegetation tends to be dominated by grama grass, wiregrass, bluestem, thickspike and western wheat grass, June grass, native forbs, and clubmosses. It is abundant in planted grasslands including grazed, ungrazed, mowed, and unmowed sites. It readily inhabits areas planted for waterfowl production, termed Dense Nesting Cover (DNC) in Canada and Conservation Reserve Program (CRP) lands in the United States. Common species in planted grasslands include crested wheat grass, wild rye, alfalfa, smooth brome, Kentucky bluegrass, timothy, and yellow sweet clover. Occasionally, it nests in row-crop fields and it may be common along roads, in or beside prairie sloughs, and in lakeside marshes (Askins et al. 2007; Davis 2004, 2005; Davis et al. 2006; Hartley 1994; Ludlow et al. 2015; Patterson and Best 1996; Sutter and Brigham 1998; Swanson 2002; Taber in Austin 1968; Wheelwright and Rising 2020; Wilson and Belcher 1989; Winter et al. 2004). It occurs throughout British Columbia, but avoids forested areas. Breeding is most concentrated where grasslands, shrublands, weedy fields, alpine meadows, and subalpine tundra are widely distributed. It nests in meadows, edges of cultivated crops and swamps, moderately grazed meadows, hay and alfalfa fields, grassy and herbaceous edges of small lakes and ponds, upland edges of riparian willow thickets, and recent clear-cuts and burns. At the northern extent of the province, it nests in areas dominated by dwarf willows and birches and in grassy flats of low subalpine vegetation (Campbell et al. 2001). It was common in northern British Columbia in alpine tundra and subalpine meadows (Martin et al. 2009). It nests in similar habitat in Wyoming, Colorado, and elsewhere. These areas may either be dominated by low shrubs or spring wildflowers (Hendricks and Pidgeon 1990; Jones and Bock 2002; Rotenberry and Wiens 1980). In the Yukon, the Savannah Sparrow is the third-most abundant species in tundra habitat where it is most common in moist to wet sedge tundra. It is also common in grassy and low shrub habitats and occurs at numerous airstrips (Sinclair et al. 2003). Similar habitats are used in Alaska and in 1 location it nested in a grassy cemetery (Taber in Austin 1968). It frequently nests in reclaimed surface mines in West Virginia and Ohio, and probably in other areas. Most of these are dominated by nonnative grasses and forbs with varying degrees of invasion by woody plants (Graves et al. 2010; Wray et al. 1982). In Wisconsin, it was rare in pine and oak barrens and occurred only in diverse barrens (Mossman et al. 1991). In Maine, it nested in areas that were or had previously been managed for commercial blueberry production. The vegetation consisted mainly of lowbush blueberry with lesser amounts of Indian grass, poverty oat grass, sedges, chokeberry, alder, and birch (Vickery et al.

1994). In Michigan, it inhabits open grasslands, bogs, and coastal marshes and occurs wherever farming has produced pastures and fallow fields (Potter 1972). In Illinois, it inhabits all types of grasslands including marshes, hay crops, and oat and soybean fields. Populations were highest in pastures and ungrazed grasslands. Alfalfa and sweet clover were poor nesting habitat (Graber and Graber 1963).

Some studies examined whether the Savannah Sparrow initially selects habitat at the landscape level before selecting a suitable nesting patch. In the Prairie Hardwood Transition Bird Conservation Region, its abundance was positively correlated with the amount of grassland in the landscape at the 800-ha scale (Murray et al. 2008). In the Prairie Provinces, it was associated with cropland, pastures, and the number of wetland basins at the 400-m scale and wetland area at the 1,600-m scale. It was negatively correlated with the amount of trees and shrubs within 400 m (Fedy et al. 2018). In Vermont and New York, its abundance was positively correlated with the proportion of open land within 500 m and 2,500 m. At initial settlement early in the year, it showed patterns of habitat use that were strongly influenced by features outside the immediate patch and was most strongly influenced by features within 250 m. It showed an affinity for hayfields that had been recently cut. Characteristics of the field were more important after cut fields had been selected. It was attracted mostly to larger fields with less wooded edges, and landscape habitat was relatively unimportant in site selection. Shustack et al. (2010) concluded that it was a generalist species that will use hayfields with grass that is only a few centimetres tall and that have a high proportion of bare ground. Habitat use patterns changed over time due to changes in habitat. In Michigan, patch variables had more influence on the Savannah Sparrow's abundance than landscape variables (Crozier and Niemi 2003). In South Dakota, its percent occurrence and density were positively correlated with the amount of grassland within 3,200 m. The probability of occurrence was 20% when the surrounding landscape contained less than 5% grassland and 40% when grassland occupied 80% of the landscape. It was selecting for large expanses of habitat rather than large patches (Greer et al. 2016). In Minnesota, local habitat variables were more important than landscape variables in habitat selection. It was positively associated with the amount of grass cover within 100 m, but negatively associated with the amount of grass cover within 500 m. Grassland area at large spatial scales was positively correlated with woody vegetation. Tree avoidance is a potentially more important driver of habitat selection than extent of grassland (Thompson et al. 2014). In Wisconsin, densities were higher in landscapes with smaller patches of residential areas and lower cover-type density within 800 m. With 2 exceptions, lower crop-type diversity was due to the dominance of hay and grassland. In 1 exception, the landscape was more than half row crops but still had a significant proportion of hay and grassland. The other exception was a dry prairie in a landscape dominated by woods, but with grassland as the other major component. The less diverse the habitat, the higher the Savannah Sparrow density was (Ribic and Sample 2001). In Illinois, its occurrence was negatively correlated with habitat heterogeneity (Herkert 1994a). Renfrew and Ribic (2008) found that its abundance was positively correlated with the amount of grass cover within 1,200 m and negatively correlated with wooded cover. In Alberta, there were no differences in its abundance in landscapes dominated by native grasslands and those dominated by cultivated areas. In cultivated areas, roadside ditches were overgrown with tall grasses and shrubs and provided suitable habitat. It was absent from large areas of cultivated land where there was no rank edge vegetation. Edge

vegetation is often lacking in native grasslands (Owens and Myers 1973). It preferred landscapes with 0-4% forest cover in North Dakota (Cunningham and Johnson 2019). At Breeding Bird Survey (BBS) stops in the Great Plains, it was associated with pastures and hay, tallgrass prairies, and CRP grasslands. It selected for mesic sites, exotic grasses, and tall dense cover (Niemuth et al. 2017).

Presence of woody vegetation often decreases habitat quality for the Savannah Sparrow. Thompson et al. (2014) determined that it avoided treed habitat at the landscape level, and its density was negatively correlated with all woody vegetation covariates. Even larger grassland patches may not be occupied if they contain trees or are close to wooded areas. They predicted that if 4.3 shrubs, 4.7 trees, and 0.06 ha of woodlot were removed from a 100-m radius, it would increase by 32%. In North Dakota, Arnold and Higgins (1986) surveyed shrub plots with 30-80% coverage by wolfberry and silverberry and shrubless plots with 10% or less shrub coverage. The Savannah Sparrow was absent on shrub plots and present at low density on shrubless plots; the differences were not significant. Also in North Dakota, it reached its maximum probability of occurrence in open treeless grasslands. Its probability of occurrence declined to 50% when 10% of the area within 500 m was treed with aspens. Where it was present, there were no shrubs taller than 1 m or aspens within 100 m, significantly different from where it was absent. It was classed as a woodland-sensitive species, decreasing with increasing tree coverage (Grant et al. 2004). In Minnesota and North Dakota, its abundance decreased as the amount of tree and shrub coverage within 200 m increased (Winter et al. 2006). In Saskatchewan, nests were negatively correlated with distance to the nearest shrub. Its presence was negatively correlated with the amount of woody vegetation within 2.8 km^2 (Davis 2005; Swanson 2002). In Maine, its abundance was negatively correlated with blueberries and tall shrubs. It preferred sites with higher graminoid cover (Vickery et al. 1994). It was negatively correlated with shrub cover in Wisconsin (Swanson 2002). In Ohio, its abundance was negatively correlated with the amount of woody vegetation within 100 m, but it did not show strong evidence of selecting nest patches with lower amounts of woody vegetation than random sites (Graves et al. 2010). In Washington, the Savannah Sparrow was most abundant in new CRP lands, about half as common in old CRP lands, and least abundant in shrubsteppe habitats. New CRP lands were vegetated predominantly with grasses and forbs; old CRP lands and shrubsteppe areas supported a shrub layer. Its abundance was negatively correlated with shrubs, but nest survival was positively correlated with shrub cover and height of herbaceous vegetation at the nest site (Vander Haegen et al. 2015). In North Dakota, the frequency of occurrence of shrubs shorter than 1.5 m within 5 m of the nest was 19.0% and the mean distance from the nest to the nearest patch of woody vegetation taller than 1.5 m was 207.5 m. Nest survival did not appear to be affected by the presence of shrubs (Murphy et al. 2017).

Some studies compared Savannah Sparrow usage of native and planted grasslands. In Saskatchewan, nonnative vegetation consisted of pure stands of crested wheat grass or crested wheat grass mixed with wild rye and alfalfa. Introduced vegetation had significantly lower plant species richness and diversity and higher evenness than prairie vegetation. Native vegetation had higher grass and sedge coverage, less bare ground, deeper litter, and more contacts with vegetation below 10 cm than introduced vegetation. Although its abundance was 2.6 times greater in native vegetation, differences were not significant. In introduced vegetation, it was positively correlated with grass and sedge coverage, maximum height of vegetation, and litter depth. In native

vegetation, it was positively correlated with litter coverage and depth, number of contacts above and below 10 cm, and grass and sedge coverage. It was negatively correlated with bare ground and forb density. It preferred dense vegetation (Sutter and Brigham 1998). In Saskatchewan, a mean of 1.82 were detected on native grassland plots and the probability of occurrence was 100%. On DNC fields, 1.14 were detected per plot with 93.7% occurrence and 0.21 were detected in plots in wheat fields with 57.9% occurrence (Hartley 1994). Another Saskatchewan study determined that its abundance increased with the amount of native grassland within 400 m, and declined with the amount of cropland (Davis et al. 2016). In Manitoba, the mean number detected along transects was 1.5 times greater in native prairie than in introduced vegetation (Wilson and Belcher 1989). In Alberta, density decreased with increasing coverage of the nonnative crested wheat grass. Density was nearly 2 times lower in areas with 60% coverage by crested wheat grass compared with areas without it, but nests in this grass had higher fledging success. Results suggested a density-dependent relationship whereby a lower density in a patch of crested wheat grass may provide increased opportunities to acquire food resources (Ludlow et al. 2015). In Wisconsin, densities in dry pastures and alfalfa fields were significantly greater than in fields with nonnative grasses and dry prairies. Pastures and alfalfa fields supported medium-height or short vegetation that is typically occupied by the Savannah Sparrow (Ribic and Sample 2001).

Numerous studies correlated vegetation parameters with Savannah Sparrow presence or abundance, and some linked nest success with vegetation characteristics. Almost all studies concluded that it is positively correlated with litter coverage and depth. In Nova Scotia, its abundance was strongly negatively associated with vegetation height and density and this was the strongest predictor of occupancy. The same relationship occurred in an Iowa prairie, but there was a positive relationship with vegetation height and density in Wisconsin. The positive relationship in Wisconsin may have been because the pastures were so open that birds used the tallest of what was otherwise very short grass or nested in isolated clumps of tall grass. In another Wisconsin study, there was a negative correlation between its abundance and forb cover (Nocera et al. 2007b; Swanson 1996). In Tennessee, portions of fields were dominated by forbs. It nested only in grassy areas with no forbs (Knight 1989). A negative correlation with forbs also occurred in Ohio (Swanson 2002). In contrast, it is highly correlated with forb density in montane meadows (Rotenberry and Wiens 1980). At 1 Saskatchewan site, nests were positively correlated with the density of dead vegetation less than 30 cm tall, and with cow dung. Areas with cow dung may be selected because of the dense vegetation patches associated with them. The Savannah Sparrow was associated with tall dense vegetation and a moderate density of forbs 10-20 cm tall. It was negatively correlated with bare ground (Davis 2005). Other studies have documented the same relationship (Vickery et al. 1994). Wheelwright and Rising (2020) concluded that it preferred dense ground vegetation, especially grasses, and moist microhabitats. In North Dakota, its abundance was correlated with grass cover (Swanson 1996) and this relationship was also observed in Saskatchewan at 1 site but the relationship was negative at an arid site in that province (Swanson 2002). In grazed mixed-grass prairie in South Dakota, it was positively correlated with percent grass cover, litter depth, visual obstruction, density of low-growing shrubs (silverberry and snowberry), vegetation density, and plant communities dominated by Kentucky bluegrass and native grasses. It was negatively correlated with percent coverage by clubmosses. The strongest predictors were decreasing

clubmoss, increasing grass cover, increasing litter depth, and decreasing visual obstruction (Swanson 2002). In North Dakota where it was absent, there was significantly more litter, Kentucky bluegrass, and brome grass than where it was present. At occupied sites, there was significantly less live vegetation, shrubs taller than 1 m, aspen within 100 and 500 m, native herbaceous vegetation, and legumes than at unoccupied sites. Its occurrence was greatest in areas dominated by Kentucky bluegrass intermingled with native grasses and forbs (Grant et al. 2004).

Although the Savannah Sparrow occasionally sings from the ground, it typically uses a perch. In the east and Midwest, sturdy emergent forbs and fence posts are most frequently used as perches. Fields where there are shrubs or small trees are not inhabited. Further west, where forb growth is not as luxuriant and fence lines are widely spaced, it may use small deciduous shrubs. In Wisconsin, 43% of territories contained posts, 38% contained a fence line, 15% contained a wire bale, and 8% contained trees (Swanson 2002; Wiens 1969). In Ontario, forbs and shrubs in fencerows may be used as perches and these may also demarcate territory boundaries (personal observation). Harrison (1977) provided artificial perches 1.5 m and 2.0 m tall in Michigan and they were used equally by the Savannah Sparrow.

Several studies compared habitat at nest sites to the remainder of the territory, or of territories to unoccupied sites. In Saskatchewan, the Savannah Sparrow nested in taller vegetation than occurred at random sites. Mean values at nest sites were 25 cm vegetation height, 11 mm litter depth, and 3.5% bare ground, significantly less than the 12% found at random sites (Davis 2005). In North Dakota, there was 5.9% bare ground at nests compared with 1.7% in general habitat. It selected nest sites with less grass cover (9.5% compared with 35.1%), less coverage by forbs (1.1% compared with 20.2%), and more litter cover (79.5% compared with 41.5%) than random sites (Winter et al. 2004). In Montana, Dieni and Jones (2003) compared nest sites with random sites. Parameters for which there were significant differences included 0.6% bare ground (significantly less than random), 1.0% cactus cover (significantly less), 4.6% clubmoss coverage (significantly less), 65.5% grass cover (significantly more), 13.4% litter cover (significantly more), 0.1% rock coverage (significantly less), 21.2 cm litter depth (significantly more), 17 cm visual obstruction (significantly more), 34.3 cm plant height (significantly taller), and 5.4 vertical density (significantly higher). Nest patches had a well-developed litter layer and little bare ground, and clubmoss was avoided. It selected several nesting habitat characteristics but showed great plasticity in their use. It tended to select western wheat grass as a nesting substrate and its presence may be an important factor in nest-site selection. In Quebec, there was no difference in vegetation height at nests and random sites but successful nests were surrounded by a significantly higher proportion of tall vegetation than unsuccessful nests (Bédard and LaPointe 1984). In Wisconsin, forb height and density were significantly greater in territories than in unoccupied areas. In occupied areas, vegetation near the ground was significantly denser, mean effective height was significantly less, more light penetrated to the ground, there was less coverage by lawn-like habitat, and litter was significantly deeper but the cover and composition of litter was similar. Parameters for territories and unoccupied areas, respectively, included 65% and 66% grass cover, 45% and 40% very narrow-leaved grass cover, 30% and 29% narrow-leaved grass cover, 1% and 2% forb coverage, 35% and 36% bare ground, 3.1 cm and 2.2 cm litter depth, 0-13 cm and 0-20 cm range of litter depth, and 81% and 67% cover. These parameters were measured in mid-June. In April, coverage by grass was much lower, vegetation

density was lower, and nearly all vegetation was less than 5 cm tall. Vegetation density and mean effective height were significantly greater near nests than in the entire area that was inhabited. Forb density in areas selected for nesting was much less than in territories, but mean forb height was significantly higher. Litter at nest sites was significantly deeper than in the entire territory and was deeper yet at nests. Light intensity in nest cups was low with 11.1% open-sky intensity (Wiens 1969).

Additional studies identified other microhabitat features of the Savannah Sparrow. In Saskatchewan, it occurred in wetlands and wetland margins within farmland of all types and within DNC. Presence within wetlands was positively correlated with the amount of water within wetlands but negatively correlated with water depth in late July, the percent coverage by woody vegetation around the wetland, and diversity of habitat around the wetland (Swanson 2002). In another Saskatchewan study, its abundance was associated with taller vegetation and reduced cover by cow dung (Davis et al. 2016). In Massachusetts, it was associated with grass 10-50 cm tall and negatively associated with litter and shrubs 2-5 m tall (Zuckerberg and Vickery 2006). In Wisconsin, mean habitat characteristics included less than 1% woody cover, 75% herbaceous cover, and 54 cm maximum vegetation height. It avoided habitats with the tallest, densest vegetation and nested predominantly in managed or disturbed areas with shorter sparser vegetation. Territories in West Virginia were characterized by 7% grass cover, 11% forb cover, 58% litter cover, 24% bare ground, 1 cm litter depth, and 66 cm vegetation height (Swanson 1996).

The Savannah Sparrow may nest in association with the Upland Sandpiper, Clay-colored Sparrow, Vesper Sparrow, Grasshopper Sparrow, Henslow's Sparrow, Dickcissel, Bobolink, and Eastern and Western meadowlarks. The 2 most common associates in Ontario are the Bobolink and Eastern Meadowlark, and the Vesper Sparrow is also a fairly common associate. The other grassland species are less common in Ontario, but the Savannah Sparrow typically breeds wherever they are present. A possible exception is the Clay-colored Sparrow, which may inhabit areas that are too shrubby to be suitable for the Savannah Sparrow. In Nova Scotia, the strongest predictor of Savannah Sparrow occupancy was its negative relationship with vegetation height, vegetation density, and forb cover. The patterns of vegetation height and density that were beneficial to the Savannah Sparrow were detrimental to the Nelson's Sparrow and Bobolink, with these species positively associated with vegetation height and density (Nocera et al. 2007b). In North Dakota tallgrass prairie, Savannah Sparrow and Bobolink nest sites were similar but differed greatly from those of the Clay-colored Sparrow. The Savannah Sparrow and Bobolink placed their nests most frequently within thick clumps of litter and less frequently in shrubs; most Clay-colored Sparrow nests were elevated in shrubs. Savannah Sparrow nests had a higher percentage of cover, shorter vegetation, and slightly more bare ground around them than Bobolink nests. Shrub removal would benefit the Savannah Sparrow and Bobolink but be detrimental to the Clay-colored Sparrow (Winter et al. 2004). Wiens (1969) compared the habitat requirements of the Vesper, Savannah, Grasshopper, and Henslow's sparrows, the Bobolink, and the 2 meadowlark species in Wisconsin. In Savannah Sparrow territories, grass and forb height was mostly 10-40 cm, similar to most other species. Forb density was intermediate in territories, with mean forb height greater than in areas occupied by the Western Meadowlark and Vesper Sparrow but less than for Bobolink, Eastern Meadowlark, and Henslow's Sparrow. The density of vegetation in Savannah Sparrow territories was intermediate among the species and was similar to those of the Grasshopper Sparrow and Eastern Meadowlark.

Total vertical vegetation density differed significantly only from the Henslow's Sparrow, being lower in Savannah Sparrow territories, but vegetation near the ground was significantly denser than in areas occupied by the Western Meadowlark and sparser than in areas occupied by the Bobolink and Henslow's Sparrow. Light penetration to the ground was somewhat greater for the Savannah Sparrow than for most species. Effective height measurements for Savannah Sparrow areas exceeded those of the Western Meadowlark and Vesper Sparrow and were lower than areas occupied by the Bobolink, Eastern Meadowlark, and Henslow's Sparrow. Savannah Sparrow territories were intermediate in litter depth, coverage, and composition. Litter depth differed significantly only from Henslow's Sparrow territories, which had greater litter depth. In April, the Savannah Sparrow selected areas with slightly less grass coverage and slightly more bare ground than the Eastern Meadowlark. The Savannah Sparrow spent less time in grass cover and more in forbs than the Bobolink and Eastern Meadowlark. Species presence could be arranged in order of increasing habitat richness (vegetation density and height, and litter coverage and depth): Western Meadowlark, Vesper Sparrow, Savannah Sparrow, Grasshopper Sparrow, Eastern Meadowlark, Bobolink, and Henslow's Sparrow. The range of difference within this ranking was low, especially among the Savannah Sparrow, Grasshopper Sparrow, and Eastern Meadowlark. In shrubsteppe vegetation, the Savannah Sparrow's niche overlapped most closely with that of the Vesper Sparrow, but also with Upland Sandpiper, Grasshopper Sparrow, Eastern Meadowlark, and Dickcissel (Rotenberry and Wiens 1980). Wiens (1973) compared territories of Savannah and Grasshopper sparrows in Wisconsin. For Savannah Sparrows, areas colonized during the early and middle portions of the season had significantly more grass cover, deeper and patchier litter, greater vertical vegetation density, and lower forb density and coverage than those that were occupied last. Grasshopper Sparrows nested in somewhat more open situations than Savannah Sparrows and had considerably less litter associated with their nest sites. Savannah Sparrows concentrated their feeding at perimeters of grass clumps. Grasshopper Sparrows foraged more frequently in open unvegetated areas. The initial territories settled by these 2 sparrows had quite different habitat but, with the growth of new vegetation, their habitat became similar by mid-June.

In many areas, the Savannah Sparrow appears to avoid edges of fields. This is not consistently the case. Edge avoidance may depend upon the type of edge, but even this varies geographically. In Vermont and New York, Keyel et al. (2013) measured openness and edge effects on nest-site selection. Openness was quantified at points by measuring the distance to edges in 4 directions and the angle to the horizon. Openness was unaffected by edge when the edge was a road, wetland, or agricultural land and was affected predominantly by trees. Nests were placed away from edges and in more open locations than expected. It avoided both edges and non-open habitat. When only nests within 50 m of edge were considered, it still selected areas that were more open. Visually open fields were more likely to be used as breeding habitat. In Wisconsin, Savannah Sparrow territories tended to be located more centrally in grassland habitat than those of other species. Few territories were located along fence lines and mean distances to adjacent cultivated fields (94.0 m, range 0-240 m) and fence lines (49.4 m, range 0-160 m) were the greatest of the species studied. Distances to adjacent woods (225.0 m, range 20-410 m) were also large (Wiens 1969). In Alberta, Sliwinski and Koper (2012) examined responses to 3 edge types: cropland or hay, roads and fences, and wetlands. Its abundance increased as distance to crop edge increased, but not significantly, suggesting that it

may not respond to crop edges. It showed no attraction to or avoidance of roads. It decreased with distance to wetlands and was therefore attracted to wetlands. In South Dakota, Vermont, and New York, its density decreased as the percentage of wooded edge increased (Greer et al. 2016; Shustack et al. 2010). In Wisconsin, the density of nests per ha increased significantly with distance from edge from 0.2 at 25 m from edge to 0.4 at 100 m and 0.8 at 200 m. Type of edge was not a significant predictor of nest density within 50 or 100 m of edge. Edge effects were unlikely to affect predation rates because the fields were small, with few areas more than 225 m from edge, and because the highly fragmented habitat was saturated with predators. Edge avoidance would not necessarily reduce predation (Renfrew et al. 2005). Perkins et al. (2013) examined the distribution of 995 nests in relation to edges, including agriculture with a management-defined boundary, forests, hedgerows, human development, roads, and wetlands. Areas within 50 m of edge were used significantly less than expected. Sixty percent of available habitat was within 50 m of edge, but only 26.6% of nests were in that area. Thirty-one percent of habitat was 50-100 m from edge and this area supported 45.5% of nests. About 1% of nests were as close as 10 m from edge. Nests were closer to forested edges than expected: 35% of available edge supported 52% of nests, but this was not statistically significant. Portions of fields near hedgerows were used significantly less than expected: 16% of habitat and less than 1% of nests. There was no avoidance of or attraction to wetlands, roads, human development, or agriculture. Later-nesting birds nested closer to edge. Dominant or older birds may force subordinate and young birds to nest closer to edge. Early colonizers may settle into sites furthest from edges and settlement gradually moves from the centre to edges of the habitat patch. Despite the exhibited edge avoidance, nesting near edges had only minor consequences for nest success. In Illinois, it tended to nest more than 50 m from a wooded edge (Swanson 2002). In Colorado and Ohio, it appears to avoid edges of large urban centres (Jones and Bock 2002; Swanson 1996). In Nova Scotia, it nested in a 1.2-ha field surrounded by spruce–balsam fir forest. Nests were found within 3 m of this forest and density of birds nesting in the field was among the highest ever recorded (Wheelwright and Mauck 1998; Wheelwright and Rising 2020; Wheelwright et al. 1994). The Savannah Sparrow avoids edges in some areas but not in others. Where edge avoidance occurred, it was predominantly treed edges that were avoided. In another study, there appeared to be an attraction to treed edges but avoidance of hedgerows.

Several studies examined area sensitivity by the Savannah Sparrow. Results are often ambiguous and conflicting, partially because it may respond differently in different landscape types, but often because of the study methods and interpretation. Many grassland-bird researchers consider a species to be area sensitive if its density increases with habitat area. Few studies considered the minimum patch size required to support the species, which is a more meaningful measure of area sensitivity. In New York, Norment et al. (2010) studied fields as small as 5 ha and found that field size had little effect on occupancy or nest survival. In California, saltwater marshes with adjacent meadows that supported the Savannah Sparrow were highly fragmented and isolated. Nine breeding territories were in a 1-ha marsh connected to other habitat, and there were 3 territories in an isolated 2.9-ha marsh completely surrounded by urban habitat. Although nesting occurred in even the smallest fragments, no successful nests occurred in patches smaller than 10 ha (Fernández-Juricic et al. 2009; Powell and Collier 1998). In Wisconsin, its density was not associated with field size (Ribic and Sample 2001). In Nova Scotia, high numbers of Savannah Sparrows nested successfully in

a 1.2-ha field (Wheelwright et al. 1994). In Michigan, Potter (1972) studied a population in a 4.74-ha field. Johnson and Igl (2001) studied CRP fields 2.2-270.5 ha in 4 states and found no relationship between its density and patch size, although positive and negative relationships were observed at 1 site each. Because they were measuring abundance, this suggests that no significant edge avoidance was occurring. In Saskatchewan, there was no relationship between patch size and its abundance. It was area insensitive, with occurrence independent of patch size. There was no edge avoidance and in 1 of 2 years it was more abundant near edge (Davis 2004; Davis et al. 2006). In South Dakota, its density was unaffected by area but was positively correlated with patch size in another study in that state (Greer et al. 2016). In Ohio, it occupied CRP fields as small as 3 ha. The minimum area to support a breeding population in Missouri was estimated at 1-10 ha (Swanson 2002). In sedge marshes in Michigan, its abundance was correlated with patch size (Crozier and Niemi 2003). Shustack et al. (2010) found a similar relationship in Vermont and New York. In Illinois, Herkert (1994a) studied fields 0.5-650 ha and determined that its occurrence was positively correlated with patch area. It occurred on approximately 10% of 1-ha patches and 20% of 10-ha patches; 50% occurrence was achieved at 40 ha. In small patches, only 33% of transects had suitable habitat, but area requirements still appeared to limit its distribution within small fragments. He concluded that it was area sensitive, with its distribution affected by both habitat availability and patch size. In another Illinois study, Walk and Warner (1999) studied grasslands 7-120 ha in area. It was rare and occurred on only 3 of 9 sites and only on tracts larger than 40 ha. They concluded that the minimum area required to support a population was 65 ha. In Maine, Vickery et al. (1994) studied grassland barrens dominated by blueberries that were 0.3-404 ha. Percent occurrence was 10-20% on plots smaller than 1 ha, 30% at 1 ha, and 50% at 10 ha. Area sensitivity of the Savannah Sparrow may be affected by landscape features and it may only be area sensitive in regions where grasslands are scarce (Dornak 2010; Ribic and Sample 2001) or at the periphery of its range. In Minnesota and North Dakota, its density was influenced by patch area, but the magnitude and direction of the response varied annually. Field size had no influence on nesting success. The fields studied were fairly large, averaging 226.1 ha (range 2.4-1,245.6 ha; Winter et al. 2006). Coleman et al. (2000) concluded that it was area sensitive in Ontario and required a minimum of 50 ha of grassland. Rising (in Cadman et al. 2007) stated that it can use small areas of suitable habitat in the province. Given the abundance of the Savannah Sparrow in Ontario, it is unlikely that it is area sensitive. It commonly nests in fields much smaller than 50 ha. Most studies that found evidence of edge avoidance or area sensitivity were conducted in western grasslands, and these results may not be transferable to other locations.

Adults roost on the ground at night but the female spends the night on the nest while she is incubating or brooding (Wheelwright and Rising 2020).

One Ontario nest was 0.3 m from the ground in a cedar, but all others were on or very close to the ground. Most were in small depressions (one was in the side of a mossy hummock) and concealed in grasses, sedges, forbs, cattails, and occasionally shrub stems. Some were at or under bases of shrubs, seedlings, and clumps of forbs or grasses. One was in a clump of willows standing in 15 cm of water. Several were partially or completely arched over with vegetation, but 3 nests were fully exposed (Peck and James 1987). A nest on South Limestone Island in Georgian Bay was within a Common Tern colony (Mills 1981).

Almost all nests are on the ground. A few British Columbia nests were in low vegetation as high as 0.5 m from the ground. Nests at a California site averaged 3.3 cm from the ground. Typical nests are in shallow depressions in the ground that may be either natural or formed by the female. They are often within clumps of grasses, sedges, mosses, or herbaceous plants or at the base of low woody shrubs, with the rim of the nest flush with the ground; some may extend slightly above ground. Many nests are concealed by overhanging grasses or other vegetation that may form a partial dome. Others are fully exposed. In Wisconsin, 70.4% of nests were either partially domed or under overhanging litter. One nest had a 1.2-m long tunnel leading to it under long matted grass. Yearlings orient their nests in random directions. Older females preferentially construct nest entrances away from the prevailing winds. There is no evidence of nests being reused (Baird in Austin 1968; Campbell et al. 2001; Hendricks and Pidgeon 1990; Jehl and Hussell 1966a; Mousley 1916a; Powell and Collier 1998; Shields 1935; Swanson 1996; Taber in Austin 1968; Welsh 1975; Wheelwright and Rising 2020; Wheelwright and Schultz 1994; Wiens 1969).

In most areas, males establish territories shortly after their arrival. In Nova Scotia, territories in the shelter of woodlands were established first. Nests in these territories had full clutches while territorial boundaries were still being adjusted in other portions of the field. In Wisconsin, a portion of a field that had been mowed the previous autumn was settled first in several clusters of 2 or 3 contiguous territories. Territorial birds may continue to arrive into early June and new territories are wedged among existing ones. Boundary fluctuations may be extensive and are frequently demarcated by a singing perch such as a sturdy forb, a fence post or wire, or a shrub or small sapling. Perches at boundaries may be shared, with 2 males both singing from the top and the opposite side of a shrub or sapling, but at different times. In Wisconsin, 1 tall heavy-stemmed forb that was frequently used as a singing perch was in 3 different territories. Once territory boundaries are established, there are few conflicts. Some males may reduce the size of their territories while they are feeding nestlings, but reclaim any area lost to neighbours as soon as the young fledge. Bigamous males may be the only ones that do not reduce the size of their territory during the nestling period. Territorial defence wanes by late July and adults with fledglings may wander on to neighbours' territories without conflict. Territories vary in shape from almost square to long and rectangular, but territory shape has no effect on mating success. There is very little overlap in territories once boundaries are established. Females are aggressive toward other females within 20 m of the nest. Successful nests in adjacent territories have been as close together as 2.2-10 m. In New Brunswick, there was strong evidence that juveniles selected a territory and began defending it within a month of hatching. Adult males frequently defended their territories against juveniles in July and early August. Individuals located their first nest closer to the location of their last sighting as a juvenile than to their natal nest. Some territory holders are unsuccessful in obtaining a mate. In Michigan, only 1 of 9 territories as small as 0.06 ha contained a nest; territories this small may not be attractive to females. In Quebec, the distribution of territories of unmated males tended to be clumped rather than regularly dispersed. The location of unmated male territories shifted each year suggesting that failure to obtain a mate was not related to habitat quality. In some locations, the territory and home range are the same, with all activities occurring within the territory. In other areas, adults regularly leave the territory to forage in undefended areas. Where the habitat is homogeneous, feeding tends to occur within the territory. Where there is adjacent habitat that is unsuitable for breeding but offers rich food

resources, it often forages outside the territory. Birds nesting near saltwater tidal marshes, freshwater marshes, and margins of lakes and wetlands may forage outside their territories. Territories tend to be quite small, typically considerably less than 1 ha. Reported territory sizes include 0.11 ha on an island in New Brunswick, 0.01-0.29 ha (average 0.10 ha) in Michigan, 0.1-0.47 ha in Quebec, 0.09-0.33 ha (average 0.17 ha) in Nova Scotia, 0.008 to 0.10 ha (average 0.04 ha) in California, 0.16-1.74 ha (average 0.69 ha) in Wisconsin, and 0.38-0.53 ha in densely vegetated habitat and 1.09-1.25 ha in sparse habitat on Sable Island. In Wisconsin, centrally located territories were significantly smaller (0.45 ha) than those at the periphery of the field (0.65 ha) where there were no neighbours on some sides. Polygynous males have larger territories than monogamous males (0.28 ha compared with 0.19 ha). In Quebec, successful territories in fields were significantly larger (0.28-0.34 ha) than unsuccessful territories (0.28-0.30), but the relationship was the opposite in marsh habitat. Successful territories in marshes were 0.18 ha compared with 0.19-0.30 ha for unsuccessful territories. At this site, yearlings defended significantly smaller territories of 0.19-0.27 ha than the 0.47 ha defended by older males in 1 year but not in another (Bédard and LaPointe 1984a; Potter 1972; Powell and Collier 1998; Welsh 1975; Wheelwright and Mauck 1998; Wheelwright and Rising 2020; Wheelwright et al. 1992; Wiens 1969, 1973).

Natal philopatry rates vary throughout the Savannah Sparrow's range, but are consistent within a given area. High return rates are associated with areas where the habitat is isolated, such as islands or mountains above the treeline. In Montana, 3 of 193 nestlings (1.6%) returned to breed; 1 bred at its natal site and another bred 4.8 km distant (S.L. Jones et al. 2007). In Michigan, 1 of 130 juveniles (0.8%) returned to breed in a subsequent year (Wheelwright and Rising 2020). On Sable Island, 18 of 455 nestlings (4.0%) and 26 of 227 fledglings (11.5%) returned. Most yearlings settled 500-1,000 m from where they were raised but one nested 7.5 km from its natal territory. Survival rates were higher among birds from larger broods, among those hatched earlier in the year, and among those reared in dense habitat. It was concluded that all surviving individuals returned to the island (Ross and McLaren 1982). In New York and Vermont, Perlut et al. (2014) reported a natal philopatry rate of 7.5%; the survival rate of juvenile males was higher than for females. Also in New York and Vermont, 36 of 883 juveniles (4.1%) returned. The median dispersal distance was 885 m (mean 913 m, maximum 2,825 m). Of the 36 returning birds, 27.8% were detected in the same field and 72.2% in a different field. Most yearlings either dispersed less than 300 m or more than 900 m. Returning yearlings showed no propensity to select fields under the same management treatment as their natal field. They were equally likely to make favourable or unfavourable decisions regarding habitat quality (Fajardo et al. 2009). Perlut and Strong (2016) recaptured 62 of 865 nestlings (7.2%) in Vermont. The mean dispersal distance was 1,426.2 m (median 1,001.3 m). In British Columbia montane meadows, an average of 17% of juveniles returned annually (Martin et al. 2009). On Kent Island in New Brunswick, 11% of nestlings and 26% of fledglings returned to breed (Wheelwright and Schultz 1994; Wheelwright et al. 1994). At the same study area, Wheelwright and Mauck (1998) studied distances of first nests of yearlings from their natal sites and proximity of their close kin. Of 1,615 nestlings whose parentage was known, 11.2% returned to breed the following year. Of more than 7,000 Savannah Sparrows recovered during the breeding season, none were found more than 3 km from the original banding location. One nested as a yearling 3 km from its natal area, the only bird that dispersed more than 1 km. Two other islands within a few 100 m were accessible by foot during low

tide. Birds banded on Kent Island never accounted for more than 2% of the breeding birds on these islands in any given year. On 3 other islands 3-7 km distant, recruits from Kent Island accounted for 0-1% of breeding birds. Over a 6-year period, an average of 73% of newly breeding males and 71% of newly breeding females had been raised in or adjacent to the study area the previous year. Yearlings appeared to disperse random distances from their natal nests and, in some cases, avoided the natal area. The median dispersal distance between the natal site and the first nest was 228.5 m (range 0-1,400 m for males and 0-1,600 m for females), a distance of approximately 6 territories. Yearling males and females returned in approximately the same numbers and dispersal distances were not significantly different: 202.8 m for males and 248.4 m for females. Females were more likely to remain in their natal fields than males. If a female changed fields, she tended to move further than males that changed fields. Natal dispersal was unaffected by population density (and therefore competition for territories), the date that an individual hatched, or its mass at age 7 days. There was no significant relationship between dispersal distances of yearlings and those of its biological mother or father, suggesting that dispersal distance was not a heritable feature. Yearlings were more than twice as likely to nest in a field other than their natal field if their opposite-sex parent returned, but the probability of changing fields was unaffected by whether the same-sex parent returned. Birds nested significantly further from siblings raised in the same year than expected by chance. Distances between a yearling's first nest and the nearest nest of a sibling of either sex were: median of 327.9 m and mean of 399.8 m for birds raised in the same nest in the same year; median of 338.5 m and mean of 332.4 m for birds raised in a different nest in the same year; and median of 129.9 m and mean of 281.2 m for birds raised in different nests and different years. Siblings raised in different years that were therefore unfamiliar with each other nested closer to each other than by chance. The mean distance of first nests of siblings of the same sex (274.3 m) was significantly less than that of siblings of the opposite sex (517.6 m). Of 1,073 breeding attempts, no cases of pairing between full siblings, parent and offspring, half siblings, uncles and nieces, or grandparents and grand-offspring occurred, even though 20% of adults had one or more close relatives breeding in the population at the same time. Birds actively avoided breeding with close relatives, partially by dispersal from the natal area. Returning juveniles were not relegated to inferior habitat and their territories were dispersed among those of older birds. Returning yearling males produced significantly more offspring than those that had been raised outside the study area. Brewer et al. (2018) reported that a juvenile banded near Bewdley was recaptured at the same site 5 years later.

Site fidelity by adults is high and distances between nesting areas in subsequent years are usually negligible. In Michigan, 20 of 22 males (90.9%) returned the next year and 16 of 18 (88.9%) returned the following year (Potter 1972). Near Quebec City, 167 of 344 breeding adults (48.5%) returned for at least 1 and a maximum of 4 breeding seasons. There was a slight tendency for males to return at a higher rate. Distances moved by returning birds were small, with 80% of interyear movements less than 60 m, the average diameter of 1 territory. There was no significant difference in the distance moved by the sexes. Some moved further than 140 m. There were no significant differences in distances moved by birds that had been successful or unsuccessful the previous year, or if mates were changed between years. Moves that took place between 2 successive nesting attempts within a year were always shorter than moves between seasons. Males tend to return to the same territory each year even if it is of poor quality. Yearling males that have to squeeze in

between other territories do not attempt to upgrade in subsequent years. One male returned to the same territory for 5 years even though he never managed to attract a female, and males that failed to raise young in several successive years also did not move (Bédard and LaPointe 1984b). In Montana, S.L. Jones et al. (2007) reported an adult return rate of 5.4%, with 2 of 37 returning. Both returning adults occupied the same territory as the previous year. In an alpine meadow in British Columbia, 68% of adults returned (Martin et al. 2009). On Kent Island, 51% of adults returned after their first year of breeding and 47% returned after their second year of breeding. Birds that nested later in the season were more likely to return than those that nested earlier. Dispersal by adults was negligible once they established a territory. The median distance between nests within breeding seasons was 16.9 m and the distance between nests in different breeding seasons was 31.8 m. No females moved more than 0.5 km between seasons (G.W. Mitchell et al. 2012; Wheelwright and Mauck 1998; Wheelwright and Schultz 1994). In Vermont and New York, 226 of 553 adults (40.9%) returned. The mean dispersal distance between years was 113 m (median 63 m, maximum 2,009 m). Males moved significantly further than females, with a median of 78 m for males and 50 m for females. Results may have been biased because females were more difficult to detect. Birds that dispersed between years exhibited a strong selection for sites under the same management practices as the site used the previous year. Only 6 of 226 breeding dispersal events (2.7%) were to fields under different management practices. The Savannah Sparrow was more likely than expected to make unfavourable decisions regarding management practices, with 53.0% remaining in or moving to low-quality habitat. Birds that were unsuccessful the previous year were equally likely to breed in the same location as the previous year as birds that had been successful. It exhibited high site fidelity regardless of habitat quality (Fajardo et al. 2009). In California, no movement of 277 adults was detected among habitat patches within seasons and between years (Powell and Collier 1998). A Michigan adult was captured at the same site where it had been banded 6 years previously (Swanson 2002).

Limiting Factors

Eggs have been reported in Ontario nests from the last week of April until mid-August, with most present from the last week of May until the last week of June (Peck and James 1987). In Algonquin Park, eggs are present from late May to mid-June, nestlings are present from mid-June to late July, and dependent fledglings have been observed from late June to early August (Tozer 2012). The mean dates of clutch completion were 14 June at Moosonee (range 6-20 June), 17 June at Attawapiskat (range 6-25 June), and 21 June at Winisk (range 11-30 June; Schueler et al. 1974). Manning (1952) observed the first volant juveniles along the Hudson and James bay coasts on 19 July.

First nests take 4-5 days to complete but replacement nests are usually built in 2 days, typically within 20 m of the original nest. An average of 3 days elapses between nest completion and when the first egg is laid. Eggs are laid at the rate of 1 a day but a day may rarely be missed. In 1 Nova Scotia nest, 1 egg was laid in the morning and another was laid in the afternoon. It was uncertain if both eggs were laid by the same female or if this was a case of intraspecific nest parasitism. At high elevations and latitudes, egg laying within populations tends to be synchronized within a short period. Egg laying may be spread throughout the season in more temperate areas. At Churchill, more than 65% of all clutches were initiated within a 3-day period. In New Brunswick, clutch

initiation extended over 52 days. The timing of clutch initiation may vary annually depending upon weather conditions. Full-time incubation does not start until the penultimate egg is laid. The incubation period has been reported as 10-13 days, but mostly 12 days. At 1 closely monitored Ontario nest, the incubation period was only 9 days. Hatching may be asynchronous due to initiation of incubation before the clutch is complete. The nestling period is 7-14 days, with most young fledging in 9-11 days. Near Quebec City, nestlings from early nests (12 June or earlier) fledged significantly later (10.4 days) than those from later nests (9.8 days) in 1 year. In another year, young fledged in 10.0 days from early nests and in 9.0 days from later nests (Baird in Austin 1968; Baptista 1984; Bédard and LaPointe 1985; Bédard and Meunier 1983; Dixon 1978; Hendricks and Pidgeon 1990; Martin et al. 2009; Peck and James 1998b; Ross 1980; Weatherhead 1979; Welsh 1975; Wheelwright and Mauck 1998; Wheelwright and Rising 2020; Wheelwright and Schultz 1994; Wheelwright et al. 1992; Wiens 1969; Winter et al. 2004).

The Savannah Sparrow has been documented raising 1-4 broods annually. A number of factors affect how many broods can be reared, especially the length of the breeding season and nest success rates. Populations at high altitudes and latitudes typically raise only a single brood. On Sable Island, 3 or 4 broods are often raised annually because the nesting season is long and there are few predators. In other areas, only 1 or 2 broods are raised. Over several years of study in New Brunswick, only 1 bird raised 3 broods. The number of broods raised may vary even among areas that are close together. In West Virginia, almost all birds were double brooded. At another site in the same state, all were single brooded and birds left the area by mid-July. Ontario egg dates suggest that double broods occur, but this has yet to be confirmed. In southern coastal British Columbia, it is double brooded but presumably single brooded in much of the remainder of the province. In Wisconsin, most birds were double brooded but a few raised only a single brood. Single broods are raised near Churchill, Quebec City, and in alpine meadows in British Columbia. When another brood is attempted after raising the first brood, a new nest is built in the same territory. There is no difference in the vegetation in the vicinity of subsequent nests. On Sable Island, yearlings averaged 2.4 clutches per year compared with 3.0 for older birds. The female may begin or even complete the second clutch before the young of the first brood fledge. Renesting is common if a nest is lost or abandoned. In some areas where losses are high due to predation or agricultural activities, females may lay 3 or 4 clutches in an attempt to raise a single brood. Replacement nests are close to the original nest. Successive nests have been as close together as 0.5 m. In New Brunswick, replacement nests averaged 17 m from the original nest (range 3-31 m). Distances between successive nests in Nova Scotia were 6-38 m. Within 2-8 days of nest loss, females construct new nests and begin to lay the replacement clutch. Yearlings take significantly longer to replace their clutches, with an average of 4.9 days for yearlings and 3.0 days for older females. When adverse weather late in the season resulted in the loss of most nests near Churchill, no renesting occurred (Bédard and Meunier 1983; Dixon 1978; Jehl and Hussell 1966a; S.L. Jones et al. 2010; LaPointe and Bédard 1986; Martin et al. 2009; G.W. Mitchell et al. 2012; Peck and James 1987; Ross 1980; Shields 1935; Swanson 1996; Weatherhead and Robertson 1980; Welsh 1975; Wheelwright and Rising 2020; Wheelwright and Schultz 1994; Wheelwright et al. 1992; Wiens 1969; Winter et al. 2004; Wray et al. 1982).

Clutches of 3-5 eggs have been reported in Ontario (average 4.05 eggs). Most (59.5%) clutches contained 4 eggs. Throughout its range, the Savannah Sparrow lays 2-6 eggs, with 4-egg clutches

most frequent. Clutch size increases with latitude, with a mean of 5.0 in Alaska and 3.2 in California. Within a given area, other factors may affect clutch size such as habitat type, whether it is early or late in the season, and age of the female. At La Pérouse Bay, clutch size was significantly higher in short willows (4.78 eggs) than in tall willows (4.17 eggs). Either food availability was lower or predation pressure was more intense in tall willows. There was no difference in nestling growth rates in the 2 habitats suggesting that reduced food availability may have been compensated for by smaller clutch sizes in tall willows. Significant clutch size declines with season are often associated with more northern populations where clutch initiation is highly synchronous. In these areas, replacement clutches tend to be significantly smaller than initial clutches and clutches laid outside the peak of clutch initiation are smaller. Near Quebec City, clutch sizes by the same female were 4.1 eggs for first clutches and 3.8 eggs for replacement clutches. In British Columbia alpine meadows, first clutches averaged 4.65 eggs and replacement clutches averaged 4.00 eggs. In most areas, there is a decline in clutch size as the season progresses, consistent with the waning abundance of food resources. An exception is in New Brunswick and Nova Scotia where replacement clutches are larger than initial clutches. In Nova Scotia, clutches averaged 4.0 eggs in May, 4.5 in June, and 3.6 in July and a similar trend occurred in New Brunswick. Both sites were on the Atlantic Ocean coast and cool, wet, foggy weather early in the year depressed insect availability. More food resources were available for nests initiated slightly after the initial peak of nesting. Older females consistently lay larger initial and replacement clutches than yearlings, but both age classes lay similar-sized second clutches. In Quebec, individual females laid similar-sized clutches as yearlings (4.2 eggs) and in their second (4.2) and third (3.8) years. Despite this, older birds consistently fledged more young than yearlings. On Sable Island, adult females had larger clutches (4.54 eggs) than yearlings (4.16 eggs). In New Brunswick, 24.1% of females increased their first clutch size between ages 1 and 2 years, 69.0% had the same clutch size, and 6.9% had a smaller clutch. Clutch size of individuals increases between ages 1 and 2 years and then declines each year to age 6 years. As females age, they nest progressively earlier each season. In New Brunswick, a greater percentage of eggs in 4-egg clutches fledged young (40.4%) than other clutch sizes: 25.0% of 2-egg clutches, 32.5% of 3-egg clutches, and 19.7% of 5-egg clutches. In normal food years, adults may not be able to feed 5 nestlings adequately. During a year with prolonged cold, foggy, wet weather, 3-egg clutches were most successful. Mean clutch sizes are available from several locations: 11 clutches at Moosonee all contained 4 eggs, mean size of 29 clutches at Attawapiskat was 4.1 eggs (range 4-5), 12 clutches at Winisk averaged 4.5 eggs (range 4-5), 4.20 eggs in New York, 5.00 in a year of high grasshopper abundance and 4.60 in a year of low grasshopper abundance in Alaska, 3.9-4.2 in West Virginia over 3 years, 4.17 and 4.02 in New Brunswick, 4.0 in mid-May and 3.5 at the end of July in North Dakota, 4.4 and 4.8 in Saskatchewan, 4.5 in Alberta, 4.3 in Montana, 4.1 in Wisconsin, 3.97 near Quebec City, 4.2 on the Nova Scotia mainland, 52% of clutches with 4 eggs in British Columbia, and 4.65 for initial nests and 4.0 for replacement nests in British Columbia alpine meadows (Baird in Austin 1968; Bédard and LaPointe 1985; Bédard and Meunier 1983; Campbell et al. 2001; Davis 2003; Dixon 1978; Gaudet et al. 2020; S.L. Jones et al. 2010; LaPointe and Bédard 1986; Ludlow et al. 2014; Martin et al. 2009; Miller et al. 1994; G.W. Mitchell et al. 2012; Norment et al. 2010; Ross 1980; Schueler et al. 1974; Weatherhead 1979; Welsh 1975; Wheelwright and Rising 2020; Wheelwright and Schultz 1994; Wiens 1969; Winter et al. 2004; Wray et al. 1982).

Both sexes are capable of breeding when they are yearlings and breeding occurs annually thereafter. Some yearling males are unsuccessful in obtaining a mate. Near Quebec City, 20%, 40%, and 35% of males failed to attract a female over 3 years. Failure to mate was unrelated to habitat quality because the same area was often defended by a mated male in different years. In southwestern Ontario, 7-13% of territorial males failed to mate. Some populations are entirely monogamous but some polygyny may occur in other populations, particularly those in the Maritime Provinces. Monogamy is the rule in northern and high-altitude populations where the breeding season is short and a single brood is raised. Nesting is highly synchronous in these populations, giving males limited opportunities to acquire a second mate. Polygyny opportunities arise in populations where nest initiation occurs over an extended period due to multiple broods, renesting, later nesting by younger birds, and a long breeding season. In New Brunswick, 15-43% of males were polygynous, depending upon the year. Females were rarely synchronous in their breeding attempts, allowing the male to provision the young of both females if he chose to do so. Polygyny occurred as a result of 4 situations: younger females often returned from spring migration several days later than older females and chose to mate with a male who was already mated; territorial males sometimes vanished and neighbouring males expanded their territories and mated with the resident female; new females occasionally appeared as much as 6 weeks after the first eggs were laid; and females occasionally returned to their territory to find it already occupied by another female. The quality and size of a male's territory was unrelated to the probability of his attracting more than 1 mate. Polygynous males fledged 32% more young than monogamous males, but there were no differences in productivity of females mated to monogamous or polygynous males. In the event of nest loss, secondary females in polygynous relationships were more likely to leave the territory and move to a new one 100-500 m distant. Females mated to polygynous males incur higher mortality and appear to be in poorer condition than those mated monogamously. The pair bond typically persists throughout the breeding season. Divorce is rare but mates are replaced if one is lost. Both sexes exhibit high site fidelity and frequently reunite in subsequent years (Bédard and LaPointe 1984; Martin et al. 2009; Powell and Collier 1998; Ross 1980; Weatherhead 1979; Weatherhead and Robertson 1980; Welsh 1975; Wheelwright and Mauck 1998; Wheelwright and Rising 2020; Wheelwright and Schultz 1994; Wheelwright et al. 1992, 1994; Wiens 1969).

Extra-pair copulations may be common. In New Brunswick, 14 of 24 nests (58.3%) contained at least 1 extra-pair offspring and 31 of 92 first-brood offspring (33.7%) were a result of extra-pair fertilizations. Females mated to a polygynously mated male were more faithful than those mated to monogamous males. Extra-pair fertilizations accounted for 62% of offspring for monogamously mated females, 24% for primary females in a polygynous relationship, and 20% for secondary females. All monogamous females produced at least 1 extra-pair young; 54.5% of primary polygynous females and 33.3% of secondary females produced extra-pair young. Seventy-five percent of young in nests of polygynous males were due to in-pair fertilizations compared with 40% for monogamous males. In 95% of cases, extra-pair sires were neighbours whose nests were within 88 m of another female's nest. Thirty percent of young were extra-pair in first broods but only 16.3% of young in second broods were extra-pair. Males that provided more care to the nestlings were less likely to have extra-pair young in their broods (Freeman-Gallant 1996, 1997; Welsh 1975; Wheelwright and Mauck 1998; Wheelwright and Rising 2020). Intraspecific nest parasitism appears

to be rare. Weatherhead and Robertson (1978) reported a nest at La Pérouse Bay that contained 10 eggs. Eight eggs were readily separated into 2 groups by appearance indicating that they had been laid by different females. Hatching sequence suggested that the eggs were laid simultaneously.

The Savannah Sparrow forages mostly on the ground in open areas, avoiding dense vegetation. Foraging occurs in short vegetation in pastures, hayfields, roadsides, sedge bogs, tundra, beach wrack, mudflats near cover, and in tidal marshes and pools during low tide. It hunts for insects and other arthropods while walking on the ground, peering around bases of grasses or herbaceous plants, or searching seaweed and beach wrack. On Kent Island, it gleans flies and caterpillars from tips of white spruce branches. Males forage higher than females when this technique is used. Occasionally it leaps from the ground to make short sallies to capture butterflies or flies in flight. It captures spittle bugs by stabbing into the spittle mass on vegetation. Seeds are consumed by picking them off the ground after they have fallen or by stripping them from grasses. This latter method is used mostly when snow or freezing rain covers seeds on the ground. Less frequently, it double scratches with both feet in the litter to uncover seeds and invertebrates (Baird in Austin 1968; Bédard and LaPointe 1984a; Wheelwright and Rising 2020; Wheelwright and Schultz 1994; Wiens 1969; Williams 1987). In Nova Scotia, its abundance was positively correlated with the abundance of flies and beetles (mostly ground beetles) which are prey items. Abundance was negatively correlated with abundance of centipedes (Nocera et al. 2007b).

In Nova Scotia, caterpillars formed a significant proportion of the food brought to young nestlings. Later, adult lepidopterans formed the bulk of the diet. Only very small insects were fed to the young in the first 2 days, with the size and amount of food increasing as they grew (Welsh 1975). In Saskatchewan, nestlings were fed spittle bugs, wasps, spiders, flies, bugs, and beetles. Birds breeding near marine shores may feed young amphipods and seaweed fly larvae. Less commonly, nestlings are fed fruits of strawberries and blueberries (Wheelwright and Rising 2020). Near Quebec City, the diet of nestlings consisted entirely of arthropods. Major food items in decreasing order of numerical importance included caterpillars and sawfly larvae, fly larvae and adults (predominantly flower flies and picture-winged flies), and bugs (mainly froghoppers and leafhoppers). Groups of secondary importance included adult lepidopterans, orthopterans, spiders, and beetles. Caterpillars and sawfly larvae constituted 27% of prey items and the consumption of these remained constant throughout the sampling period. There was an abrupt increase in the use of soft-winged bugs during the week of 27 June to 3 July when they comprised 38% of the diet. Adult lepidopterans were seldom consumed until after 18 July when they constituted 20% of the diet. Nonstaple items such as orthopterans, spiders, and beetles were always of minor importance in the diet even though they were abundant. Adult lepidopterans and beetles were disregarded despite their abundance at times. Caterpillars and sawfly larvae were selected even when they were scarce. There was a tendency for adults to collect a greater diversity of prey items as the season progressed. Soft-winged bugs constituted 38% of prey items brought to nestlings 1-3 days old but only 10% for 7-9-day-old nestlings. Adult lepidopterans were seldom brought to 1-3-day olds but represented 18% of the diet of older nestlings. Caterpillars and sawfly larvae increased from 24% at age 1-6 days to 30% during the final 3 days in the nest. Nestlings in broods of 2 received significantly more adult lepidopterans and adult flies than broods of 3 and 4. Both sexes brought all types of prey, but males brought significantly more caterpillars, sawfly larvae, and adult flies than females, and females brought

significantly more soft-winged bugs than males. Adults brought adult lepidopterans and fly larvae in equal proportions. Sexes may bring different prey because males can forage over larger areas. Females are more likely to forage near the nest. Although adults prefer certain prey, they are opportunistic and can respond to temporary increases in palatable prey. There was no indication that food abundance was a limiting factor (Meunier and Bédard 1984). In Alaska, Miller et al. (1994) compared the diet of nestlings during periods of grasshopper high abundance and rarity. During the year of abundance, significantly more grasshoppers were fed to nestlings and in the year of scarcity, nestlings were fed significantly more caterpillars and flies. In the year of abundance and scarcity, respectively, the nestling diet consisted of 25.2% and 25.2% spiders, 60.8% and 0% grasshoppers, 0% and 0.1% neuropterans, 0% and 5.9% adult beetles, 0% and 3.7% beetle larvae, 1.4% and 2.2% adult lepidopterans, 5.6% and 25.2% caterpillars, 2.1% and 11.9% flies, 4.9% and 4.4% crane flies, and 0% and 20.7% hymenopterans.

Adult Savannah Sparrows subsist predominantly on seeds in early spring, late autumn, and winter, and feed mostly on insects during the breeding season. Judd (1901) analyzed the contents of 119 stomachs. The diet consisted of 46% animal material and 54% vegetable material. The animal matter consisted of 15% beetles, 9% lepidopterans, 8% orthopterans, 5% hymenopterans, 2% true bugs, 4% flies and miscellaneous insects, and 3% spiders with a few snails. It consumed more beetles than other sparrow species and ate them every month, but in lesser quantities in winter. Beetles comprised a third of the diet in May and June, particularly weevils and leaf and ground beetles, but it also ate fireflies and click, dung, rove, and pill beetles. It preferred weevils and they constituted 11% of the August diet. The lepidopterans that were consumed were mostly owlet moth caterpillars. Grasshoppers were common in the diet from June to August and comprised 34% of the July diet. The hymenopterans were mostly ants and the flies consisted of crane flies and horse flies. The vegetable matter that was consumed was almost entirely seeds. Foxtails and panic grasses comprised 31% of the diet; 22% of food items were seeds of herbaceous species. In Utah, 14 stomachs contained 136 unidentified seeds and numerous invertebrates. These included 1 grasshopper nymph; 50 soft-winged bugs including leafhoppers and aphids; 39 true bugs including plant and seed bugs; 28 beetles including larvae, leaf beetles, and weevils; 8 caterpillars and 17 lepidopteran eggs; 15 flies that were mostly midges; and 4 hymenopterans including ants (Knowlton 1950). At La Pérouse Bay, birds collected prior to 11 June had a diet of 45% seeds by volume. Birds collected later had not eaten any seeds. It has eaten odonates, small insects, crustaceans, and aquatic insect larvae and nymphs. Birds nesting on marine shores may eat crabs, isopods, and amphipods. It consumes a wide range of sizes of prey, from 3-mm long midges to 4-cm caterpillars. Seeds consumed include those of foxtails, crabgrasses, ragweed, panic grasses, amaranths, knotweeds, oats, nightshade, barley, and sorghums. Foxtails, crabgrasses, and panic grasses are particularly important in the diet. It occasionally eats fruits of blueberries and strawberries. At any given time, it may feed almost exclusively on 1-4 types of seeds (Baird in Austin 1968; Wheelwright and Rising 2020). During years of high grasshopper abundance in Alaska, grasshoppers constituted 45.8% and 56.2% of the diet compared with 8.2% in a low grasshopper population year. Beetles comprised 14.7% and 17.2% of the diet in high years and 47.6% in years of low grasshopper abundance. There was no significant difference among years for other taxa: 1.9-18.0% for true bugs, 5.2-7.4% for soft-winged bugs, 0.6-14.5% for beetle larvae, 0-0.2% for adult

lepidopterans, 1.3-2.5% for caterpillars, 0.4-1.4% for flies, 0-8.2% for hymenopterans, 4.7-13.8% for spiders, and 0-2.7% for molluscs. The Savannah Sparrow exhibited a high degree of dietary flexibility in response to fluctuating prey (Miller and McEwan 1995). In California, de Rivera (2000) observed adults chasing fiddler crabs, which carry their eggs ventrally. On 18 of 49 chases (36.7%) sparrows successfully ate eggs from crabs without otherwise harming them. Birds never chased male crabs or females without eggs. Adults also fed crab eggs to fledglings which later started chasing crabs. The Savannah Sparrow is very flexible in its diet and food availability is not a limiting factor for it (Wheelwright et al. 1992).

The Savannah Sparrow is commonly parasitized by the Brown-headed Cowbird. In grassland landscapes, the rate of parasitism may be influenced by tree cover. In North Dakota, there was a significant negative relationship between parasitism rates and the amount of tree cover within 2 km. The probability of parasitism was 90% when there was 2% tree cover within 2 km, dropping to 0% at 3-5% tree cover and remaining at 0% with increasing tree cover. All nests were in areas with 2-15% tree cover and 92% of parasitism occurred in areas with 2-3% tree cover. Woodlands support higher densities of breeding birds and a greater diversity of potential hosts for cowbirds (Pietz et al. 2009). In Saskatchewan, there were no significant differences in distances to potential cowbird perches or amount of concealment for parasitized and unparasitized nests. In Minnesota, parasitism rates decreased with increasing distances to wooded edges (Swanson 2002). Klippenstine and Sealy (2008) artificially parasitized Savannah Sparrow nests with natural and artificial cowbird eggs and blue eggs. Some nests were naturally parasitized by cowbirds. Sparrows successfully ejected 1 real cowbird egg and were unsuccessful in ejecting another resulting from natural parasitism. For artificially parasitized nests, 11.1% of artificial and 0% of natural cowbird eggs were rejected and 13.3% of blue eggs were rejected. Puncture ejection was used to expel eggs from nests. It appeared to be reluctant to eject cowbird eggs, possibly due to their similarity to their own eggs which increases the risk of ejecting their own eggs. Although the Savannah Sparrow may successfully fledge both its own young and cowbirds from parasitized nests, parasitism decreases reproductive productivity. Parasitized nests have smaller clutches and fledge fewer young. In Saskatchewan, clutch size was 2.9 eggs in parasitized nests and 4.4 in unparasitized nests; 0.1 fledgling was produced in parasitized nests compared with 1.1 in unparasitized nests, and 2.0 fledglings were produced in successful parasitized nests compared with 3.5 in successful unparasitized nests. In Alberta, clutch size was 1.6 eggs in parasitized nests and 3.1 in unparasitized nests. Successful nests produced 1.9 fledglings in parasitized nests and 3.6 in unparasitized nests. Predation rates did not differ between parasitized and unparasitized nests (Davis 2003; Ludlow et al. 2014; Winter et al. 2004). Cowbirds may further reduce productivity by attacking nestlings or destroying eggs in unparasitized nests. This may result in renesting which potentially provides additional opportunities for parasitism (Granfors et al. 2001). In Ontario, 44 of 607 nests (7.2%) were parasitized. Parasitism rates from other locations include 0 of 41 nests in West Virginia; 45 of 675 nests (6.7%), 31 of 150 nests (20.7%), and 13 of 83 nests (15.7%) in North Dakota; 24 of 83 nests (28.9%) and 2 of 27 nests (7.4%) in Saskatchewan; 11% of nests in Alberta; 34 of 160 nests (13.1%) in Montana; 4 of 405 nests (1.0%) in Wisconsin; 5 of 398 nests (1.3%) in New Brunswick; 0 of 479 nests in Michigan; 1 of 128 nests (0.8%) in New York; 2 of 232 nests (1.3%) on Sable Island; 46 of 687 nests (6.7%) in Minnesota and North Dakota; and 2 of 203 nests (1.0%) in British Columbia (Campbell et al. 2001; Davis 2003; Dixon 1978;

Gaudet et al. 2020; Granfors et al. 2001; S.L. Jones et al. 2010; Ludlow et al. 2014; Norment et al. 2010; Peck and James 1998b; Pietz et al. 2009; Renfrew et al. 2005; Wheelwright and Rising 2020; Winter et al. 2004; Wray et al. 1982).

Habitat loss and degradation is occurring in southern Ontario due to natural succession, reforestation, urbanization, and changes in agricultural practices. Marginal farmlands have been abandoned and allowed to succeed into forest and other areas have been actively planted with trees. Natural succession is the most important factor affecting habitat on the southern Canadian Shield and the area immediately south of it. Natural succession is less of an issue in southern Ontario agricultural landscapes, where changes in agricultural practices are a more important source of habitat loss and degradation. These include reductions in the amount of pastureland and hayfields and conversion to cash crops such as soybeans and corn. Although the Savannah Sparrow may nest in row crops, it does so at much lower densities than in grasslands, hayfields, and pastures. Declines in the Carden Plain between the 2 atlases were a result of conversion of pastures and hayfields to row crops and invasion of shrubs in grasslands (Merondun et al. 2024). Similar results have been documented in most areas (Bonneau in Gauthier and Aubry 1996; Wheelwright and Rising 2020).

Another significant factor affecting habitat quality for the Savannah Sparrow is the change in composition of hayfields. Ontario hayfields were originally dominated by grasses and clovers in the genus *Trifolium*. They are now dominated by alfalfa. Alfalfa grows much denser than other hay types and is less appealing to Savannah Sparrows. Alfalfa grows more quickly and can be cut earlier and more frequently than other hay crops. This results in hay being cut before young can fledge from nests. Numerous studies examined the effects of mowing on the Savannah Sparrow, but there is no consistent pattern of response. Shustack et al. (2010) studied hayfields that were mowed 1-4 times annually in Vermont and New York. It had an affinity for recently cut fields and was negatively correlated with the amount of time since cutting and fields with taller vegetation. It was positively correlated with fields that were cut more often. Seventy-one percent of fields that were cut retained the same number or gained Savannah Sparrows. It appeared to be attracted to mowed fields and may have immigrated into them. Most birds renested in New York and Vermont hayfields after mowing and successfully fledged young after both the first and second cuts (Fajardo et al. 2009). In the same area, fields cut before 11 June and again in early to mid-July resulted in 99% nest failure. After haying, sparrows immediately renested but fledging success was low. Reproductive success was greater in fields cut once between 21 June and 10 July and in those cut after 1 August (Perlut et al. 2006). Densities increased in Wisconsin hayfields after mowing (Swanson 2002). Norment et al. (2010) studied pastures, hayfields, and fallow fields in New York. Fallow fields were left undisturbed. Pastures or hayfields were lightly grazed or mowed after 1 August. Nest survival was higher in pastures and hayfields than in fallow fields. In Vermont and New York, Perlut et al. (2008) compared Savannah Sparrow survival rates in hayfields cut before 11 June and again in early to mid-July, hayfields cut once between 21 June and 10 July, hayfields cut after 1 August, and rotationally grazed pastures. Survival on late-hayed fields was more than 25% higher than for all other treatments. Male survival rates were 35% higher than for females. Recruitment was higher in more intensively managed fields than in late-hayed fields, indicating a greater turnover of individuals in more disturbed areas. In Nova Scotia, Nocera et al. (2007b) concluded that third hay cuts after August could be beneficial. This potentially delays the first harvest in the following year. In Massachusetts, it

was equally abundant in grasslands that had been mowed and those that had been left undisturbed (Zuckerberg and Vickery 2006). Zalik and Strong (2008) studied the effects of hay cropping in Vermont on invertebrate biomass and Savannah Sparrow productivity. In control fields, invertebrate biomass increased throughout the season. Biomass declined 28-82% after cutting in treatment fields. As vegetation height increased, invertebrate biomass quickly recovered. There were no differences in clutch sizes for either first or second broods in control or treatment fields. The number of young fledged per successful nest where clutches were completed after 24 June was lower on cut fields (2.2) than uncut fields (3.2), but not significantly. Adults brought 48% more food mass per trip on uncut than cut fields and the number of trips made was similar in both habitats. In both Saskatchewan and Alberta, the Savannah Sparrow was more abundant in grasslands and tame hayfields that had not been cut for 3 or more years, although it did nest in fields that had been cut the previous summer. In another Alberta study, it occurred significantly more on undisturbed plots than those that had been mowed or grazed. In Illinois, it was more common in recently mowed grasslands (within 4 months of 1 May) than in unmowed grasslands. These provided the low and medium height vegetation that it prefers. In North Dakota, it was more abundant in CRP lands that had been mowed the previous year than in undisturbed areas (Owens and Myers 1973; Swanson 2002). Wheelwright and Rising (2020) concluded that earlier and more frequent harvest in agricultural grasslands was a major cause of decline for the Savannah Sparrow. Tews et al. (2013) considered it to be at high risk due to haying operations in Canada. It had the highest annual mortality of any species, in part due to its high density and broad geographic range. They estimated direct mortality of 940,697 eggs and nestlings; 75,094 of these were estimated to occur in the Carolinian Forest Region of Ontario and an additional 187,737 mortalities were estimated for Bird Conservation Region 12 which includes the remainder of the area in Ontario south of the Shield as well as portions of Manitoba and Quebec. Wolcott et al. (2023) recommended that grassland management be deferred until August to protect both nests and fledglings.

van Vleit et al. (2019) compared nesting success and fledgling survival of the Savannah Sparrow in southwestern Ontario in agricultural and non-agricultural habitats. Agricultural sites were monocultures of corn, soybeans, or winter wheat. Non-agricultural sites were open areas dominated by nonnative grasses and herbaceous species. In agricultural lands, all nests were in grassy laneways and margins between crops. The daily survival rate of nests was negatively influenced by intensive agriculture, with 11% probability of nest survival in agricultural land compared with 27% in non-agricultural land. Land use did not affect fledgling survival, clutch or brood size, arthropod abundance, or condition of adults or nestlings.

In Manitoba, the Savannah Sparrow nested on transmission line and highway rights-of-way. It was less abundant on rights-of-way surrounded by more wooded lands or more urban lands. Numbers on plots were 4-6 at 0% wooded lands (trees and shrubs) within 100 m, declining to 1 at 50% wooded lands. Numbers were 5.8 when there was no urban land within 100 m, declining to 1.3 at 50%. Densities increased along rights-of-way that were mowed more frequently and were higher within hayed than unhayed rights-of-way. Occupancy decreased as the percent bare ground increased (Leston and Koper 2017).

In Alberta, abundance and productivity increased when winter and spring wheat crops were managed with minimal tillage practices rather than conventional tillage. In Iowa, the Savannah Sparrow nested at low density in untilled corn and soybean fields that were idle in spring and autumn and contained crop residue year-round. Conservation tillage may create an ecological trap. Birds may be attracted to the habitat but have low nesting success (Swanson 2002).

Grazing may be detrimental or beneficial depending upon the intensity of grazing and the initial density of the vegetation. Light to moderate grazing in dense vegetation may make it more suitable for the Savannah Sparrow. Intensive grazing or grazing where vegetation is initially sparse may be detrimental. In short and mixed-grass prairies, moderately and heavily grazed areas do not provide the dense ground cover it requires. In the Great Plains, there were higher densities on idle or lightly grazed grasslands than on moderately or heavily grazed grasslands. In Saskatchewan, densities were more than 25 times higher in ungrazed than grazed grasslands. It foraged there most frequently in grazed grasslands but nesting density was consistently lower in grazed than ungrazed grasslands (Swanson 2002). In addition to altering the habitat by grazing, cattle can have direct impacts on nesting success. Cattle may trample nests or lie on them and even actively depredate eggs and nestlings (Nack and Ribic (2005). Campomizzi and LeBrun-Southcott (2022) studied the effects of rotational grazing in Grey County on a 234-ha pasture subdivided into 21 2.6-20.5-ha fields by temporary fencing. Grazing was initiated in late May for 1-12 days and rested 4-7 weeks before being grazed again. The Savannah Sparrow was resilient to grazing, but nested more frequently in ungrazed grasslands. It renested after nest loss and continued to nest throughout the season.

The impacts of fire on the Savannah Sparrow vary depending upon the initial structure of the habitat and intensity of the fire. In Saskatchewan, it was adversely affected by an autumn burn in fescue prairie. Density in the burn was 48% of that in the control area the first year postfire, 36% in the second year, and 68% in the third year. This population used shrubs for nesting cover and song perches and fire greatly reduced the density of shrubs. The response in the third year may have been related to recovery of snowberry, the dominant shrub (Pylypec 1991). In Massachusetts, there was no difference in its abundance in burned and unburned native grasslands (Zuckerberg and Vickery 2006). In Illinois, densities were highest in grasslands during the first season postfire and it was absent by the third season postfire. It preferred recently burned grasslands for nesting. In Wisconsin, highest densities occurred in recently burned restored tallgrass prairie. In Minnesota, Wisconsin, and South Dakota, highest densities occurred in grasslands that had not been burned for a year or more. At other sites, it was concluded that 2 or more years were required for sufficient litter to accumulate to provide suitable nesting habitat. At 2 sites in North Dakota, highest densities were attained 1-5 and 6-8 years postfire (Madden et al. 1999; Swanson 1996, 2002).

In tundra areas, Savannah Sparrow habitat may be lost or degraded due to excessive browsing by Snow Geese. Grubbing by geese removes graminoid species, resulting in higher soil temperatures, higher evapotranspiration rates, and increased soil salinity. Sites may take decades to recover even after goose grazing has ceased. Near Cape Churchill, the Savannah Sparrow nested in freshwater sedge meadows dominated mostly by water sedge. Areas that had not been grazed by geese supported 1.85 times higher density of sparrows than grazed areas. At La Pérouse Bay, grubbing by geese affected the dwarf willow and birch habitat that it favoured. Density of sparrows

in 1965-67 was 6 times greater than in 2000 and 4 times greater than in 2011. There was no change in density during 1977-2012 on a BBS route 30 km distant where there was no goose damage. It was estimated that the Savannah Sparrow population in the Churchill region declined about 50% from 1965-67 to 1991 as a result of goose grazing, and there was an 80% decline over 36 years at La Pérouse Bay (Jehl 2004; Peterson et al. 2014; Sammler et al. 2008).

Shaffer and Buhl (2015) studied the reactions of the Savannah Sparrow to wind turbines in North Dakota and South Dakota. There was a significant and immediate displacement behaviour, with lower density 100-300 m from turbines than at reference sites. Displacement was observed at 200-300 m at 1 site and 100-300 m at another. Hamilton et al. (2011) and Ludlow et al. (2015) studied responses to facilities associated with oil and gas extraction in Alberta. These include wells, roads, trails, and a network of pipelines. Areas near these sites had a higher proportion of nonnative plant species, particularly crested wheat grass, and the vegetation is often taller in these areas. At 1 study area, the Savannah Sparrow was significantly more abundant with higher occurrence in disturbed areas, particularly in areas of high well density. It preferred taller vegetation and disturbed areas where there was more crested wheat grass. In the other location, nest locations relative to wells, roads, and trails did not differ from random and proximity to these features did not affect nest success. Sparrows fledged more young closer to wells than distant from them and the number of young fledged per successful nest increased as the percent coverage by crested wheat grass increased. Despite the higher success rate in crested wheat grass, density was lower in this grass. In Alberta, its abundance, clutch size, and nesting success were affected by distance to infrastructure and by gas well density. Infrastructure seemed to positively affect clutch size with largest clutches adjacent to oil wells, roads, and shallow gas wells. Abundance declined with increasing gas well density, suggesting that these affected a very large area for this sparrow. Clutch sizes declined with increased density of gas wells. Noise did not appear to be a factor because results were similar at quiet gas wells and noisy oil wells (Daniel and Koper 2019). In Alberta, Warrington et al. (2018) studied the effects of noise from 4 types of oil and gas extraction infrastructures on the Savannah Sparrow's song. There was no effect on its entire song, but song minimum frequency increased with ambient background noise. Most effects occurred at generator-powered oil well pumps, the loudest type of infrastructure which measured 80-88 dB within the frequency range of the Savannah Sparrow's song.

Severe weather and catastrophic events may affect reproductive success of entire populations in certain years. In more northern areas and at high altitudes, cold and wet weather can cause widespread nest losses that may affect annual production. Such events have been documented near Churchill, Quebec City, and in British Columbia alpine meadows (Jehl and Hussell 1966a; LaPointe and Bédard 1986; Martin et al. 2009). In British Columbia alpine habitat, nest survival was lower in colder years and was negatively correlated with cumulative precipitation. Nest mortality was approximately 4.6 times greater after 2 or more days with rain than following days without rain (Martin et al. 2017). Birds nesting near saltwater marshes may have their nests inundated by spring tides, which are higher during full and new moons. Birds can still nest successfully if they squeeze the nesting cycle between 2 high tides and situate the nest above the upper level of the neap tide (Bédard and LaPointe 1984).

Certain herbicides and pesticides may have adverse effects on the Savannah Sparrow. In Wyoming, mortality was observed after fenthion was sprayed to control mosquitoes. In Maine, density decreased for 2-6 years following application of the herbicide hexazinone on lowbush blueberry. In Ontario corn fields, there was no significant difference in its abundance before and after application of fonofos and tertbufos to control corn rootworm, or between treated and control fields (Swanson 2002).

Niemuth et al. (2008) concluded that the Savannah Sparrow was adversely affected by drought in North Dakota. Densities were lower in drought than wet years and its abundance was significantly correlated with the number of ponds present in May in the same and previous years.

Nixon et al. (2016) used climate models to predict the change in area of suitable climate in Alberta for the Savannah Sparrow. They predicted that there would be a 10% decline in area of suitable habitat by the 2050s and a decline of about 24% by the 2080s. It was anticipated that it would experience declines in suitable land cover within its projected suitable climate of 28% by the 2050s and 60% by the 2080s.

Wheelwright et al. (1997) studied nesting of the Savannah Sparrow in relation to an American Herring Gull colony in New Brunswick. The American Herring Gull is a potential predator of eggs and nestlings, but may also help to defend nests against the American Crow, a more efficient predator. Density was almost 2 times higher where gulls were absent than where they were present. Those nesting near gulls disproportionately selected nest sites with dense patches of lowbush blueberry and goldenrods. Vegetation surrounding their nests was 4.5 times taller than those nesting in areas of low gull density. Gulls were ineffective in finding Savannah Sparrow nests and typically found them only when females flushed from the nests. Gulls reacted strongly to crow models and attacked them. Where gull densities were intermediate or high, 70.7% of sparrow nests fledged at least 1 young, significantly more than in areas of low or no gull densities (55.7%). Despite the apparent advantage of nesting among gulls due to protection from crows, Savannah Sparrows avoided gulls.

Miller and Fair (1997) concluded that parasitism by blow flies did not have an impact on Savannah Sparrow reproductive success.

Swanson (2002) provided management recommendations for the Savannah Sparrow: remove woody vegetation within and along the periphery of grassland patches to discourage predators and enlarge the amount of interior habitat; grassland restoration areas should be 50 ha or larger and preferably 100 ha or larger; avoid burning, mowing, and moderate-to-heavy grazing in suitable habitat from 1 May to 1 August; burn grasslands in early spring or late autumn; in grasslands 50 ha or larger, burn 25-30% annually and burn every 5-7 years in mixed-grass prairies; where possible, delay mowing hayfields until mid-July; when mowing must be done during the breeding season, mow only half per year; and grazing that leaves 40% of vegetation cover 25 cm or more tall can be used to create the intermediate vegetation height and density that it prefers.

Price (2004) predicted that the Savannah Sparrow might not continue to breed in southern Ontario if the average summer temperature increased by 2°C.

Status

McIlwraith (1894) stated that the Savannah Sparrow was not plentiful. By the 1940s, it was common in Hamilton and could be found in almost all cultivated and pasture lands in rural areas in the 2000s (Curry 2006). It was scarce on the mainland near Kingston in the early 1900s, but common on Simcoe Island where the forest cover had already been cut. It was rare inland from Kingston and Lake Ontario in 1859 but a very common summer resident in the 2000s (Weir 1989). In Elgin County, it was common in 1891 and 1954. In 2000, it was still common but local in distribution, with considerable habitat loss in the previous 50 years due to cash cropping (Lancaster et al. 2004). Baillie and Harrington (1937) considered it one of the most common sparrows that bred in suitable habitat throughout the province. Manning (1952) concluded that it was the most common nesting passerine along the Hudson Bay and James Bay coasts and Peck (1972) stated that it was probably the most common species at Cape Henrietta Maria. During the first atlas, Rising (in Cadman et al. 1987) concluded that it was the most common species nesting in fields and meadows throughout the province. Its range covered the entire province except for notable gaps in the heavily forested areas in the northern portion of the Boreal Forest Region and in the Algonquin Park area. Although it occurred in the southern portion of the Shield, it was not very common in this largely forested habitat. Highest densities occurred along the Hudson Bay and James Bay coasts and in agricultural landscapes south and east of the Shield. James (1991) considered it an abundant summer resident throughout the province.

The second atlas revealed no significant change in the distribution of the Savannah Sparrow. It was found in more blocks within the Boreal Forest Region but continued to be relatively scarce in this area. There was no change in its probability of observation except in the Hudson Bay Lowland, where it increased significantly. It experienced a nonsignificant increase in the province. It was most abundant along the Hudson Bay coast, at the northern extent of the James Bay coast, and in portions of the agricultural landscape south of the Shield. In this region, highest densities occurred in agricultural areas in Lambton, Huron, Bruce, Dufferin and Wellington counties; on the Carden Plain; in the Haldimand Clay Plain; and in the extreme southeast of the province. It remained scarce in the Algonquin Park area and the Shield, where it is restricted to the Clay Belt, pastureland, airports, and natural forest openings (Rising in Cadman et al. 2007).

BBS results indicate that the Savannah Sparrow decreased at annual rates of 2.11% in Canada and 4.05% in Ontario 1970-2021, and 3.93% in Canada and 5.35% in Ontario 2011-21. Results were highly reliable except that the long-term trend for Ontario was of medium reliability (A.C. Smith et al. 2023). The BBS method is a bit deficient because it does not sample northern populations where there are no roads.

POSTFLEDGING PERIOD

Adults divide the brood shortly after the young fledge. Males are most likely to care for the smallest fledglings, perhaps because they remain closer to the nest and the centre of the male's territory. Males contribute most of the care to first broods if the female is incubating a second clutch. Females tend to care for more fledglings from late broods. The sexes contribute equally to fledgling care and fledgling survivorship is not affected by the sex of the adult that cares for them (G.W. Mitchell et al. 2012; Wheelwright and Rising 2020; Wheelwright et al. 2000).

On Sable Island, young hide in the grass after leaving the nest until they are about 3 weeks old. On the mainland of Nova Scotia, fledglings concentrated in an area along the shoreline that was outside any territory. As many as 6 females attended their young there. This was the most luxuriant growth in the study area, being covered by a dense growth of seaside pea and beach grass. The highest concentration of midges and flies occurred there, offering an abundance of food for fledglings. Fledglings that are still being cared for by adults often wait to be fed in nest-like tunnels in the grass. Young are able to fly 1-5 m about 3 days after leaving the nest or when they are 13-15 days old and are erratic but proficient fliers by age 20 days. In New Brunswick, fledglings remained with a single parent a median of 15 days and a maximum of more than 40 days. Young became independent at age 22-24 days and gradually started to disperse from each other. The wings are fully developed by age 27 days (Ross 1980; Weatherhead 1979; Welsh 1975; Wheelwright and Rising 2020; Wheelwright et al. 1992, 1994, 2000). On Kent Island, some fledglings remained near their natal territories throughout the postfledging period whereas others travelled distances of 200 m or more shortly after fledging. Fledglings from second broods travelled further than those from first broods. Male fledglings travelled further than female fledglings. Birds from areas with high nest densities travelled further than those from areas with low or moderate nest densities. The distance fledglings moved between consecutive days increased with age, peaking around day 20-30 and then levelling off. Some individuals moved greater distances again between days late in the postfledging period, around day 70-80 (Mueller et al. 2025).

Independent juveniles 26 or more days old begin to congregate in monospecific flocks that may swell to more than 100 birds in late summer. These are often found in grassy areas and saltwater marshes. Juvenile flocks may wander distances of 0.5-1 km daily, but delay migration until 2-3 months after fledging (Baird in Austin 1968; Wheelwright and Mauck 1998; Wheelwright and Rising 2020). McIlwraith (1894) reported that the Savannah Sparrow became abundant along the marshy shores of Hamilton Bay in late summer. In Saskatchewan, juveniles and adults flock together and with other sparrow species. At first, they mix mostly with Vesper and Clay-colored sparrows but are later seen in the company of Song, Swamp, White-throated and other sparrows. These flocks tend to inhabit trees and shrubs bordering pastures and cultivated fields (Leighton et al. 2002).

In Michigan, females left the breeding grounds before initiating the moult. They usually left within 2 weeks of completing their last nest regardless of whether it failed or successfully produced young. Females left gradually through June and July. Males stayed an average of about a month later and occasionally 1.5 month later, with most leaving in the last 2 weeks of July (Potter 1972).

MIGRATION

All populations of the Savannah Sparrow migrate except those that are resident along the California coast or breed in Mexico. It is predominantly a nocturnal migrant but migration may continue into the morning either as a continuation of migration or as redirected movement. In autumn, it may occur in flocks of conspecifics or in mixed-species flocks of sparrows. Autumn migration is stimulated by cold fronts associated with high pressure that causes a sharp drop in temperature, clear skies, and strong winds from the north or northwest. Acoustical surveys conducted during spring migration on the shoreline and in Lake Erie demonstrated that the Savannah Sparrow readily crossed the lake, but fewer crossed in the central basin. The central basin of Lake Erie may act as a

partial barrier during spring migration (Baird in Austin 1968; Gesicki et al. 2016; Wheelwright and Rising 2020).

Arrival of males usually spans several days. In Michigan, all males arrived within a 10-day period in both of 2 years. Near Quebec City, males arrived over periods of 16, 19, and 24 days in 3 years. Returning males do not have to rush back in spring to claim territories because of the very high site fidelity to territories and the later arrival of yearling males. Although the first females may occasionally arrive as soon as the first males, females tend to arrive a minimum of a week later than males. In Michigan, the first females arrived 15 and 21 days after the first males in 2 years, and the intervals between male and female arrivals near Quebec City were 12, 18, and 20 days in 3 years. Females do not need to rush to acquire a mate and territory because of high site fidelity (Bédard and LaPointe 1984; Potter 1972; Wheelwright and Rising 2020).

In Ontario, the Savannah Sparrow arrives in early to mid-April with most birds passing through from late April to mid-May. Some arrive in late March or rarely in early March (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008).

In New Jersey, the average autumn stopover period for the Savannah Sparrow was 7.3 days (maximum 28 days; Seewagen and Newhouse 2018). In the southern Shield, autumn migration begins in August, peaks in September, and continues until mid-October, with some remaining until late October (Mills 1981; Tozer 2012). In southern Ontario, autumn migration occurs from mid-September to late October, but there are occasional sightings into mid-November and rarely until early December (Black and Roy 2010; LaForest 1993; Lancaster et al. 2004; Weir 2008). Near Guelph, juveniles migrated earlier than adults. The first detection of migrant juveniles away from the site was on 14 September compared with 14 October for adults. Both age classes moved in a southwest direction but 2 juveniles made northward movements (Horn et al. 2022).

In Algonquin Park, the Savannah Sparrow is first observed in spring on patches of bare ground along roadsides and in clearings and fields (Tozer 2012). It may be observed in open fields, roadsides, dune vegetation, coastal marshes, edges of sewage lagoons, and other ponds in open areas. It rarely occurs in open woodlands (Wheelwright and Rising 2020). In British Columbia, migrants occur in cultivated fields, farmsteads, airports, log-littered beaches with vegetation, along dykes, adjacent to tidal marshes, rocky islets on the ocean coast where gullies are well vegetated and support abundant invertebrates, logging clear-cuts, subalpine tundra, timberline shrubbery of dwarf birch and willow, and edges of alpine meadows (Campbell et al. 2001). In the Yukon, migrants occur in shrubby wetlands, on open mudflats, and in weedy patches near settlements and along roads (Sinclair et al. 2003). On 2 islands in the Gulf of Maine during spring migration, it was significantly more abundant on the shrubby island than the treed island (Suomala et al. 2010).

Sinclair et al. (2003) reported that the Savannah Sparrow frequented bird feeders during migration in the Yukon. During migration, it feeds predominantly on seeds and some fruits, and also consumes some invertebrates where they are available (Wheelwright and Rising 2020).

In Arizona, Bock and Bock (1992) studied the response of autumn migrant Savannah Sparrows to a wildfire. The fire burned native and nonnative grasslands, eliminating litter cover and reducing grass cover, except for an invasive love grass that covered approximately 90% of both burned and

unburned nonnative grasslands. It was absent or very rare in unburned grasslands of both types. It responded positively to fire, but only in the year of the fire. Burning increased seed production of grasses and the reduction of litter made them more available. Its abundance was negatively correlated with grass cover.

The Savannah Sparrow is frequently killed during migration by striking communication towers, tall buildings, and other structures. Severe snowstorms during migration may cause mortality (Baird in Austin 1968).

James (1991) considered the Savannah Sparrow a common migrant in the province.

Hussell et al. (1992) reported a 1.1% nonsignificant annual decline in the number of Savannah Sparrows banded at Long Point 1961-88. Trends by period were: 1961-70, −3.0%; 1970-79, −3.2%; and 1979-88, +4.4%.

WINTER

In the east, the Savannah Sparrow winters predominantly where the average minimum January temperature is higher than −1°C (Root 1988). Males winter further north than females and both sexes may move even further south later in winter in response to adverse weather. In the east, it typically winters only as far north as Delaware (Baird in Austin 1968; Wheelwright and Rising 2020). Birds observed in Ontario are far north of their normal wintering range.

In winter, the Savannah Sparrow inhabits open areas that provide an abundance of food and have a mix of sparse and dense habitats. Suitable areas may include recently fallow fields dominated by annual plants such as horseweed, fields with heavy crops of crabgrass or other suitable plants for foraging, agricultural fields with fencerows and drainage ditches, undisturbed native prairies, native prairies disturbed by mowing or fire, nonnative grasslands, pastures, golf courses, roadsides, landfill sites, salt marshes, shrub thickets, and vegetated beaches. It prefers areas with bare soil or light litter cover where it can easily move and forage, an abundance of small seeds, and an overhead cover of low- to medium-height grasses. Where habitat is uniform, birds are distributed evenly. In fields of dense horseweed where some plots were mowed to a height of 15 cm, birds were evenly distributed in unmowed areas. Those in mowed plots concentrated around edges of plots adjacent to unmowed areas. Density within 22 m of the edge of mowed plots was 3.1 times greater than in central portions. During clear and overcast days with no rain, most birds on mowed plots were within 7.5 m of the taller edge vegetation. Density on mowed plots was 3 times higher on rainy days than on clear days. Densities remained constant in unmowed areas. The usage pattern in the mowed plots appeared to be related to the potential for predation by the Northern Harrier which foraged more frequently on clear and overcast days than on rainy days. In Arkansas, Kentucky, and Mississippi, density of the Savannah Sparrow was more than 2 times greater in fields with buffers of warm-season grasses and forbs than in fields without buffers. It exhibited higher densities in buffers wider than 23 m than in narrower buffers (Baird in Austin 1968; Campbell et al. 2001; Evans et al. 2015; Gordon 2000; Saafeld et al. 2016; Smith et al. 2005; Watts 1990; Wheelwright and Rising 2020). In South Carolina, it was more aggregated where crabgrass was common (Norris 1960).

During winter, the Savannah Sparrow roosts on the ground, either solitarily or in loose aggregations of as many as 30 birds. Texas roost sites had greater total cover and grass cover than

random sites, and roosts were interspersed within or around foraging sites. The greater horizontal vegetation depth at roosts may be important because it provides space for birds to roost and move under the vegetation without being exposed. It roosted in areas that provided better protection from weather. Those foraging on the coast travelled further inland to roost. The distribution of foraging and roosting areas influences movement patterns and overall home range size. It often roosts outside its foraging range and has specific habitat requirements for foraging and roosting areas (Baird in Austin 1968; Ginter and Desmond 2005).

Although large numbers of birds may occur together, birds act as individuals most of the time. At any given time 10-15% of birds are likely to be in small flocks of 2 or 3 but the composition of these flocks constantly changes. In Texas, each individual foraged within a small flock on at least 1 occasion, always with conspecifics in loose aggregations. In Georgia, the proportion of birds was influenced by the openness of the habitat. In habitat mowed to a height of 15 cm, 17% and 20% of birds in 2 plots were individual compared with 52% and 62% in unmowed plots. Large flocks were significantly more common in open than weedy plots. Fifty percent of birds in flocks in open areas were in flocks larger than 3 compared with 25% in weedy plots. The greater tendency to flock in open habitat was probably related to predator detection (Baird in Austin 1968; Ginter and Desmond 2005; Norris 1960; Watts 1996; Wheelwright and Rising 2020).

The Savannah Sparrow is not territorial in winter but it maintains a home range. In Arizona, birds at 1 site were highly sedentary; the average net movement at another site was 186 m over 40 days. In South Carolina, birds ranged over a maximum of 5.7 ha within a week (average 3.4 ha, minimum 0.8 ha). Winter home ranges in Georgia were 6-60 ha. Movement patterns are variable and probably related to the distribution of food, predator avoidance, and the distribution of suitable foraging and roosting habitat. Birds in Texas had a mean winter home range of 9.1 ha, a mean foraging area of 5.6 ha, and a mean roosting area of 6.6 ha. The mean core foraging area (50% of activity) was 0.9 ha (range 0.15-31.7 ha). One bird moved 2 km before returning 5 days later and subsequently disappearing; another moved 800 m. Many birds occupied small areas for 1-2 months but some may wander long distances. The mean distance moved from the centre of foraging areas to roosting sites was 165 m, with some birds travelling 400-600 m (Ginter and Desmond 2005; Gordon 2000; Norris 1960).

The Savannah Sparrow may exhibit winter site fidelity. In South Carolina, 33 of 453 (7.3%) returned in subsequent years and return rates of 38% and 41% occurred in other areas. There was little evidence of winter site fidelity in Texas (Baird in Austin 1968; Ginter and Desmond 2005).

In winter, the Savannah Sparrow forages in areas that provide a mix of open and dense cover. Foraging areas had more bare ground, less visual obstruction, and less horizontal depth than random sites. Seed biomass did not differ between foraging areas and random sites. The most common food seeds of little bluestem, spikerushes, panic grass, paspalum, and crabgrass were universally present. It foraged in areas of higher seed abundance suggesting that it is attracted to areas of high resource abundance. It forages almost exclusively on the ground in winter (Ginter and Desmond 2005). The winter diet consists of about 90% seeds of grasses and forbs, with those of crabgrass, ragweed, and sorghum important. It consumes insects and spiders where they are available. In California, where invertebrates are still available in winter, the winter diet consisted of

39.2% animal and 60.8% vegetable matter. Animal food consisted of 22.7% crustaceans (10.7% crabs), 8.4% insects (4.7% beetles, plus ants and lepidopteran cocoons), and 0.4% spiders. Much of the plant material was unidentified, but 12.3% consisted of wild oats and oats, 4% stork's-bill, and 4% nightshade. At another site, 10 of 11 birds had eaten snails. These comprised 18.5% of the diet for these birds but only 7.3% for the entire sample of 28 birds (Taber in Austin 1968; Wheelwright and Rising 2020).

James (1991) considered the Savannah Sparrow rare in winter in the extreme south, north to Peterborough and Kingston. In the Kingston area, it is seen on average 1 in 4 winters (Weir 2008). In the Hamilton area, a few have overwintered since 1960, and it occurred almost annually beginning in the mid-1990s (Curry 2006).

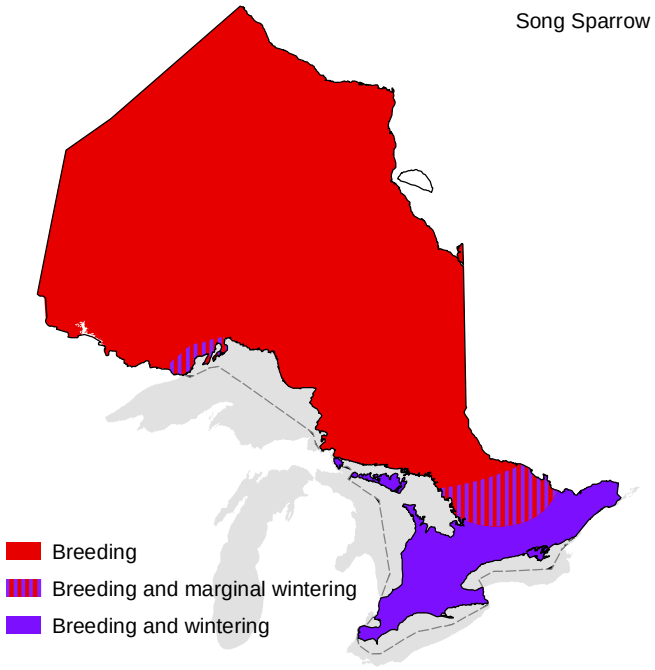
Song Sparrow

Melospiza melodia

BREEDING SEASON

Habitat Requirements

The Song Sparrow is an open-country species that nests in a wide variety of habitats, but it typically requires some shrubby areas within its territory. Of 655 Ontario nests, 40.5% were in farmland, including fields, conifer plantations, pastures, willow swales, wet meadows, orchards, vineyards, raspberry patches, hedgerows, and gravel pits; 16.9% were in woodlands including bogs, swamps, beaver ponds, and burns; 13.9% were in rural and urban areas including gardens, cemeteries, campgrounds, and cottage lots; 12.7% were in river valleys and shorelines of lakes, rivers, ponds, and marshes; 8.7% were on road, railway, or hydro transmission line rights-of-way; 5.8% were on rocky islands and outcrops; and 1.5% were in sand dunes. Nests in wooded areas were either at their edges



or where the canopy was open. Most nesting habitats were dry, but 31.3% were near water or in wet areas (Peck and James 1987).

In the Hudson Bay Lowland, Wilson and McRae (1993) found several territories at Moosonee. Most were within the town site and all were along creeks bordered with shrubs.

From Pickle Lake northward in the Boreal Forest Region, the Song Sparrow was most abundant in deciduous scrub followed by heath habitat, coniferous scrub, and mixed scrub. It was absent in all types of forest and tundra (McLaren and McLaren 1981). Near Pickle Lake, it occurred in small numbers in bogs and at lake edges (James 1980). In the Clay Belt, it was common in farms, natural clearings, lakeshore thickets, along river banks, and in old burns and similar habitats. It was common in alder thickets on rocky islands or points in rivers (Smith 1957). Near Hearst, Welsh and Fillman (1980) reported it in 3- and 6-year-old clear-cuts in lowland coniferous forests. Erskine (1977) considered it characteristic of prairie-forest ecotones where it occurred in early shrubby stages of succession and in various edge situations. It was characteristic of swamp and floodplain forests and numerous in wetter areas dominated by sedges and low shrubs such as sweet gale and willow. It is also common in northern urban areas.

In the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region, the Song Sparrow was rare in jack pine stands near Gogama. It occurred predominantly at forest edges and near water where deciduous shrubbery was present among small jack pines. It was also present in low density in a 7-year-old jack pine stand (James and Peck 1995a). In Algonquin Park, it seldom occurred within dense forests but was abundant in shrubbery, at edges of woods, and along banks of streams and lakes (MacLulich 1938). Tozer (2012) noted that it bred mostly along lakeshores or rivers, but also in other edge habitats such as margins of bogs, edges of gravel pits, and shrubby borders of fields, clearings, and log landings. Also in Algonquin Park, it was common in both wet and dry bogs where it was the third-most abundant species (Martin 1960). In Algonquin Park white pine stands, it occurred in 8.3% of cuts that were 2-9 years old. It was absent in cuts 10-16 years old and in uncut forests (Kingsley and Nol 1999). In Muskoka and Haliburton, it was associated with low canopy volume and tree density, shrubby areas, and lawns. It was associated predominantly with mixed conifers and a reduced understory and was typically found in cottage areas where much of the vegetation had been removed (Clark et al. 1983). In Muskoka and Parry Sound districts, it was abundant in all areas except deep forest; it occurred in roadsides, gardens, farmlands, and margins of streams, ponds, bogs, and lakes (Mills 1981).

South of the Shield in the Great Lakes–St. Lawrence Forest Region near Ottawa, the Song Sparrow bred in hedgerows and fence lines predominantly in corn and soybean fields, but also in hay and wheat fields. The hedgerows it inhabited varied from grassy strips with occasional shrubs to fully treed (Girard et al. 2012). In Durham Region, it occurred in old fields, hayfields, gravel pits, woodlot edges, pastures, and stream sides. It showed a strong preference for old-field habitat with very few in pastures (Speirs and Orenstein 1967). It also occurred in very young pine plantations, old orchards, open-canopy forests, woodlots grazed by cattle, and small remnant woodlands including those that were mature. It was associated with early stages of forest succession and reached its greatest abundance in young seral stages, but occurred in all stages (Speirs and Orenstein 1975).

At the landscape level in southern Ontario, Austen et al. (2001) considered the Song Sparrow an edge species. Its abundance was positively correlated with the amount of forest cover within 2 km and the amount of forest cover in the region but was negatively correlated with woodlot size and the amount of forested habitat more than 100 m from edge. These relationships were not significant. In farmland, it was equally abundant on organic and conventional farms. It was positively associated with hedgerows, woods, trees, and pastures. It was negatively correlated with use of herbicides, farmsteads, grassy strips between fields with a fence, and railway, road, and hydro corridors (Kirk et al. 2011). In Oxford and Elgin counties, it was abundant in some fields, using shrub habitats for nesting and agricultural crops for foraging (Knapton 1990). In the Hamilton area, it was found wherever there was human habitation. It commonly nests along streams that run through suburbs (Curry 2006; McIlwraith 1894).

The Song Sparrow is a generalist species that occupies several habitats. In Ontario, it is absent from only tundra, deep forests, and the interior of grasslands and agricultural fields where there are no shrubs. Despite its adaptability, it has specific habitat requirements that include some shrubs or tall herbaceous vegetation for perching and dense nesting cover but with patches where sunlight can penetrate to the ground. It is most abundant in shrubbery bordering watercourses, water bodies, and wetlands and often attains very high densities on islands. It tends to be more abundant in landscapes altered by humans where woodlands are fragmented. Shrubbery around fields, pastures, and human dwellings provides good nesting habitat. In many areas, it appears to require wet or moist soils and is usually associated with water, but this is not the case in Ontario (Arcese et al. 2020; Bonneau in Gauthier and Aubry 1996). In Ohio, some territories consisted solely of herbaceous species with no trees or shrubs (Nice 1943).

Song Sparrow breeding habitat includes thickets of willows, alders, and similar shrubs along watercourses, lakeshores, pond margins, and in and at edges of wetlands; bogs and fens; open or forested islands of all sizes; woodland edges and openings; riparian woodlands; urban parks; suburban and rural residential lots; farmsteads; native and planted grasslands where it occurs in very low densities; clear-cuts; very young plantations; old fields and pastures; shelterbelts; subalpine and alpine shrubby areas; Great Lakes and marine coastal meadows; hedgerows; roadsides; along logging roads in forests; in recent forest burns; along drainage ditches; in marshes; in unmanicured orchards; in hayfields and occasionally row-crop fields; in fields managed for biofuel production by grasses; in areas managed for blueberry production; along pipeline and hydro transmission line corridors; along railway rights-of-way; and near brush piles. In British Columbia, 30% of nests were

near the edge of a forest, 24% were in wetlands, 22% were in clear-cuts, 21% were in shrublands, 2% were in grasslands, and 1% were in miscellaneous habitats (Arcese et al. 2020; Burhans et al. 2010; Campbell et al. 2001; Dawson 1979; DeGraaf 1989; Finch 1989b, 1991a; Graber and Graber 1963; Hartley 1994; Hoffman 1989b; Howe 1979; Keller et al. 2003; Judd 1901; Morse 1977; Mossman et al. 1991; Nice in Austin 1968; Nolan in Austin 1968; Patterson and Best 1996; Renken and Dinsmore 1987; Riffell et al. 2001; Robertson et al. 2012; Taylor and Taylor 1979; Vickery et al. 1994; Wilson and Arcese 2006; Yahner et al. 2002). The Song Sparrow frequents all these habitat types in Ontario and is found essentially wherever there are at least scattered shrubs. It may be found in almost all edges between habitat types.

At the landscape level, the Song Sparrow greatly prefers open or fragmented landscapes to forested areas. In Quebec, its frequency of occurrence is highest in the highly disturbed south with its abundance of abandoned fields and edge habitat resulting from forest fragmentation. It is less abundant in the north where the landscape is dominated by coniferous forest. There it is confined to disturbed areas and openings such as clearings, logging roads, and margins of lakes, rivers, streams, and wetlands (Bonneau in Gauthier and Aubry 1996). Its relative abundance is similar in Ontario. In Saskatchewan, it was significantly more abundant in small forest fragments or in landscapes with low local forest cover (Hobson and Bayne 2000). In North Carolina, it was negatively correlated with the amount of tree canopy coverage at the 200-m scale. As tree cover increases, shrub coverage decreases. It was positively correlated with habitat heterogeneity at the 200-m scale. Heterogeneous landscapes consisted of a mosaic of forest patches, lawns, and pastures. Homogeneous landscapes consisted of unbroken forest tracts (Gilbert and Ferguson 2019). It preferred areas with 51-75% forest cover in North Dakota and 23-45% tree cover in New York (Cunningham and Johnson 2019).

Several studies identified microhabitat preferences of the Song Sparrow in open habitats or compared its usage of shrubby and forested habitats. In riparian willow habitat in Colorado, it was equally abundant in short dense willows and tall sparser willows (Olechnowski and Debinski 2008). In Massachusetts grasslands interspersed with shrubs, it was positively associated with grasses 0.1-0.5 m tall and shrubs of the same height but negatively correlated with litter 0-0.1 m from the ground (Zuckerberg and Vickery 2006). In Massachusetts, DeGraaf (1989) compared territories in suburban and rural areas, which consisted mostly of country roadsides with scattered houses. The size of rural territories was significantly correlated with the amount of herbaceous vegetation. Suburban territories were significantly associated with the number of adjacent territorial males, shrub density, and shrub crown volume. All territories contained at least 70 shrubs per ha. Territory size was smallest where herbaceous vegetation and shrub cover were low. Territories that were not bordered by other territories appeared to be marginal but acceptable habitat. There may be a requirement for some openness in territories because territories were larger when both shrub numbers and volumes were greater. Habitats consisting entirely of shrubs may be marginal. In suburban areas of Massachusetts, its abundance was positively correlated with the volume of deciduous vegetation 1.8-3 m from the ground and herbaceous vegetation, and negatively correlated with the volume of deciduous vegetation 7.9-9.1 m from the ground. It preferred open situations and open shrub-herbaceous areas provided optimum habitat (Thomas et al. 1977). In Utah, Arizona, and Nevada, it occurred in areas of high shrub density with little canopy cover and

moderate ground cover (Whitmore 1977). In Michigan Great Lakes coastal marshes, its abundance was positively associated with increasing frequency of bulrushes and negatively correlated with tall dense grass (Riffell et al. 2001). In Iowa riparian habitat, its abundance decreased with sapling and tree richness and density, shrub density, and number of trees (Stauffer and Best 1980). In Pennsylvania, Smith and Hatch (2008) compared Song Sparrow usage of forested and shrubby habitat. The number detected per 100 m of transect was 0.07 in forest and 0.35 in shrubs. The number captured per 1,000 hours of netting was 0.2 in forest and 0.35 in shrubs. Usage of shrubs was significantly greater for both survey techniques. In British Columbia, it was significantly more abundant in riparian vegetation consisting of a dense understorey of deciduous vegetation than in adjacent coniferous forest (Wiebe and Martin 1998). In Illinois, it was most abundant in early shrub habitat where the oldest trees were 10 years old, followed by late shrub habitat where the oldest trees were 37 years old, and in areas dominated by bare soil. It was not detected in bottomland forest or upland maple-oak forest (Karr 1968). On hydro corridors in Pennsylvania, it was absent where shrubs were cut and more abundant where low basal area was retained and where foliage had been sprayed (Yahner et al. 2002). In Indiana, its abundance was almost 0 where there was 0-85% low ground vegetation, increasing abruptly as ground cover increased to 95% (Grundel and Pavlovic 2007a).

In forests, the Song Sparrow prefers very young stands, stands dominated by early successional species such as aspens, forests with very low canopy cover or with large openings where shrubs can grow, or riparian forests rather than upland forests. In Nova Scotia northern hardwoods, it was most common in stands 1-2 years old, uncommon in stands 5-12 years old, and absent in stands 20 or more years old. It was characteristic of young stands and one of the more abundant species. Also in Nova Scotia, it was absent in uncut forests, abundant in clear-cuts, uncommon in thinned forests, and absent in strip-cuts and shelterwood cuts. In New Brunswick spruce plantations, it was common in stands 3-8 years old and absent in stands 13 or more years old (Freedman and Johnson 1999; Freedman et al. 1981). In Quebec, it was common in clear-cuts in both deciduous and mixed stands, slightly less common in final cuts using the strip-cut method, and absent in young, medium-aged, and old strip-cuts (Falardeau et al. 1999). In Minnesota, it was associated with harvested areas but not forested plots (Hanowski et al. 2003). In the Prairie Provinces, it was associated with mixed-wood or deciduous forests that tended to be nutrient-poor and slightly damper than average. It was a very early successional species associated mostly with stands 0-9 years old (Kirk et al. 1996). In green ash woodlands in South Dakota, it occurred in low densities in young stands and was absent in old stands. Young stands had less overhead tree cover and small trees and shrubs in the understorey, and some had grass in the understorey (Rumble and Gobeille 1998). In Wisconsin upland deciduous forests, it was associated with young dense forests occasionally interspersed with snags after clear-cutting, but did not occur in more mature stands (Hoffman 1989a). In northern hardwoods in the northeast, it occurred in 20% of plots in mature undisturbed habitat and 47% of disturbed and early successional forests (Noon et al. 1979). In poplar-birch stands in the northeast, it was the fourth most abundant species. It was common in sapling-pole-stage forests but absent in pole-stage and mature stands (Back 1979). In pine forests in the northeast, it was common in seedling-sapling-stage forests, less common in pole-stage forests, and absent in older stands. After fire in pitch pine stands, it was absent 0-1 years after fire and present at low density 2-20 years after fire (Capen 1979). In

northeastern mixed forests, it was associated with increasing abundance of aspens (Temple et al. 1979). In clear-cuts in Minnesota, the Song Sparrow was the fourth most abundant species. It was negatively correlated with the density of both dead and live trees and the basal area of live trees. It occurred in open habitats dominated by shrub patches (Niemi and Hanowski 1984a). In North Dakota, it occurred in all forested habitats but was most abundant in willow shrub communities (Faanes and Andrew 1983). In California, Larison et al. (2001) examined Song Sparrow usage of natural and restored cottonwood-willow riparian habitats. Restored areas were not underplanted and were occasionally grazed in winter. The probability of a site being selected for nesting increased as foliage cover 0-1 m from the ground increased. In restored areas, it was increasingly likely to nest as foliage cover 2-3 m from the ground increased but this was not the case in natural areas. At the nest-patch scale of 5 m, the probability of nesting increased as lateral cover increased. The probability of nesting decreased with increasing foliage height in natural stands and increased in restored habitats. Nest-scale variables were much more important than nest-patch variables in selecting nest sites. The mean foliage cover was 67.8% at 0-1 m and 13.1% at 1-2 m from the nest. Restored stands had significantly fewer plots with above-average foliage cover at 0-1 m and 2-3 m than natural stands. Nests with higher forb cover were less likely to be depredated. Although forb cover was important in determining predation rates, it was not important in nest-site selection. Restored sites had low foliage cover and provided poorer nesting habitat. Birds that nested in restored areas had lower reproductive success. On islands in Wisconsin, the Song Sparrow occurred in red pine and poplar stands. It was significantly associated with aspen and appeared to prefer pioneer forests and pine to some extent (Beals 1960). In Illinois forests, its abundance was significantly correlated with shrub density and mean litter depth (Herkert 1994a). In Wisconsin and Minnesota, it occurred significantly more often in floodplain than upland forests (Kirsch et al. 2013). In North Carolina, forest-breeding Song Sparrows were positively correlated with the number of buildings within 200 m and negatively correlated with forest canopy closure (Lumpkin and Pearson 2013). In Wisconsin floodplain forests, it demonstrated a slight preference for wet forests (Mossman 1988). In aspen forests in western North America, highest densities occurred where large well-spaced trees with moderate shrub coverage were present. Where it occurred, there was always surface water present nearby (Flack 1976).

In Pennsylvania, the habitat of Song and Swamp sparrows differed considerably with the greatest difference being the amount of water cover in the territories: 92% for the Swamp Sparrow and 13% for the Song Sparrow. The distinction was even greater if a single Song Sparrow territory was removed from the analysis: 92% compared with 8%. There were significant differences in certain habitat characteristics in Song and Swamp sparrow territories respectively: forb cover, 59.4% compared with 34.4%; rush cover, 7.1% compared with 25.0%; raspberry cover, 2.7% compared with 0.1%; water cover, 13.2% compared with 92.2%; and water cover and moist areas, 15.9% compared with 97.0%. Other average characteristics of Song Sparrow territories that did not differ from Swamp Sparrow territories included 22.8% grass cover, 92.1% total ground cover, 0.75 m ground cover height, 0.59 shrubs per 3.14 m^2, and 5.5 cm water depth. Whether a particular area was defended by a Song or Swamp sparrow could be predicted with 90% accuracy based solely upon whether there was standing water or saturated soils. A beaver pond was defended by 5 Swamp Sparrows in a year prior to its drainage. The following year, it was defended by 5 Song Sparrows. Extensive rains resulted

in reflooding and Swamp Sparrows moved 50-300 m into Song Sparrow territories, but the Song Sparrows did not abandon their territories. The earlier-arriving and dominant Song Sparrow did not attempt to colonize marsh habitat and left it for the Swamp Sparrow. The Song Sparrow is incapable of moving through water and searching for food on its surface as the Swamp Sparrow does (Greenberg 1988). In Wyoming, Salt (1957) examined habitat partitioning by the Song, Lincoln's, and Fox sparrows in willow thickets and marshes. The Song Sparrow inhabited stream margins and open water where willow formed a dense thicket 1.8-3 m tall. The Lincoln's Sparrow inhabited drier areas with clumps of willow 0.6-1.2 m tall. The Fox Sparrow frequented grassy glades surrounded by willows 3-3.6 m tall. The Song Sparrow occurred wherever there was open water, typically along streams and willows. In Maine in large mainland forests and deciduous edge areas, the Song Sparrow coexisted with the White-throated Sparrow and Dark-eyed Junco. The junco did not nest on adjacent small islands and the White-throated Sparrow did so only sporadically and did not nest on islands where there was a high density of Song Sparrows. On islands, the Song Sparrow foraged regularly in the interior of spruce forests and, on small islands, it foraged in the low live foliage of spruce, a foraging technique not observed elsewhere. There was a competitive release for the Song Sparrow on small islands (Morse 1977). On very small islands in Minnesota, the Song Sparrow spent considerable time on the forest floor and also in dense shrubs, along rocky shorelines, amongst fallen trees, and near the top of the canopy. It used a wider diversity of habitats on islands with fewer regularly occurring species (Howe 1979).

The Song Sparrow is not an area-sensitive species. In areas of suitable habitat, area has either no effect on its abundance or it may be negatively correlated with larger patch sizes. In forested habitats, it tends to decrease with increasing patch size. It may inhabit very small areas, particularly on islands. In Michigan, it nested on 7 small islands ranging from 0.04 to 1.1 ha. It remained on the island where it nested and did not visit adjacent islands or the mainland (Howe 1979). In Maine, Morse (1977) studied islands 0.1-4.0 ha in area and it nested on every island every year including the 2 smallest islands (0.10 and 0.11 ha). Two pairs nested on an island that was only 0.16 ha. In Illinois grasslands, it occurred in all sizes of grasslands; the smallest field was 7 ha (Walk and Warner 1999). In Michigan Great Lakes coastal marshes, its abundance was significantly associated with the perimeter-to-area ratio but patch size had no effect on its abundance (Riffell et al. 2001). In Illinois grasslands, it was negatively correlated with patch size (Herkert 1994a). In pure grasslands, there may be few or no shrubs in the interior of the patch and it may be confined to edges. In Maine grasslands managed for blueberry production, its abundance was negatively correlated with patch area but positively correlated with shrubs 0.6-2.0 m tall and with forbs. Larger sites were more intensively managed and supported a lower proportion of tall shrubs. The probability of occurrence of the Song Sparrow was 80% in 0.5-ha patches, 40% in 1-ha patches, 10% in 10-ha patches, 0.2% in 100-ha patches, and 0% in 1,000-ha patches (Vickery et al. 1994).

At night, the Song Sparrow roosts in dense herbaceous vegetation and shrub thickets, usually close to the ground. It also frequently roosts in hedges and conifers. One nest was constructed for a night roost. In Maryland, a Northern Mockingbird constructed a nest 1.8 m up in a white cedar against the wall of a house. After the mockingbird abandoned the nest, a Song Sparrow immediately adopted it as a night roost (Arcese et al. 2020; Brackbill 1976; Nice 1943).

Most (61.0%) Ontario nests were on the ground but the remainder were elevated in shrubs, trees, vines, and herbaceous plants; on human-made objects and buildings; and on muskrat houses and brush piles. Ground nests were usually well concealed in or under clumps of grasses, ferns, mosses, and other plants; under trees, shrubs, and vines; under fallen branches, brush piles, dead leaves and litter, logs, and roots; under sandbank overhangs; at bases of stumps, fence posts, and boulders; and on an anthill. Twenty-nine nests (3.7%) were on bare ground with 9 in depressions in the ground. One ground nest was under a piece of plywood imbedded obliquely in a sand beach. Elevated nests were in coniferous trees and shrubs (7 species, 55.0% of elevated nests) or in deciduous trees, shrubs, and vines (21 species, 45.0% of elevated nests). The most frequently selected species were juniper (48 nests), white cedar (34), spruce (29), hawthorn (27), pine (25), and raspberries (20). Elevated nests were in tufts of grass (17 nests); cattails, sedges, or rushes (7); goldenrods (4); vetch (3); ferns (2); 1 nest each in artichoke, purple loosestrife, and daisy; in cavities in stumps and trees; and 1 each in a roll of fence wire, on a low fence wire in a grass clump, in weeds left in a wheelbarrow, on a ledge in a boathouse, in a mound of hay, in a bed of plants in a greenhouse, in a tin can, and in a depression in mosses and grasses covering a stump and roots. Elevated nests in trees and shrubs were 0.08-3.7 m from the ground with most 0.3-0.9 m up. One nest was built on top of an old Red-winged Blackbird nest (Peck and James 1987, 1998b). In Willowdale, first nests were usually on the ground and second nests were about 0.5 m above ground. If a third nest was built, it was usually about 0.9 m from the ground, often in a thorny shrub. One nest was 2.9 m from the ground in a horizontal hole in a willow (Nice in Austin 1968).

Most early nests are on or near the ground in grasses or forbs. Later nests may be higher once leaf cover is available in shrubs and saplings. Nests may rarely be as high as 10 m from the ground, but almost all are less than 4 m up; most are less than 1 m from the ground. Most nests are low in grasses and shrubs, predominantly on the ground under tufts of grass or shrubs, but they may also be in sedges and cattails, trees, and over water. Nests may rarely be in tree cavities, hollow logs, rails, woodsheds, or nest boxes. The Song Sparrow often nests close to houses in flowerbeds or other areas that provide sufficient cover. In Alaska, most nests are about 1 m from the ground in conifers. In tidal marshes, it nests as high as possible while maintaining overhead cover. Lower nests are at risk of flooding. Most elevated nests are woven onto branches but some may be wedged among erect branches. Elevated nests are typically deep within the nest plant on the leeward side to provide optimal protection from the wind. In British Columbia, 61% of nests were in low vegetation and attached to plant stems, 19% were in tall grasses, and 9% were in shrubs or low trees. Red elderberries were avoided as a nest substrate, with only 1 of 1,051 nests (0.1%) in this species. It nested preferentially in blackberries and in rose and snowberry as often as expected by their occurrence. In Michigan, 11 consecutive nests by 1 female averaged 87.8 m apart (range 18-160 m). Ten were on the ground and 1 was 50 cm above ground in a blackberry thicket. Seven successive nests of a Maryland female were all in backyard hedges of barberry 1.1-1.8 m from the ground. Nests are rarely reused with only 4 reports of reuse out of thousands of nests. One pair raised 4 broods within a single nest in a season, relining it between each use. In Ontario, 1 pair raised 3 broods and used the same nest for the second and third broods, and both nests were in the same tree (Arcese et al. 2020; Berger 1951; Brackbill 1950a; Campbell et al. 2001; Crombie et al. 2017; Flaspohler and Matteson 1994; Larison et al. 2001; Nice in Austin 1968; Nolan in Austin 1968; Peck and James 1998b).

The Song Sparrow defends an area that normally includes mating, nesting, and feeding areas. In Ohio, most activities took place within the territory except that birds left their territories several times a day to drink water and bathe. On a small island in British Columbia, adults foraged within the territory when they were feeding nestlings. When they were foraging for themselves, they frequently entered grassland habitat adjacent to the territory and occasionally the tidal zone that functioned as a common feeding area. Territories within shrubs were well defined by obvious perching trees and singing perches. Territory boundaries in meadows were difficult to define and overlapped. Meadows appeared to be part of the home range rather than the territory. On this island, all available habitat was occupied and territoriality limited population levels. Both males and females defend territories and unmated males may also defend territories. Males vigorously defend their territories against floaters to prevent losing a portion of or all their territory, and females defend against floaters to prevent polygyny. Intrusion pressure declined slightly over the season, probably because some floaters were successful in procuring a territory. Territories overlapped with a mean of 5.4 floaters (range 0-10). Of successful settlement attempts by floaters, 52.6% resulted in partial acquisition of the owner's territory and 47.4% resulted in the eviction of the owner. Males that were evicted from their territory lost weight after eviction. Other birds did not, suggesting that evicted males were in poor condition. Floaters most often intruded upon males that were least able to defend themselves: the young, old, and handicapped. Intrusion pressure was unrelated to territory size, density of floaters, fertility of females, or whether a female was present in the territory. Territory boundaries remain remarkably stable from year to year even if different birds are defending the territory. If a male disappears and is not replaced, neighbours may annex part of his territory. On a British Columbia island, birds of both sexes that were removed were rapidly replaced. Where birds were simultaneously removed, the number of occupied territories increased 40% with a significant decline in average territory size. There was a total reorganization of territorial boundaries after simultaneous removal and replacement. Where birds were successively removed, replacement birds settled on a 1-to-1 basis and territorial boundaries remained constant except for some minor modifications. All but 1 of the replacement birds were juveniles. Those juveniles that failed to establish a territory in October either dispersed or remained overwinter, attempting to establish dominance in winter flocks to obtain a territory the following spring. In habitat patches, territories may be contiguous and have several abutting territories. In other areas, territories may be arranged linearly, such as along hedgerows, roadsides, streams, and lakesides (Arcese 1987; Arcese et al. 2020; Knapton and Krebs 1974; Nice 1937; Nice in Austin 1968; Nolan in Austin 1968; Tompa 1962, 1971).

Territory size may be affected by population density, settling patterns, habitat quality, and the mating status of the owner. The extent of the male's singing repertoire and the number of neighbours may also influence territory size. With higher breeding density, territory size shrinks. This is accompanied by increasing resistance by territory holders until a point is reached where no further decrease in territory size can be tolerated. Territories are smaller when habitats are settled simultaneously instead of gradually. This may be correlated with density because density was higher in areas settled simultaneously. In Massachusetts, territory size in rural areas was significantly correlated with the area of herbaceous vegetation. Suburban territories were significantly correlated with both shrub density and crown volume. On a British Columbia island, differences in territory sizes between areas were related to differences in the density and species of shrubs present. On

another British Columbia island, unmated males had territories that averaged 82 m^2 (range 65-105 m^2) and a home range of 120 m^2 (range 98-135 m^2). Mated males had territories that averaged 288 m^2 (range 110-400 m^2) with a home range of 473 m^2 (range 167-822 m^2). Island territories may be only 10% of the size of those in mainland habitats. In Ohio, the minimum territory size was 0.2 ha, the average was 0.27 ha in well populated areas, and the maximum was 0.61 ha. Birds nesting on small Minnesota islands defend territories as small as 0.016 ha. Linear lakeshore territories in the same state average 0.19 ha (range 0.14-0.28 ha). In Maine, territories averaged 0.49 ha on the mainland and 0.18 ha on small islands; 2 pairs nested on a 0.16-ha island. In Algonquin Park, territories averaged 0.43 ha (range 0.06-1.03 ha). Territories extended from the ground to the top of the canopy (6 m), but not to the top of dead snags (9 m). Territories in urban habitat in California were 0.1-0.4 ha. Territories on university campuses and near freeways averaged 47.9 m from a road, 491.6 m from a major freeway, and 36.3 m from a building. Those in urban parks had territories averaging 262.0 m from a road, 2,628.3 m from a major freeway, and 261.5 m from a building. In anthropogenic habitats, 29.6% of the area within 50 m of a male's capture site consisted of impervious surfaces compared with 1.0% in parks. In Massachusetts, there were no differences in territory sizes between birds nesting along country roads (0.21 ha) and those nesting in suburban habitat (0.26 ha). The number of neighbours and shrubs combined to account for 51% of the variability in territory size. Although unmated males may have territories as small as 0.0065 ha on islands, territories may be as large as 0.65 ha in habitat consisting of a mix of shrubs and forest. On a British Columbia island, territories were as small as 0.02 ha at a density of 2,500 pairs per km^2 compared with 0.5 ha at a density of 200 per km^2 on the mainland. On a California island, territories averaged 0.07-0.23 ha. They were smaller in dense shrubs (0.15-0.25 ha) than in open areas (0.28-0.42 ha) and in territories held by newly settled (0.18 ha) than established (0.23 ha) males. Other reported territory sizes include 0.038-0.050 ha in tidal marshes, 0.11 ha along a Minnesota lakeshore, and 0.09-0.57 ha in rural Massachusetts (Arcese et al. 2020; Bonneau in Gauthier and Aubry 1996; DeGraaf 1989; Grunst et al. 2014; Knapton and Krebs 1974; Martin 1960; Morse 1977; Nice 1943; Nice in Austin 1968; Nolan in Austin 1968; Tompa 1962). Territory size may be affected by the number of competing species present. On Pacific Coast islands, territory size was unaffected by insect abundance and amount of dense shrub vegetation 0.6-1.2 m tall. Territory size increased with the number of competitive species and was about 0.32 ha in complex communities with 10-15 species and 0.06 ha in simple communities of 1-2 species (Yeaton and Cody 1974).

The rate of natal philopatry depends upon whether the population is migratory or resident. Near Kingston, 1 of 146 nestlings (0.7%) returned to breed. It was a male that nested 5 territories from its natal site. In Ohio, where some birds are migratory and others are resident, yearling males took up territories 90 m to 1.6 km from their natal site. Females settled 45 m to 1.6 km from their natal territory. Of 317 fledglings, 26 males and 14 females (total of 12.6%) returned to breed, an estimated 50-60% of young that survived; 4.5% of eggs laid produced young that returned to breed. In resident island populations in British Columbia and California, natal philopatry was very high. It is possible that philopatry rates are lower in mainland areas. On British Columbia islands, very few yearlings immigrated. Juveniles remained in the breeding area until territoriality peaked again in October. At this time, some successfully obtained a territory and remained for the winter; approximately 20% emigrated. In spring, unmated juveniles that overwintered attempted to establish a territory. Those

that failed either left the island or remained as nonterritorial floaters. Of 112 young on 1 island, 21 (18.6%) were recovered the following year. These included 6 breeding males and females and 2 unmated males. Median distances of settlement from the natal territory were 200-240 m for males and 150-200 m for females in California, 280 m for males and 270 m for females in Ohio, and 185 m for the sexes pooled at San Francisco. At this site, 42% of birds settled within 150 m of the natal territory and 81% settled within 360 m (Arcese et al. 2020; Keller and Arcese 1998; Knapton and Krebs 1974; Nice 1937; Nice in Austin 1968; Schlossberg 2009; Tompa 1962; Weatherhead and Boak 1986).

In a migratory population near Kingston, adult site fidelity was low; 53 of 77 males (68.8%) on territories at the beginning of the breeding season abandoned them by the end of the season and 83.2% were not seen again. Males exhibited a similar lack of fidelity between years but returned more frequently to territories that had been successful the previous year. Thirty of 152 males (19.7%) returned and 21 (70.0%) retained their original territory. Four males were seen in all 4 years of the study. Three retained the same territory in all 4 years but the fourth bird occupied more than 1 territory in 3 of the 4 years. Females showed little site fidelity between and within years. Only 3 of 23 females (13.0%) remained in their original territory for the entire breeding season. In another Ontario population, returning females moved an average of 180 m from their previous year's territory, significantly further than males (90 m). Males with larger song repertoires either retained their original territory or bred significantly closer to their previous territory than males with smaller repertoires. In 2 studies with 442 adults in migratory populations, 25% were site faithful. In Ohio where there is a mix of resident and migratory birds, some males retained their territory in successive years; others made slight changes. Females returned to their former territory in 20 of 54 cases (37.0%), settled on the adjacent territory in 19 cases (35.2%), or settled at distances of 90-730 m. In resident populations, both sexes exhibit extremely high site fidelity, usually remaining in the same territory in successive breeding seasons and even in nonbreeding seasons. Changes in territory holders are most often due to mortality. On a British Columbia island, 29 of 55 adults (52.7%) survived over winter. With 1 exception, all kept their old territories except for minor boundary adjustments. A male that was unmated the previous year moved to a neighbouring territory where the owner had died overwinter. On the same island, only 9% of surviving females had a territory that did not overlap with the previous year's territory (Arcese et al. 2020; Hochachka 1993; Keller and Arcese 1998; Nice 1937, 1943; Nice in Austin 1968; Potvin et al. 2015; Schlossberg 2009; Tompa 1962; Weatherhead and Boak 1986).

Limiting Factors

Nests with eggs have been reported in Ontario from mid-April until the first week of September, with most present from the last week of May until the last week of June (Peck and James 1987). In Algonquin Park, eggs are present from mid-May to early August, nestlings are present from late May to late August, and fledglings have been observed from mid-July to late August (Tozer 2012). Nice (in Austin 1968) reported that nesting began around 20 April in Willowdale.

The female may build 1, 2, or rarely 3 nests and abandon them before finally building the nest that receives the eggs. Nest-building activity is stimulated by high temperatures and inhibited by low temperatures. As many as 5-10 days may be required to complete a nest depending upon weather, the time of the year, and which nest of the season it is. The first egg is usually laid the day

after the nest lining is complete but as many as 13 days may elapse between nest completion and egg laying if the weather is inclement. Eggs are laid at the rate of 1 a day. In 1 Ontario nest, there was a 3-day delay between laying of the second and third eggs. In clutches with 3 or fewer eggs, incubation begins with the laying of the last egg; in larger clutches, incubation begins with the laying of the penultimate egg. The incubation period of 18 Ontario nests was 11-15 days, mostly 11-12 days. At London, the incubation period averaged 12.6 days. Overall, incubation periods of 10-15 days have been reported. In Ohio, most eggs hatched in 12 or 13 days (mean 12.6 days, range 12-15 days). The incubation period was 12-14 days on a British Columbia island and averaged 13.0 days on a California island. Hatching is usually synchronous in 3-egg clutches and asynchronous in larger clutches. Young may leave the nest when they are 7-15 days old but leave at age 7 and 8 days only when they are disturbed or if other siblings have left the nest. Most leave when they are 10-12 days old (Arcese et al. 2020; Berger 1951; Campbell et al. 2001; Nice 1937; Nice in Austin 1968; Nolan in Austin 1968; Peck and James 1987, 1998b; Scott and Lemon 1996; Smith 1978a; Smith and Merkt 1980; Smith and Roff 1980).

The Song Sparrow normally raises 2 broods per season, but may occasionally rear 3 or rarely 4 broods. There is 1 confirmed case of a pair raising 3 broods in Ontario. Two cases of 4 broods have been reported: one from British Columbia and the other from Ohio. Its ability to raise more than 2 broods is dependent upon the length of the breeding season and how many fledglings there are in early broods. Third and fourth broods can only be raised in years of early springs and when there is no autumn drought. On a British Columbia island, no third broods were raised in a year when the egg-laying season was 75 days, but 1 pair raised 3 broods in a year when the egg-laying season was 98 days. Those that successfully raise 3 broods overlap successive broods more and raise more young per year. At London, 16.7% of pairs raised 0 broods, 59.5% raised 2 broods, and 23.8% raised 3 broods (average 1.07 broods). The interval between fledging of 1 brood and initiation of the next clutch increases by approximately 3.3 days for each extra young in the brood. The interbrood intervals are approximately 9.5 days for a brood of 1 fledgling, 12.5 days for 2 fledglings, 15 days for 3 fledglings, and 17 days for 4 fledglings. The interbrood interval is not consistent year to year and birds may adjust it depending upon the length of the breeding season. In most cases, the female begins incubating the next clutch before the fledglings of the previous brood are independent. A brood size of 1 fledgling is the only size that allows the Song Sparrow to raise 4 broods (Arcese et al. 2020; Nolan in Austin 1968; Peck and James 1998b; Scott and Lemon 1996; Smith 1982; Smith and Roff 1980; Tompa 1962). Failed nests are typically replaced and as many as 7 nests may be attempted to raise 1 or 2 broods. The interval between nest loss and initiation of the replacement clutch is 5-8 days, seldom as long as 12 days. In Ohio, replacement nests averaged 23 m from the previous nest (range 9-50 m). In California, the internest distance averaged 17 m (range 5-49 m). The female may occasionally renest outside her mate's territory which leads to vigorous conflicts with the neighbours (Arcese et al. 2020; Berger 1951; Nice in Austin 1968; Smith and Roff 1980). Clutches of 2-7 eggs have been reported in Ontario. Two nests in Prince Edward County in 2 different years contained 8 eggs. It is possible that more than 1 female contributed to these clutches. Most clutches contained 5 eggs, followed closely by 4-egg clutches. Two- and 7-egg clutches were rare; the normal clutch range was 3-6 eggs. Excluding the 8-egg clutch, the mean clutch size of 499 Ontario nests was 4.43 eggs. Nests had smaller clutches later in the season, and all August clutches

contained 3 or 4 eggs (Peck and James 1987). Most London clutches contained 5 eggs (Scott and Lemon 1996). Elsewhere, clutches of 3-5 eggs are typical, with 6-egg clutches rare to uncommon. Clutches of 1 and 2 eggs occur, but are likely due to egg losses. Largest clutches occur in migratory populations, but clutch size also increases with latitude and altitude. Individual females usually have larger second than first clutches, but the overall average clutch size declines with the season because younger birds lay later and have smaller clutches. In North Carolina, 175 nests had predominantly 4 eggs, with only 1 5-egg clutch but several 2-egg clutches and a single 1-egg clutch. Average clutch sizes reported elsewhere include 3.05 eggs in Baja California, 3.69 in southern California, 3.28-3.31 in southcentral California, 3.71 in San Francisco Bay, 3.53 in northcentral California, 3.81 in Washington and Oregon, 3.99 in the Sierra Nevada, 4.17 in Alaska, and 3.1 for first clutches and 3.6 for second clutches on a California island (Arcese et al. 2020; Campbell et al. 2001; Nice in Austin 1968; Nolan in Austin 1968; Smith and Roff 1980).

Both sexes are capable of breeding in their first year and all females breed in their first year and annually thereafter. Some yearling males may be unsuccessful in defending a territory and attracting a female. Some males may not breed until they are 2 or 3 years old. Some nonbreeding yearlings remain as floaters within defended territories, waiting to supplant a male that dies or actively challenging territory holders for a portion or all their territory. Other nonbreeding yearling males remain in loose groups in unsuitable nesting habitat that offers rich food resources. On a British Columbia island, 27.9% of males were floaters in 1 year and 17.0% were floaters in another year. The success of a male in obtaining a mate was dependent upon the amount of shrubbery he defended (Arcese 1987; Arcese et al. 2020; Knapton and Krebs 1974; Tompa 1971). All populations with high proportions of nonbreeding yearling males were residents living on small British Columbia islands. In these areas, all suitable habitat is occupied and defended by year-round residents. The incidence of nonbreeding yearling males is probably much lower in mainland areas and in migratory populations. Migratory populations are more flexible in their selection of territories and may use ephemeral habitats such as clear-cuts and temporary openings in forests. Mainland yearlings have the option of settling in suboptimal habitat; the islands that were studied were either good or unsuitable nesting habitat.

The mating system is predominantly monogamous, but the Song Sparrow is adaptable and may adopt a variety of reproductive strategies. These may include polygyny, polyandry, extra-pair copulations, and intraspecific parasitism. Inbreeding may also occur in resident populations. Both sexes are more faithful to their territories than they are to each other. Often there is no attempt by the female to maintain the same pair bond even between broods. Near Kingston, 3 females that remained in the same territory all season retained their mates, but those that switched territories within seasons also switched mates, with the male remaining in the original territory. Zero to 25% of pair bonds remain intact in resident populations from year to year, with many mate changes due to mortality of one of the mates. In Ohio, 8 of 30 possible pairs (26.7%) reunited in a subsequent year. The low proportion is likely due to the many opportunities that a male has of acquiring a mate before his former partner returns. A female that returns to find her former mate already mated joins with another male (Arcese 1987; Arcese et al. 2020; Berger 1951; Hochachka 1993; Nice 1937, 1943; Nice in Austin 1968; Weatherhead and Boak 1986).

The sex ratio often defines the dominant mating strategy of the Song Sparrow. If the male to female ratio is less than 1, polygyny may occur; if the ratio is near 1, monogamy is favoured; and if the ratio is greater than 1, polyandry may occur. Over 3 years on a British Columbia island, 7 of 213 pairings (3.3%) were polygynous. In all cases, the mates consisted of a single male and 2 females. In 4 cases, polygyny followed the death of a neighbouring male. In the remaining cases, 2 females were paired with a male from the beginning of the breeding season. All polygynous mating occurred within the only year when the number of breeding females exceeded the number of males. Territories of males with 2 females were larger than those of monogamous males because they were often a combination of 2 territories. Nestling survival was good in all polygynous nestings. Polygyny was disadvantageous to females only if the male did not feed the young (Smith et al. 1982). In Ohio over a 6-year period, 4 of 173 males (2.3%) were in polygynous relationships. These all occurred when an incubating female lost her mate and mated with the neighbouring male (Nice in Austin 1968). Twenty-one percent of females and 13% of males engage in a polygynous relationship at least once in their lifetime. One male was mated to 4 females on a tiny island in British Columbia, but only those 5 birds were present. Although the incidence of polygyny is positively related to a female-biased sex ratio, polygyny has occurred when territorial males outnumbered females by 1.4 to 1 (Arcese et al. 2020). In British Columbia, when males were experimentally removed, most widowed females elected to mate with neighbours rather than waiting until an unmated male was available (Smith et al. 1982).

Polyandry occurs when 2 or more males mate with a female and contribute care to a single brood. Cooperative polyandry is where a female receives parental care from more than 1 male and maintains social contact with them. Sequential polyandry occurs when 2 males care sequentially for a brood, such as after a territory takeover. At a British Columbia site, an average of 16% of females (range 0-37%) occupied territories with 2 or more social mates over an 11-year period. Females gained new social mates by forming social bonds with replacement mates after a territory takeover (111 cases) or by occupying 2 or more territories within a season (55 cases). Cooperative polyandry was confirmed once and suspected twice and there were 7 confirmed and 8 suspected cases of sequential polyandry. Overall, 18 of 492 females (3.7%) and 33 of 505 males (6.5%) bred at least once in a polyandrous group; 3 males occurred in polyandrous groups twice in their lifetime. The percentage of females in polyandrous relationships was unrelated to the sex ratio but was significantly related to the number of females that had more than 1 social mate in a season and the percentage of females that mated with replacement males while still caring for the young of a previous mate. Fifteen of 18 males (83.3%) that fed their new mate′s young were previous neighbours but 3 were formerly nonterritorial floaters (Janssen et al. 2008).

Extra-pair copulation may be a common reproductive strategy. Arcese (1987) observed 3 cases of extra-pair copulations involving neighbours. In this population, 15-27% of nestlings were fathered by a male other than the social mate. Most extra-pair sires were neighbours (Arcese et al. 2020; Janssen et al. 2008). Near Newboro, 8-15% of nestlings were a result of extra-pair paternity (Potvin et al. 2015).

In both California and New York, Latif et al. (2006) confirmed intraspecific parasitism. At 1 California nest, a second female entered the nest and laid another egg in the nest. Two days later,

the first female ejected an egg out of the nest but it was one of her own eggs. Two of 14 nests (14.3%) had 2 eggs laid in them in a single day. In New York, 2 eggs were laid in a nest within 2 hours and 1 was ejected. At another nest on 2 different days, a marked egg disappeared and was replaced by 2 new eggs. At another California site, no intraspecific parasitism occurred. Parasitism occurred in both the west and east but not in all populations. When parasitism occurs, an egg may be removed by the host, not the parasite. Females appear unable to recognize parasitic eggs and may eject their own eggs.

In a resident British Columbia population on a 6-ha island, there was no evidence of inbreeding avoidance and no preference or avoidance of relatives as mates. The Song Sparrow may not be able to recognize relatives. Inbreeding occurred regularly with 283 of 479 matings (59.1%) occurring between relatives; 18 matings (3.8%) were between full siblings or parents and their offspring. Inbreeding depression was significant with eggs produced by full-sibling matings suffering a 49% reduction in survival to breeding age. The occurrence of inbreeding is probably less frequent in mainland populations and may be rare to absent in migratory populations (Keller and Arcese 1998).

The Song Sparrow forages mostly on the ground where it may run under the vegetation in a mouse-like manner. It forages for seeds on the ground by scratching with both feet, takes seeds from plants by reaching up from the ground or perching in the plant, occasionally picks fruit up from the ground but more frequently takes it from the plant, and eats flower parts of blue-eyed grass by reaching from branches of an adjacent shrub. It commonly feeds on foliage and bark in shrubs and saplings but also on the ground and in herbaceous vegetation. In freshwater marshes, it often forages at the edge of water, occasionally with its feet in the water. In intertidal areas, it eats small snails or flips over vegetation to find amphipods. It may make short jerky runs or hops to capture salt-marsh flies and cling to steep dirt or rock slopes partially supported by its tail to capture insects. It tears rolled leaves open to extract leafroller moth caterpillars and catches winged termites as they emerge from their colony. It occasionally flies high into the air to capture insects. Flights are usually from a perch atop a 1-3 m shrub and may extend 10 m into the air. On a British Columbia island, adults foraged outside their territories in grassland for lacewings and other insects later in the breeding season when caterpillars became scarce. It may forage for insects in foliage and on the bark of conifers at heights as high as 9 m. On the lower Colorado River, 50% of foraging occurred on the ground, 40% in shallow water, and 10% on bark and leaves. It has been documented seizing and devouring small minnows (Arcese et al. 2020; Girard et al. 2012; Hailman 1960b; Judd 1901; Nolan in Austin 1968; Salt 1957; Smith 1978b; Tompa 1962).

Males may engage in anticipatory feeding by offering food to eggs. In the Ottawa area, the diet of nestlings in 3 nests was highly variable and included hoppers (leafhoppers, planthoppers, and froghoppers), spiders, caterpillars, beetles, hymenopterans, true bugs, flies, and unidentified larvae. The mean proportion of the diet from seminatural habitats was significantly greater than the proportion of seminatural habitat within 100 and 35 m of the nest. Hoppers had the highest mean contribution to the nestling diet but the proportion of hoppers in the diet was not significantly greater than caterpillars. Taxa making the lowest contributions to the diet included picnic beetles, ground beetles, and spiders. Invertebrate biomass was higher in hedgerows and hayfields than in cropland. Song Sparrows may select hedgerows and hayfields as foraging habitat because they

support the highest biomass of insects. At nests with less than 7% seminatural cover, hedgerows provided at least 90% of the seminatural habitat and the majority of nestling food. Hoppers are pests of alfalfa and soybean crops and may be more prevalent in the diet of nestlings in farm habitats than other areas (Girard et al. 2012). Elsewhere nestlings have eaten spiders, beetles, grubs, flies, caterpillars (especially leafrollers), grasshoppers, worms, crane flies, and aphids. Young may also be fed seeds from feeders. Nestlings are fed smaller items for their first 2 days, particularly aphids, spiders, leafrollers, and flies. Food items brought to older nestlings are identical to those consumed by adults, including caterpillars longer than 4 cm (Arcese et al. 2020; Nolan in Austin 1968). Juveniles on a British Columbia island foraged extensively on leafrollers, slow-flying flies, and hymenopterans (Arcese 1987).

Judd (1901) analyzed 401 adult stomachs collected throughout the year from 26 states and British Columbia. The diet consisted of 66% vegetation (mostly seeds) and 34% animal matter (mostly insects with occasional spiders and snails). That the Song Sparrow often inhabits damp habitats was indicated by some of the food items such as seeds of wild rice, sedges, smartweeds, amphipods, aquatic snails, tiger beetles, mayflies, and dragonflies. Foraging in upland with other bird species also occurs: picking up seeds of crabgrass and ragweed with the Dark-eyed Junco and American Tree Sparrow in winter; eating earthworms on lawns with the American Robin; fighting for bread crumbs with the House Sparrow in cities; eating raspberries with Gray Catbirds and Brown Thrashers; and feeding on honeysuckle berries with the White-throated Sparrow. Of the vegetable diet, 24% of the entire diet consisted of grasses, 16% smartweeds, 3% ragweeds, and 18% miscellaneous seeds of wild sunflowers, amaranths, lamb's-quarters, clovers, gromwell, plantains, nightshade, purslane, spurges, wood sorrel, dandelions, duckweed, docks, and sheep sorrel. More than 50% of the grass seeds consumed were those of crabgrass and foxtails, but it also ate timothy, paspalum, old witch grass, barnyard grass, bluestems, orchard grass, and wild rye. Fruits comprised 8% of the July diet, especially those of blackberries, strawberries, raspberries, blueberries, mulberries, and black cherry. It also eats fruit of elderberries, wild grape, pokeweed, and bayberry. Fruit is largely ignored once grasses and weedy herbaceous species seed. Insects comprise about 33% of the annual diet and more than 50% from May to August. These include 9% beetles, 7% orthopterans, 6% lepidopterans, 4% hymenopterans, 3% bugs, 2% flies, and 1% miscellaneous taxa such as neuropterans, stoneflies, and mayflies. Beetles were eaten year-round, but especially in late spring and early summer. Leaf beetles comprised 5% of the July diet and weevils comprised 11% of the June and 4% of the annual diet. In addition to these beetles, it ate ground, click, clown, scarab, long-horned, tiger, and tumbling flower beetles and fireflies. Orthopterans were important in the August diet when they comprised 28% of all food items. These were mostly short-horned grasshoppers but it ate some long-horned grasshoppers and crickets. The lepidopterans that it consumed were all moths, mostly geometer and owlet moth caterpillars. Twenty-five percent of the May and June diet consisted of caterpillars; it captured cutworms on the ground and ate some cankerworms and gypsy moth larvae. More than 50% of the hymenopterans were ants; other prey in this order included braconid and scoliid wasps, sawflies, ichneumonid wasps, and small bees. The flies that it consumed were mostly larval and adult midges and crane flies and it sometimes ate adult deer flies. The diet included 2% miscellaneous animals that were mostly aquatic snails, but it also ate spiders and millipedes. Arcese et al. (2020) summarized the contents of 342 stomachs from the northeast and

354 from the Pacific region. Plant material accounted for 54% of the spring diet, 60% in summer, 92% in autumn, and 86% in winter. The most important plants in the diet were smartweeds, foxtails, ragweeds, and amaranths (each 10-25% of the diet), and 5-10% knotweeds in the Pacific region. The most important animal foods included beetles, caterpillars, crickets, ants and other hymenopterans, and bugs. A sample of stomachs of 222 breeding and 99 wintering birds demonstrated that females ate 42% animal food compared with 39% for males. Diet in saltmarsh habitat was high in animal matter. This material was mostly snails but it also ate polychaetes, insects, and other invertebrates. In Illinois, it ate 8-10-mm-long gizzard shad. On a British Columbia island, it ate berries of Saskatoon, red elderberry, and raspberries and rarely those of snowberry. It also fed on flies and amphipods in tidal areas. Other breeding season food items include brown-tailed moths, northern corn rootworms, tarnished plant bugs, gull feces, apical buds of spring-beauty, and crowberries (Arcese et al. 2020; Garfinkel et al. 2020; Nolan in Austin 1968). In British Columbia, most prey captured while flycatching consisted of robber flies (Smith 1978b). The Song Sparrow regularly drinks fresh water and may leave its territory to drink. In areas without water, it relies on rain water, dew, and condensed fog (Arcese et al. 2020).

Arcese and Smith (1988) provided supplemental food in 16 territories of a British Columbia island population. Sixteen neighbours had some access to the food and the remaining 40 pairs were considered controls. Pairs with supplemental food began laying an average of 18 days earlier than control birds, laid 3.31 eggs compared with 2.77 eggs, and 60% of fed adults successfully raised young compared with 45% of controls. Experimental females initiated more clutches (2.81) than control females (2.24) and raised almost 4 times as many young. Parasitism rates by the Brown-headed Cowbird were significantly less for experimental (18.4%) than control (44.7%) nests, probably because fed females spent less time foraging and could defend their nests more diligently. Food availability was an important stimulus for the onset of breeding. The amount of food available per pair decreases as the number of pairs increases. They acknowledged that effects would be less striking in lower density populations; density of their study population was approximately 1,200 pairs per km^2.

Hipfner et al. (2013) compared the diets of the Song and Fox sparrows in British Columbia. The Song Sparrow ate more animal material and less plant material than the Fox Sparrow. These dietary differences probably allow the species to coexist.

The Song Sparrow is one of the most common hosts of the parasitic Brown-headed Cowbird, but also one of the species least harmed by parasitism. Cowbird eggs are typically accepted but nests may be deserted if egg removal by cowbirds lowers the clutch size below an acceptable threshold. In a British Columbia population, desertion rates due to parasitism were 8.9-16.5%. In Ontario south of the French River, 27% of parasitized nests were deserted compared with 2% of unparasitized nests. No cases of cowbird egg ejection occurred. Acceptance rates were similar before and after the peak of nest initiation, and in singly and multiply parasitized nests. In southern Ontario, desertion appears to be an adaptive response to parasitism. Cowbird eggs laid before the first sparrow egg is laid may be buried in the nest. This is unlikely to be an adaptation to avoid parasitism but rather a continuation of nest building (Arcese et al. 2020; Graham 1988; Nolan in Austin 1968; Rothstein 1975; Smith and Arcese 1994; Smith et al. 2003). The Song Sparrow is capable

of raising its own young in parasitized nests and there tends to be no difference in nestling growth rates in parasitized and unparasitized nests. The number of young fledged in parasitized nests is lower, usually a result of the cowbird removing sparrow eggs from the nest. In Ohio, parasitized nests fledged an average of 1.0 young less than unparasitized nests. In British Columbia, the loss was 0.3-0.5 young per nest. Greatest losses occur when female cowbirds remove entire clutches or broods from nests in an endeavour to induce renesting and create additional opportunities for parasitism. Young were found dead in or near 4.7% of nests in British Columbia. Presence of cowbird young in the nest may increase the probability of nests being depredated (Arcese et al. 2020; Nice 1937; Nice in Austin 1968; Smith 1981; Smith and Arcese 1994; Smith et al. 2003; Zanette et al. 2007).

The probability of parasitism may be affected by cowbird abundance, increasing density of Song Sparrow populations (at least on islands), distance of islands from the mainland or a large island such as Vancouver Island, age of the female Song Sparrow, percent forest cover in the landscape, percent pasture and rangeland, presence of suitable perches for cowbirds, and nest concealment. Parasitism rates are higher where cowbirds are more abundant. On British Columbia islands, parasitism rates were higher in years of higher sparrow densities. When sparrows were abundant, the probability of a cowbird successfully finding a nest to parasitize was higher. When sparrows were scarce, cowbirds did not expend the energy required to visit the island. Nests on islands closer to the mainland are more likely to be parasitized than those on distant islands; cowbirds are less likely to visit islands far from shore. Females that are 3 or 4 years old are more likely to have their nests parasitized than yearlings and 2-year-olds. Older females initiate more nests per season which increases their probability of being parasitized. The rate of parasitism decreases as forest cover in the landscape increases but increases with increasing coverage by pasture and rangeland. In New York, parasitized nests were significantly closer to trees and permanent objects at least 2 m tall than unparasitized nests. Overhead visibility of the nest did not affect parasitism rates. In California, the probability of parasitism increased as foliage cover at 2-3 m increased and decreased as lateral cover below 1 m increased. When foliage cover 2-3 m from the ground reached 20%, the parasitism rate was 88.9%. Foliage at this height may enhance a cowbird's ability to find the nest. Parasitism was significantly reduced when lateral cover below 1 m reached 90%. Dense cover may conceal the host's activities and make it more difficult to find the nest (Hauber and Russo 2000; Larison et al. 1998; Saunders et al. 2003; Smith 1981; Smith and Arcese 1994; Wilson and Arcese 2006).

The rate of parasitism varies greatly geographically and even annually at given sites. In Ontario, 457 of 2,032 nests (22.5%) were parasitized. In the 1990s, only 37 of 220 nests (16.8%) were parasitized, thereby slightly lowering the overall rate (Peck and James 1998b). McLaren et al. (2006) analyzed parasitism rates in Ontario in the previous 130 years using Ontario Nest Record Scheme data. The first cowbird was reported in the province in 1870. Of nests with sufficient data, 230 of 484 (47.5%) were multiply parasitized and 484 of 2,177 (22.2%) were parasitized. There was a significant increase in multiple parasitism until 1970 followed by a nonsignificant decline. For the entire period and separately for pre- and post-1970, the overall frequency of parasitism did not change significantly. The significant increase in multiple parasitism prior to 1970 supports the hypothesis that the intensity of parasitism is related to cowbird density. The post-1970 trend may have reflected declines in the cowbird population. At the University of Western Ontario campus in London, 46 of 54 nests (85.2%) were parasitized. This appears to be the highest rate of parasitism ever

documented. Both the Song Sparrow and cowbird began laying in late April but the cowbird completed its egg-laying period well before the sparrow. The chronology of cowbird laying relative to that of the Song Sparrow was 4% during the prelaying period, 8% with 1 egg in the nest, 28% with 2 eggs, 24% with 3 eggs, 4% with 4 eggs, 8% with 5 eggs, and 24% later in the nesting period (Scott and Lemon 1996). In British Columbia, 53 of 753 nests (7.0%) were parasitized (Campbell et al. 2001). On 1 island in British Columbia, 332 of 1,509 nests (22.0%) were parasitized and annual parasitism rates ranged from 0 to 46%. The frequency of parasitism varied seasonally, rising to a peak in early June and declining thereafter. On 11 other small British Columbia islands, 29 of 64 nests (45.3%) were parasitized (Arcese et al. 2020; Saunders et al. 2003; Smith and Arcese 1994; Smith et al. 2003). At Delta Marsh, the Song Sparrow was the most frequently parasitized species and was consistently multiply parasitized. The parasitism rate was 30% (McLaren et al. 2003). Other parasitism rates include 65% in the Sierra Nevada and 28% in New York (Latif et al. 2006); 9 of 28 nests (32.1%) in New York (Hauber and Russo 2000), 1 of 29 nests (3.4%) in Missouri (Burhans et al. 2010), 5 of 11 nests (45.5%) in North Dakota (Granfors et al. 2001); 9.5% in the United States, with greater than 20% in the upper Midwest, 15-19.9% in the Rocky Mountain states, 10-14.9% in the Pacific region, 5.99% in Kansas, Missouri, and Tennessee; and less than 5% in the east and northeast (Arcese et al. 2020); 2 of 50 nests (4.0%) in New York (Hahn and Hatfield 1995); 1 of 10 nests (10.0%) in a forested landscape in Minnesota (Hanski et al. 1996); 135 of 398 nests (33.9%); 98 of 223 nests (43.9%, 24.6-77.7% annually) in Ohio (Nice in Austin 1968; Nolan in Austin 1968); and 9 of 1,168 nests (0.8%) in California (Chase et al. 2005).

Habitat for the Song Sparrow remains abundant, particularly south of the Canadian Shield, but habitat loss is occurring. The original deforestation for forest resources and agriculture was beneficial and created much habitat where little previously existed. Although it nests in urban habitats, it does so at much lower densities than in agricultural landscapes. Modern subdivisions, where the lots are very small and houses are very closely spaced, provide little to no habitat. In farmlands, hedgerows which are prime habitat continue to be regularly removed to create larger fields. Pesticides used on farms may also depress food resources for the Song Sparrow. In the Canadian Shield, habitat loss has occurred due to natural regeneration, with abandoned farmland reverting to forest (Arcese et al. 2020; Bonneau in Gauthier and Aubry 1996; Girard et al. 2012; Tozer 2012).

Where the habitat is suitable, the Song Sparrow is well adapted to urban life. Grunst et al. (2014) compared the adrenocortical stress responses of urban sparrows living in activity centres where there was noise from air conditioners, traffic, and humans to those dwelling in parks. Males in activity centres had lower stress responses than those in parks indicating that they were not pathologically affected by human disturbance. They also had better quality feathers suggesting that activity centres may be superior habitat. In Virginia, urban birds had significantly shorter flight initiation distances from approaching humans than rural birds, suggesting that urban birds are habituated to humans (Battle et al. 2016). In Oregon, urban Song Sparrows altered their songs in response to anthropogenic noise. Those singing in noisier environments had higher-frequency low notes and less amplitude in the low-frequency range of their songs. There was no difference in high frequency, maximum amplitude, number of notes, or frequency of the buzz note. Songs in noisy and quiet areas differed only in those aspects that were masked by the prevailing noise (Wood and Yezerinac 2006).

Predation may be the greatest limiting factor to the Song Sparrow. Populations that suffer a 50% or higher rate of predation tend to be sink populations that are replenished by immigration. On islands, predation is lowest on smaller islands and those more distant from the mainland. In urban and agricultural landscapes, cats may be a significant predator (Arcese et al. 2020; Wilson and Arcese 2006). In Seattle, Marzluff et al. (2007) studied the distribution of the Song Sparrow in relation to the presence of predators. It was most abundant in forests rather than edges or open habitat. Its abundance was significantly negatively correlated with the American Crow at the 1-km^2 scale but nonsignificantly associated with it at the forest-patch and within-patch scales. It was negatively associated with squirrels and chipmunks at the forest-patch scale and the Steller's Jay within patches. The Song Sparrow appeared to avoid areas where corvids and scuirids were abundant but was rarely able to avoid specific habitat patches with predators. It strongly avoided areas within forest patches that were rich in a single predator or all predators combined. It managed this despite co-occurring with nest predators at larger scales.

Weather can affect the reproductive success of the Song Sparrow. On a British Columbia island, a late spring snowstorm eliminated about a third of the adult population, but the young surplus population was left fairly intact. About 60% of pairs were either partially or completely eliminated. Yearling unmated birds filled the vacancies and the number of breeding pairs increased. The population showed signs of stress such as a 1-week delay in the onset of nesting, more frequent fights among neighbours, and a hatching failure rate of 13.7% compared with 3.8% in previous years (Tompa 1971). The effects of this storm were not overly devastating because it was a resident population with a surplus of nonterritorial birds that were able to occupy vacancies. Storms that affect migratory populations and those without many nonterritorial birds may result in greater losses of reproductive effort. Chase et al. (2005) conducted a 21-year study in California that included an 8-year dry period and 2 years of very high precipitation. The number of young fledged per female was greater in wet years, with rainfall accounting for 30% of the variation in the number of fledglings produced. Daily nest survival was significantly lower during the dry period and was significantly correlated with precipitation but negatively correlated with May rainfall. Nesting occurred over a longer period in years of high precipitation, starting earlier in spring and extending later into autumn. Nesting ended significantly earlier in years with high summer temperatures. In wetter years, the availability of annual grasses and other dense vegetation may be greater. This may reduce predation and increase insect populations. Wet weather in May has the potential to lower nest survival by causing exposure, starvation, and parental neglect or desertion. Egg addling is an important cause of hatch and nest failure where cover is sparse and the heat is extreme. Inclement weather, particularly continuous rain and cool temperatures lasting 3 or more days, often causes nest neglect (Arcese et al. 2020). In British Columbia, the length of the breeding season is determined by the onset of the summer dry season. It breeds later in wet summers there, with more adults breeding into late July and early August (Campbell et al. 2001). Nice (in Austin 1968) observed the same phenomenon in Ohio.

Knapton (1990) studied the effects of application of terbufos and fonofos in Oxford and Elgin county cornfields on Song Sparrows nesting in margins of fields. There was no difference in the disappearance rates of birds in control and treatment areas, and no differences in clutch size, number of unhatched eggs, or number of young fledged per nest. He concluded that the Song

Sparrow was not taking up the pellets as food or grit, at least not in sufficient quantities to kill it, and there were no apparent sublethal effects.

Grazing has the potential to cause adverse impacts on the Song Sparrow. In Wyoming, it was significantly more abundant in areas distant from elk feeding areas (Anderson 2007). In Oregon, its abundance increased significantly after livestock grazing was terminated in riparian aspen stands (Earnst et al. 2012). Livestock grazing in Ontario is usually at a high intensity so that all or most shrubs are eliminated. This renders the habitat marginal or unsuitable for the Song Sparrow. High populations of white-tailed deer also have the potential to degrade habitat.

Forest management may be beneficial to the Song Sparrow. Clear-cuts create temporary habitat for 4-10 years depending upon the rate of natural succession. In New York, it was common 2 years after clear-cutting and uncommon by 6 years after cutting. The sparrow-dominated guild declined as leaf area increased and the shrub-opening edges used by this group disappeared with natural succession. This guild represented 37% of the total avian population in 2-year-old cuts and only 9% in 6-year-old cuts (Keller et al. 2003). In Maine, clear-cuts were sprayed with glyphosate. This reduced vegetation structural and species diversity. It is likely that spraying young clear-cuts would be detrimental because this would kill the shrub layer. Spraying older clear-cuts may be beneficial because natural succession would be retarded and dead saplings could provide cover until new woody growth became established. In southern Ontario, the Song Sparrow was absent in uncut woodlots and occurred in low density in those that had been selectively thinned or where diameter-limit cuts had been made. These types of harvests do not create conditions that are very favourable for it and any openings that are created are very ephemeral (Arcese et al. 2020; Holmes et al. 2004; Santillo et al. 1989). In the Canadian Shield in Ontario, there was no difference in its abundance in burned and logged forests in either early successional stands or mid-successional stands. It was significantly more abundant in early successional stands than in mature stands but significantly more abundant in mature stands than in mid-successional stands (Zimmerling et al. 2017).

The effect that mowing and burning have on the Song Sparrow depends on the density of shrubs when the management is undertaken. In Massachusetts, unmanaged grasslands eventually become invaded with shrubs. Habitat quality declines if shrub density becomes too high. Management that substantially reduces shrub cover decreases Song Sparrow abundance. Grasslands that were burned and mowed supported similar populations of sparrows. Populations were significantly lower than in unmanaged grasslands, so the management was detrimental (Zuckerberg and Vickery 2006). In Indiana savannahs and oak woodlands, the Song Sparrow responded positively to fire. It reached its greatest abundance with the maximum frequency of fire: 7.3 fires per 15 years (Grundel and Pavlovic 2007a).

Price (2004) predicted that the breeding range of the Song Sparrow might contract in southern Ontario if the average summer temperature increased by 2°C.

Status

McIlwraith (1894) considered the Song Sparrow an abundant breeder in Ontario. It was probably at its peak population then, shortly after deforestation by European settlers and before intensive farming and agriculture occurred. Baillie and Harrington (1937) considered it a very common summer resident north to northern James Bay and west to Lake of the Woods and probably

northward from there. It was common in 1930 between latitudes 53°N and 54°N along the Manitoba border. They concluded that it bred everywhere within this range. The first atlas demonstrated that its range included the entire province except for an area in the extreme northeast including Cape Henrietta Maria and areas south and west of there. It was scarce in the Hudson Bay Lowland and common to abundant south of James Bay. Highest densities were in the south from Brantford east along the north shore of Lake Ontario to Brockville. On the Breeding Bird Survey (BBS) at that time, highest densities occurred south of the Shield and in western Rainy River District (Rising in Cadman et al. 1987). Weir (2008) reported that it was the third most abundant species in the Kingston area. James (1991) considered the Song Sparrow abundant in the south, common in the north to the north shore of Lake Superior, and rare in the Boreal Forest Region north to the Hudson Bay coast.

The second atlas confirmed that the Song Sparrow bred throughout the province, including the area in the northeast where it was not documented during the first atlas. It occurred in every square south of the Shield, in most squares in the Shield portion of the Great Lakes–St. Lawrence Forest Region, and in most blocks in the north. There was no difference in its province-wide probability of observation between atlases, but the probability increased significantly in the Shield portion of the Great Lakes–St. Lawrence Forest Region and in the Hudson Bay Lowland. It was most abundant south of the Shield, except for small pockets of lower density in the Toronto area and in the intensively farmed areas of Essex and Chatham-Kent. Abundance declined northward, except that it was locally common in western Rainy River District (Rising in Cadman et al. 2007).

BBS data indicate that the Song Sparrow decreased at annual rates of 0.923% 1970-2021 in Canada and 0.928% in Ontario. For 2011-21, it decreased at annual rates of 0.227% in Canada and 1.21% in Ontario. All results were highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Young are unable to fly when they leave the nest and remain hidden in plant cover. A few may be able to fly weakly when they are 10-11 days old but they are not proficient until they are 17-18 days old. Young disperse in different directions from the nest and emerge from dense vegetation when they are about 17 days old and able to fly (Nice 1943; Nolan in Austin 1968). In British Columbia, young that left the nest a day before the other young moved about 10 m in the first 4 hours and remained there for the next day. Young remained near the nest in dense shrub coverage but some dispersed as far as 30 m within 3 days. Most young were separated by several metres, but some were as close together as 2 m. Fledglings that were 23 days old were much more mobile and followed their parents, begging persistently and sometimes feeding independently. By age 31 days, most fledglings were independent although birds in second broods may be fed a little longer. All fledglings as young as 13 days remained within the breeding territory but some older young cared for by females were fed in neighbouring territories. The presence of these birds was not contested by neighbouring birds (Smith 1978a; Smith and Merkt 1980; Smith and Roff 1980).

It appears as though brood division occurs, with each individual being fed largely or exclusively by a single parent. By age 13, young in British Columbia were not fed randomly by both parents. In only 2 of 68 cases (2.9%) was a fledgling fed by both adults, and there was a significant division of labour in 53 of 68 broods (77.9%). In 4 cases when there was only 1 young in the brood, it was fed by the female. In broods of 2, 11 of 14 (78.6%) were split evenly, in 2 cases (14.3%) the female fed

both young, and in 1 case the male fed both young. In broods with 3 young, females fed 2 young and the male fed the other in 23 of 35 cases (65.7%); in the other cases, the male fed the extra young. Five of 6 broods (83.3%) of 4 young were divided equally and in the sixth case, the female fed 3 young and the male fed 1. In all cases of unequal parental investment, females were significantly more likely to care for the extra young. By age 23, there was still a significant division of broods in 6 of 11 cases (54.5%). At this age, there were some cases where both adults fed a young. This was associated with males making a higher proportion of provisioning trips, increasing from 42% to 66%. At this time, females were often incubating their next clutch and fed young only when they were off the nest. In 4 cases, a fledgling was fed solely by the female at age 13 days and only by the male at age 23 days. The tendency for males to increase care for older fledglings occurs even when the female does not initiate another clutch. If a first brood contains only a single fledgling, the female may continue to feed it while she incubates her next clutch (Smith 1978a; Smith and Roff 1980). Reed (1981) concluded that there was no evidence that parents partitioned the brood. His study was conducted on nestlings and was not relevant to brood partitioning of fledglings.

The dense shrubbery required by young fledglings can be provided by numerous habitats and most territories contain at least patches of shrubs. At the landscape level in Seattle, Song Sparrows used forested and urban landscapes to an equal extent during the postfledging period. Probability of survival increased as the amount of forest cover at the 4,000-m scale increased. Despite a high occurrence of residential areas, 13 of 16 birds (81.3%) had no commercial, industrial, institutional, parking lots, or roads within their home ranges. Use of residential housing areas was significantly higher where this habitat was least common, possibly because of the presence of feeders. Its mean home range size was 8 ha, which comprised 51% forest cover, 26% residential areas, and 15% nonresidential built areas. Differences in its use of land cover were not significantly different from what was available (Whittaker and Marzluff 2009). Fledglings, adults, and family groups may be common in regenerating clear-cuts during the postfledging period. In such habitat in Pennsylvania, the Song Sparrow was the third most abundant species. It was rare in adjacent mature forest that had similar coverage by shrubs: 69 adults and 95 juveniles were captured in clear-cuts compared with 0 adult and 2 juveniles in forest (Stoleson 2013). It also inhabits clear-cuts in Ohio and Minnesota during the postfledging period (Streby et al. 2011b; Vitz and Rodewald 2006). In Pennsylvania, family groups and all age classes of birds were common on hydro corridors but absent in the adjacent forests that they passed through (Yahner et al. 2002). In Michigan, Akresh et al. (2009) studied its usage of riparian and upland forests during the postfledging period. The capture rate per 100 net-hours was 0.1 in upland forest and 7.0 in riparian forest. All juveniles were captured in riparian forest. In riparian habitat, trees and shrubs formed an open canopy with a structurally dense understorey. Upland habitat consisted of 100-year-old stands of large-toothed and trembling aspens.

When the young become independent, family units break up and juveniles form loose flocks and congregate in good foraging areas such as where there are shrubs with ripening berries. They may also frequent bathing sites with fresh water. In resident populations, juveniles may attempt to establish territories after completion of the prebasic moult in August, emigrate to other areas to obtain a territory, migrate, or wait until February to attempt to attain a territory. Those that remain through the winter and fail to establish a territory by early spring either emigrate or persist as nonterritorial floaters. In British Columbia, young float among territories for about 7 months after

reaching independence, maintaining a home range that encompasses 3-25 territories and nonbreeding habitat (Arcese et al. 2020; Nice 1937, 1943; Nice in Austin 1968; Tompa 1962).

MIGRATION

Song Sparrow populations may either be resident, completely migratory, or a mix of resident and migratory birds. Although some birds overwinter in Ontario, it is probable that all birds are migratory, with wintering birds representing birds that bred further north. In Ohio, about 50% of males and 20% of females were residents. Ninety percent of males and 98% of females remained either migratory or sedentary without changing their migration strategy. Cold weather in October stimulated migration in most birds and warm weather inhibited it in some. Banding of 2-3 successive generations gave no evidence of a hereditary tendency to either migrate or be a resident (Arcese et al. 2020; Nice 1937; Nice in Austin 1958). Migration occurs at night but there is some northward movement during the day in spring. Birds breeding the furthest north are most likely to migrate and those wintering the furthest south are most likely to have migrated from the far north. The mean distance migrated for birds travelling more than 250 km was 850 km for adults and 885 km for juveniles. Spring migration is leisurely with British Columbia birds taking nearly 2 months to travel the length of the province. This may be due to different subspecies following different timetables. In Ohio, there were 2 peaks of spring migration, with an early migration of breeding males in late February or early March and the main flight of breeding males, females, and transients in mid-March. Early migrants were dependent on a warm spell in late February or early March; severe cold weather stopped migration during this period. Early males moved at significantly higher temperatures (average 10°C) than later males (6.1°C). The migration of early males appeared to follow the 7°C isotherm. The main migrants were only dependent on a moderate rise in temperature. Of 22 males, 5 arrived consistently early, 6 were consistently late, and the others varied their timing depending upon weather and their age. Older birds arrived sooner than yearlings and adult males arrived before adult females. Autumn migration takes place in late September and throughout October and can be hastened by cool, wet weather. Mild weather may delay or suppress autumn migration. In Ohio, breeding females left by mid-October and males left a little later (Arcese et al. 2020; Brewer et al. 2018; Campbell et al. 2001; Nice 1937; Nice in Austin 1968; Nolan in Austin 1968).

In southern Ontario, migrants arrive by mid-March with the main influx in the first 3 weeks in April. In the southern Shield, most arrive in late March. Southward movement begins in September with greatest numbers moving through in October with the main flight of other sparrows. Most leave the province by mid-November but some may remain into early December (LaForest 1993; Lancaster et al. 2002; Mills 1981; Tozer 2012: Weir 2008).

At Delta Marsh, there was no significant relationship between Song Sparrow arrival date and temperature from 1939 to 2001 (Murphy-Klassen et al. 2005). In Rhode Island, Smith and Paton (2011) analyzed weather and autumn arrival dates over a 45-year period. The mean autumn temperature increased by 0.03°C per year 1960-2007. The mean arrival time of the Song Sparrow was 15 days later in 2007 than in 1960, a delay of about 3.2 days per year.

In Algonquin Park, spring migrants are first seen at feeders or along shorelines where the snow has melted. Those that stay late in autumn are often in dense vegetation bordering water (Tozer 2012). Migration habitat is similar to breeding habitat, with less reliance on the presence of water.

During migration, the Song Sparrow is rarely found far from cover. In British Columbia, migrants occur in a variety of habitats including among driftwood and flotsam on beaches; forest edges; sedges or cattails bordering lakes, ponds, and marshes; shrubby tangles at woodland edges; patches of fireweed; meadow marshes; shrubby farm clearings; weedy vacant lots; hydro corridors; roadsides; and hedgerows (Campbell et al. 2001). In New York, it used mature shrubland habitat more than early successional forests. An exception was that 1 forest patch supported almost as many sparrows as shrublands. It had a more open canopy with greater than 60% coverage by shrubs that were mostly fruit-bearing honeysuckles. Detections increased as coverage by gray dogwood increased and decreased with the abundance of shrubs 0-2.5 m above ground and with Bella honeysuckle fruit abundance. Gray dogwood appeared to be important habitat in autumn (Mudrzynski and Norment 2013).

In Algonquin Park, spring migrants fed at edges of ice where debris and seeds may accumulate (Tozer 2012). Dance et al. (2012) observed the Song Sparrow eating giant ragweed seeds in Oxford County during autumn and winter and foraging for arthropods on this plant. In New York, 5% of autumn migrants had consumed honeysuckle fruit, but none had eaten dogwood or buckthorn berries. Gray dogwood patches were preferred habitat but its fruit was avoided as food (Mudrzynski and Norment 2013). In Georgia, a spring migrant aggressively defended a board supplied with millet and canary seeds from Northern Cardinals, Eastern Towhees, White-throated Sparrows, Swamp Sparrows, and Field Sparrows. It won all encounters except 2 with the towhee, and often maintained exclusive control of the food (Young 1990). An autumn migrant in North Dakota spent 10 minutes on top of a shed, repeatedly darting up into a cloud of midges, turning and snapping frenziedly in every direction. Although 1 pursuit was further into the air, most were only 30 cm or less (Royall 1991).

The Song Sparrow seldom strikes towers and other human-made structures during migration (Arcese et al. 2020).

James (1991) considered the Song Sparrow a common migrant in Ontario. It may be locally abundant in some areas with daily numbers of 200-500 (Curry 2006; LaForest 1993; Weir 2008).

Hussell et al. (1992) reported a nonsignificant decline of 0.9% per year in Song Sparrow captures at Long Point Bird Observatory 1961-88. Trends by period were: 1961-70, +0.3%; 1970-79, −8.2%; and 1979-88, +5.7%.

WINTER

During winter, the Song Sparrow is absent from areas with a minimum January temperature lower than −12°C. In the east, most concentrations are in regions that receive more than 102 cm of precipitation annually. Abundance peaks within this area are associated with open water (Root 1988). It is an avoider of snow. The longer the snow season length, the less likely it is to be present (Keyser et al. 2023).

Smith (2003) analyzed results of southern Ontario Winter Bird-Population Studies to determine general habitat preferences of the Song Sparrow. Densities per km^2 included 5.8 in natural urban areas (ravines, valleys, woodlots, and parks), 3.3 in urban areas with ponds, 1.0 in mixed rural areas, 0.6 in forests, and 0.1 in small urban natural areas. It was not reported in farm fields or in commercial

and residential areas. In Ontario, it appears to be most common where there are bird feeders or open water. It may be most common in cattail marshes but also occurs in swamps, dense shrubs along open streams and rivers, and in weedy fields (Curry 2006; LaForest 1993; Mills 1981; Nolan in Austin 1968; Sheppard et al. 1936; Tozer 2012).

The Song Sparrow has winter habitat requirements that are similar to its breeding habitat, but in many areas it has a preference for cattail marshes with open water, habitat that is not usually used during the breeding season. Other habitats that it frequently uses include old fields, fencerows, drainage ditches, shrubby areas along streams and margins of water bodies, and numerous other locations where shrubs or tall grasses and herbaceous species provide food and cover (Kalinowski and Johnson 2010; Knapton and Krebs 1974; Smith et al. 2005; Young 1990). In Ohio, Doherty and Grubb (2000) studied the usage of small woodlots (less than 6 ha) by the Song Sparrow. Its probability of occurrence declined as woodlots became more isolated. Its probability of occurrence decreased from early to mid-winter and increased from mid- to late winter. In Ohio, it was abundant in brushy thickets, fallow fields with rank weedy growth, weedy fields of uncut corn, brushy edges and openings of woodlands, shrubby fencerows, shrubby and weedy swamps, weedy edges of a canal, and cattail marshes. It was less numerous or absent in snow-swept fields and pastures, farmhouse areas containing little shrubbery, and orchards and woodlots without ground cover (Nice in Austin 1968). In Vancouver, it inhabits patches of native and exotic shrubs bordering lawns, parking lots, and buildings, habitat that is not used during the breeding season (Arcese et al. 2020). In British Columbia, highest densities occur on vegetable farms. It seldom uses grass and grain fields, cropland, or dense forests of any type (Campbell et al. 2001). In Illinois, preferred winter habitats included ungrazed grasslands, shrub habitats, marshes, and drainage ditches (Graber and Graber 1963). Another Illinois study found it in low densities in bottomland hardwoods but it was absent in upland forests and urban residential areas (Graber and Graber 1979). In Kansas, it inhabited fields, meadows, and marshy areas with dense ground cover. Preferred escape cover included brush piles and fencerows of dogwoods, saplings, and vines. Highest densities occurred in marshy areas around edges of a pond where there were tangles of smartweeds, rice cutgrass, cattails, and other marsh vegetation. In old fields, it preferred weedy areas with foxtails (Fitch 1958). In North Carolina, prime habitat consisted of fields with crabgrass, asters, and shrubs, and to a lesser extent, broomsedge mixed with pines and tall herbaceous plants. It made almost no use of bare fields, horseweed, broomsedge, and pine and deciduous forests (Pulliam and Enders 1971).

Several studies demonstrated the importance of dense cover to wintering Song Sparrows. In Mississippi, Smith et al. (2005) established 6.1-m-wide borders dominated by crabgrass, Johnson grass, and a variety of herbaceous species around fields. Densities were significantly greater in fields with borders; it was 3.7 times more abundant in bordered fields. Once fields were harvested, borders provided suitable foraging and escape habitat. Evans et al. (2015) reported similar results in Arkansas, Kentucky, and Mississippi. Densities of Song Sparrows were 2 times greater in fields with buffers than fields without buffers. In Maryland, Blank et al. (2011) mowed portions of grassy and herbaceous buffers between row-crop fields and forested wetlands in autumn. Vegetation height in mowed areas was reduced to 10-15 cm. In winter, the Song Sparrow was the most abundant species in buffers, representing 45% of all detections. It was more abundant in buffers wider than 60 m than in those 30-60 m wide. Densities per km^2 were 21 in mowed buffers and 701 in unmowed buffers,

demonstrating the negative impacts of autumn mowing. In Virginia, Greenberg (1989) established feeders 1.5 and 2 m from cover and within cover. At 1.5 m from cover, there was a nonsignificant decrease of 6% in visitation to the feeders. Usage declined by 10.6% when the feeder was 7 m from cover. Ninety-two percent of all sparrow species observed feeding less than 1 m from cover were Song Sparrows, but it was observed away from cover out of proportion to its overall abundance. In Virginia, Beck and Watts (1997) cut vegetation to a height of 30 cm in half of plots, added brush to some, and added seed trays to some plots. The Song Sparrow exhibited a significant preference for cover and occurred significantly more often in uncut areas. It was also more abundant where supplemental food was provided. For food-addition plots, a shift into cut areas occurred when brush was added. Vegetation had a significant effect on its distribution. In cut areas, bird distribution was skewed to the centre of plots; birds were evenly distributed in uncut plots. More birds were associated with plots containing brush, which probably provided protection from predators. Birds responded positively both to cover that reduced predation risk and to food availability. In Georgia, Watts (1990) studied the Song Sparrow in dense homogeneous stands of horseweed. He mowed 2 plots to a height of 15 cm, mowed 2 30-m wide strips on 2 plots so they alternated with uncut strips, and left 2 plots uncut. All plots were within a bigger matrix of horseweed. Brush refuge stations were established at 1 end of each grid so that half the grid had no refuge cover and the other had 2 refuge stations. Eighty-five percent of Song Sparrows were observed on unmowed plots and 88.1% occurred on the brush-addition side of plots. Kills of Song Sparrows by Northern Harriers occurred significantly more frequently in open areas than expected; 88.4% of all observations were in uncut areas but 82.6% of kills were in mowed areas. The Song Sparrow accounted for only 13.8% of all sparrow observations but represented 71.8% of all harrier kills.

Greenberg (1988) demonstrated that the Song and Swamp sparrows partitioned their breeding habitat based on the presence of standing water. The habitat differences of these 2 species do not carry over into winter and they commonly co-occur in marshes with open water.

McNicholl (1979) reported communal roosting of the Song Sparrow in Prince Edward Island. Fifteen emerged in rapid succession from a hole 4 cm in diameter in a snowbank. The opening led to a tunnel 10 cm long into a cavity 18-20 cm long, 11-14 cm wide, and 8 cm deep; there was no other opening. Although it was early April, the weather was cold and windy. During severe winters in British Columbia, Song Sparrows roost together among bales of hay or in woodpiles in human-made shelters (Campbell et al. 2001). In Alaska, 1 roosted in a niche in a rock face (Arcese et al. 2020).

Migratory birds occupy home ranges in winter but do not defend them. Some birds may perch conspicuously and behave much like territorial residents but rarely interact aggressively. Most spend the majority of their time under or near shrub cover and behave in the same manner as nonterritorial floaters do during the breeding season. In British Columbia, individuals occupied very small home ranges (0.1 ha) from late September until they departed in late March. They mostly remained within their home ranges but occasionally fed together in small flocks. The sex ratio in this population was 10 males per female suggesting that males wintered further north than females (Schiffer and Smith 2000). In Kansas, the average winter home range of migratory birds was 2.75 ha and one had a home range of 3.60 ha (Fitch 1958). Resident birds remain on or near their territories in winter. Maintenance of winter territories is essential to retain ownership in spring. Territories may or may not be defended

and birds use a larger home range than the territory. Ohio males had an average winter home range of 3.4 ha, 6-10 times larger than the breeding territory. In cold weather, birds may travel 270-500 m to visit feeders. Resident winter birds remain solitary but may gather together in loose flocks during severe weather (Arcese et al. 2020; Nice in Austin 1968; Nolan in Austin 1968). In resident populations, a dominance hierarchy is established. In all hierarchies, the adult male and his female were the dominant birds at feeding stations located within their territory and juveniles were arranged in a linear fashion below them. Males were dominant to females which may result in higher average annual survivorship of males. Territorial males dominated at feeders and achieved 2 times as many displacements as they suffered, followed by territorial females, yearling males, and yearling females (Arcese et al. 2020; Knapton and Krebs 1976).

In a Kansas migratory population, 1 of 29 birds (3.4%) was recaptured in the same home range in a subsequent winter (Fitch 1958). In a California resident population, Sandercock and Jaramillo (2002) banded 1,107 juveniles and 825 adults in winter. The recapture rate was 54.3% for juveniles and 43.7% for adults. The winter survival rates were 31.0% for juveniles and 34.0% for adults after their first capture, and 55.8% in later years.

In winter, the Song Sparrow forages predominantly on the ground, in or near dense underbrush or thickets, in willows and other vegetation along watercourses, in cattail marshes, in grassy and weedy areas, and around root tangles and piles of driftwood. It entered barns to eat seeds. On a British Columbia island, 90% of adults left their territories temporarily and flew as far as 500 m to feed on seeds and tiny flies in a roost occupied seasonally by 12,000 European Starlings (Arcese et al. 2020). In North Carolina, it mostly ate seeds 1.5 mm in length, with lesser amounts of seeds 1.5-2.5 mm long and negligible amounts of items 6.5-8.5 mm long. Almost all food items larger than 3.5 mm were soft fruits; smaller items were hard seeds. Its seed-size utilization overlapped 100% with the White-throated Sparrow and Northern Cardinal and 0% with the Field Sparrow and Dark-eyed Junco. Feeding activities included 72% feeding from a standing plant while on the ground, 17% on bare ground, and 11% while perched on a plant. Abundance of the Song Sparrow was significantly correlated with food abundance. It spent 22% of its time in forest and 18% of the diet consisted of fruit that occurred only in forested habitat. It was limited by its winter food supply (Pulliam and Enders 1971). The Song Sparrow is a widespread user of winter bird feeders but abundance at Ontario feeders is usually only 1 or 2 birds. The Project FeederWatch season extends to almost the end of March so many birds recorded may be spring migrants rather than wintering birds. Larger numbers occur at rural and suburban feeders than at urban feeders. It selects small easily opened seeds over harder ones even if they have higher energy content. Favourite feeder foods are mixed seeds and millet. Infrequent choices include sunflowers, safflower, cracked and whole corn, milo, wheat, niger, hulled peanuts or hearts, peanut butter mixes, bird puddings, baked goods, water and sugar water, canary seed, and popped corn (Dunn and Tessaglia-Hymes 1999). Horn et al. (2014) determined that it preferred white proso millet over other seeds and preferred hopper feeders based on 9,090 feeding events.

James (1991) considered the Song Sparrow a rare winter resident north to Manitoulin Island and Ottawa and occasional and rare in the north near Thunder Bay. It occasionally winters in Muskoka District and Algonquin Park (Mills 1981; Tozer 2012). The number of birds that winter at Presqu'ile is

variable depending upon the weather (LaForest 1993), and this is likely true throughout the province.

Freedman and Riley (1980) analyzed Christmas Bird Count (CBC) results for southern Ontario during 1929-77. Numbers were stable until 1957, then increased, averaging 2 times more abundant after 1957. The increase was probably due to an increase in availability of seed crops, weedy fields, or cover. Curry (2006) considered the Song Sparrow fairly common in winter in the Hamilton area, but noted that numbers have been declining since the 1960s. He attributed this to a decrease in the number of weedy fields. CBC data indicate that the Song Sparrow decreased in Ontario at an annual rate of 1.82% 1970-2021 and increased at an annual rate of 0.69% 2009-21 (National Audubon Society 2022).

Lincoln's Sparrow

Melospiza lincolnii

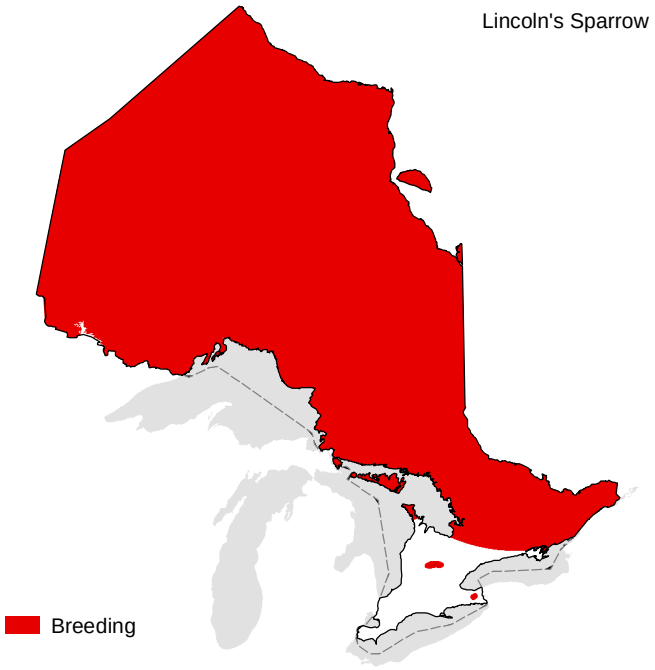
BREEDING SEASON

Habitat Requirements

Ontario Lincoln's Sparrow nests were in bogs and fens with growths of grasses, sedges, swamp laurel, Labrador tea, willow, black spruce, and tamarack (52.4% of nests); in alder and willow swales (19.0%); in shrubby roadside clearings (9.5%); in a small grove of black spruce (4.8%); in a rural garden near a woodlot (4.8%); on a river bank with fern clumps (4.8%); and in a wet pasture (4.8%). Eight-one percent of nests were in wet areas. Treed areas that were used were usually open and 2 bog areas were old burns (Peck and James 1987).

In the Hudson Bay Lowland, the Lincoln's Sparrow was one of the most common species in growths of willows and tamarack in the Moosonee town clearing (Manning 1952).

From Pickle Lake northward, the Lincoln's Sparrow was most numerous in coniferous scrub, followed by deciduous scrub, coniferous forest with understorey, mixed scrub, and coniferous forest



without an understorey. It was absent in deciduous or mixed forests, heath, and tundra (McLaren and McLaren 1981). Near Pickle Lake, it nested in small numbers in larger bogs (James 1980). At Dorion, an essential component of its habitat was the presence of low shrub growth, typically 1.2-2.4 m tall, with openings where tufts of grasses or sedges occurred. Territories were often swampy or wet, but this was not always the case. It occurred in recent clear-cuts full of brush piles and stumps, fallen logs, and new shrubby growth interspersed with grassy openings and rain pools. Marsh marigolds were a conspicuous feature of many territories. Other common plants included Labrador tea, sweet coltsfoot, wood anemone, and young cherry saplings. Small spruces, alders, willows, dogwoods, white birches, and trembling aspens occurred in most territories. Many territories were adjacent to stands of larger trees of trembling aspen, white birch, and spruce. Birds sometimes went into these woods when they were disturbed. Many territories included large isolated trees of these species that it occasionally used as perches. Nesting habitat consisted of the edge area between the forest and buildings with their surrounding lawns and roads. This area was brushed every few years to impede natural succession and cuttings and slash covered the ground. Most vegetation was about 30 cm tall and consisted of anemones, grasses, sedges, roses, strawberries, and the woody species previously mentioned. The actual species of plants were probably unimportant but their size and interspersion were important. Shrubs less than 2.4 m tall provided concealment and song perches; openings with grasses, heaths, or annuals less than 60 cm tall provided foraging sites; and a substrate of brush cuttings, grass clumps, or sphagnum provided a suitable nesting substrate. In Thunder Bay District, it occurred on high rocky hillsides with low shrub growth of dogwoods, alders, willows, and birches with occasional taller aspens and birches, and with openings where clumps of grasses and sedges grew around temporary pools. Habitat structure was very similar to that at Dorion except that the site was dry. In Abitibi Region, it frequently occurs in dry upland openings in the forest and in Nipigon District it nests in raspberry patches. Many nests have been documented in open sphagnum bogs in spruce forests. Originally and in areas currently undisturbed by humans, it depends on fires and margins of water bodies, watercourses, and wetlands to provide suitable habitat. It now nests in human-made openings such as clear-cuts and rights-of-way for roads and hydro transmission lines (Speirs and Speirs in Austin 1968). North of Lake Nipigon, the Lincoln's Sparrow was common in a clear-cut that was quite wet with alders 2.4 m tall (Kendeigh 1947). Near Hearst, it nested in an unharvested black spruce lowland forest, in clear-cuts in lowland coniferous forests 3-19 years old, and in clear-cuts in upland mixed forests 3-5 years old. Lincoln's and Savannah sparrows were the dominant species in the 3-year-old lowland coniferous clear-cut. This community was open, wet, and meadow-like

(Welsh and Fillman 1980). Near Manitouwadge, the Lincoln's Sparrow occurred in stands 1-21 years old but was absent in stands 24-36 and 60-223 years old (Venier et al. 2009). In jack pine forests near White River, it was significantly associated with stands that had been clear-cut 3-5 years previously. It was a significant indicator of this age class. This age class of forest was dominated by species that foraged and nested on the ground. Its abundance was significantly correlated with coarse woody debris volume and negatively correlated with vertical structure 2.5-5 m tall. It was associated with dense shrubs but avoided areas where woody vegetation height exceeded 2.5 m (Venier and Pearce 2003). In the Clay Belt, it was most likely to occur in black spruce stands followed by those dominated by jack pine, tamarack or white cedar, and white spruce–birch. It occurred predominantly on wet sites but occasionally in dry areas treed with jack pines. Most sites where it occurred were nutrient-poor, but a few were moderately rich in nutrients (Welsh and Lougheed 1996). Also in the Clay Belt, it nested at the edge of a spruce-tamarack-alder bog and in a spruce sphagnum bog (Smith 1957). In the eastern Boreal Forest Region, it occurred mainly in young or at least low spruces, and was one of the more common species in bogs and fens (Erskine 1977).

In jack pine stands near Gogama in the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region, it was rare and occurred only where the pines were small and well-spaced and where sedges, grasses, and scattered deciduous shrubs were present. It was absent where pines were more than 15 years old (James and Peck 1995a). In Algonquin Park, MacLulich (1938) observed it only around beaver meadows and in shrubby areas. Tozer (2012) reported that it nested in the park in bogs, beaver meadows, and dry upland clearings with low shrubby growth interspersed with open areas with grasses and sedges.

South of the Shield, the Lincoln's Sparrow nests almost exclusively in large bogs and fens (James 1991). Wainfleet Bog is the only breeding location within the Carolinian Forest Region (Black and Roy 2010).

Throughout its range, the Lincoln's Sparrow prefers short shrubs interspersed with open areas, predominantly in damp to wet locations. It nests in montane meadows, willow and alder thickets, aspen groves in the west, open spruce stands, bogs and fens, clear-cuts, burns, young coniferous plantations, drainage ditches along roads, moist overgrown fields, hydro corridors, shrubby beaver meadows, and riparian shrubs. In Quebec, it nests in drier shrubby portions of sphagnum bogs, especially older ones suitable for the production of peat rather than the wet sphagnum moss of more-recent bogs. It often frequents edges of bogs among Labrador tea, laurel, and rhododendrons with scattered conifers and a ground cover of cloudberry. In Matane, it nested among low alders fringing streams and, in Gaspé, it nested near the top of a mountain among scrubby conifers (Speirs and Speirs in Austin 1968). In Quebec, it prefers more remote habitat such as peatlands, wet meadows, clearings created by fire or logging, and thickets of alders, willows, or stunted conifers along rivers, streams, and lakes. In the James and Hudson bay regions, it occurs at margins of most open habitats, particularly those that are wet. It is often found inland among willows surrounding open grassy meadows. In northern Quebec, highest densities were in tamarack peatlands and shoreline scrub. In the Boreal Forest Region, it inhabits alder thickets in open areas where there is open water nearby (Langevin in Gauthier and Aubry 1996; Manning and MacPherson 1952). Near Quebec City, the Lincoln's Sparrow was absent in recent burns, common in clear-cuts with shrubs

less than 2 m tall, and absent where shrubs were taller than 5 m and in mature stands. Imbeau et al. (1999) considered it an early successional species associated with clearings due to recent clear-cuts. Although it is common in Quebec clear-cuts, it is absent in strip-cuts. It probably requires openings wider than 20 m in forest cover (Falardeau et al. 1999). In northcentral Quebec, it was typical of shrub stands and appeared after the falling of dead trees approximately 15 years after fire, and disappeared progressively as stands matured (Crête et al. 1995). In New Brunswick, it nested in spruce plantations 3-15 years old but was absent in older plantations (Freedman and Johnson 1999). In Newfoundland, Whitaker et al. (2008) netted Lincoln's Sparrows in natural landscapes where openings consisted mostly of peatlands and in harvested landscapes where openings were most clear-cuts as well as some peatlands. Sixty-seven percent of captures were in harvested landscapes suggesting that clear-cuts improved habitat. At another Newfoundland site, its overall occurrence tended to be higher in natural than harvested landscapes, especially at higher levels of forest cover. Its occurrence was positively correlated with scrub, bogs, and regeneration and it was negatively affected by the amount of forest cover within a 150-m radius. It was unaffected by the amount of forest cover within 1,250 m but declined nonsignificantly as forest cover increased. Probability of occurrence was 40% at 10-40% tree cover, 30% at 60% tree cover, 18% at 80% tree cover, and 0% at 97-100% tree cover. Taylor and Krawchuk (2006) considered the Lincoln's Sparrow an open and edge species. In Newfoundland balsam fir forests, it was documented only at edges between forests and clear-cuts or roads and not in riparian vegetation and forest interior. Whitaker and Montevecchi (1997, 1999) concluded that it was associated with early successional openings and edges and also occurred in riparian alder thickets. It was common in open bogs and low shrubs in the northeast. It was common in shrubs with scattered conifers and uncommon in young or low black spruce (Dawson 1979).

In the western mountains, particularly south of Canada, the Lincoln's Sparrow is most common in montane meadows. In Minnesota, it occurred in low shrubs along a hydro corridor and in open spruce stands (Niemi and Hanowski 1984a). In the Prairie Provinces, it occurred predominantly in wet marshy or boggy habitats and some riverine mixed-wood forests. It occurred in sites that were mostly nutrient-poor and wet. Forest stands it occupied were young. It was not detected in stands older than 20 years (Kirk et al. 1996). In Alberta, it was significantly more abundant in clear-cuts than in uncut forests. It was present in low numbers in forests prior to cutting and moved into clear-cuts in the first year after logging. In clear-cuts, it decreased in abundance with increasing basal area (Tittler et al. 2001). In aspen forests, it was rare in young and old-growth forests and absent in mature stands (Schieck et al. 1995). On Haida Gwaii, it breeds in open wet habitats with clumps of soft rush. In the mountains, it breeds in willow swamps. It prefers to nest in wet habitats with low dense shrub growth, particularly willows 1-2.5 m tall, with openings with mosses, sedges, or grasses. It nests in swamps, muskegs, bogs, thickets near beaver ponds, brushy fields, marshy areas with alder or willow thickets, sedge and rush meadows, streamside willows, black spruce–tamarack bogs, floodplain forests, regenerating burns and cuts, trembling aspen groves, subalpine parklands, and shrubby areas near the timberline. It also nests in roadside willows, red-osier dogwood, and fireweed with trees as tall as 8 m; wetlands with dwarf birch, rough horsetail, Labrador tea, sphagnum moss, and some open water; and in wet shrub thickets with a dense herbaceous understorey. In trembling aspen forest, it is most abundant in 4-6-year-old clear-cuts. Thirty-nine percent of nests were associated with wetland habitats, 25% with forested areas, and 19% with human-influenced areas.

Of the wetland habitats used, 14% were marshes, 11% were lakes, and 11% were willow swamps and balsam fir bottomland forests. Twenty-two percent of the total 25% of nests in forested areas were in trembling aspen or other deciduous woods. Human-influenced habitat included farmland, pastures, suburban areas, logged areas, and roadsides. Sixty-eight percent of nests were at forest edges and regenerating clear-cuts. It also nested in muskeg, beaver ponds, roadsides, farmyards, and airports (Campbell et al. 2001). In the Yukon, the Lincoln's Sparrow prefers moist shrubby habitats in or near forested areas with willow, dwarf birch, or a mixture of these species. It also breeds in wetlands including taiga and bogs where it nests in tall dense shrubs. It nests in marshy and shrubby areas adjacent to lakes and in streamside shrubs and clear-cuts (Sinclair et al. 2003). In Alaska, it was most abundant in floodplains and terraces, followed by lowlands, subalpine areas, hills and bluffs, and alpine areas (Handel et al. 2009). In the same state, it responded positively but not significantly to spruce mortality resulting from the spruce beetle. The beetles attacked only large white spruce, resulting in gaps in the canopy (Matsuoka et al. 2001). In Yellowstone National Park, there was no significant difference in its abundance in areas where willows averaged 66 cm and 152 cm tall. There was a tendency for a decline with increasing willow height but this relationship was not significant (Campbell et al. 2001; Olechnowski and Debinski 2008; Speirs and Speirs in Austin 1968). In Wyoming, it occurred at all elevations, but was most abundant in subalpine areas. Habitat there consisted of willow thickets interspersed with wet or boggy meadows surrounded by spruce-fir forests. It foraged and nested on the ground and selected habitats that were structurally simple. It preferred areas with a sparsely foliaged overstorey and few trees. It was positively associated with increasing shrub density and foliage density of the low understorey. Its habitat size was significantly less than random indicating that it was a habitat specialist (Finch 1989b, 1991a). Another Wyoming study found that its abundance was positively correlated with elevation. It was negatively correlated with non-willow shrub coverage 0.5-1 m tall (Anderson 2007). In montane habitat in the western United States, it was most common in moderately wet to flooded meadows with low levels of grazing damage. It was absent from the single site that lacked standing water and had signs of heavy grazing. It significantly selected for wet areas, with only 3% of birds occurring in areas of dry ground; 93.1% were seen in either boggy (54.2%) or flooded (38.9%) areas. Presence of nearby surface water was the most important attribute; presence of willow, pine, and corn lily were important. Eighty-four percent of males occurred near clumps of willow, significantly more than random, and 59% were in areas with at least scattered patches of corn lilies, although this relationship was not significant. Concentrations were significantly greatest near edges of meadows (67% of observations) where it often perched or sang in pines. Most were observed in meadows but singing males or pairs were occasionally seen in small nearby openings in surrounding forest provided that suitable habitat was present. Important breeding habitat attributes included boggy or flooded ground; thick ground cover by herbaceous plants, often with raised tussocks of live or dead grasses or sedges; patches of corn lily; willow thickets or other low shrubs; and some conifers. Raised clumps of herbaceous vegetation were probably critical for breeding under such wet conditions (Cicero 1997).

Some studies compared the habitat preferences of the Lincoln's Sparrow with other sparrows. Salt (1957) examined the distribution of the Lincoln's, Fox, and Song sparrows in willow marshes in Wyoming. The Lincoln's Sparrow occurred in drier areas where willows were in low scattered clumps 0.6-1.2 m tall with patches of grasses and sedges in between. The Song Sparrow inhabited dense

willows 1.8-3 m tall along watercourses and the Fox Sparrow occurred in drier glades surrounded by willows 3-3.7 m tall. The Lincoln's Sparrow is generally a species of grassy meadows, but it also occurs in willow scrub. It occasionally inhabits herbaceous undergrowth of aspen groves, but these groves are commonly near water and may represent peripheral foraging areas. In California and Oregon, there was a strong negative relationship between Lincoln's and Song sparrows. Although some meadows had approximately equal numbers of both species, most sites were dominated by one or the other species. Where the 2 species co-occurred, the Lincoln's Sparrow occurred in the wettest areas and the Song Sparrow occurred only in the drier, more heavily grazed areas (Cicero 1997). Ammon (2020) concluded that the Lincoln's Sparrow selected wetter sites for breeding than co-occurring White-crowned Sparrows and Dark-eyed Juncos.

Ammon (2020) stated that the Lincoln's Sparrow often occurred near forest edges, but most frequently in the open side of the edge. Forest edges are used by males for singing and sentinel perches. The territory and nest are not significantly associated with edge.

Most Ontario nests (82.4%) were on the ground, usually in pure moss or in moss, grass, or sedge hummocks. Other ground nests were in clumps of ferns and in goldenrod stems and raspberry canes. The remaining nests were 0.2-0.3 m above ground or water in shrubs. Sixty-four percent of ground nests were at the base of a small tree or shrub. Nests were often concealed by standing dead grasses and sedges (Peck and James 1987). A nest at Dorion was 4.9 m from an access road and 2.4 m from forest edge. Another was in a grass clump between a road and roadside ditch, 10 m from forest edge (Speirs and Speirs in Austin 1968).

Ammon (2020) considered the Lincoln's Sparrow a microhabitat specialist that nests on the ground, often in a low willow or dwarf birch with nearby sedge cover that is fairly dense. Nest sites are more elevated with denser ground and lower shrub coverage than random sites in the territory. Nests are typically well concealed at the base of shrubs but may be in forbs such as buttercups. Colorado nests had a distinct nest-entrance tunnel through ground vegetation oriented east to northeast, significantly different from random orientation. In shrub cover, nests are most often 30-50 cm inside the shrub's edge. Occasionally nests may be a few metres inside a forest. Usually more than 90% of nests are on the ground. Nests may be elevated as high as 1 m, but are usually 30 cm or less from the ground. Ground nests are in a depression in moss but nests in shrubs or grasses are woven among the branches or grass stems. If a nest is artificially removed after breeding, sometimes the same depression is used the following year (Ammon 2020; Campbell et al. 2001; Cicero 1997; Langevin in Gauthier and Aubry 1996; Philipp and Bowdish 1917; Sinclair et al. 2003; Speirs and Speirs in Austin 1968).

The territory is used mostly for nesting with much foraging taking place outside the territory. Territory boundaries break down temporarily 5-8 days after the young fledge but territorial activity resumes at the time when a second brood would be initiated even if one is not attempted. In Ontario, territories appeared to be occupied until autumn migration. Territories at Dorion were 0.4 ha; 2 territories near Lake Nipigon averaged 0.32 ha. In high-density populations in Colorado, territories averaged 0.09 ha (Ammon 2020; Kendeigh 1947; Speirs and Speirs in Austin 1968).

The only information on natal philopatry and adult site fidelity is from Colorado. Three of 137 young (2.2%) returned to the natal area over a 5-year period. Thirty-seven percent of 123 adult males and 36% of 85 females returned to breed (Ammon 2020).

Limiting Factors

Eggs have been reported in Ontario nests from mid-May until the first week of August, with most present in the last 3 weeks of June (Peck and James 1987). In many areas, territories are established immediately upon arrival but at Dorion males waited until it warmed up. Nest building did not start until 10-14 days after territories were established. Nest construction takes 3 days. Egg laying usually begins 2-4 days after the nest is complete but several more days may elapse before eggs are laid. Eggs are laid at the rate of 1 per day. Incubation begins with the laying of the last egg. The incubation period of 1 egg near Dorion was 13.25 days. In Colorado, the incubation period averaged 11.5 days (range 10-13 days). Eggs usually hatch within a 36-hour period but occasionally 1 egg hatches a day later, suggesting that incubation may begin with the laying of the penultimate egg in some cases. The nestling period at Dorion was 9-10 days; nestling periods of 10-12 days have been reported elsewhere (Ammon 2020; Speirs and Speirs in Austin 1968).

In Ontario, egg dates, resumption of courtship behaviour in early July, and presence of young juveniles in September all suggest that double broods may occur, but this has not been confirmed. In Colorado, only 1 brood was typically reared in a season. In a season where breeding started 10 days earlier than normal, 3 of 65 pairs (4.6%) attempted a second clutch. Second clutches were initiated before the nestlings of the first brood fledged. Renesting usually occurs if a nest is lost or abandoned. Clutches of 3-5 eggs (mean 4.08 eggs) have been reported in Ontario, with 76.9% of clutches containing 4 eggs. Three to 5 eggs are typically laid and 4 eggs is the most frequent clutch size. There appears to be no seasonal variation in clutch size. In Colorado, the mean clutch size was 4.24 eggs, increasing to 4.48 eggs during a year of insect outbreak (Ammon 2020; Campbell et al. 2001; Peck and James 1998b; Speirs and Speirs in Austin 1968).

Both sexes are capable of breeding when they are 1 year old, but many yearling males do not breed. The Lincoln's Sparrow appears to be monogamous. There is circumstantial evidence that extra-pair copulations may be part of its breeding strategy in high-density populations. Populations in Colorado and Newfoundland were strongly male biased and intense mate guarding occurred during nest building and egg laying (Ammon 2020; Whitaker et al. 2008).

The Lincoln's Sparrow forages predominately on the ground. Foraging occurs in dense cover where it scratches with both feet to uncover prey or chases prey on the ground. It mostly gleans on the ground and low vegetation but also on tree foliage and branch tips. It flycatches infrequently, but during moth outbreaks this may be a common foraging technique. It visits feeders at any time of the year and in the breeding season defends food resources at feeders even if they are outside its territory (Ammon 2020; Speirs and Speirs in Austin 1968).

Nestlings at Dorion were fed predominantly green caterpillars that were likely geometer moths, grayish caterpillars that were possibly owlet moths, small whitish moths, yellowish larvae that were possibly beetles, small caterpillars, and small larvae that may have been budworms. Females were observed feeding fledglings 20 days after they had left the nest. Caterpillars are a staple of the

nestling diet, but young are also fed other soft-bodied insects such as mayflies (Ammon 2020; Speirs and Speirs in Austin 1968).

Judd (1901) analyzed the contents of 31 adult Lincoln's Sparrow stomachs, mostly migrants collected in Massachusetts and New York. They contained 42% animal matter and 58% vegetation. Insects comprised 40% of the diet and the remaining 2% of animal food consisted of spiders and millipedes. The insects included hymenopterans, beetles, ants, flies, grasshoppers, and some bugs. Plant material in the diet included 27% grass seeds, 16% miscellaneous seeds that were predominantly weeds, 13% ragweed and smartweed seeds, and 2% grain. During outbreaks, it may forage mostly on moths during the breeding season. It has been documented eating clover-root weevils, alfalfa weevils, crane flies, and aquatic beetles (Ammon 2020). In Wyoming, Raley and Anderson (1990) compared the breeding-season diets of the Wilson's Warbler and Lincoln's Sparrow with each other and available prey. Fifty-four families of arthropods, excluding spiders, were identified in the Lincoln's Sparrow's diet in 2 years. It preferred beetles over all other groups. Larvae (immature beetles, hymenopterans, and caterpillars) ranked high in preference; stoneflies and mayflies ranked low. Preferred prey in decreasing order of preference included beetles, larvae, flies, soft-winged bugs, spiders, mayflies, hymenopterans, stoneflies, true bugs, caddisflies and adult lepidopterans. In this list, beetles through mayflies were used more than their availability and the remainder were used less than their availability. Soldier beetles represented a large proportion of the beetles that were consumed. These beetles have soft elytra, are fairly large (7 mm), are slow fliers, and tend to crawl rather than fly from disturbance. It selected more cryptic invertebrates than the Wilson's Warbler and those that were more uniformly distributed. It spent more time in any given shrub than the Wilson's Warbler and was more likely to detect cryptic prey. Fifty-three percent of the flies consumed were crane flies. These are slow fliers and tend to be in the inner and lower portions of shrubs where the Lincoln's Sparrow commonly foraged. Crane flies were also present in sedge-grass meadows. The Lincoln's Sparrow and Wilson's Warbler both selected prey disproportionately and preferred different prey items.

The Lincoln's Sparrow is an uncommon host of the Brown-headed Cowbird, probably because of the species' different habitat preferences. One of 28 Ontario nests (3.6%) was parasitized. In Colorado, 0-3% of nests were parasitized annually depending upon location and year. In British Columbia, 4 of 66 nests (6.1%) were parasitized. Lincoln's Sparrows were observed feeding cowbird fledglings there (Ammon 2020; Campbell et al. 2001; Peck and James 1998b; Speirs and Speirs in Austin 1968).

It is uncertain whether habitat loss and degradation are occurring for the Lincoln's Sparrow. Fire suppression has probably decreased the amount of available habitat, but clear-cutting and other human activities that create shrubby habitat are beneficial. Some populations south of the Canadian Shield may be at risk due to degradation of bogs and fens. At Wainfleet Bog, it formerly bred in the interior of the wetland, but the entire open area of the bog has been invaded by silver birch, making the habitat unsuitable. It now nests only at the edges of the bog (Black and Roy 2010). The Wylde Lake Bog at Luther Marsh supports a small population of Lincoln's Sparrow. This bog is becoming increasingly treed, although with native species typical of bogs and fens (Sandilands 1984). Invasion of both these bogs by trees is probably due to human alterations of their hydrology.

The Lincoln's Sparrow responds positively to forest management, but only when a high proportion of the canopy is removed. In Alberta, it colonized coniferous forests once 80-100% of tree cover was removed. In deciduous forest, colonization occurred when 25-100% of the canopy was removed, but the increase was not significant until 90% of trees were removed. In Newfoundland, breeding-season and annual survival rates were marginally higher in landscapes where most openings consisted of clear-cuts than in natural landscapes (Ammon 2020; Harrison et al. 2005; Whitaker et al. 2008). In Maine, Santillo et al. (1989) studied the effects of spraying glyphosate on clear-cuts on the Lincoln's Sparrow. It was significantly less abundant in treated than untreated clear-cuts. The application resulted in vegetation that was structurally and floristically less complex for 1-3 years after treatment. Invertebrates were less abundant in treated areas and confined mostly to untreated skipped areas. The reduction of invertebrates, berry-producing shrubs, and seed-producing grasses and forbs reduced food for it. The Lincoln's Sparrow particularly benefits from short-rotation logging (Imbeau et al. 1999). In Ontario, it was equally abundant in early successional and mid-successional areas created by fire and clear-cutting. It was significantly more abundant in early successional stands than mature stands. It was also more abundant in mid-successional than mature stands but not significantly (Zimmerling et al. 2017).

Browsing by ungulates can degrade habitat for the Lincoln's Sparrow. This is particularly true of livestock grazing, which can alter vegetation structure and even hydrological regimes. In Colorado, it avoided areas that were heavily grazed by cattle. Decreases in its abundance have been associated with livestock grazing in British Columbia and other locations (Ammon 2020; Campbell et al. 2001; Cicero 1997). In Wyoming, it was not sensitive to elk grazing and tended to be more common in heavier grazed areas. Most species that were adversely affected nested in willows but there were few effects on ground-nesting species (Anderson 2007). In Anticosti Island clear-cuts in balsam fir–dominated forests, Cardinal et al. (2012) recommended that deer densities should be 7.5 or fewer per km^2 to avoid adverse effects of browsing. Browsing is unlikely to be a significant limiting factor for the Lincoln's Sparrow in Ontario. Its main range is outside the area where heavy grazing by cattle occurs. Densities of other browsers of woody vegetation, such as moose, deer, and caribou are low within the core of its Ontario breeding range.

Bayne et al. (2016) studied the effects of oil and gas infrastructure on the Lincoln's Sparrow. It was significantly more abundant at pipelines and well pads than in forest-interior habitat adjacent to these features. There was no difference in its abundance at seismic lines and in adjacent forest interior. The larger forest openings created by pipelines and well pads were attractive to it but the narrower (8-10 m) seismic lines probably were not wide enough to be attractive. It did not shift frequencies of its song between noisy compressor stations and quiet well pads, but it sang more in noisy areas (Sánchez et al. 2023).

The Lincoln's Sparrow appears to be particularly sensitive to human disturbance and readily abandons its nest. Significantly higher desertion rates occur in sites used for picnicking, fishing, and hiking than in areas not used for recreation (Ammon 2020; Campbell et al. 2001).

Application of waste sludge from paper mills resulted in an almost doubling of the Lincoln's Sparrow's density in treatment areas. This was probably due to the increase in vegetation because the number of ground invertebrates did not change (Ammon 2020).

Price (2004) predicted that the Lincoln's Sparrow might no longer breed in southern Ontario if the average summer temperature increased by 2°C. In southern Quebec, DesGranges and Morneau (2010) considered it highly sensitive to climate change and projected that its range was likely to shift northward. It was a boreal forest species correlated with cooler and wetter summers. In central Quebec and Labrador, it was not significantly correlated with any climatic variables (DesGranges and LeBlanc 2012).

Status

McIlwraith (1894) considered the Lincoln's Sparrow almost unknown in eastern Canada but acknowledged that it could have been overlooked due to its retiring nature. The first record for Ontario consisted of 2 birds collected at Hamilton Beach on 23 May 1885 followed by 2 more 2 days later. After that, he knew of only single records at Ottawa and London and was not aware that it bred in the province. Baillie and Harrington (1937) stated that it was distributed locally from York Region to beyond the transcontinental railway at Smoky Falls, and probably northward to Hudson Bay. It occurred commonly in many localities in the more northern portions of the province. In addition, 6 pairs were found in Wainfleet Bog in Niagara Region in 1936. The first atlas revealed that the Lincoln's Sparrow bred throughout the Boreal Forest Region and Hudson Bay Lowland, although it was not documented in many blocks within these regions. This was attributed to the species being overlooked rather than being absent. Many breeding records were obtained in the southern portion of the Canadian Shield from Lake Nipissing south to the Perth area, a southward extension of the previously known breeding range. There were very few records south of the Shield, and these were associated mostly with large bogs and fens. Highest densities occurred in the north from the Wawa area north to James and Hudson bays (Speirs in Cadman et al. 1987). James (1991) considered the Lincoln's Sparrow common in the north, south to Thunder Bay and Kirkland Lake; and an occasional rare and local summer resident in the south, mostly on the Shield, but south to Luther Marsh and Wainfleet Bog.

The second atlas found no significant changes in the range of the Lincoln's Sparrow. It was found in almost all northern Ontario blocks confirming that it had simply been overlooked in some areas during the first atlas. Its probability of observation increased significantly province-wide and in all regions except the Carolinian Forest Region, where it continued to occur at Wainfleet Bog only. Although its increase may be due in part to increased song recognition by fieldworkers, it appears to have increased. The increase in the Great Lakes–St. Lawrence Forest Region both in and off the Shield may be due to its increased use of early successional upland habitats and shrub thicket swamps. It was most abundant in a broad band south of the Hudson Bay coast. Moderate densities occurred throughout the Hudson Bay Lowland and in a broad band of the Boreal Forest Region across the province north of Lake Superior. In the Hudson Bay Lowland, treed bogs and fens are abundant and provide excellent habitat. The band through the Boreal Forest Region where it reaches highest abundance coincides with the region where forest management has created young regenerating forests with dense shrub and sapling cover. In younger clear-cuts, it is often the most abundant bird species (Zimmerling in Cadman et al. 2007).

Breeding Bird Survey results from 1970 to 2021 indicate an annual increase of 1% in Canada and an annual decrease of 0.39% in Ontario. Trends 2011-21 were annual decreases of 1.44% in Canada

and 4.16% in Ontario. All trends were of medium reliability except for the short-term Ontario trend which was of low reliability (A.C. Smith et al. 2003).

POSTFLEDGING PERIOD

Young are largely flightless the day they leave the nest. They can fly 6-8 m 3-5 days after leaving the nest and more than 10 m 6 days after fledging. The first 4 days after fledging are mostly spent under dense cover. Brood division may occur, but no studies with banded birds have been conducted. Young often return to the nest for several nights after fledging. Older juveniles sleep on the ground in tunnels under ground vegetation. Five to 8 days after fledging, family groups begin to forage throughout the breeding habitat. No large aggregations of postbreeding birds occur and, once the juveniles are independent, most birds remain solitary or in pairs. Occasionally, the Lincoln's Sparrow forms loose foraging flocks with conspecifics and other sparrows. Juveniles remain in the vicinity of the nest until autumn migration (Ammon 2020; Langevin in Gauthier and Aubry 1996; Speirs and Speirs in Austin 1968).

MIGRATION

The Lincoln's Sparrow is a nocturnal migrant as evidenced by kills at towers and captures while netting for owls. It is unknown if any diurnal migration occurs. The entire population is migratory with no resident birds. During migration, it occasionally mixes with Song, Swamp, White-throated, and White-crowned sparrows. A juvenile banded northeast of Moosonee was captured in Michigan the following spring (Ammon 2020; Brewer et al. 2018; Speirs and Speirs in Austin 1968; Weir 2008).

In southern Ontario, most migrants pass through in the first 2 weeks of May, with the peak in the middle of the month. Birds may arrive in late April and most have passed through by the end of May (LaForest 1993; Mills 1981; Tozer 2012; Weir 2008). At Dorion, the Lincoln's Sparrow first appeared at a feeder on 16 May but none were seen on the breeding grounds until 19 May when the sky cleared and the temperature rose (Speirs and Speirs in Austin 1968). Kendeigh (1947) saw the first one north of Lake Nipigon on 17 May.

At a reclaimed landfill in New Jersey, the mean autumn stopover period of the Lincoln's Sparrow was 4.7 days (maximum 16 days; Seewagen and Newhouse 2018). Wilson and McRae (1993) considered singles seen on 4 dates in late August at Brant to be migrants. Migrants appeared in Moosonee in September with the highest count on 3 September. The Lincoln's Sparrow was last seen at Dorion on 19 September (Speirs and Speirs in Austin 1968). The main autumn migration in the southern Shield is from early September to early October, with most leaving by late October (Mills 1981; Tozer 2012). In southern Ontario, migration is noticeable by late August and continues throughout September with most leaving by mid-October, but with records to mid-November or rarely into December (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Speirs and Speirs in Austin 1968; Weir 2008).

During autumn migration along the James Bay coast, the Lincoln's Sparrow was abundant in willows at edges of sedge marshes on sandy islands. Those further north up the coast were in open spruce or deciduous thickets (Manning 1952). During spring migration at Dorion, it preferred watercourses lined with shrubs, but also occurred in dense shrubbery almost anywhere; it may occur in urban parks (Speirs and Speirs in Austin 1968). In Muskoka and Parry Sound districts, autumn migrants frequent overgrown fields and other scrubby areas (Mills 1981). During autumn migration

in Toronto, it prefers marshy areas and weedy fields where it is often found in the company of White-throated and White-crowned sparrows (Speirs and Speirs in Austin 1968). Autumn migrants at Algonquin Park skulk in dense vegetation such as raspberries (Tozer 2012). During migration, it inhabits shrub-dominated areas providing dense cover, especially in riparian areas. In the east, it often occurs in urban and suburban areas in shrubby forest edges, weedy fields, hedgerows, marshes, and raspberry thickets (Ammon 2020). Quebec migrants frequent thickets, fallow land, hedges, understorey of open woods, clearings, forest margins, and roadsides (Langevin in Gauthier and Aubry 1996). In the Saskatoon area, migrants are seen in underbrush in city gardens and rural areas (Leighton et al. 2002). In British Columbia, migration habitat includes logging slash, hydro corridors, hedgerows, shrubby field edges, old fields and shrubby pastures, young forests and older forest edges, orchards, grass and sedge meadows, river floodplains, native tussockgrass prairies, and shrub thickets adjacent to sewage lagoons, lakes, marshes, sloughs, swamps, beaver ponds, estuaries, and beaches (Campbell et al. 2001). In Minnesota, migrants frequent hedgerows, weed patches, borders of woods, tamarack swamps, and similar dense vegetation. Several autumn migrants fed on mudflats just outside grass cover where a lake had dried. At another lake, it frequented thick tangled weeds and grass in low areas and accompanied Harris's and White-throated sparrows in tall shrubby and weedy areas and in plum thickets. It was also common in cornfields and old grassy gardens (Speirs and Speirs in Austin 1968). In Kansas, migrants preferred low dense thickets in swampy areas. Spring migrants appeared to settle for days or even weeks within small areas. Patches of green foxtail near the edge of a woodlot were much used in late April. Late autumn migrants also used brush piles (Fitch 1958). On 2 islands in the Gulf of Maine, there was no significant difference in their usage by spring migrants. During autumn migration, significantly more Lincoln's Sparrows used the island with shorter trees and higher shrub density (Suomala et al. 2010). During spring migration in Pennsylvania, the number of Lincoln's Sparrows captured per 1,000 net-hours was 0 in forested habitat and 1.8 in shrub habitat (Smith and Hatch 2008). Presence of dense shrubby or herbaceous vegetation is the prime habitat requirement of the Lincoln's Sparrow during migration, and it is seldom seen outside dense cover. These microhabitat requirements may be found in a wide variety of macrohabitats, but it prefers areas without extensive tree canopy.

The Lincoln's Sparrow may visit feeders during migration, particularly in spring and infrequently in autumn. It uses only ground feeders close to dense cover; elevated platforms are not used. It has been observed eating rolled oats and millet at feeders (Ammon 2020; Leighton et al. 2002; Tozer 2012).

The Lincoln's Sparrow often strikes television towers and other tall structures during migration. Seven were killed out of 936 birds during 4 late September nights at the Barrie television tower and 18 were killed at the Lennox generating station chimneys from 1972 to 1981. It is one of the species most vulnerable to striking high-rise buildings in Toronto (Ammon 2020; Colling et al. 2022; Speirs and Speirs in Austin 1968; Weir 2008).

James (1991) considered the Lincoln's Sparrow an uncommon migrant in Ontario. It may actually be common but seldom seen. Records at Prince Edward Point indicated that it was far more common (daily maxima 35-60) than observations suggested. In southern Ontario, maximum daily

counts seldom exceed 20 birds (Curry 2006; LaForest 1993; Weir 2008). Wilson and McRae (1993) observed 50 at Moosonee on 3 September.

Captures of the Lincoln's Sparrow at Long Point Bird Observatory declined at a nonsignificant rate of 0.6% per year 1961-88. Trends by period were: 1961-70, −2.6%; 1970-79, + 0.3%; and 1979-88, − 0.2% (Hussell et al. 1992).

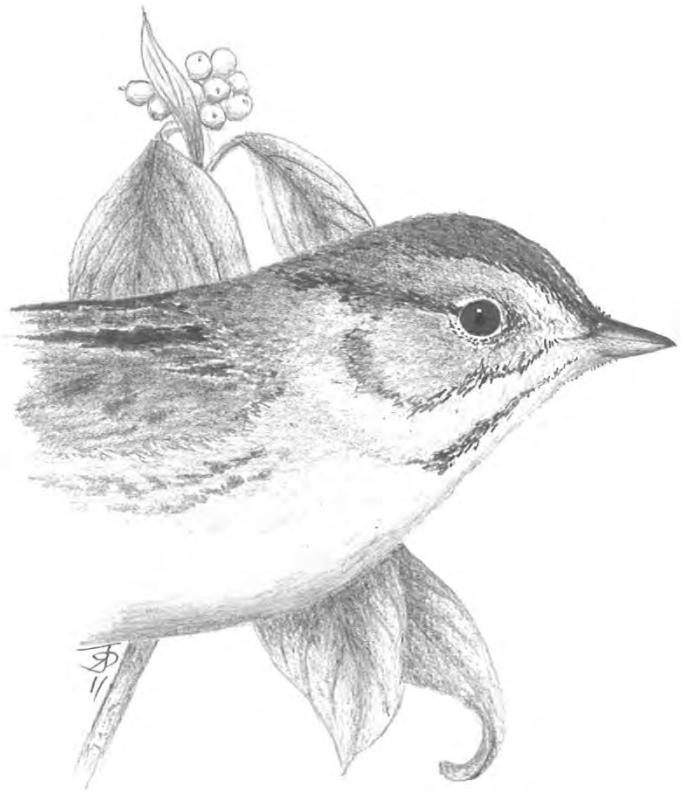
WINTER

Root (1988) reported that the Lincoln's Sparrow wintered north of latitude 35°N only in warm winters. The entire winter range, including the irregularly occupied northern areas, occurs where the average minimum January temperature is higher than −7°C. More regularly frequented wintering areas occur where the minimum January temperature is −1°C. Speirs and Speirs (in Austin 1968) stated that it rarely stayed as far north as New York to winter and its normal winter distribution extends only as far north as Georgia, Kansas, and Missouri (Ammon 2020).

James (1991) considered the Lincoln's Sparrow an occasional wintering species north to Peterborough. Almost all Ontario winter records are from late December and early January with no apparent February sightings (Curry 2006; LaForest 1993; Lancaster et al. 2004; Speirs 1985; Weir 2008). There are records from 31 March in Kingston, which was considered an early spring migrant (Weir 2008) and from 6 April in Hamilton (Curry 2006), which was considered a winter record. It is uncertain whether the Lincoln's Sparrow has ever successfully overwintered in the province. Most records of wintering birds appear to be of autumn migrants that have remained much longer than usual.

Swamp Sparrow

Melospiza georgiana



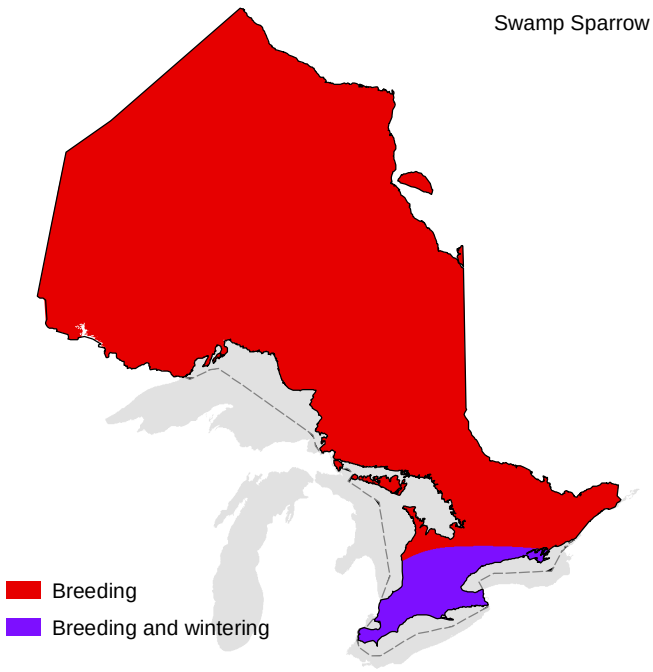
BREEDING SEASON

Habitat Requirements

In Ontario, the Swamp Sparrow breeds in wetlands and is an obligate wetland species throughout its range. Of nests reported in the province, 62.3% were in marshes of sedges, grasses, cattails, and other nonwoody wetland plants, and in marshy edges of lakes and rivers; 19.5% were in bogs and fens with growths of shrubs and small conifers; 13.8% were in shrubby areas in swamps, sedge meadows, and shorelines, and in willow thickets; 2.5% were in wet pastures; and 1.9% were in beaver ponds (Peck and James 1987).

In the Boreal Forest Region near Pickle Lake, James (1980) observed the Swamp Sparrow regularly in small numbers along margins of rivers and lakes. In the Clay Belt, it was common in swamps and marshes, particularly cattail marshes (Smith 1957). In forests in the Clay Belt, it was most

abundant in tamarack or cedar stands, followed by balsam poplar and black spruce stands. It was associated only with wet stands that ranged from nutrient-poor to nutrient-rich (Welsh and Lougheed 1996). Near Hearst, Welsh and Fillman (1980) found it in clear-cuts in lowland coniferous forests 3-17 years old, but it was most abundant in a 5-year-old clear-cut. Erskine (1977) concluded that the Swamp Sparrow and Common Yellowthroat were the most distinctive species of wetter areas in the Boreal Forest Region that were dominated by sedges and low shrubs such as sweet gale and willow. The Swamp Sparrow occurs mostly in bogs and fens.



In Quetico Park in the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region, the Swamp Sparrow occurred at low density in stands 1-23 years old, was rare in stands 112-176 years old, and was absent in stands 67-73 and 367-370 years old (Apfelbaum and Haney 1985). In Parry Sound and Muskoka districts, it inhabited open sections of bogs, marshes, and sedge meadows (Mills 1981). In Algonquin Park, it was a common inhabitant of low shores and marshes but not so much of wooded swamps (MacLulich 1938). Also in the park, it was the most abundant species in wet bogs and second in abundance in dry bogs. It inhabited areas with shrubs and a few scattered trees where it occurred from the ground to a height of approximately 3 m. The shrub layer was 1 m tall. Records of higher birds were probably of males on their singing perches. It also occurred in ecotones between poplar–white birch forest and bog. Martin (1960) considered it characteristic of bogs. Tozer (2012) reported that it preferred wetlands with alders and cattails in Algonquin Park, but that it also nested in sedge meadows, beaver ponds, bogs, and marshy shorelines.

Near Kingston in the off-Shield portion of the Great Lakes–St. Lawrence Forest Region, the Swamp Sparrow nests in large cattail marshes and at margins of wooded swamps (Weir 2008). It nested in a meadow overgrown with sedges near Fesserton and in a 14-year-old regenerating burn in Durham Region (Banville and Gauthier in Gauthier and Aubry 1996). It significantly preferred rural wetlands over urban wetlands in southern Ontario (Herbert and Mowbray 2020).

In the Carolinian Forest Region, the Swamp Sparrow was very common by the shores of Hamilton Bay where it occurred at the interface between land and water (McIlwraith 1894). Currently in the Hamilton area, it breeds locally in marshes, buttonbush sloughs, and low wet swales (Curry 2006). At Long Point, it favoured dense grassy marshes, particularly those with scattered shrubs or other tall plants. It was much less common in extensive cattail marshes. Small populations occurred in some of the marshy areas lying between the main ridges of the point (McCracken et al. 1981).

In Great Lakes coastal wetlands, the Swamp Sparrow was positively correlated with wetland cover, negatively correlated with the amount of urban land cover in the watershed, and was unaffected by water levels and the amount of agricultural land in the watershed (Tozer et al. 2024).

Throughout its range, the Swamp Sparrow nests in wetlands that may include marshes with expanses of open water, meadow marshes, shrub thicket swamps, bogs and fens, and young regenerating wet clear-cuts and burns. Treed swamps are not used except in open areas at their margins or in larger openings within the forest. In almost all cases, there is standing water in the territory. It is found predominantly in freshwater wetlands during the breeding season, but 1 subspecies confined to the New England coast, the Coastal Plain Swamp Sparrow, breeds in brackish estuarine and riverine marshes. Even this subspecies avoids saline habitats (Greenberg and Droege 1990; Herbert and Mowbray 2020).In Quebec, the Swamp Sparrow is abundant in large marshes along the St. Lawrence River, especially in brackish and freshwater habitat upstream of Trois Rivières. It occurs in pure cattail stands as well as in tangled mixed growths of sedges, reeds, cattails, and shrubs such as willows and alder. In southern agricultural and urban areas, it nests in marshes, pond and stream edges, ditches, and flooded lowlands. It occurs in almost all wetland habitats without a tree canopy regardless of size, provided that there is sufficient plant cover. In the north of the province, it occurs in shoreline scrub, wet meadows, and tamarack peatlands (Banville and Gauthier in Gauthier and Aubry 1996). In British Columbia, wetlands it used for breeding ranged from secluded woodland pools to brush-lined dugouts in open agricultural areas. It often inhabits flooded willow thicket swamps and beaver ponds. Typical nesting habitat includes dense beds of sedges, reed grass, or cattails, or where emergent vegetation meets a fringe of willow, Labrador tea, or other shrubs along margins of wetlands (Campbell et al. 2001).

Marshes and shrub thicket swamps are the most important habitats for the Swamp Sparrow. Although it frequently nests in emergent vegetation lacking shrubs, some shrubs or scattered trees provide singing posts and their presence usually results in higher densities. It nests in pure shrub thickets but is more frequent where there is a mixture of shrubs and emergent nonwoody vegetation. Favoured nesting locations include the interface between wetland emergent and upland shrubby vegetation. In large cattail marshes, it may be uncommon in extensive emergents but abundant at the edge where shrubby growth is available. The Coastal Plain subspecies is typically restricted to a narrow band of shrubby habitat at the interface of upland and marsh habitat. Dykes, roads, and causeways through extensive marshes often create habitat for shrubs and enhance conditions for the Swamp Sparrow. It breeds in a variety of marsh types. In Iowa, it breeds in temporary marshes dominated by reed canary grass and cattails, and in semipermanent to permanent wetlands dominated by cattails, bulrushes, sedges, and woody vegetation. Most occur in the transition zone between wetland and upland habitats. It was significantly more likely to occur in natural than restored wetlands. Restored wetlands lacked low prairie or wet meadow zones, which were present in all natural wetlands. The lack of natural transition zone vegetation was probably detrimental. In many areas, it breeds in freshwater marshes with cattails, sedges, bulrushes, bur-reeds, reed grass, or wild rye grass with an outer ring of willow and alder. In these wetlands, it usually occurs in the inner herbaceous or graminoid ring; the Song Sparrow and Common Yellowthroat inhabit the shrub zone. The Swamp Sparrow regularly breeds in emergent vegetation adjacent to glacial lakes, beaver ponds, and watercourses. In Great Lakes coastal marshes in

Michigan, it nested in wet meadows of grasses, bulrushes, cattails, willows, alder, submergent and floating aquatic plants, open water, and some trees and snags. In Wisconsin, it is common in alder thickets. In Ohio, it nests in swamp loosestrife–cattail marshes, and in communities dominated by rushes and bulrushes, mountain holly and alder, buttonbush and alder, soft rush, and leatherleaf. In the Yukon, it is considered a habitat specialist, nesting in shrubby wetlands with areas of dense emergent vegetation that is usually sedges. The shrub component is usually dominated by willow (Beadell et al. 2003; Delphey and Dinsmore 1993; Greenberg and Droege 1990; Greenberg et al. 2010; Harms and Dinsmore 2015; Herbert and Mowbray 2020; Hoffman 1989b; Riffell et al. 2001; Sinclair et al. 2003; Wetherbee in Austin 1968).

The Swamp Sparrow commonly nests in bogs and fens dominated by shrubs, often with scattered conifers such as tamarack, cedar, or black spruce. Wet bogs support higher densities than drier bogs. Typical shrub species found in territories include Labrador tea, leatherleaf, sweet gale, willow, and black huckleberry. In a Rhode Island bog-fen-swamp complex, few territories extended into the sedge fen, mainly because of the shortage of elevated song posts. Large expanses of unoccupied habitat were dominated by coniferous or deciduous forest communities or shrubs shorter than 0.7 m. In territories dominated by coniferous forest, nests were usually in shrubs or sedges on the edge of, or outside, the forest. It was not observed in the interior of forests or in unbroken forest stands. A 0.36-ha area of short shrubs dominated by leatherleaf and black huckleberry was not occupied, although taller shrubs of the same species were used. Medium-height shrubs were scarce and the short shrub community lacked sedges and open water, which rendered the habitat unsuitable (Dawson 1979; Greenberg and Droege 1990; Herbert and Mowbray 2020; Reinert and Golet 1979).

The Swamp Sparrow occurs much less frequently in brush prairies, recent clear-cuts, and burns (Mossman et al. 1991), and forested areas. Clear-cuts and burns that it inhabits are typically in lowland areas where there is growth of alders or willows with some standing water. In the Prairie Provinces, it occurred in wet forests 15-20 years old that were nutrient-poor (Kirk et al. 1996). In northeastern northern hardwoods, it occurred in 0% of plots in mature undisturbed habitats and 3% of disturbed and successional plots (Noon et al. 1979). In northeastern poplar–white birch stands, it occurred in low density in 2-year-old clear-cuts but not in sapling, pole-stage, or mature forests (Back 1979).

The presence of standing water in or adjacent to territories is a critical habitat component of the Swamp Sparrow. In Pennsylvania, whether a particular spot was defended by a Swamp or Song sparrow could be predicted with 90% accuracy based solely on whether standing water or saturated soils were present. Habitat of the Swamp Sparrow contained 97% water or saturated soils compared with 15.9% in Song Sparrow territories. A beaver pond was initially defended by 5 pairs of Swamp Sparrows. After it was drained it was defended by 5 pairs of Song Sparrows plus 1 pair of Swamp Sparrows in an area that remained flooded. Song Sparrow territories were established 4-6 weeks earlier than those of the Swamp Sparrow. None of the Song Sparrows set up territories in areas that later supported Swamp Sparrows (Greenberg 1988). In a Rhode Island bog, 11 of 18 Swamp Sparrow territories contained standing water. Birds commonly fed at the edge of water. Because not all territories contained water, open water did not appear to be a prerequisite for breeding. At least

early in the breeding season, standing water was characteristic of most communities. Presence of standing water beneath or near 50% of nests suggested that wetness was important in nest-site selection. Reinert and Dinsmore (1979) concluded that shallow standing water was 1 of 3 main habitat requirements for the Swamp Sparrow. Herbert and Mowbray (2020) concluded that water appeared to be the universal factor required for nesting. In British Columbia, Campbell et al. (2001) concluded that shallow standing water and dense cover were required for nesting. Where either of these was absent, so was the Swamp Sparrow. Reinert and Dinsmore (1979) also considered dense cover to be essential.

Suitable song perches are another important habitat feature. The Swamp Sparrow prefers to sing from a perch above the average height of the vegetation. In New Jersey and Delaware, it often used common reed stalks as song posts. In a Rhode Island bog, it used coniferous and deciduous trees with roughly equal frequency. Of 607 observations of singing males, 55% were in trees 2-6 m tall and 32% were in trees taller than 6 m. In 63% of observations, birds sang 1-4 m above ground. The mean height of singing birds in territories dominated by coniferous trees was 4.3 m and the mean height of song posts was 5.9 m. In territories with predominantly shrub cover, the mean height of singing birds was 3.1 m and the mean height of song perches was 4.6 m. Alders, willows, and cattails are often used as singing perches. In Iowa, males used dead and live cattails for singing perches. Females remained under shorter vegetation such as sedges and short cattails (Beadell et al. 2003; Harms and Dinsmore 2015; Reinert and Golet 1979; Wetherbee in Austin 1968).

Most studies concluded that features at the landscape level are unimportant to the Swamp Sparrow in habitat selection. The vegetative characteristics of individual wetlands appear to be most important. In Connecticut, isolation of wetlands appeared to have no effect (Craig 2008). In Michigan, Crozier and Niemi (2003) determined that landscape structure had no effect on it and Fairbairn and Dinsmore (2001b) reached the same conclusion in Iowa. Brown and Dinsmore (1986) concluded that it was more likely to occur in smaller marshes in Iowa when these marshes were in wetland complexes. In Minnesota, it was negatively affected by the proportion of agricultural cover at the 12.6-ha scale. Its frequency of occupancy was 85% at 0% agriculture and declined steadily to 40% at 100% agricultural cover. It was also affected by the amount of wetland at the same scale. Its frequency of occupancy was 50% at 10% wetland coverage, 80% at 40-70% coverage, and 60% at 100% wetland. Individual wetlands or small wetland complexes were adequate for providing habitat (Saunders et al. 2019).

Several studies examined microhabitat preferences of the Swamp Sparrow. In coastal marshes in Delaware, Maryland, and New Jersey, it was most abundant in shrub-cordgrass habitat at margins of wetlands (Greenberg and Droege 1990). Counts were significantly higher in plots with a greater proportion of shrub cover. Its abundance was negatively correlated with the amount of open water. It was positively correlated with common reed, but not significantly. It was negatively correlated with marsh hay and saltmarsh cordgrasses, but not significantly. Because of its preference for areas with shrub cover, suitable habitat extended only 200-400 m outwards from the edge of the marsh-upland transition (Beadell et al. 2003). In tidal marshes in Connecticut, it was associated with cattail marsh and common reed. It appeared to respond to plant structure rather than species because it was found in many different types and sizes of marshes as long as there was tall sturdy vegetation

present to support nests (Benoit and Askins 2002). In Iowa, average habitat characteristics over 2 years did not differ: percent water cover, 21.1% and 26.8%; percent bulrush cover, 31.6% and 31.0%; percent cattail cover, 50.7% and 58.0%; percent cover by sedges, 25.9% and 21.9%; percent cover by reed canary grass, 24.8% and 28.3%; percent cover by woody vegetation, 12.8% and 18.5%; and water depth, 30.1 cm and 34.6 cm. Its abundance was positively correlated with coverage by cattails and negatively correlated with increasing abundance of woody vegetation. Woody vegetation in this area consisted of black willow, sandbar willow, and cottonwood that commonly grew to a height of 6 m and occasionally as tall as 18 m. It avoided tall woody vegetation and was associated more with shrubs that grow to a maximum height of 2 m. Its abundance was positively influenced by water depth and it was commonly found in wetlands with water depths greater than 24 cm. Most were observed in the transition zone between wetland and upland habitats. Harms and Dinsmore (2015) concluded that it was associated with shorter vegetation and increased cover by cattails. Another Iowa study determined that its density was positively correlated with the area covered by weak-stemmed wet meadow vegetation (Fairbairn and Dinsmore 2001b). In Illinois grasslands, its abundance was positively associated with mean number of total contacts, the within-transect heterogeneity index, grass height, and percent live contacts. It was negatively correlated with the mean number of live grass contacts, mean vegetation height, and mean number of live forb contacts. Herkert (1994a) concluded that it preferred areas dominated by live vegetation. In Iowa marshes, its abundance was positively correlated with the percent of wet meadow within the wetland. It was negatively correlated with the amount of mudflats (Fairbairn and Dinsmore 2001b). In Great Lakes coastal marshes in Michigan, it was strongly associated with dense, tall stands of emergent sedges and grasses typical of the most productive wet meadows. It was positively correlated with tall dense grasses rather than bulrushes, with the area of wet meadows, with increasing frequency of deciduous trees and snags, with greater shrub diversity, and with greater frequency of willow (Riffell et al. 2001). In Pennsylvania, habitat of the Swamp Sparrow differed significantly from that of the Song Sparrow for 5 parameters. Values for these parameters for the Swamp and Song sparrows respectively were: percent forb cover, 34.4% and 59.4%; percent rush cover, 25.0% and 7.1%; percent raspberry cover, 0.1% and 2.7%; percent coverage by water, 92.2% and 13.2%; and percent cover by water and saturated soils, 97.0% and 15.9%. Other Swamp Sparrow habitat characteristics that did not differ from those of the Song Sparrow included 30.4% grass cover, 85.1% total ground cover, 0.81 m ground cover height, 0.03 viburnum density, 0.27 meadowsweet density, 0.30 dogwood density, and 7.4 cm water depth (Greenburg 1988). In a Rhode Island bog-fen-swamp complex, the frequency of occurrence of vegetation communities in territories was 91% medium-height shrubs (0.7-1.4 m tall), 100% medium-height shrubs when those in the understorey of coniferous forest are included, 70% shrubs taller than 1.4 m, 83% tall shrubs including those under coniferous forest canopy, 65% sedges, 61% conifers 2-6 m tall, 57% short shrubs (0.4-0.7 m tall), 30% conifers taller than 6 m, and 17% shrubs shorter than 0.4 m. The different height classes of shrubs were all comprised of sweet gale, leatherleaf, and black huckleberry. The frequency of occurrence of vegetation communities in 4-m^2 plots around nests was: 56% medium-height shrubs, 69% medium-height shrubs including those in the understorey, 31% sedges, 14% conifers 2-6 m tall, 14% short shrubs, 8% tall shrubs, and 11% tall shrubs including those in the understorey. Shrubs occurred in all plots with a mean density of 205.6 stems per m^2 and a mean height of 69.8 cm. Sedges (woolly-fruited sedge, beaked sedge, and bog-rush) occurred in 94.4% of plots with a mean density of 345.6

stems per m^2 and a mean height of 58.7 cm. The frequency, mean height in cm, and mean number of stems per m^2 respectively for various species included: 92, 78.0, and 97.2 for sweet gale; 75, 71.3, and 106.8 for leatherleaf; 69, 57.5, and 394.8 for slender sedge; 58, 54.0, and 44.0 for beaked sedge; 47, 72.9, and 25.6 for sweet pepperbush; 42, 38.1, and 36.4 for large cranberry; 35, 30.0, and 18.4 for Fraser's marsh St. John's-wort; 28, 73.8, and 94.0 for bog-rush; 28, 36.1, and 12.0 for green arrow arum; 22, 113.3, and 27.6 for Atlantic white cedar; 14, 66.4, and 21.6 for grey alder; and 17, 33.8, and 4.0 for red maple. The occurrence of medium-height sweet gale in very wet spots probably explained its frequent use as nest cover. This shrub comprised only 7% of the total cover but constituted 39% of cover in nest plots. The occurrence of tall shrubs in 82.6% of territories reflected their importance. The Swamp Sparrow used a wide variety of plant communities and species, but the basic structure of all territories was similar. The species of vegetation is not as important as the height and density of plants in the selection of nest sites (Reinert and Golet 1979).

Most authors concluded that the Swamp Sparrow is a wetland edge species, but 1 study concluded that it avoided edge. In New Jersey and Delaware, Beadell et al. (2003) observed it only within 200-400 m of the marsh edge and it was absent in the wetland interior. Other studies concluded that it was associated predominantly with the transition zone between wetland and upland (Delphey and Dinsmore 1993; Greenberg and Droege 1990; Harms and Dinsmore 2015a). In Iowa, it was positively correlated with the wetland perimeter-to-area ratio. Fairbairn and Dinsmore (2001b) concluded that wetlands with a high ratio had a greater potential to have wet meadow and low prairie vegetation, and that the Swamp Sparrow was a wetland edge species. Riffell et al. (2001) determined that it was negatively correlated with the perimeter-to-area ratio in Great Lakes coastal marshes. They concluded that it avoids edge.

Although 2 studies reported differing conclusions, the Swamp Sparrow is not an area-sensitive species. In Connecticut, Craig (2008) studied wetlands 1.5-131 ha in size and found no relationship between its density and marsh size. It was absent from some of the 3 smallest wetlands even though suitable habitat was present. Also in Connecticut, Benoit and Askins (2002) found no significant relationship between the Swamp Sparrow and wetland size. The smallest wetland where it was found was not larger than expected by chance. In Iowa, it tended to avoid wetlands larger than 20 ha and was detected most frequently in 10-20-ha wetlands. It was seen least frequently in wetlands smaller than 5 ha, but some of these may have been smaller than its territory size. Harms and Dinsmore (2015) sampled wetlands as small as 0.1 ha. Small to intermediate-sized wetlands had a more pronounced transition zone with diverse habitat characteristics that were attractive to the Swamp Sparrow. In Illinois grasslands, the probability of encountering the Swamp Sparrow was influenced by vegetative features only and not by patch size (Herkert 1994a). In Iowa, it was negatively correlated with patch size. Smaller wetlands tended to have a greater proportion of vegetative cover than larger wetlands (Fairbairn and Dinsmore 2001a). In Michigan, Crozier and Niemi (2003) reported that its abundance increased with patch size, but this was true of every species they examined. This is not a test of area sensitivity and one would expect larger patches to support more pairs of a given species simply because there is more available habitat. In Iowa, Brown and Dinsmore (1986) considered it area-dependent because its frequency of occurrence increased with wetland size: 42% in wetlands smaller than 1 ha, 50% in wetlands 1-4.9 ha, 83% in wetlands 5-10.9 ha, and 100% in wetlands 11 ha and larger. It occurred in almost half the wetlands smaller than

1 ha. This suggests that the Swamp Sparrow is not area sensitive. In addition, some of the wetlands sampled were smaller than its territory size.

The female roosts on the nest at night during the incubation and nestling periods. The male roosts in vegetation within the territory at night (Herbert and Mowbray 2020).

Most (75.0%) Ontario nests were slightly elevated over ground or water, with some on the ground. The distribution of elevated nests was 68.3% in sedge or grass clumps, 17.1% in cattails, 13.0% in shrubs, and 1 each (0.8%) in vines in a coniferous shrub and on top of an overgrown stump. Ground nests were under grasses, clumps of other plants, ferns, shrubs, and small trees. Four (9.8%) ground nests were on mossy hummocks and 1 nest had a short tunnel leading to it under the grass. Nests in shrubs were in 6 species of deciduous shrubs (18 nests) and a single nest was in a white cedar. Nests were 0.08-0.9 m above the substrate with most 0.2-0.3 m up (Peck and James 1987, 1998b).

Throughout its range, the Swamp Sparrow nests on the ground or a short distance above water or the ground. In a Rhode Island bog, nests were 0-75 cm above ground (average 30 cm). Fifty percent of nests were over or within 1 m of water. Sweet gale, leatherleaf, or both species together supported 91.7% of nests, sedges supported 63.9% of nests, and 2 nests were in cedars. Nests were well concealed among sedges or in the foliage of shrubs or cedars. They were 24-95 cm below the top of the vegetation canopy and lodged between plant stems rather than anchored to them (Reinert and Golet 1979). In a Pennsylvania marsh, nests were almost never on the ground but between cattail stalks or on bent-down clumps of stalks and leaves. They were almost completely hidden from above by cattail blades. Nests were often directly over water 15-60 cm deep and were usually about 30 cm above the surface of the water (Wetherbee in Austin 1968). Most nests are very well concealed and some are partially or loosely roofed with an entrance at the side. In Delaware, most successful nests were in American three-square bulrush and cordgrass. Old nests are not known to be reused (Herbert and Mowbray 2020).

In some areas, the Swamp Sparrow defends an all-purpose territory where all or most foraging and nesting occurs. At other sites, birds routinely leave the territory to forage. Birds without water in their territory may leave to feed in marshes with standing water. In Massachusetts, both sexes regularly foraged in an adjacent woodlot and in Quebec birds often left their territories to feed in fields and on lawns. Aggression among males is most common shortly after males arrive and during the establishment of territories. Aggression subsides once territories are established. In Rhode Island, a breakdown of territorial defence occurred during the first week of August when nesting activity ceased. When second broods are attempted, territorial singing continues and territories are maintained even if the clutch is unsuccessful. Females usually nest at the periphery of territories and occasionally select a nest site outside their mate's territory. In these cases, the male adjusts his territory boundaries to include the nest. Territory size is variable and probably related to the amount of standing water in it, with those with more water being smaller. Males may shift territorial boundaries in response to changes in surface water, expanding into newly flooded areas. Older males establish territories earlier than yearlings and have larger territories in prime habitat. Territory size appears to be unrelated to vegetation composition. In Algonquin Park, 82 territories averaged 0.15 ha (range 0.02-0.50 ha) and similarly sized territories were reported at Fesserton. In Quebec,

average territory size was 0.15 ha. In Delaware, Maryland, and New Jersey, territories were 0.4-0.5 ha. In Rhode Island, 24 territories averaged 0.17 ha (range 0.03-0.61 ha). Mean territory size in Minnesota was 0.16 ha and 0.13 ha in 2 years (Banville and Gauthier in Gauthier and Aubry 1996; Greenberg 1988; Greenberg and Droege 1990; Herbert and Mowbray 2020; Martin 1960; Reinert and Golet 1979; Willson 1966a).

Swamp Sparrow territories usually do not overlap those of other species, or do so minimally. There is a strong segregation between Swamp Sparrows and Marsh Wrens due to differences in vegetation preferences reinforced by interspecific aggression. The Swamp Sparrow consistently chases Common Yellowthroats from its territory (Herbert and Mowbray 2020). In Pennsylvania, there was minimal overlap in Swamp and Song sparrow territories. Song Sparrow territories were overlapped by an average of 4% by Swamp Sparrow territories and Swamp Sparrow territories were overlapped by an average of 5% by Song Sparrow territories. The study was restricted to Swamp and Song sparrow territories that abutted each other, so the overlap was considerably less than reported. Interspecific aggression was rare and these cases were outnumbered by observations of them feeding or singing close together without aggression. All acts of aggression occurred in the narrow zone of overlap of the territories of the 2 species (Greenberg 1988).

Natal philopatry appears to be low based on limited information. In Rhode Island, 1 of 56 banded fledglings (1.8%) returned (Herbert and Mowbray 2020).

In Rhode Island, 33 of 64 adults (51.6%) returned, including 51.2% of males and 52.4% of females. Fifty-nine percent of males occupied the same territory as in the previous year: 70% in 1 year and 49% in another year. Returning females settled in the same habitat type but usually not in the same territory. Seventy percent of 16 returning females selected nest sites less than 65 m from the previous year's nest. Often the nest was near the edge of her current male's territory; only 18.2% of nests were in the territory of the previous year's nest. Returning females that nested successfully the previous year built significantly closer to their previous nest (average of 42.9 m) compared with 162.0 m for those that had been unsuccessful (Herbert and Mowbray 2020).

Limiting Factors

Eggs are present in Ontario nests from the last week of April until the end of July, mostly from the third week of May until the end of June (Peck and James 1987). In Algonquin Park, eggs are present from early to late June, nestlings are present from mid-June to early July, and fledglings are present from late July to late August (Tozer 2012).

Males begin to establish territories shortly after their arrival and pairs form 1-2 weeks after the arrival of females. Nests are typically built in 3-4 days (range 2-7 days). The first egg is usually laid as soon as the nest is complete, but occasionally 2-3 days elapse before the first egg is laid. One egg is laid per day. Asynchronous hatching suggests that incubation may begin with the laying of the penultimate egg. The incubation period at 1 Ontario nest was not more than 14 days. Incubation in Rhode Island averaged 12.4 days (range 12-14 days); incubation periods as long as 15 days have been reported. The eggs hatch over a period of 36-48 hours. If undisturbed, nestlings remain in the nest 9-13 days, and often leave at age 9-11 days. Nestlings as young as 6.5-7 days may jump from the nest if they are disturbed (Herbert and Mowbray 2020; Peck and James 1987; Reinert and Golet 1979; Wetherbee in Austin 1968).

The Swamp Sparrow often raises 2 broods, particularly in the southern portion of its range. Second broods have been confirmed in southern Ontario, Quebec, and the Maritime Provinces. The interval between fledging of the first brood and initiation of the second nest averages 11.0 days (range 4-23 days). Renesting is common if a nest is lost. Females may lay as many as 4 clutches in an attempt to raise a single brood, occasionally without success in areas where the predation rate is high. New nests are initiated 0.5-5 days after nest loss. Clutches of 4-5 eggs have been reported in Ontario (average 4.21 eggs); most clutches contained 4 eggs. Clutches of 3-6 eggs have been reported throughout its range with 4 eggs most frequent. In New York, the mean clutch size was 4.6 eggs (range 4-6 eggs); clutches of 5 and 6 eggs represented 40% of the sample. The mean clutch size in Pennsylvania was 4.1 eggs. In Rhode Island, the mean clutch size was 4.12 eggs (range 2-5 eggs). May and June clutches were significantly larger (4.4 eggs) than July clutches (3.1 eggs). Second clutches of females were smaller than their first clutch. There is no significant difference in the clutch sizes of yearlings and older females. The mean clutch size of the Coastal Plain subspecies was 3.45 eggs (range 2-4 eggs). Its smaller clutch size may be an adaptation to the stochastic risk of total nest failure by flooding. The reduced clutch size may allow more nesting attempts (Greenberg and Droege 1990; Herbert and Mowbray 2020; Peck and James 1987; Reinert and Golet 1979; Wetherbee in Austin 1968).

Both sexes are capable of breeding when they are 1 year old. Some males are unsuccessful in attracting mates and it is probable that these are yearlings. In a Rhode Island bog, 2 of 18 males (11.1%) were unmated and 1 of 12 males (8.3%) in Massachusetts was unmated (Herbert and Mowbray 2020; Reinert and Golet 1979; Willson 1966a). Pair bonds are maintained throughout the season and occasionally for more than 1 year. The Swamp Sparrow is predominantly monogamous, but some males are polygynous. In Massachusetts, 2 of 12 males (16.7%) were bigamous. In both cases, the 2 females each had subterritories in which they nested and foraged. Males preferred perches between the females' subterritories and visited both areas frequently. In 1 case, one of the females left the territory permanently to feed fledglings. The male's territory then shrunk so that it was not much larger than the remaining female's subterritory. In a Rhode Island bog, 3 of 18 males (16.7%) were bigamous. Another study in that state determined that 3 of 43 males (7.0%) were bigamous. The Swamp Sparrow appears to be one of the marsh-dwelling species that is regularly polygynous. Extra-pair copulations may be common with extra-pair young occurring in 41.6% of broods in 1 population (Greenlaw 1989; Herbert and Mowbray 2020; Reinert and Golet 1979; Willson 1966a).

The Swamp Sparrow forages in moist ground below the shrub and forb canopy, in shrubs and lower portions of trees, on coarse stems of cattails and other marsh plants, along edges of shallow water, and occasionally in open water. It gleans invertebrates and possibly seeds from moist soil while walking, and scratches in leaves for insects and seeds. It frequently climbs up and down stems of shrubs, cattails, and other sturdy vegetation in a mouse-like manner. In water, it may wade breast deep and pick insects and seeds from its surface. One lowered its entire head into the water and appeared to turn over submerged leaves in search of food. It has a longer tibiotarsus and femur than the Song Sparrow and other sparrows. This allows it to hang on to vegetation while leaning to reach the surface of the water, and to wade in water. The Song Sparrow appears incapable of doing this, which may explain why Swamp Sparrow territories typically have water in them and Song Sparrow

territories usually do not. In a Rhode Island bog, the Swamp Sparrow often foraged under the cover of shrubs taller than 1.4 m, but used this habitat less frequently once nesting began. During midsummer when shrub communities were somewhat drier, adults commonly left their territories to gather food for their nestlings in a wet sedge community. These observations suggested that surface water was important in its feeding ecology. A captive bird showed an aversion to taking seeds from its seed cup and preferred to take them from the surface of its drinking cup. This suggested that it naturally gathers seeds in water or that it prefers wet to dry seeds (Carrier 1991; Greenberg 1988; Herbert and Mowbray 2020; Judd 1901; Reinert and Golet 1979; Wetherbee in Austin 1968).

Adults capture damselflies, dragonflies, and aphids from leaves of water-lilies to feed nestlings and fledglings. Nestlings are also fed snails (Herbert and Mowbray 2020).

Adults consume beetles and other aquatic invertebrates, indicating the importance of water to the breeding season diet. During spring and early summer, the Swamp Sparrow is highly insectivorous, with insects constituting about 88% of the diet. It most commonly eats beetles, ants and other hymenopterans, caterpillars, grasshoppers, and crickets. It tends to eat smaller beetles, has been observed picking at dead drying herring, and will eat bread crumbs. It also eats mites, spiders, bugs, and book lice. By late summer and autumn, it is predominantly granivorous with vegetable matter constituting 84-97% of the diet. At this time, seeds of sedges, smartweeds, panic grasses, and vervain are most abundant in the diet. Juveniles and adults also eat highbush blueberry fruits, extracting the flesh and discarding the skin (Harms and Dinsmore 2015; Herbert and Mowbray 2020; Reinert and Golet 1979; Wetherbee in Austin 1968; Willson 1966a). Judd (1901) analyzed 72 stomachs collected from all seasons, mostly from Massachusetts, Connecticut, New York, and Pennsylvania. They contained 47% animal material, nearly all insects, and 53% vegetation, nearly all seeds. Insects consumed included 17% bugs, ants, flies, and small dung beetles; 11% leaf beetles and weevils; 6% parasitic and predaceous insects; and 2% grasshoppers. It exhibited a preference for ants, with 14.3% of stomachs containing these insects. It consumed more smartweed seeds than most sparrows and ate numerous seeds of sedges and aquatic panic grasses that occur in marshes. Giant ragweed seeds were well represented in the diet.

The rate of parasitism by the Brown-headed Cowbird on the Swamp Sparrow varies geographically and depends on the size of the breeding patch (parasitism rates are lower in larger wetlands), and proximity to human settlement, with higher parasitism rates near settlements. In Ontario, 34 of 257 nests (13.2%) were parasitized. Parasitism rates in other areas include: 2 of 64 nests (3.1%) in Rhode Island; 34 of 322 nests (10.6%) in Quebec, 53 of 161 nests (33.0%) in the eastern United States; and 4 of 5 nests (80.0%) in Michigan. The effects of parasitism on the reproductive success of the Swamp Sparrow are unknown. It is capable of rearing cowbirds but it is uncertain whether it can fledge sparrows from parasitized nests (Campbell et al. 2001; Herbert and Mowbray 2020; Peck and James 1998b; Wetherbee in Austin 1968).

Extensive wetland losses occurred in southern Ontario from shortly after forest clearing until wetland policies were adopted in 1986. These policies protected larger and more significant wetlands but smaller wetlands are still subject to drainage or filling for agriculture and other land uses. These losses have undoubtedly reduced the amount of habitat.

The Swamp Sparrow nests a short distance above ground or water. It is highly vulnerable to even modest increases in water levels. Sudden increases in water levels during the breeding season may be one of its greatest limiting factors. Broods of an entire local population may be lost by increasing water levels (Banville and Gauthier in Gauthier and Aubry 1996; Herbert and Mowbray 2020; Wetherbee in Austin 1968). In Ontario, climate change is projected to result in more frequent and serious summer rainstorms. This may exacerbate the risk of flooding of Swamp Sparrow nests.

Practices that remove or thin tree canopy may be beneficial to the Swamp Sparrow, but only if the underlying substrate is wet. These habitats tend to be ephemeral and are suitable for only a few years until the canopy is restored through natural regeneration. Clear-cutting in lowland forests is usually beneficial. In Minnesota, it responded favourably to tree harvest in riparian buffers, and decreased with time after harvest. In the same state, a blowdown in spruce-fir forest created temporary habitat where none existed previously (Banville and Gauthier in Gauthier and Aubry 1996; Burris and Haney 2005; Hanowski et al. 2005). In the Canadian Shield of Ontario, it was significantly less abundant in early successional clear-cuts than in early successional burns but there was no significant difference in its abundance in mid-successional clear-cuts and burns. It was significantly more abundant in early successional than mature stands but equally abundant in mid-successional and mature stands (Zimmerling et al. 2017).

In Minnesota, Hanowski et al. (1997a) examined the potential effects of mosquito control of wetlands with Bti and methoprene. They observed no change in the abundance of the Swamp Sparrow as a result of either treatment.

In Alberta, the Swamp Sparrow was significantly less abundant at seismic lines than in adjacent forest interior when unlimited-distance point counts were used, but there was no significant difference on 50-m or 100-m fixed-radius counts. There were no differences in its abundance at pipelines and well pads than in forest interior adjacent to these features (Bayne et al. 2016).

In British Columbia, grazing of shoreline vegetation by cattle is the most significant cause of habitat degradation for the Swamp Sparrow (Campbell et al. 2001).

Price (2004) predicted that the range of the Swamp Sparrow might contract in southern Ontario if the average summer temperature increased by 2°C. In the Prairie Pothole Region, Harms and Dinsmore (2015) determined that abundance of the Swamp Sparrow was correlated with the amount of rain received that year. Higher water levels resulted in more sparrows. As a result of climate change, wetlands in the eastern portion of this region are projected to have increased water levels and longer hydroperiods; the opposite is predicted for the western portion.

Status

McIlwraith (1894) considered the Swamp Sparrow a common breeder throughout Ontario. Baillie and Harrington (1937) concluded that it was common in suitable habitat throughout the province, west to Thunder Bay District and probably to the Manitoba border. The first atlas confirmed that its distribution included the entire province. There were some gaps in its distribution in southwestern Ontario in intensively farmed regions such as Essex, Chatham-Kent, Lambton, and Huron counties. It was absent in Toronto and portions of Niagara Region (Rising in Cadman et al. 1987). James (1991) considered the Swamp Sparrow a common to abundant summer resident throughout the province.

The second atlas demonstrated that there had been no significant change in the distribution of the Swamp Sparrow since the first atlas. Its probability of observation increased significantly province-wide and in the Canadian Shield and Hudson Bay Lowland. Several scattered areas of high density corresponded with areas with considerable wetland habitat. They included the southern and eastern portions of the Hudson Bay Lowland, including Akimiski Island; in Rainy River and southwestern Kenora districts and along the Manitoba border near Red Lake where there are prairie-like wetlands; in southeastern Ontario and the southern edge of the Canadian Shield; in an east-west band south of Lake Nipissing through Algonquin Park; and along the Niagara Escarpment and in the Dundalk Highlands. It was least abundant in southwestern Ontario (Rising in Cadman et al. 2007).

Population trends of the Swamp Sparrow in Ontario are uncertain because it is not adequately sampled throughout its range. The Breeding Bird Survey (BBS) seldom samples extensive wetland areas and its results may be misleading. In addition, it only monitors the southern portion of its breeding range (Herbert and Mowbray 2020). BBS results indicate annual increases of 1.04% in Canada and 1.11% in Ontario for 1970-2021. For 2011-21, it experienced an annual decrease of 0.388% in Canada and an annual increase of 0.739% in Ontario. The Canadian results were of medium reliability; the Ontario results were highly reliable (A.C. Smith et al. 2023). The Marsh Monitoring Program (MMP) is conducted within wetlands and is better suited for documenting the status of the Swamp Sparrow. Results of the MMP, which was initiated in 1995, indicate a nonsignificant decline in Ontario. The rate of decline is increasing and was 0.2% per year in 2004, 0.4% per year in 2011, and 0.5% by 2012 (Anonymous 2012b; Timmermans et al. 2006; Tozer 2013). The MMP samples mostly the Great Lakes basin and not populations in northern Ontario away from the Great Lakes. In coastal Great Lakes wetlands, it decreased at an annual rate of 0.77% 2011-21 (Tozer et al. 2024). In the Hamilton area, Curry (2006) concluded that populations appeared to have remained stable since McIlwraith's (1894) time. At Long Point, the Swamp Sparrow was not common in 1907 or 1931. Numbers have since increased substantially, probably due to the creation of suitable marsh habitat at the base of the point following construction of the causeway in 1928 (McCracken et al. 1981). Populations have declined in Elgin County. In 1891 it was quite common, especially in larger marshes. By 1954, it was a regular but not common breeder and by 2000 it was an uncommon breeder. Numbers declined due to losses of smaller swales, swamps, and marshes (Lancaster et al. 2004).

POSTFLEDGING PERIOD

After leaving the nest, fledglings remain close to the nest on the ground or in low vegetation. In the first 1-4 days after fledging, they make only short flights between low branches and stalks of grasses and reeds. They spent most of their time on the ground in dense cover. They can fly between shrubs 4-6 days after fledging and may be fed by the female for 6-17 days after fledging. Late in the season, postbreeding birds assemble in loose foraging flocks with other sparrow species (Herbert and Mowbray 2020).

In a Rhode Island bog, fledglings often occurred in shrub communities taller than 1.4 m and dominated by sweet gale, leatherleaf, and black huckleberry (Reinert and Golet 1979). In Michigan, postbreeding birds preferred mature riparian forests to mature upland forests. Riparian forests had

a canopy of aspens with a mix of alders and honeysuckles. Upland forests were dominated by 100-year-old trembling aspen and large-toothed aspen. Captures per 100 net-hours were 1.3 in riparian forests and 0.2 in upland forests; 71% of juveniles were captured in riparian forests (Akresh et al. 2009).

MIGRATION

All populations of the Swamp Sparrow are migratory, with movements occurring at night. A bird banded at Rondeau travelled southeast to the Atlantic coast of Virginia. Band returns suggest that birds retrace the same route each year in both directions. During spring migration, it may stop at specific locations for 1-2 weeks. Autumn stopovers average 1 week but some birds may remain in a single location for 2 weeks before continuing migration. It may associate with other species during migration, especially in autumn. It may be observed in flocks comprised solely of Swamp Sparrows or in the company of Song, Lincoln's, and White-crowned sparrows (Brewer et al. 2018; Greenberg et al. 2010; Herbert and Mowbray 2020; Wetherbee in Austin 1968).

Males arrive in spring about a week earlier than females but in Rhode Island females did not arrive until 3 weeks after males had established territories (Herbert and Mowbray 2020; Reinert and Golet 1979). In southern Ontario, the Swamp Sparrow typically arrives in early to mid-April but may arrive as early as mid-March. Most migrants occur from mid-April to mid-May; most have passed through by the end of May (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008). Birds arrive in the southern Shield in late April with migration extending into mid-May (Mills 1981; Tozer 2012).

Wilson and McRae (1993) observed 40 migrants at Ekwan on 4 September. In the southern Shield, autumn migration begins in early September and continues until late October and rarely into November (Mills 1981; Tozer 2012). In southern Ontario, migration extends from mid-September until mid-November (Black and Roy 2010; Curry 2006; Lancaster et al. 2004; Weir 2008).

During migration, the Swamp Sparrow is most frequently seen in dense vegetation near water. In addition to typical breeding habitat, it may occur in old fields, shrubby growth, hedgerows, pastures, raspberry thickets, and even residential shrubbery. During autumn migration, it may form large roosting flocks of 50-60 birds at night and loose foraging flocks of 6-10 during the day (Herbert and Mowbray 2020). During spring migration near Kingston, birds are often seen foraging in dry woodlands (Weir 2008) and autumn migrants at Presqu'ile concentrated in patches of beggarticks (LaForest 1993). Wetherbee (in Austin 1968) stated that spring migrants were found in many swamps where they did not breed. In autumn, some left marshes and occurred in all habitats except deep woods. In British Columbia, most migrants use habitats that are similar to breeding habitat. These include smaller damp areas such as tall grass near water, weedy spots along edges of wetlands, and damp brushy edges of fields. Any shrubby habitat near water may be used such as willow thickets, puddles on a trail through alders and trembling aspen, and a large revegetated burn (Campbell et al. 2001). Suomala et al. (2010) surveyed migrants on 2 islands in the Gulf of Maine. During both migration periods, it was significantly more abundant on the island with shorter trees and a higher density of shrubs than on the treed island.

Some Swamp Sparrows may be killed as a result of adverse weather during migration. More significant are losses due to striking television towers, buildings, and other tall structures (Herbert

and Mowbray 2020). Twenty were killed at the Lennox generating chimneys from 1973 to 1980 (Weir 2008). In the United States at all types of buildings, it was 16.7 times more likely to be killed than average and was the 11th most vulnerable species. It was not among the top 20 species killed at 1-3-storey residences. At low-rises, it was 50.6 times more likely to strike a building than average and 18.1 times more likely to strike a high-rise than average (Loss et al. 2014).

James (1991) considered the Swamp Sparrow a common migrant in Ontario.

Hussell et al. (1992) reported a nonsignificant decline of migrating Swamp Sparrows of 1.7% per year 1961-88 at Long Point Bird Observatory. Trends by period were: 1961-70, +0.9%; 1970-79, –4.2%; and 1979-88, +3.2%.

WINTER

The winter distribution of the Swamp Sparrow is confined to areas below altitude 300 m; highest concentrations occur near water. Peak winter abundance in North America is in bayous along the Louisiana coast with areas of high concentration extending up the Mississippi River (Root 1988). Birds wintering within the breeding range are usually more northern birds that have replaced the breeding population. Peak overwintering within the breeding range occurs during mild winters (Herbert and Mowbray 2020).

Curry (2006) reported that a few overwinter in sheltered marshes along Hamilton Harbour and Lake Ontario. In much of its northern winter range, the Swamp Sparrow prefers cattail marshes even when the water is frozen. Spring-fed marshes may be particularly attractive due to the presence of open water. Open marshes and streams are preferred provided that dense cover is available. It is rarely found in thickets or underbrush far from water. It also inhabits bottomland fields overgrown with broomsedge if the soil is damp and there is a stream nearby. Shrubs, bulrushes, and cattails bordering streams, ponds, rivers, lakes, and reservoirs provide good habitat. It also overwinters in wet fields with shrubby margins, seasonally flooded fields, roadside ditches, and brackish marshes at mouths of major rivers. In North Carolina, it winters in a variety of wetlands in blackberries, asters, horseweed, swamp milkweed, water dock, foxtails, sedges, rushes, willows, red maple, and Manitoba maple in varying combinations. In Texas, it overwintered in coastal prairies dominated by little bluestem, saltmarsh cordgrass, and a mixture of these 2 grasses (Baldwin et al. 2007; Campbell et al. 2001; Herbert and Mowbray 2020; Root 1988; Wetherbee in Austin 1968).

In Maryland, Blank et al. (2011) examined Swamp Sparrow usage of herbaceous buffers planted between row crops and forested wetlands. Some had been mowed the previous autumn and had significantly lower vertical density, maximum height, percent coverage by grass, and percent coverage by forbs than unmowed buffers. Densities per km^2 were 0 in mowed buffers and 55 in unmowed buffers. In Arkansas, Kentucky, and Mississippi, it was significantly more abundant in row-crop fields with a vegetated buffer of native grasses and forbs than in similar fields without buffers. It was significantly more abundant in fields with buffers wider than 23 m than in fields with narrower buffers (Evans et al. 2015).

In Texas coastal prairies, the Swamp Sparrow was positively associated with both little bluestem and saltmarsh cordgrass communities but was uncommon where the 2 species were mixed. It was not associated strongly with prairie species and overwintered in a variety of habitats. It was most

common in areas of dense shrubs. It was most abundant where there were numerous water-bounded areas with the highest concentration of shrubs and small trees. It was unaffected by different frequencies of burning (Baldwin et al. 2007).

Wintering birds often roost in large flocks in shrubs such as willow and buttonbush at edges of marshes (Herbert and Mowbray 2020). In British Columbia, a roosting bird wintered each night in vegetation overhanging a small creek (Campbell et al. 2001).

Swamp Sparrows may return to the same location to winter in subsequent years. In Mississippi, 7 of 27 birds (25.9%) were captured at the same site in the following winter (Herbert and Mowbray 2020).

The Swamp Sparrow has a strong aversion to foraging in open situations. Greenberg (1989) placed feeders within cover and 1.5 m and 7 m from cover. When the feeder was 1.5 m from cover, the visitation rate was significantly lower at 34% of the rate of the feeder in cover. When the feeder was 7 m from cover, it almost stopped visiting it entirely. Only 8% of Swamp Sparrows were observed foraging more than 1 m from cover.

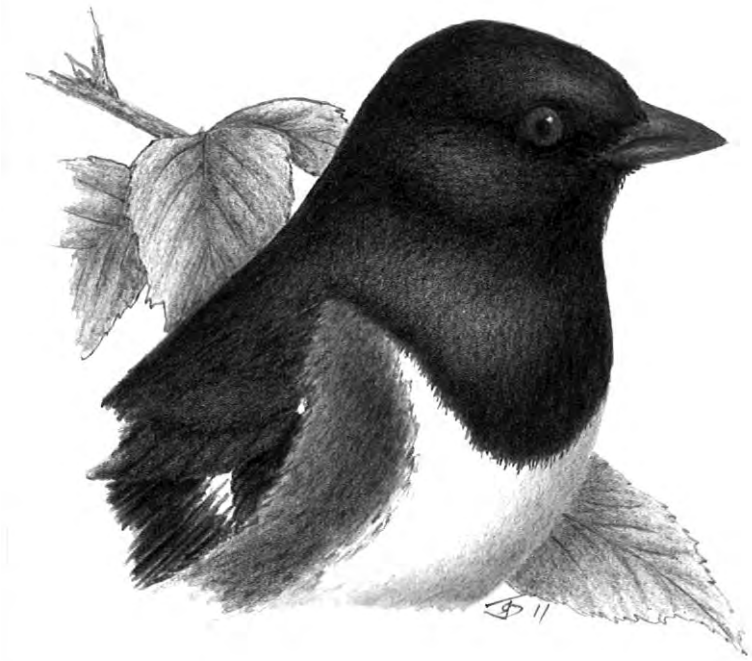
In winter, the Swamp Sparrow eats predominantly seeds and fruits but consume terrestrial and aquatic invertebrates when they are available. In North Carolina, its diet was comprised almost entirely of seeds of sedges, water dock, foxtails, panic grasses, and vervain (Herbert and Mowbray 2020).

James (1991) considered the Swamp Sparrow a rare winter resident in the south north to Barrie and Kingston. Lancaster et al. (2004) stated that it was common in winter in Elgin County, especially when the weather was warm. In Niagara Region, it is a winter straggler, with only 2 records (Black and Roy 2010). On 16 February, approximately 50 were seen near Cayuga (personal observation). The maximum winter count in the Hamilton area is 20 (Curry 2006). The Swamp Sparrow overwinters at Presqu'ile and the Kingston area only occasionally (LaForest 1993; Weir 2008).

Freedman and Riley (1980) analyzed Christmas Bird Count data for southern Ontario for 1929-77. In 1929, it averaged 0-0.01 birds per observer, started to increase around 1953, averaged about 0.11 per observer in 1974, peaked at 0.41 per observer in 1976, and decreased to 0.02 per observer in 1977. They concluded that the increase was possibly due to increased availability of seed crops, weedy fields, or cover.

Eastern Towhee

Pipilo erythrophthalmus

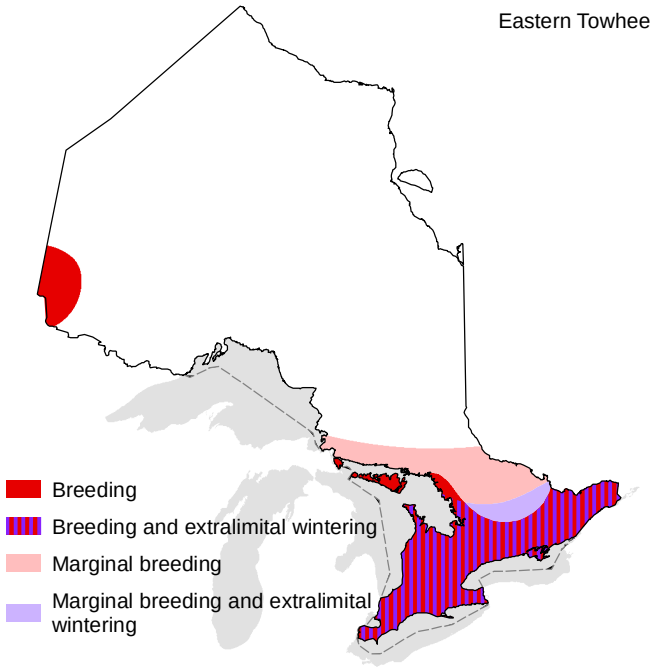


BREEDING SEASON

Habitat Requirements

Ontario Eastern Towhee nests were in coniferous, mixed, and deciduous woods (75.9% of nests); in overgrown fields (17.2%); in vines and shrubby tangles (3.4%); on overgrown bedrock outcrops (2.3%); and on slash on a pipeline right-of-way (1.1%). Wooded areas used for nesting were open; many nests were near woodland edges or clearings. Other nests were near roads or water, indicating a preference for open areas near the nest. Most nest sites were dry and where the ground cover was dense (Peck and James 1987).

Near Parry Sound, low densities of the Eastern Towhee occurred in jack pine stands. These stands had an open canopy and were mixed with a variety of deciduous tree species; bedrock outcrops were common (James 1979a). It nests throughout Parry Sound and Muskoka districts, but is most abundant along the eastern shoreline of Georgian Bay and in the southern part of this area.



It was very common in southwestern Muskoka District where the habitat consisted of bedrock outcrops with scattered common juniper and scrubby forests. Six Parry Sound nests were in similar juniper habitat on bedrock outcrops (Mills 1981). In Algonquin Park, it nests in burns, blowdowns, clear-cuts, open woods, regenerating jack pine stands, and in shrubbery, particularly on the drier side of the park (MacLulich 1938; Tozer 2012).

In Durham Region, it inhabited a black spruce bog surrounded by white spruce and tamarack with a red maple–poplar swamp. It also nested in a forest with an open canopy, areas of standing water, and a rank growth of ferns, raspberries, and other shrubs and saplings. Speirs and Orenstein (1975) considered it a mid-successional species.

Near Hamilton, highest densities occurred on limestone alvars in Flamborough Township. These include stands of scattered red cedar on bedrock but also open deciduous stands (Curry 2006). The bedrock inhibits forest growth but these sites eventually become closed-canopy stands in the absence of fire or forest management. In Niagara Region, it is particularly common in the shrubby habitat of Wainfleet Bog (Black and Roy 2010). At Point Pelee, it nested in low density in mature woodlands containing a high proportion of green ash. These stands are vulnerable to attack by the emerald ash borer and loss of these trees from the canopy may promote shrub growth and enhance conditions for the towhee (Dodds and Otis 2009). It occasionally nests in plantations in Ontario. Suitable plantations include young conifers where a canopy has not yet been established, plantations that have been thinned and have a shrub or sapling layer, and mature mixed plantations of pine and oak (personal observation).

The Eastern Towhee's requirement for open habitat and a dense layer of shrubs is almost universal. Highest densities occur in the pine and oak barrens of New York, New Jersey, Massachusetts, and Wisconsin and pine stands in the southeastern United States. It is often the most abundant species in barrens. Barrens are characterized by pine and oak stands with an open canopy or clumps of these species within an open matrix. Inhabited areas within barrens typically have a dense understorey, often of oak (Brush 1987; Brush and Stiles 1990; Mossman et al. 1991). In Quebec, it avoids wetlands, cultivated lands, and urban areas. Highest densities occur on rock outcrops with scattered red oak, often in association with white or red pine. It prefers dry habitats dominated by pines or oaks. Pine stands on the sand terraces of the Ottawa River provide ideal habitat. It also occurs in other dry brushy habitat such as abandoned fields and pastures (David in Gauthier and Aubry 1996). In Wisconsin, it is common in river terraces in stands dominated by jack pine, red cedar,

and oak (Mossman et al. 1991). In Indiana, it bred at edges of old fields with scattered brush and large patches of Virginia broomsedge, at edges of fields densely covered with raspberries, throughout fields that still supported grasses and blackberries but contained dense stands of small trees, and in fields with about 50% shrub and sapling coverage. Habitats commonly used in the eastern United States include clear-cuts, dry forests provided they have an open canopy and a dense woody understorey, recent burns, regenerating old fields, forest edges and openings, rehabilitated strip mines covered in shrubs, near trails and ditches or other disturbances in forests, roadside thickets, shrubby riparian areas along streams, shrubby sand dunes, oak savannahs, utility rights-of-way, coniferous plantations, and shrubby prairies. Wet habitats are much less likely to be inhabited, but it occasionally nests in bottomland hardwoods and deciduous swamps. Although pines and oaks appear to be greatly preferred, it occasionally inhabits stands dominated by sugar maple and aspens. The towhee has been described as an edge-associated generalist that occupies mesic and xeric habitats characterized by dense coverage near the ground by shrubs or saplings and a well-developed litter layer. The dense low cover may be continuous or discontinuous with patches of more open ground. In Kansas, it inhabited thickets of wild plum, crabapple, fragrant sumac, Osage orange, and locusts. Trees may or may not be present in the territory. If present, they are typically scattered or have an open canopy (Back 1979; Barbour 1951; Bielefeldt and Rosenfield 1994; Capen 1979; Dawson 1979; Dessecker and Yahner 1987; Dickinson in Austin 1968; Fitch 1958; Golet et al. 2001; Greenlaw 2020; Hoffman 1989a; Hurst and Bourland 1996; Karr 1968; Krementz and Powell 2000; Mossman 1988; Mossman and Hoffman 1989; Mossman et al. 1991; Nolan 1963; Noon et al. 1979; Rich et al. 1994; Samson 1979; Shugart and James 1973; Suthers 1988; Taylor and Taylor 1979; Yahner 1986, 1987; Yahner et al. 2002).

McClure et al. (2013a) examined the habitat preferences of the Eastern Towhee at the landscape and territory levels in Alabama. At the landscape scale, habitat was characterized by an avoidance of hardwoods, both on upland sites and on floodplains. Once general habitat had been selected, ground cover was an important criterion in selecting territories. Occupancy was negatively correlated with ground cover and vegetation taller than 7.6 m. It was less likely to use sites with a deep litter layer. It first selected sites that were not within hardwood forests then selected sites with certain characteristics of ground-level vegetation, depending upon whether it was summer or winter. In North Carolina, it was positively correlated with elevation at the 200-m scale, indicating that it is capable of occupying high-elevation landscapes with limited disturbance and only small forest gaps. It was positively correlated with habitat heterogeneity at the 200-m and 1,000-m scales, but not significantly. Heterogeneous landscapes consisted of a mosaic of forest patches, lawns, and pastures with scattered infrastructure. Homogeneous landscapes consisted of unbroken forest tracts. It was not correlated with the amount of exurban development (Gilbert and Ferguson 2019). It preferred areas with 23-58% forest cover in New York (Cunningham and Johnson 2019).

Numerous studies examined the microhabitat preferences of the Eastern Towhee. In Pennsylvania, it was characteristic of the ground stratum, occurring significantly more than expected 0-1 m from the ground and significantly less than expected in other strata (1.1-6.0 m, 6.1-12 m, and above 12 m). It was observed more than expected in large-toothed aspen, pitch pine, white and chestnut oak, and slash; in black cherry in proportion to its availability; and was not observed in red or scarlet oak, scrub oak, and red maple. It was positively correlated with lower

midstorey aspen and the ground stratum, negatively correlated with overstorey oak, and not associated at all with pitch pine canopy. Its density and the number of territories were negatively correlated with the density and basal area of overstorey trees, which included aspen, oak, hickory, and pine. It was positively correlated with the density of shrubs 0.5-1.5 m tall. High shrub density provided suitable foraging and nesting habitat (Yahner 1987). In Massachusetts, significant predictors for the towhee were the amount of litter 0-0.1 m from the ground, medium-height shrubs (0.5-1.0 m), and tall shrubs (2.0-5.0 m). It was negatively correlated with grass 0.1-0.5 m tall. Densities were highest in shrublands that had been burned or left unmanaged (Zuckerberg and Vickery 2006). In Arkansas, it was associated with the densest shrub vegetation (Shugart and James 1973). In Georgia, it was an indicator of shrub habitat (Brittain et al. 2010). In West Virginia, its density was positively correlated with raspberries, black cherry, black locust, grape, and hickory shorter than 3 m. It was negatively correlated with black gum, red maple, spicebush, witch-hazel, and tulip tree. Highest densities occurred on ridgetops where there was the most open canopy, lowest tree density, and lowest small-tree density. It was positively associated with plant species that were most abundant on drier ridgetops and midslope plots and negatively associated with plants that grew in the moister valleys. The negative correlation with small-diameter trees may be because a high density of trees results in less space to carry out activities such as foraging. Raspberries and grapes appeared to provide a more appropriate dense cover close to the ground (Bell and Whitmore 1997). In northeastern mixed-wood forests, Temple et al. (1979) considered it a mid-successional species associated with increasing abundance of sugar maple and yellow birch. In the mid-Atlantic states, its abundance was positively correlated with the amount of canopy coverage by conifers. It was negatively correlated with moisture and overall canopy cover (Robbins et al. 1989). In Maryland, it was positively correlated with tree density and negatively correlated with tree diversity (Lynch 1987). In 1 of 2 years in Illinois, it was positively correlated with hawthorn, black cherry, and basal area and negatively correlated with the number of tree species (Blake and Karr 1987). In pine and oak barrens in Wisconsin, it increased with increasing coverage by tall shrubs (Mossman et al. 1991).

In a Connecticut woodlot over a 59-year period, there was a progressive shift to larger trees, a sparser shrub layer, and a less diverse tree canopy dominated more by oaks and maples due to a severe decline in hemlock. The Eastern Towhee declined within the woodlot, but at a lower rate than it did statewide (Buchanan et al. 2016).

Most authors consider the Eastern Towhee a species that may occur both at forest edges and within the interior of forests (Askins et al. 1987; Austen et al. 2001; Freemark and Collins 1992). In New Jersey, Suthers (1988) considered it an obligate edge species. In Tennessee, it was significantly more abundant at the edge of a forest than in its interior. It was not detected further than 268 m from edge (Kroodsma 1984). In Pennsylvania, it exhibited the greatest horizontal breadth of any species, indicating a lack of specialization with reference to edge (Yahner 1987). In Ohio clear-cuts, Rodewald and Vitz (2005) mist-netted at distances of 20, 50, and 80 m from edge. There were no significant differences in capture rates among distances from edge for either adults or juveniles. Keller et al. (2003) found that it exhibited no edge preference in New York clear-cuts. In North Carolina shrub patches, Shake et al. (2012) found no evidence for an effect of patch shape or edge on the towhee. In New Jersey forests, there were no differences in its abundance on plots in forest edge and forest interior (Rich et al. 1994). In Mississippi, it was absent in fields with no borders and

borders 10 m or less in width, and uncommon in borders 30 m or more in width (Conover et al. 2009). In forested habitat, the towhee may be restricted to edge or occur throughout the forest. This is a function of habitat suitability. If the forest interior has a closed canopy and limited understorey, it is likely to be avoided but the interior of forests may be inhabited if there is a dense shrub layer. In shrubby patches, it occurs throughout with no evidence of avoidance of either edge or interior.

Corbat et al. (1988) and Freemark and Collins (1992) did not consider the Eastern Towhee an area-sensitive species. All researchers agreed except for two. Rodewald and Vitz (2005) mist-netted birds in small (4-8 ha) and large (13-16 ha) clear-cuts in Ohio. There was no significant difference in capture rates of either adults or juveniles in small or large patches. In southern Ontario, its abundance was positively correlated with the amount of forest cover 100 m or more from edge and negatively correlated with forest size, forest cover within 2 km, and the amount of regional forest. Only the latter relationship was significant (Austen et al. 2001). In Illinois, its abundance was unrelated to forest size (Blake and Karr 1987). In red maple swamps in Rhode Island, it was equally abundant in patches smaller than 1 ha, 1-5 ha, 6-10 ha, and 11-20 ha (Golet et al. 2001). In North Carolina, Shake et al. (2012) surveyed patches 0.3-24.9 ha in area and found no evidence of area sensitivity by the towhee. It was also unaffected by the amount of forest cover within 1 km. In Pennsylvania, it was more likely to be captured in large than small patches (Keller and Yahner 2007). In Missouri, Hayden et al. (1985) considered the towhee area sensitive. The smallest patch it occurred in was 2.2 ha and 100% occurrence was attained in forests 42.2-53.6 ha in size. The authors acknowledged that categorizing it as an area-sensitive species was statistically questionable.

The few nocturnal roosts that have been described were 3-5 m above ground in dense foliage. The towhee appears to roost solitarily (Greenlaw 2020).

Of 106 Ontario nests, 84 (79.2%) were on the ground and 22 (20.8%) were elevated in shrubs, trees, vines, saplings, and brush piles. Of 63 ground nests, 60.3% were under or at the base of a tree, shrub, or sapling; 11.1% were amidst plant stalks and leaf litter, 7.9% were in tufts of grass, 6.3% were under fallen branches, 6.3% were among dead limbs and tall grasses, 3.2% were in tangles of grapevines, and 1.6% each were under a log, in a patch of shrubs, and on mosses. Ground nests were often well hidden and 9 were in depressions in the ground. Four species of coniferous trees and shrubs supported 57.9% of elevated nests and 42.1% were in 4 species of deciduous shrubs, trees, and vines. Junipers and hawthorns were the most frequently selected species. Elevated nests were 0.5-2.4 m from the ground, with most 0.6-1.2 m up (Peck and James 1987, 1998b). In Parry Sound District, Mills (1981) reported 6 nests, 4 of which were 0.3-1.2 m from the ground in common junipers and 2 were on the ground.

Throughout its range, the Eastern Towhee either nests on the ground or a short distance above it in shrubs, vines, and saplings. Replacement nests and those at more southern latitudes are most likely to be elevated. In Kentucky, all first nests were either on the ground or on small stumps. Subsequent nests were 0.76-2.84 m from the ground (average 1.37 m). Only 2% of Michigan nests were 0.3-0.6 m from the ground in a shrub or tangle of vines. Ground nests are in a dry spot, usually at the base of a shrub or sapling, or in clumps of grasses and forbs. They may be hidden under brush piles. Nests may be either well concealed or fully exposed, but most are well shaded by overhead vegetation. Elevated nests are usually less than 1.5 m from the ground but 1 was 5.5 m up. In Indiana,

elevated nests were 0.75-3.1 m from the ground (average 1.6 m). It nests both in coniferous and deciduous trees and shrubs, including hophornbeam, white pine, red cedar, multiflora rose, hawthorns, blueberries, oaks, wax myrtle, elm, and shagbark hickory. Tangles of vines such as wild grape, Japanese honeysuckle, and greenbrier are favoured nesting sites. Nests may be elevated in clumps of grasses, on rotting stumps, or among roots of old treefalls. There is no evidence of nest reuse (Barbour 1951; Dickinson in Austin 1968; Greenlaw 2020; Hoyt 1948; Johnston 1993; Krementz and Powell 2000; Nolan 1963; Zimmerman 1989).

The Eastern Towhee defends its territory by singing, chasing, and fighting. In larger territories, males may have 2 activity centres focused on the nest and a foraging area. The females' activity centres are around the nest. In Kansas, some territories contained 2 or 3 shrub thickets separated by a field approximately 150 m wide. Birds regularly flew across the field but never used it. In Pennsylvania, territories were large and often contained different forests: 1- and 5-year-old clear-cuts and 60-year-old uncut stands. In New Jersey mesic oak stands, territories averaged 1.6 ha (range 0.64-2.44 ha); in xeric pine-oak stands, territories averaged 1.2 ha (range 0.71-1.65 ha). In Kansas, territories that were confined to a single shrub patch were 0.8-1.7 ha (average 1.16 ha). Territories that encompassed 2 or 3 discrete shrub patches were larger, with an average size of 2.23 ha (range 1.8-2.7 ha). In Massachusetts pine barrens, average territory size was 0.52 ha. Males may travel as far as 300 m outside their territories to encroach on other males' territories (Corbat et al. 1988; Fitch 1958; Greenlaw 2020; Wasserman 1983). Krementz and Powell (2000) studied daily movement patterns of towhees in mature pine stands and clear-cuts planted with pines in South Carolina. Except for the incubation period when females remained on or near the nest, both sexes moved over the entire stand where they had been captured. Outside the incubation period, only 2 females remained in the same stand and the other 15 moved among stands. Those marked in young stands moved to either intermediate-aged stands 20-35 years old or to mature stands. Birds marked in mature stands moved to intermediate-aged stands. No birds moved to young stands. These were daily movements and were not permanent. Daily movements averaged 99 m (range 39-173 m). The maximum distance moved over the sampling period averaged 464 m (range 110-1,256 m). Daily distances moved were unrelated to sex or stand type. Excursions from the daily activity centres were common, sometimes long, and crossed through different-aged pine stands, with intermediate-aged pine stands being the usual targets of these movements. In pine barrens in Massachusetts, towhee territories were evenly distributed in each year indicating that intraspecific competition was important in determining the dispersion of individuals (Morimoto and Wasserman 1991a). In the same study area, Wasserman (1983) made 10%, 20%, 30%, or 50% of existing food in territories inaccessible. When 0-30% of foraging areas in territories were made unavailable, there was no change in territory size, indicating that adequate food was still available. Only when 50% of foraging areas were made unavailable did males increase the size of their territories. Territories typically contain more than adequate food supplies.

Natal philopatry rates are approximately 2%. In Ohio, 3 of 170 juveniles (1.8%) were encountered as adults and 2 (1.2%) were discovered in the natal clear-cuts (Lehnen and Rodewald 2009b). Schlossberg (2009) reported a natal philopatry rate of 2% based on 1 study of 199 juveniles. In New Jersey, 2 of 108 yearlings (1.9%) returned to breed (Suthers 1988).

In Ohio, 12 of 77 adults (15.6%) returned and 11 (91.7% of returning birds) were encountered in the same clear-cut (Lehnen and Rodewald 2009b). Return rates were 43% in New Jersey and 48% in Pennsylvania. One New Jersey male returned to the same section of a 24-ha oak forest in 5 of 6 years (Greenlaw 2020). Schlossberg (2009) calculated an annual site fidelity rate of 28% based on 2 studies and 206 adults. The low rate of site fidelity may be an adaptation to the temporary nature of its habitat. Most early successional habitats are suitable for only short periods.

Limiting Factors

Eggs have been reported in Ontario nests from the beginning of May until mid-August, with most present from the last week of May until the last week of June (Peck and James 1987). The female starts building the nest approximately 1 week after pairing. Nest construction takes only a few hours, but may be spread over 5 days. As many as 3 days may elapse between nest completion and laying of the first egg but in most cases the first egg is laid the day after the nest is completed. Incubation may start with the laying of the penultimate or last egg. In Ontario, incubation periods of 11-13 days have been reported and 12-13 days have been reported elsewhere. The nestling period is 10-12 days, but young may leave the nest at age 7-8 days if they are disturbed. Although it has been concluded that the breeding season is over in all areas by mid- to late July, later nesting has been reported in Ontario and Virginia (Dickinson in Austin 1968; Gates and Gates 1975; Greenlaw 2020; Johnston 1993; Peck and James 1987).

Egg dates suggest that second broods may be raised in Ontario but this has not been confirmed (Peck and James 1987). David (in Gauthier and Aubry 1996) concluded that it was likely that only a single brood was raised in Quebec due to the shortness of the season. In the northeastern Atlantic states, second broods are undertaken in late June or early July. In the United States, 1 brood is considered likely in the northeast, 2 broods occur elsewhere, and third broods have been reported in Florida. Double broods have been positively confirmed only in New Jersey, Massachusetts, South Carolina, and Kentucky. The rate of second broods was 50% in climax oak forests in New Jersey, 16.7% in Kentucky, and 0% in New Jersey pine barrens. The second clutch is reared in a new nest, and the first egg of the second clutch is laid 7-21 days after the first brood fledges. Replacement clutches are commonly laid in a new nest if the first clutch is lost. The first egg is laid in replacement nests about 9 days after the loss of the first nest (Barbour 1951; Dickinson in Austin 1968; Greenlaw 1978, 2015; Krementz and Powell 2000). Ontario nests had clutches of 3-6 eggs (mode 4 eggs, mean 3.84 eggs; Peck and James 1998b). Throughout the towhee's range, clutches of 2-6 eggs have been reported, with most containing 3 or 4 eggs. Clutch sizes may increase northward, with mean clutch sizes of 2.4 eggs in Florida, 3.0 eggs in South Carolina, 3.4 eggs in New Jersey, and 3.6 eggs in Indiana. Early clutches may contain 0.5-1.0 egg more than later clutches. In New Jersey and New York, mean clutch sizes for early nests were significantly larger in oak-hickory forests (3.88 eggs) than in pine-oak barrens (2.67 eggs), and pitch pine barrens (3.25 eggs). The disparity in clutch sizes was because towhees in forests started nesting 2 weeks before those in barrens due to earlier leaf-out and greater abundance of arthropods in forests. In forests, 4- and 5-egg clutches were prevalent in May and early June; 2- and 3-egg clutches were frequent thereafter (Dickinson in Austin 1968; Greenlaw 1978, 2020; Krementz and Powell 2000).

Both sexes are capable of breeding in their first year. It is likely that all yearling females breed but some yearling males may be unsuccessful in attracting a mate. A New Jersey population consisted of 46 pairs on territories and 15 unpaired males that held territories for a few weeks before disappearing. The mating system is monogamous but 1 case of polygyny has been documented. The pair bond is retained for the entire breeding season, including for replacement nests and second broods. There is 1 case of a pair remaining together for at least 3 breeding seasons and they maintained the same territory in each year. The male guards the female closely once pairing occurs. Guarding is infrequent or absent after egg laying and the male begins to make long excursions at this time. This suggests that extra-pair copulations may be part of the towhee's breeding strategy (Dickinson in Austin 1968; Greenlaw 2020).

A high proportion of the Eastern Towhee's foraging occurs on the ground, where it uses a 2-footed scratching behaviour to displace loose litter on the ground and uncover hidden seeds and arthropod prey. Foraging usually occurs in dense low cover that provides a well-developed litter of deciduous leaves, conifer needles, or a mix of these. It may occasionally feed in the open briefly, but is seldom far from cover. Scratching for food occurs year round, but is especially important in winter when nearly all its food comes from the ground. In late spring and summer, both sexes often search for prey in arboreal foliage, particularly when new leaves are developing or defoliating caterpillars are abundant. In trees, most foraging is by gleaning, but it may also flutter down through the canopy after falling prey or sally from a perch to vegetation that is otherwise out of reach; flycatching is infrequent by males. Other foraging strategies from the ground include stretching or leaping at overhead vegetation and sallying from the ground, sometimes followed by hovering or clinging to the side of a trunk. There are no differences in the feeding behaviours of the sexes (Burtt and Hailman 1979; Greenlaw 2020). In Massachusetts pine barrens, the sexes foraged similarly, feeding 75-80% of the time on the ground. Ten percent or less of foraging occurred at heights of 0.5-1 m, 1-1.5 m, 1.5-3 m, and 3-6 m. No foraging occurred above 6 m. When the towhee foraged above ground, it preferred pitch pine, deciduous trees (predominantly oaks), and scrub oak, and avoided herbaceous species and ericaceous shrubs. It foraged significantly more along the distal half of branches. Females foraged distally significantly more often than males (Morimoto and Wasserman 1991b). In Pennsylvania clear-cuts, it often foraged around slash piles and in aspen stands that were only 1 year old (Corbat et al. 1988). In New Jersey pine barrens, it foraged less in oaks and more in pines as the breeding season progressed. It used oak in proportion to its foliage density in May, but disproportionately less in June and July when arthropod abundance declined in oaks. In a second study area, it used oaks more than expected in May and foraged on both oaks and pines in proportion to foliage density in June and July. It chose tree genera and habitat according to the relative biomass of arthropods in the foliage (Brush and Stiles 1990).

In Kentucky, the diet of 18 nestlings consisted of (by volume) 30.77% caterpillars, 15% adult beetles, 10% orthopterans, 7.22% lepidopteran cocoons, 6.68% beetle larvae, 3.61% spider eggs, 2.78% adult spiders, 0.83% fly pupae, 0.61% snails, 0.28% crustaceans, and 21.39% inorganic matter. Other food items in the diet of nestlings include moths, ant pupae, and fruits of wintergreen, blueberries, and huckleberries (Barbour 1951; Dickinson in Austin 1968; Greenlaw 2020).

Adults eat a mixture of animal and plant foods. It has been suggested that the towhee eats everything it uncovers while scratching in the litter, but it demonstrates clear preferences for certain food items and the proportions of animal and vegetable matter in the diet change seasonally. The diet, by volume, in the northeast in January and February consisted of 34.5% invertebrates and 65.5% plant material. The invertebrates included 27.2% adult insects, 4.1% immature insects, 0.4% spiders, and 2.5% millipedes. In March and April, the diet consisted of 59.1% invertebrates and 40.9% plant material, with the invertebrates including 48.7% adult insects, 7.2% immature insects, 1.2% spiders, and 0.4% harvestmen. In May and June, the diet consisted of 36.2% invertebrates and 63.8% plant material, with invertebrates including 29.6% adult insects, 5.4% immature insects, 0.3% spiders, 0.5% millipedes, and 0.3% snails. In July and August, the diet consisted of 21.4% invertebrates and 78.6% plant material, with invertebrates including 16.8% adult insects, 4.0% immature insects, 0.1% spiders, 0.3% millipedes, 0.3% centipedes, and 0.1% harvestmen. In September and October, the diet consisted of 2.4% invertebrates and 97.6% plant material, with the invertebrates including 0.6% adult insects, 0.8% spiders, 0.6% millipedes, and 0.4% centipedes. The most frequently consumed insects included beetles (14 families documented in the diet, including ground beetles and others found in litter such as weevils and leaf beetles), 5 families of grasshoppers and crickets, stink bugs, 3 families of bugs, hymenopterans (4 families including ants and wasps), and 5 families of moths and caterpillars. It eats beetles more frequently than any other insect group and particularly favours weevils. Moths, caterpillars, bugs, and ants are important in the diet and it also eats scale insects, cicadas, leafhoppers, carpenter ants, and sawflies. It also eats numerous spiders and snails and lesser numbers of harvestmen, millipedes, centipedes, isopods, ichneumonid wasps, cockroaches, and walkingsticks. It prefers ant pupae to adults. At 1 site in New Jersey where ants were abundant in the litter, they comprised 40% of the adult diet in early summer but were unrepresented in the diet in another area where ants were less prevalent. When adults are feeding nestlings, they eat invertebrates almost exclusively. Caterpillars are the favoured food at this time. Although hairy caterpillars, such as those of the gypsy moth, may be consumed, hairless caterpillars are greatly preferred. Plant material is particularly important in the diet in late summer and autumn, but some is eaten at all times of the year. The towhee occasionally eats soft foliage buds, young furled grass stems, and the soft flower buds of Virginia spring-beauty. It has been reported that it eats small acorns that have fallen to the ground, but this appears to have been documented only once. Most plant material that is eaten consists of seeds or fruits. Favoured seeds are those of ragweeds, smartweeds, foxtails, panic grasses, and docks. In autumn, it may eat seeds of wheat, oats, and flax. Frequently consumed fruits included those of strawberries, huckleberries, blueberries, bayberry, and blackberries. It also eats the fruit of red elderberry and mulberries. It rarely eats vertebrates such as snakes, lizards, and salamanders. On an annual basis, the diet consists of approximately 30% animal matter and 70% vegetation (Bell and Whitmore 1977; Dickinson in Austin 1968; Greenlaw 1978, 2020; Holt 1918; Stutchbury et al. 2005a).

The Eastern Towhee is a common host of the Brown-headed Cowbird. The towhee is an acceptor species that has not been documented rejecting eggs, covering eggs, or abandoning the nest in response to parasitism. The impacts of parasitism on the towhee are uncertain, but it is capable of fledging both species. It is likely that cowbirds remove some towhee eggs, thereby decreasing productivity. In Ontario, 30 of 164 nests (18.3%) were parasitized. Parasitism rates in other

areas include 4 of 109 nests (3.7%) in Georgia and South Carolina, 15 of 15 nests in Kansas resulting in 50 cowbird fledglings, 13 of 24 nests (54.2%) in Pennsylvania, 21 of 42 nests (50.0%) in Wisconsin, 2 of 6 nests (33.3%) in Michigan and Kentucky, 22 of 103 nests (21.4%) in Ohio, 3 of 41 nests (7.3%) in West Virginia, 3 of 57 nests (5.3%) in Missouri, 4 of 81 nests (4.9%) in Massachusetts, 2 of 58 nests (3.4%) in New York and New Jersey, 2 of 4 nests (50.0%) in Illinois, 2 of 12 nests (16.7%) in Indiana, and 2 of 9 nests (22.2%) in New York (Barbour 1951; Bell and Whitmore 1997; Greenlaw 2020; Hahn and Hatfield 1995; Kilgo and Moorman 2003; Nolan 1963; Peck and James 1998b; Rivers et al. 2010; Roach et al. 2018; Robinson 1992; Rothstein 1975).

Habitat loss and degradation are probably the greatest limiting factor to the Eastern Towhee. Direct habitat loss may occur due to urbanization, tree planting, and conversion of shrublands to agriculture. Urbanization may result in increased pressures due to cowbird parasitism and predation by cats, raccoons, and skunks. Habitat is also impaired or lost as forests mature and lose their woody understorey (Anonymous 2003; Hagan 1993; Greenlaw 2020; Krementz and Powell 2000).

Browsing by the white-tailed deer has the potential to decrease the density of shrubs and saplings, thereby degrading habitat for the towhee. In 1 Virginia study area, the ground cover in forests was almost completely eradicated because of overgrazing by deer. Towhees nested there in roadsides that still had shrubby borders (Johnston 1993). In Delaware, Tymkiw et al. (2013) compared towhee abundance in areas of low (10 or fewer per km^2), moderate (11-19 per km^2), and high (20 or more per km^2) deer densities and found no significant differences. In much of the eastern United States, deer densities have been increasing at a rate of 6% per year, consistent with the hypothesis that deer browsing caused the decline in towhees. In New Hampshire, both deer and towhee populations are declining, so deer are unlikely to be the sole reason for the decline of the towhee (Hagan 1993).

In Massachusetts, Zuckerberg and Vickery (2004) examined the effects of management for grassland birds on the towhee. Prescribed burning, repeated mowing, and brush cutting were conducted to maintain grassland habitat. In 2 of 3 breeding seasons, the towhee was more abundant in control or burned shrublands than in shrublands that had been mowed. It was most abundant in areas that had been burned, with no significant difference between controls and mowed areas. Abundance decreased with the frequency of mowing. After a single mowing event, abundance dropped by about 25%. After a second mowing, abundance was 47% of that in unmowed areas. Abundance was greatest in shrublands that had been burned or left unmanaged. It generally benefits from burning, but the frequency of burning must be considered. In Florida, densities were highest about 4 years after fire in scrub pinelands, followed by declines afterwards. In Indiana oak savannahs and woodlands, its density peaked at intermediate fire frequencies of about 4 every 15 years. Numbers declined once fire frequency increased above this level (Greenlaw 2020; Grundel and Pavlovic 2007a). In North Dakota, it responded favourably to fire, but occurred more frequently only after severe fires. It was most abundant in areas that burned 5-10 years prior to sampling (Rose and Simons 2016).

The Eastern Towhee benefits from forest management because opening the canopy promotes shrub growth. In New York, Keller et al. (2003) determined that it responded positively and immediately to clear-cutting, remaining abundant for 6 years after cutting. It was in a guild of early

successional species that gradually declined as leaf area and canopy increased. In Pennsylvania, Stribling et al. (1990) compared stand improvement cuts where snags were cut to those where snags were retained. Stand improvement involves removal of dead, dying, diseased, suppressed, or low-quality trees. Towhees were more abundant in stands where snags were retained. Snag retention resulted in greater availability of woody plants 0-1.5 m from the ground, and this enhanced habitat. In aspen and oak forests in Pennsylvania, 60-year-old forests were divided into 4-ha blocks and these were subdivided into 1-ha squares. Over time 0-3 of the squares in each block were cut. The towhee was 1 of 3 species that increased significantly and immediately after cutting. It was absent in 0% cuts, became the dominant species in 50% cuts, and was encountered more than expected in 75% cuts. It increased on the site but decreased regionally during the same timeframe (Yahner 1993, 2003). In the same general area, Corbat et al. (1988) found no difference in its abundance in cut and uncut areas. This was because mature aspen stands had a dense understorey of scrub oak so that cutting did not increase shrub density or habitat for the towhee. Five-year-old stands were used more than their availability, 1-year-old stands were used in proportion to their availability, and mature stands were used less than their availability. Aspen stands were used more than their availability and oak stands were used less than their availability. Habitat preferences were related to shrub density.

Windthrow, tree diseases, and defoliating insects may open the forest canopy, promote shrub growth, and improve towhee habitat. In West Virginia, gypsy moths retarded succession by decreasing the number of large overstorey trees and increasing the amount of understorey vegetation and the number of regenerating small trees. Density of the towhee increased 9 fold after the outbreak and its density was significantly higher on all 42 plots. These results support the hypothesis that forest succession is a major cause of the decline of the towhee (Bell and Whitmore 1977). The towhee is likely to benefit from the invasion of the emerald ash borer in Ontario, which is killing large numbers of ash trees.

Farwell et al. (2019) studied the effects of shale gas infrastructure (well pads, access roads, and pipelines) on the Eastern Towhee in contiguous forest in West Virginia. It exhibited no significant response to any of these features.

In South Carolina, nests suffered very high rates of predation. Towhee nests are especially vulnerable to predation because they are close to the ground. Where predators include high populations of snakes and mammals, predation may be a contributing cause of towhee declines (Krementz and Powell 2000).

In New York and New Jersey, food availability affected the timing of nesting and reproductive rates. Invertebrate biomass densities were significantly higher in an oak-hickory forest than in pine barrens. In the oak-hickory forest, the first 10% of nests were initiated by early to mid-May. The first 10% of nests in pine barrens were not initiated until the last half of May and mostly in the last week of May. Clutches in the oak-hickory forest were significantly larger than those in the pine barrens. Second broods were fairly common in the oak-hickory forest but rare or absent in the pine barrens. These differences were due to plant phenology and the subsequent relative abundance of food. In the oak-hickory forest, an herbaceous layer appeared in late April and early May but not on the sterile sandy soils of the barrens. Invertebrates occurred in concert with the development of leaves and

herbaceous vegetation. In the barrens, foraging birds seldom captured food above ground from late April to mid-May buts such manoeuvres were frequent at this time in the oak-hickory forest. Spring weather may also affect leaf-out, invertebrate availability, and towhee fecundity. Early springs advance the onset of breeding and result in increased production of fledglings. Late springs delay breeding and few young are likely to be produced (Greenlaw 1978, 2020).

In Chicago woodlots, Schneider and Miller (2014) examined the effects of invasive shrubs on the towhee. It was negatively associated with litter. Sites dominated by buckthorn were characterized by very little ground litter. There were almost no remaining native shrubs in the area, so buckthorn appeared to provide a nesting substrate. The scarcity of litter suggests that food resources may have been low for the towhee in this habitat.

Near lead mines in Missouri, elevated lead concentrations in soil near towhee nests decreased the probability of a female fledging a young from 51% to 15%. Most nest failures were due to predation, suggesting that lead affected birds' behaviour and activity at nests, or affected nest-site quality (Thompson et al. 2024).

Price (2004) concluded that the range of the Eastern Towhee might increase in southern Ontario if the average summer temperature increased by 2°C.

Status

The status of the Eastern Towhee prior to deforestation by European settlers is uncertain. Extensive tracts of mature forest would have provided little habitat but forest fires would have provided suitable conditions. It is likely that it benefitted from forest clearing. It appears as though its current range extends further northeast than it did historically. McIlwraith (1894) reported that it was unknown from the Ottawa area and David (in Gauthier and Aubry 1996) stated that it did not occur in Quebec at the turn of the 20th century. In Elgin County, it was common in 1891 and 1954 but was only a local breeder in 2000, suggesting that it had declined (Lancaster et al. 2004). Baillie and Harrington (1937) considered it a fairly common breeder throughout southern Ontario north to Muskoka District and east at least to Leeds County and Ottawa. They had records from Algoma District suggesting that it bred further north. Godfrey (1986) reported that it occurred north to Sudbury, North Bay, and Ottawa. The first atlas confirmed that the towhee was widespread south of the Canadian Shield, including on Manitoulin Island. In the Shield portion of the Great Lakes–St. Lawrence Forest Region, it was most widespread along the eastern Georgian Bay shoreline with scattered records further east and north to north of Lake Nipissing and in the Rainy River area. Extensive forested areas, such as Algonquin Park, and intensively farmed areas, such as portions of Essex and Lambton counties, were avoided. Some areas of apparently good habitat were unoccupied and it was less abundant than anticipated. There was some evidence that it was declining in the northern portion of its range and it appeared to be extirpated in Sudbury District (Inch and Inch in Cadman et al. 1987). James (1991) considered the towhee an uncommon summer resident north to Muskoka District and Ottawa, rare to Sudbury, and a vagrant to Fort Severn and James Bay.

The second atlas revealed that there had been no significant change in the distribution of the Eastern Towhee since the first atlas. Breeding was confirmed in western Rainy River District, representing the most northern occupied area in the province. There was no difference in its

probability of observation province-wide, but significant declines occurred in the Carolinian Forest Region and the Shield portion of the Great Lakes–St. Lawrence Forest Region. Most losses in the Shield were in more southern areas, possibly a result of forest maturation. There was considerable turnover in the squares that were occupied between atlases, possibly reflecting the transitional nature of its preferred habitat. There were several areas of high abundance. The largest area was from Prince Edward County east to the United Counties of Leeds and Grenville. Other areas of high abundance included the eastern shoreline of Georgian Bay, the Carden Plain, and the northern shoreline of Lake Erie from Rondeau to the Norfolk Sand Plain. Its areas of high abundance corresponded well with those of other shrub-dependent species such as the Field Sparrow (Timpf in Cadman et al. 2007).

Hagan (1993) analyzed population trends of the Eastern Towhee in the United States using the Breeding Bird Survey (BBS), autumn migration data from the Manomet Bird Observatory in Massachusetts, and Christmas Bird Counts (CBC). BBS data indicated that significant declines had occurred in 18 states and Ontario since 1966. The most severe declines occurred in the New England states where decline rates were higher than 5% per year. The rate of decline in Ontario was 3.2% per year. Of 52 species analyzed for their trends at Manomet, the towhee showed the most dramatic decline. In 1970, 2.7 were caught per 1,000 net-hours compared with 0.3-0.5 in 1988. CBC results showed significant declines of 2-5% per year, stronger declines than indicated by the BBS. This was expected because the CBC measures populations of both northeastern breeders and southeastern residents. Greenlaw (2020) summarized BBS data and concluded that the towhee had been declining since 1966. From 1966 to 1979, significant declines were observed in 21 states and provinces compared with only 10 states 1980-95. Despite the declines, it still remains widespread and common in some habitats. BBS results for 1970-2021 indicate annual decreases of 1.55% in Canada and 1.62% in Ontario. For 2011-21, it increased at annual rates of 1.11% in Canada and 1.3% in Ontario. The long-term trends were highly reliable; the short-term trends were of medium reliability (A.C. Smith et al. 2023).

Hanberry and Thompson (2019) compared BBS trends and forest composition over time in the eastern United States. They attributed the decline of the Eastern Towhee in part to the reduction in the amount of open forests and increase in the amount of closed-canopy forest. Savannahs and open woodlands were formerly more abundant but have undergone succession to closed-canopy forests.

POSTFLEDGING PERIOD

Brood division may occur once young leave the nest. If the female initiates a second brood, the male cares for the first brood. Adults continue to feed the young 3-4 weeks after they leave the nest, but the average duration of dependence is 30 days from hatching (Greenlaw 1978, 2020). In Rhode Island, fledglings 0-6 days out of the nest could not fly above 2-3 m and were mostly confined to the ground or to making short jumps. Seven to 13 days out of the nest, they could make lateral flights of 5-15 m but were unable to reach the canopy or high perches. By 14-20 days out of the nest, they were capable fliers that could reach high perches and the canopy. By 21 or more days, they were fully independent and received little or no parental care, but adults still occasionally moved with the young (Brenner and McWilliams 2019).

During the postfledging period, adults, young, and family groups may be common in young clear-cuts and on shrubby hydro transmission line corridors. In Pennsylvania, Stoleson (2013) captured 7 adults and 32 juveniles in 3-6-year-old clear-cuts that supported 10-15% residual basal area. In adjacent mature forest, 1 adult and 1 juvenile were captured. In Ohio, Vitz and Rodewald (2003) captured 19 adults and 100 juveniles in clear-cuts 4-7 years old. Marshall et al. (2003) captured 16 adults and 2 juveniles in 4-10-year-old clear-cuts in Virginia and West Virginia. In Missouri, Porneluzi et al. (2014) netted in clear-cuts 2-15 years after cutting and captured 13 towhees. Four were captured 2 years after cutting, 5 were captured 3 years after cutting, 2 4 years after cutting, 1 5 years after cutting, and 1 10 years after cutting. None were captured 5-8 and 11-15 years after cutting. There were too few captures to determine statistical significance, but 92.3% of captures were 2-5 years after cutting. On a shrubby hydro transmission line corridor, it was one of the most abundant species during the postfledging period; adults, juveniles, and family groups were common. None were seen in the forested habitat that the corridor passed through (Yahner et al. 2002).

Brenner and McWilliams (2019) studied postfledging movements and habitat use of the Eastern Towhee in Rhode Island in areas managed for the American Woodcock. Management provided early successional forests by clear-cutting, brush thinning, and mowing. Six study areas 4 km^2 in area were selected that consisted of recent (less than 15 years) forest clear-cuts 0.76-10 ha. These were classified as areas of high likelihood or low likelihood of woodcock use. High-likelihood areas had more early successional forest or upland shrubs, more hydric soils, and more mature deciduous or mixed forest. Low-likelihood areas had more mature coniferous forest and less early successional forest and upland shrub areas. Adult towhees were radiotracked from the first week that their young fledged for at least 3 weeks. Home range size of adults averaged 2.8 ha (range 0.78-8.06 ha), with no significant differences in high-likelihood (3.09 ha) and low-likelihood (2.37 ha) landscapes. Environmental variables did not explain home range size, which was determined by the fledgling development phase and landscape type. During the early, mid-, and late-fledging periods, there were no significant differences in the daily distance travelled by adults in high- and low-likelihood landscapes. Adults moved 37-47 m per day during these periods. Once fledglings reached independence, adults in high-likelihood landscapes travelled significantly further (49.5 m) than those in low-likelihood (36.7 m) landscapes per day. Most (54.5%) adult towhee locations occurred within young forest and scrub, with 26.2% of locations in mature upland forest and 14.6% in grasslands and fields. Adults in high-likelihood landscapes used less young forest and scrub than those in low-likelihood landscapes during the early fledgling stage (51.7% compared with 69.3%) and the mid-fledgling stage (43% compared with 60%). There was no significant difference in use of young forest and scrub by adults in high-likelihood and low-likelihood landscapes during the late fledgling (55% compared with 60%) and independence (55.4% compared with 60%) stages.

MIGRATION

The Eastern Towhee is a nocturnal migrant; it is unknown if it migrates in flocks or singly. At stopover sites, it often associates with the Dark-eyed Junco and White-throated Sparrow. Most birds in the northern portion of the breeding range migrate to the southeastern states to winter, although a few stay over winter even in the extreme northern portion of the range. More birds remain northward in mild than in severe winters. Southeastern and Gulf State populations are largely sedentary or

partially migratory (Greenlaw 2020). One banded in southeastern Ontario was recovered in Tennessee. One banded at Long Point was recovered almost due west in Michigan and another travelled almost due east to New York. These recoveries were 1-3 years after banding, so they may have travelled south for the winter before being recovered (Brewer et al. 2018). McIlwraith (1894) observed that the towhee always arrived at London and Chatham in spring before it did in Hamilton. He concluded that it probably entered the province in the southwest. In New Jersey and New England, autumn migration spans 4-5 weeks compared with 2-3 weeks for spring migration (Greenlaw 2020).

At Long Point Bird Observatory (LPBO), males arrived before females and adults arrived before yearlings. Mean capture dates of males were 21.2 April for adults, 25.2 April for yearlings, and 23.3 April for birds of undetermined age. For females, mean capture dates were 0.4 May for adults, 2.3 May for juveniles, and 2.0 May for birds of undetermined age (Stewart et al. 2002). In Massachusetts, males arrived an average of 4.8 days before females. Over a 32-year period, neither sex arrived significantly earlier with time; the timing differential between the sexes was not related to any climate variables (Bauböck et al. 2012). In Ontario, birds arrive in late March or early to mid-April and the peak of migration occurs in the first half of May (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008).

No information is available on the relative timing of autumn migration of sex or age classes. In Rhode Island over a 45-year period, migration was delayed by about 5 days per decade, the greatest increase of all species examined. During this period, the temperature increased by 1.44°C. Smith and Paton (2011) concluded that these results were likely specific to their region. In the southern Shield, autumn migrants occur from late August until October (Mills 1981; Tozer 2012). In the Kingston area, migration is from late August until mid-October (LaForest 1993; Weir 2008). In the southwest, migrants arrive from mid-September to early or late October and leave early to late November, with occasional stragglers until early December (Black and Roy 2010; Curry 2006; Lancaster et al. 2004).

The Eastern Towhee was more likely to be found in fragmented than forested landscapes during migration in Pennsylvania. There is more edge habitat in fragmented landscapes which may be attractive to the towhee (Keller and Yahner 2007). Migration habitat is similar to breeding habitat, but it often occurs in isolated habitat during migration that is too small or wet to support breeding. These may include wooded fencerows, cemeteries, blackberry or cherry thickets or other shrubby patches in residential suburban areas, and wetland thickets (Greenlaw 2020). In Pennsylvania during spring migration, detections per 100 m of transect totalled 0.01 in forest and 0.36 in shrubs; captures per 1,000 net-hours were 0.6 in forest and 4.2 in shrubs. It was significantly more abundant in shrubby areas than in forests (Smith and Hatch 2008). During spring migration in Wisconsin and Minnesota, the towhee was one of few species that was significantly more abundant in mature upland forests than mature floodplain forests. Upland forests were dominated by oak and elm. Floodplain forests were dominated by silver maple and green ash. Despite the fact that floodplain forests leafed out earlier and may have supported more arthropods, it selected the drier oak forests (Kirsch et al. 2013).

The Eastern Towhee is vulnerable to being killed at towers and other tall structures during migration, particularly in autumn (Greenlaw 2020). At the Lennox generating station chimneys near Kingston, 0 were killed in autumn 1973-82 but 3 were killed during spring migration (Weir 2008).

James (1991) considered the towhee an uncommon migrant in Ontario.

At LPBO, the towhee declined at a significant rate of 4.1% during migration 1961-88. Trends by period were: 1961-70, +0.4%; 1970-79, –14.8%; and 1978-88, –3.4%. More recent data from LPBO indicate long-term declines of 2.8% per year in spring and 2.4% in autumn (Anonymous 2003; Hussell et al. 1992).

WINTER

Wintering towhees avoid areas with an average minimum January temperature lower than –7°C. It occurs in high concentrations in areas of mixed and deciduous forests where there is an average minimum January temperature warmer than about –4°C. Root (1988) concluded that it was most likely to be found in hedgerows, thickets, shrubby woodlands, swamps, thickets along forest edges, and in the understorey and second growth of semiopen forests.

At the landscape level in Alabama, the towhee avoided areas dominated by hardwoods. In the breeding season, it was more likely to colonize sites with dense ground cover and less likely to colonize areas with deep leaf litter. Habitat selected in winter differed from breeding habitat. It was negatively associated with dense ground cover in winter. This may be related to the increased importance of plant material in the winter diet or the need for leaf litter for nesting and foraging in summer. McClure et al. (2013a) concluded that sites managed for breeding towhees were unlikely to support any in winter.

In Kansas, wintering towhees inhabited blackberry thickets at or near edges of woodlands. Within a day, they shifted among thickets and spent little time in other habitats. They were most often seen outside thickets when the ground was covered with snow and food was scarce (Fitch 1958). In Kentucky, it inhabited an area that was predominantly forested and another area that was predominantly herbaceous. It was associated mostly with forest edges, but also with streams. Six of 9 flocks were found most often along edges of large streams. The other 3 flocks frequented streams that were often dry. They were attracted by the abundant food and cover that was available along watercourses; presence of water was not essential (Barbour 1941). In winter, the Eastern Towhee continues to be strongly associated with shrubby habitat. In Kentucky, it selected shrubby habitat (45% of locations compared with 35% availability of habitat). Blackberry thickets were the most abundant habitat (39% coverage) but least used (19%). When snow was present, it moved into wooded habitat. In the north, it is frequently associated with bird feeders, including those in residential areas provided that shrubby habitat is nearby. In the Hamilton area, it winters in sheltered valleys. Wintering birds are occasionally seen in winter north and east of their breeding range. Some older reports may refer to the Spotted Towhee which occasionally wanders eastward in winter. Prior to 1995, the Spotted and Eastern towhees were considered conspecific and were called the Rufous-sided Towhee (Curry 2006; David in Gauthier and Aubry 1996; Dickinson in Austin 1968; Martin et al. 2021; Greenlaw 2020). In Arkansas, Kentucky, and Mississippi, it was equally abundant in row-crop fields with and without buffers of native grasses and forbs (Evans et al. 2015).

In most cases, the towhee winters solitarily, although it is often associated with the Field Sparrow, Song Sparrow, White-throated Sparrow, Dark-eyed Junco, and Northern Cardinal. In Kentucky, towhees occurred in flocks; 9 flocks averaged 17 birds (range 8-27). These consisted mainly of males, with females representing only 23.7% of flocks. This was probably because females migrated further south. One flock of 27 birds had a home range of 4.4 ha; another flock of 20 had a home range of 12.5 ha. In the latter area, food and cover plants were much sparser. The area used by a flock was determined by flock size, the amount of cover present, the amount and quality of food available, and weather conditions (Barbour 1941). In Kansas, the average home range size of individual males was 7.0 ha (Fitch 1958). At a Kentucky site, the mean home range was 7.31 ha and the mean core area was 1.52 ha. The mean overlap of the home range of any 2 individuals was 3.16 ha (36%) and the mean overlap of core areas was 0.42 ha (24%). Occasionally 3 home ranges overlapped (Martin et al. 2021).

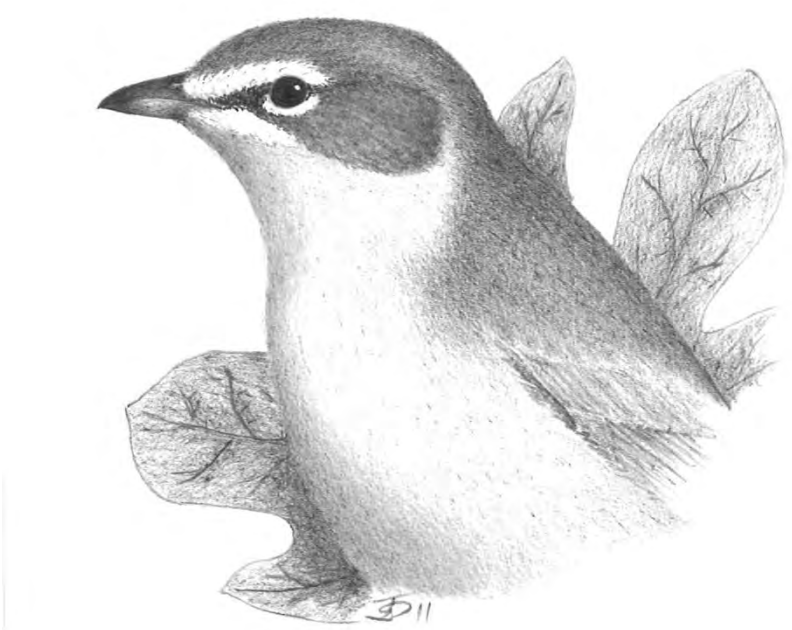
During winter, the towhee mostly scratches the ground to obtain food, even where food is abundant at bird feeders. In autumn and winter, the diet consists mostly of vegetable matter, including seeds of grasses and herbaceous species, grains, fruits, and fallen acorns. In winter, it eats berries of Canada moonseed and holly. At feeders, mixed seeds and millet are preferred food items. Less frequently, it consumes sunflower seeds of any type, cracked corn, suet, peanut butter, bird puddings, water, canary seed, milo, and wheat (Breiding 1946; Dunn and Tessaglia-Hymes 1999; Fitch 1958; Petrides 1942). In the north, the towhee may be dependent upon feeders for winter survival (Greenlaw 2020).

In Illinois, Graber and Graber (1979) documented the effects of severe winter weather on the towhee. Prior to and after the storm, it was absent in upland forest and urban residential habitats. In bottomland forests, it declined from an initial density of 43.0 per km^2 to 5.2 per km^2 after the storm, a decline of 87.9%. They found 4 dead towhees and concluded that it had suffered very high mortality. It is particularly vulnerable to snowstorms (and probably ice storms) because it is a ground feeder.

James (1991) considered the towhee rare in winter in the south north to Sault Ste. Marie and Sudbury, with scattered records in the north from Geraldton, Thunder Bay, and Marathon. It is possible that some of the northern records may have been Spotted Towhees. McIlwraith (1894) had no winter records for the province. In Hamilton, 1, 2, or more Eastern Towhees are reported each winter. March observations suggest that most of these successfully overwinter (Curry 2006). In the Kingston area, it was recorded in 20 of 60 winters (Weir 2008). Most winter observations are at feeders.

Yellow-breasted Chat

Icteria virens

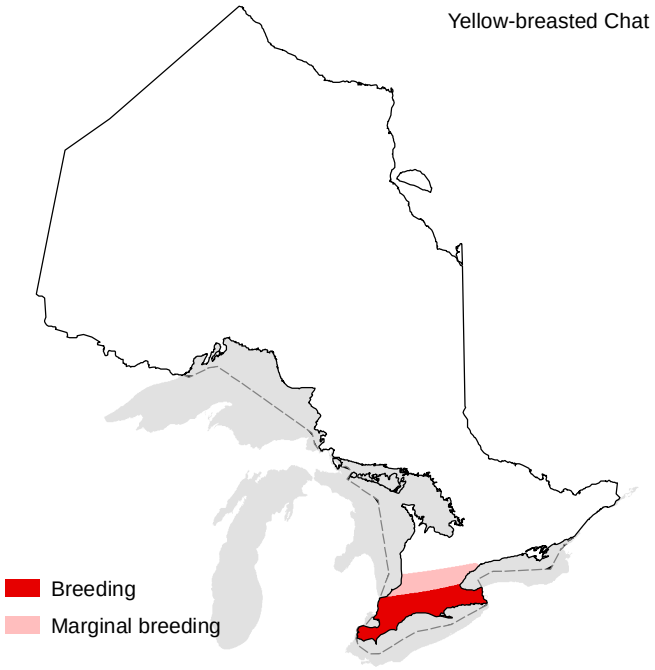


BREEDING SEASON

Habitat Requirements

In Ontario, the Yellow-breasted Chat nests regularly only in the Carolinian Forest Region with scattered and irregular breeding in the Great Lakes–St. Lawrence Forest Region south of the Canadian Shield. Nests have been reported in shrubby fields and pastures overgrown with dogwoods, hawthorns, raspberries, roses, grapes, and willows; and in open deciduous woods and clearings within woods with dense undergrowths of raspberries, grapes, and other shrubs (Peck and James 1987).

Ontario habitats include early successional areas that may include dense low deciduous or coniferous vegetation. Coniferous vegetation within territories is often red cedar but the Yellow-breasted Chat may frequent very young coniferous plantations that are still overgrown with shrubs. It may inhabit abandoned agricultural fields, railway and hydro transmission line rights-of-way,



fencerows, forest edges and openings, and thickets near streams, ponds, and swamps. It occurs in young shrublands where there are scattered deciduous trees and patches of herbaceous vegetation. The most consistent nesting locations in the province are at Point Pelee and on Pelee Island. Tangles of raspberries and grape vines are common features of territories. Habitat at Point Pelee consists of regenerating abandoned farmland. On Pelee Island, prime habitat is shrub alvar that is succeeding to treed alvar. At Rondeau, it was unknown as a breeding species until a severe windstorm opened up the forest canopy and created suitable habitat. In Niagara Region, it nests in shrubby thickets in and adjacent to Wainfleet Bog. A nest discovered in 1884 in Waterdown was in an abandoned mill race that had grown up in dense raspberry thickets. Almost all nesting territories contain patches of very dense shrubs. These consist either of raspberry stands or taller deciduous shrubs covered with grapes or other vines (Austen et al. 1994; Black and Roy 2010; Cadman et al. 2011; Kirk and Pearce 2011; Lancaster et al. 2004; McIlwraith 1894; Peck and James 1998a).

There are 2 subspecies of the Yellow-breasted Chat and both occur in Canada. The eastern subspecies occurs in Ontario and the eastern United States west to Texas. The western subspecies occurs in British Columbia, Alberta, Saskatchewan, and the western United States (Eckerle and Thompson 2020). Habitat structure used by the 2 subspecies is similar. Western birds nest almost exclusively in riparian shrub thickets that are permanent and do not regenerate into forests or other late-successional habitats. The eastern subspecies nests in early successional habitats dominated by shrubs. These regenerate into forests unless they are managed or the tree canopy is opened up as a result of fire, wind, insect damage, tree diseases, or harvesting. In Ontario, alvars provide the most permanent habitat but eventually even these become treed. The eastern subspecies nests in rehabilitated strip mines, burned and clear-cut forests, regenerating old pastures, young plantations that are still dominated by shrubs, sapling-stage forests, forest openings, shrubby hedgerows and roadsides, abandoned orchards, lightly grazed pastures, shrubby ravines, forest edges, shrubs adjacent to watercourses and water bodies, shrub thicket swamps, and hydro and railway rights-of-way. In the east, dense patches of raspberries or hawthorns may be preferred, but it may inhabit any area of very dense shrubs. In British Columbia, the chat nests almost exclusively in patches of wild rose. Hawthorn thickets are available there but not used. It also nests in thickets dominated by snowberry, willow, and other shrubs with an open overstorey of birch or cottonwood. Thickets that it uses are typically in low-elevation riparian areas such as streams, oxbows, and other wetlands. In Alberta, it is found mostly in the understorey of riparian poplar forests in major river valleys or in

dense tangled shrubbery along smaller watercourses that lack tree cover. It occasionally nests on shrubby slopes in upland areas, but upland areas usually are not suitable habitat. Mostly it uses thickets dominated by buffalo-berry, hawthorn, rose, willow, and birch. In Saskatchewan, it nests along major watercourses and in dune complexes where it selects the densest tall shrubby vegetation, including hawthorn, willow, Saskatoon, chokecherry, and buffalo-berry. In North Carolina, numbers observed during the breeding season in different habitats included 3.96 in dry thickets, 2.92 in wet thickets, 1.11 in pine-hardwood forest, 0.37 in floodplain forest, 0.20 in oak-hickory forest, and 0 in pine and beech forests. In Indiana, the chat preferred to nest in fields that supported grasses and blackberry thickets with dense stands of small trees 1-7 m tall. It was also present in old fields with poor soils due to erosion, thin ground cover, few shrubs, and with large patches of Virginia broomsedge; and in fields with dense coverage by blackberry, rose, herbaceous plants, and numerous small trees 0.3-5 m tall. In the early 20th century, it occasionally nested in villages but villages and rural residential lots no longer provide suitable habitat (Alterman et al. 2005; Bent 1953; Brooks 1940; Buffington et al. 1997; Campbell et al. 2001; Chapman 1907; Dennis 1958; Eckerle and Thompson 2020; Fitch 1958; Graber et al. 1983; Harrison 1984; Hurst and Bourland 1996; Karr 1968; Kirk and Pearce 2011; Miño et al. 2011; Nolan 1963; Parnell 1969; Ricketts and Ritchison 2000; Shugart and James 1973; Thompson and Nolan 1973).

The chat has been described as an obligate open-country species, nesting in areas with an open overstorey and a shrubby understorey, with its population density directly related to shrub density to a height of 4.5 m. Open areas of grasses and forbs are tolerated within the territory as long as dense shrub thickets are nearby. Once a tree canopy forms, habitat becomes marginal or unsuitable (Eckerle and Thompson 2020). In the east, most suitable habitat is short lived. Populations peak when dense shrub thickets with scattered trees are available and decline when trees become dominant. On Illinois rehabilitated strip mines, the population increased to a maximum in shrub habitat that was 1.5-4.6 m tall 14-20 years after mining and then declined. At peak populations, the oldest trees were 10 years old and no chats remained once trees were 37 years old. In New York clear-cuts, it occurred at high density 2-9 years after cutting and began to decline in the tenth year (Graber et al. 1983; Karr 1968; Keller et al. 2003; Kirk and Pearce 2011).

At the landscape level, the percent forest cover within the landscape did not appear to have any effect on shrub patch occupancy by the chat in North Carolina (Shake et al. 2012). The landscape of southern Ontario is ill suited to supporting the Yellow-breasted Chat. It consists predominantly of blocks of agricultural land, forest, or urban areas. There are few large patches of shrubs and these tend to either regenerate into forest or be converted to agricultural or urban land uses (Cadman et al. 2011).

Microhabitat preferences of the Yellow-breasted Chat are similar for the 2 subspecies. In British Columbia natural habitats, territories that had a higher percentage of shrub cover within 50 m were occupied in earlier years than those with less shrub coverage. In restoration sites, areas that had lower shrub coverage were not occupied later than those without higher shrub coverage. Vegetation at the nest site did not influence daily nest survival or parasitism rates (Forrester et al. 2020). In Texas, its abundance was positively correlated with the number of shrubs and shrub stems, foliage density at heights of 1 and 3 m, and percent coverage by pines 5-16 cm diameter at breast

height (DBH). It was negatively correlated with vegetation height, canopy closure, foliage density 12-15 m from the ground, percent coverage by pines 17-32 cm DBH, and number of stems 17-32 cm and larger than 32 cm DBH. It was associated with low shrubby vegetation, increasing density of shrub stems, foliage density within 1 m of the ground, number of shrub species, and sapling pines. The chat and White-eyed Vireo were associated with foliage density at 1 and 3 m and favoured later successional stages than the Prairie Warbler (Conner et al. 1983). In Kentucky, foliage cover below 2 m was significantly greater at nest sites than other areas of the territory; nest sites had more lateral cover below 1 m. Differences in these parameters had no effect on nest success (Ricketts and Ritchison 2000). In Arizona, the chat was associated with dense low shrubs (Brown and Trosset 1989). In Missouri, Burhans and Thompson (1999) measured vegetation parameters in an 11.3-m radius around nests and the patch dimensions in which nests were located. Nest patch diameter varied from 0.3 to 65 m (median 5.5 m). They grouped patches into large (5.5-m diameter and greater) and small (less than 5.5-m diameter). Large patches were selected significantly more for nesting (52% of nests in large patches) than small patches (19% of nests). The chat tended to place nests in larger patches with more small stems than those in unused sites, but patch size was the only variable distinguishing nest sites and random sites. Nest predation was lower but parasitism rates were higher in large than small patches. Large patches may have made it more difficult for predators to find nests, but they tended to have more large stems that provided perches for cowbirds. Predation and parasitism rates cancelled each other out so that there was no difference in success rates of nests in large and small patches. In Tennessee, it selected areas with dense overstorey vegetation and an open subcanopy layer. Understorey plants were typically smaller than normal. These habitat features were often in areas that had been burned. It was correlated with the foliage, branch, and biomass of trees 1.2-8.4 cm and 8.5-22.8 cm DBH, the number of trees 8.5-22.8 cm DBH, and the foliage, branch, bole, and stump biomass of trees larger than 22.8 cm DBH (Anderson and Shugart 1974). In the mid-Atlantic states, it was positively correlated with canopy cover and percent coverage by conifers. It was negatively correlated with slope, moisture, the number of trees, and trees larger than 38 cm DBH (Robbins et al. 1989). In British Columbia, Campbell et al. (2001) reported nests in thickets 9-195 m^2 comprised predominantly of roses. Rose height within used thickets averaged 1.25 m and large shrubs were usually about 3.5 m tall. Trees growing close to or in the thicket did not exceed 6 m. It was absent where pathways or cattle trails dissected the thicket or where there was a tall overstorey of trees. In British Columbia territories, the average cover consisted of 48% shrubs, 31% trees, 20% grasses and forbs, 1% bare ground, and 1% other cover. Wild rose was the dominant shrub with an average coverage of 30%. Alder was the main tree in the subcanopy and constituted 30% of cover in 20% of territories. Dominant trees included balsam poplar, birch, and willow. Vegetation parameters were measured in 50-m radius plots within territories and in random areas. Percent coverage by shrubs (43.9% in territories and 32.4% in random areas) and percent wild rose coverage (27.3% in territories and 18.4% in random areas) were significantly higher in territories. The percent coverage by trees (30.0% in territories and 35.3% in random areas), coverage by grasses or forbs (23.7% in territories and 28.7% in random areas), and coverage by balsam poplar (5.9% in territories and 10.3% in random areas) were significantly lower in territories. Vegetation was characterized in 5- and 11.3-m radius plots around 238 nests. Wild rose was the dominant species in both-sized plots and covered 41-57% of 5-m plots and 32-48% of 11.3-m plots. There were significant differences between the 2-sized plots. Coverage by wild rose and snowberry

was significantly higher in 5-m plots. Coverage by birch, balsam poplar, willow, other trees, grasses and forbs, bare ground, and other cover was significantly lower in 5-m plots than 11.3-m plots. Nest patches had higher percent coverage by wild rose, red-osier dogwood, and willow and a lower percent coverage of bare ground, grasses, and forbs than random areas within territories. The chat consistently selected patches of wild rose with a specific mix of shrubs and avoided sparsely vegetated areas. Trees were a distinct component of the territory, but tended to be distant from the nest site. Grasses and forbs were always part of the territory, but presence of dense shrubs was more important (McKibbin and Bishop 2010). In Texas, nests were in sites with greater concealment at nest level and with more vines and less grass below the nest (Novak et al. 2016).

Some studies concluded that the chat avoids edge and is thus a shrubland-interior species; other research found no evidence of edge avoidance. In Maryland and Delaware, it was equally abundant in riparian vegetation 50-800 m wide. This was forested habitat so the study did not deal with edge avoidance in shrub patches (Keller et al. 1993). In Ohio, Rodewald and Vitz (2005) set mist nets in a clear-cut 20, 50, and 80 m from the edge of a mature forest. There were no differences in habitat, fruit abundance, or arthropod abundance with distance from edge. Capture rates for juveniles per 100 net-hours were 1.5 at 20 m from edge, 2.1 at 50 m from edge, and 2.7 at 80 m from edge. Capture rates at these distances for adults were 1.0, 1.2, and 1.8. Habitat within 20 m of forest edge was used about half as much as areas 50-80 m from the same edge, suggesting edge avoidance. In Missouri, the area within 20 m of edge constituted 45% of the available habitat yet supported only 27% of nests. Habitat 21-40 m from edge represented 31% of the habitat and supported 37% of nests; the area more than 40 m from edge comprised 24% of the habitat and supported 36% of nests. Results within 20 m and more than 40 m from edge were significantly different from expected values. The chat preferred to nest in areas more than 40 m from edge and avoided areas within 20 m of edge. Habitat preference was not correlated with nest success and edges did not act as an ecological trap. Daily nest predation rate was lower within 20 m of an edge than more than 40 m distant from edge (Woodward et al. 2001). In North Carolina, Shake et al. (2012) assumed that it was an edge-avoiding species and predicted that it should decrease in irregularly shaped patches with a high shape index. They found no evidence for an effect of patch shape on occupancy. The most linear patch in their study area was approximately 30 m wide and it supported chats. They concluded that edge effects were not important but that patch size was. In Kentucky, it readily occupied linear strips less than 10 m wide that were larger than 0.5 ha and located along fencerows, roadsides, and edges of woodlots. Daily survival rates of nests in linear habitats were similar to those in larger, more rectangular habitats (Ricketts and Ritchison 2000). In British Columbia, the mean distance of 238 nests from patch edge was 26.9 m (McKibbin and Bishop 2010). The Yellow-breasted Chat is not an obligate shrubland-interior species, but there are areas where it is less abundant close to edge than in the interior of patches. Where edge avoidance occurs, it may be related to predation and parasitism pressures or to microhabitat.

Some studies determined that the chat is mildly area sensitive and others found no evidence of area sensitivity. In North Carolina, Shake et al. (2012) studied patches 0.3-24.9 ha (mean 6.1 ha). Occupancy rates of the smallest patches were low and patch size was a good predictor of chat occupancy. They estimated a minimum-area requirement (probability of occupancy of 50%) of 2.3 ha and an optimal area (90% probability of occupancy) of 4.4 ha. In Ohio, it was significantly more

abundant in large (13-16 ha) than small (4-8 ha) patches. Although patch size was a good predictor of abundance, productivity was similar in small and large patches (Lehnen and Rodewald 2009a; Rodewald and Vitz 2005). In Virginia, Dennis (1958) did not record it in small isolated patches of suitable habitat that were 1.2 ha or smaller. In Arkansas, it was common in 10-16-ha clear-cuts with residual seed trees. It nested in only 1 of 21 group-selection cuts and it was the largest cut at 0.79 ha. The other 20 cuts were less than 0.40 ha. Alterman et al. (2005) concluded that cuts this size were probably too small to support the chat. In British Columbia, Morgan et al. (2007) studied chats in 4 large (15-70 ha) riparian patches and 5 patches smaller than 2 ha. All sites were occupied, but incubation occurred later in the small isolated patches. This suggested that larger patches were preferred habitat that filled up earlier, forcing late arrivals to nest in small patches. In Kansas, one nested in a thicket that was only 0.36 ha and well separated from other suitable habitat (Fitch 1958). In Kentucky, it nested in patches smaller than 0.5 ha, but these were surrounded by old-field habitat (Ricketts and Ritchison 2000). The similarity of the surrounding habitat may have made these small patches more attractive. The minimum patch size that the chat will inhabit probably varies depending upon factors such as its local abundance, whether it is in the core or periphery of its range, and abundance of suitable habitat within the landscape. In Ontario, where the chat is rare and at the northern edge of the range and where suitable habitat is rare, it is likely that larger patch sizes will be necessary to attract it. The management plan for this species in Canada recommends maintaining minimum patches of 4 ha or more of suitable habitat until it is demonstrated that it successfully uses smaller areas (Cadman et al. 2011).

Ontario nests were in shrubs and vines, typically in dense growth, at heights of 0.3-1.8 m, with most 0.9-1.2 m from the ground. Shrub species supporting nests included 38.5% raspberries, 15.4% grape vines, 15.4% dogwoods, and 7.7% (1) in each of hawthorn, cedar, fragrant sumac, and common juniper (Peck and James 1987, 1998a).

Throughout its range, the Yellow-breasted Chat nests close to the ground in shrubs and vines and occasionally in tree saplings. Eastern nests have been documented in wild plum, sumac, raspberries, grape vines, roses, honeysuckles, dogwoods, black locust, red cedar, hawthorns, birches, huckleberry, hazel, crabapple, willows, white cedar, hackberry, ash, maples, gooseberry, elms, and holly. Raspberries are a common nest substrate in the east and supported 27.3% of Illinois nests. Almost half of Kentucky nests were in raspberries. Of 246 nests in British Columbia, 59.3% were in wild rose, 11.4% in snowberry, 3.3% in red-osier dogwood, 2% in poison ivy, 1.6% in smooth sumac, 1.2% in red raspberry, and 0.8% in dead shrubs; 1 nest each (0.4%) was found in Canada thistle, trembling aspen, Saskatoon, chokecherry, and birch. Forty-two nests (17.1%) were in a combination of 2 intertwined plant species and one was in a combination of wild rose, snowberry, and bracken fern. Other species that were intertwined as part of the nest support included balsam poplar saplings and rough horsetail. Nests were typically supported by stems smaller than 2.5 cm in diameter; 97-99% of stems in a radius of 25 cm below the nest were of this size. Average characteristics of nests were: nest-shrub height, 177.7 cm; shrub width, 82.8 cm; 92.0 cm of vegetation above the nest; 31.2 cm to the shrub edge; 63.4% nest concealment; 269.1 cm to the nearest patch edge; 5.4 stems smaller than 2.5 cm bracing the nest, 0.1 stem larger than 2.5 cm bracing the nest, and 98.9% of stems in a radius of 25 cm from the centre of the nest smaller than 2.5 cm. In New Mexico, the chat nested disproportionately more in Russian olive than its abundance. It is common in monotypic

stands of this nonnative shrub in Idaho. It was probably selected because its spreading growth pattern and thorns provide good protective cover. There was no difference in nest success rates in Russian olive and native shrub species. It appears to select species that provide the densest vegetation for nest concealment, and these species vary geographically. In most cases, the nest is shaded and well concealed. The chat tends to nest in the lower half of shrubs, typically at about 30% of shrub height. The overall range of nest heights is 0.15-2.4 m, but average nest height is usually under 1 m: 0.84 m in Illinois, 0.79 m in British Columbia, 0.79 m in Kentucky, 0.92 m in Texas, 1.0 m in Maryland, and 0.9 and 0.62 m in 2 Indiana study areas. Nests are not reused following predation or fledging but different females may build nests in the exact locations in different years. One pair began building a nest in a nest box. The box was blown down in a thunderstorm and subsequently replaced, but the chats did not return (Bent 1953; Campbell et al. 2001; Chapman 1907; Dennis 1958; Eckerle and Thompson 2020; Graber et al. 1983; McKibbin and Bishop 2010; Nolan 1963; Petrides 1938; Ricketts and Ritchison 2000; Stoleson and Finch 2001).

In Virginia, chat territories were clumped, with pairs congregating in a restricted area while identical surrounding habitat was unoccupied. The unoccupied habitat was rather limited in extent (Dennis 1958). Territorial aggregation has not been identified by other researchers, but is possible due to its mating system. Early arriving males may range over areas as large as 5 ha, but the defended area shrinks as more birds arrive. Despite defence of territories, intrusions by other birds of both sexes occur regularly; consequently, territory sizes are consistently smaller than home ranges. Territory boundaries may shift during the season. If 1 male shifts his area of high activity, neighbours may intrude into his former territory. When a neighbouring pair disappears, its territory may be absorbed by others. In Illinois, 18 territories were 0.4-1.4 ha (average 1.0 ha). In Virginia, territories were 0.51-1.01 ha; home ranges were much larger but their size could not be quantified. In Indiana, mean territory sizes over 4 years were 1.12, 1.22, 1.17, and 1.58 ha (overall average 1.24 ha). Mean territory size in 1 British Columbia study was 0.37 ha. One Virginia territory was estimated at 0.15 ha, but this may have been an underestimate. Territory size in another British Columbia study averaged 0.25 ha; 0.22 ha in isolated patches smaller than 2 ha and 0.29 ha in patches 15-70 ha. In a small tract of deciduous swamp and thicket around 3 Illinois ponds, territory size averaged 0.13 ha (range 0.06-0.29 ha). In Kansas, 1 territory coincided with the boundaries of an isolated thicket that was 0.36 ha; another territory in more extensive habitat was 0.8 ha. In British Columbia, birds had mean territory sizes of 0.62 ha and home ranges of 1.16 ha. Territory sizes were determined for additional birds that were not radiotracked and these averaged 0.54 ha. When territory sizes of both radiotracked and non-radiotracked birds were combined, they averaged 0.55 ha (range 0.29-0.95 ha). Territories seldom overlapped but home ranges frequently overlapped. In Ohio, birds occasionally moved as far as 1 km from their territory and sometimes left their patch to travel to nearby patches. One Virginia male was caught 530 m from its territory, but it may have been unmated (Brewer 1955; Davis 1987; Dennis 1958; Fitch 1958; Graber et al. 1983; Lehnen and Rodewald 2009a; McKibbin and Bishop 2010, 2012a; Morgan et al. 2007; Thompson and Nolan 1973).

Almost no information on natal philopatry is available for the eastern subspecies. In Indiana, 0 of 39 nestlings returned; 0 of 15 juveniles banded in the area that were not produced there returned (Thompson and Nolan 1973). In Ohio, 2 of 270 young (0.8%) returned and 1 (0.4%) returned to the natal patch (Lehnen and Rodewald 2009b). In British Columbia, 39 of 385 nestlings (10.1%) returned

to nest. None returned to the natal territory but 62% of males and 54% of females returned to the natal habitat patch. Seven of 10 returning male nestlings that returned to a study area other than their natal site were observed the year after banding and dispersed 2.5-15.6 km from their natal site (median 10.3 km, mean 10.2 km). Two of 6 returning female nestlings were observed the year after banding at a site other than the natal study area. They dispersed distances of 2.3 and 2.6 km. The large size of the study area (189 ha) may have contributed to the higher return rate (McKibbin and Bishop 2012b). It is unlikely that natal philopatry rates are as high for the eastern population because adult site fidelity is much lower in the east than the west.

Adult site fidelity rates vary considerably geographically. Stewart (1989c) summarized band recoveries of the Yellow-breasted Chat in North America. Of birds that were not recaptured in the same area shortly after banding, 46 of 55 (83.6%) were recovered in the same 10-minute latitude-longitude block occupied during an earlier nesting season. This indicated a strong tendency to return to the same general location in successive breeding seasons. Two birds (3.6%) were recovered outside their original latitude-longitude block but in the same state; 7 (12.7%) moved to another state. Birds went from Maryland to West Virginia, Massachusetts to New Jersey, Indiana to Ohio, and Ontario to Michigan. In Indiana, 5 of 63 males (6.3%) returned and probably bred. When an additional 49 ha of adjacent habitat was examined, only 1 additional returning male was discovered, bringing the total to 7.9% site fidelity for males. Of 57 females, none returned in subsequent years, but females are difficult to find so some may have been overlooked. There was considerable within-season movement of adults. Seventeen of 39 males (43.6%) disappeared during the breeding season; 8 were breeders and 9 were territorial nonbreeders. All 8 breeding males disappeared after their nests failed and their females disappeared from the study area. Twelve females disappeared during the breeding season and all did so shortly after nest failure. Some males that disappeared were reencountered in subsequent years indicating that they had moved from the study area rather than having died. None of the females that disappeared were seen again. Many birds that disappeared were replaced later in the season by birds that were new to the area. It was likely that most of the new replacement birds had nested earlier at another location because the females had brood patches. Eastern birds may breed at more than 1 location within a single nesting season (Thompson 1977; Thompson and Nolan 1973). In Ohio, Lehnen and Rodewald (2009b) radiotracked male chats in 3 clear-cuts separated from the nearest shrubland patches by 70-, 95-, and 100-m wide strips of mature forest. Of 464 adults, 92 (19.8%) were recovered in a subsequent year and 89 (19.2%) were recovered at the same site. The mean number of sites used by 37 males was 1.4, with 13 (35.1%) located in at least 2 patches. The mean distance moved by the 13 males was 502 m (median 531 m). The mean number of patches they visited was 2.2. Three males established territories in patches other than their original patches; 2 may not have established territories prior to being captured and the third moved after nest failure. Of the remaining 10 birds, 5 made numerous visits to a neighbouring patch, moving a mean distance of 179 m (range 88-330 m). The remaining 5 males made fewer extra-patch visits, but travelled further (mean 649 m, range 445-1,045 m). Patches visited by males were younger (mean 5.5 years) than those where they were originally captured (mean 7.3 years). Dispersing birds did not move to larger patches. Birds may have been assessing the quality of other habitat patches for future breeding, seeking extra-pair copulations, or foraging.

All information on site fidelity for the western subspecies is from British Columbia. Of 45 males, 20 (44.4%) were resighted in subsequent years: 15 the first year after banding, 4 2 years after banding, and 1 3 years after banding. Seventeen of the 45 males (37.8%) and 17 of 20 returning birds (85.0%) returned to the same study area. Of these 17 birds, 2 bred in the area in at least 5 years, 5 in 3 years, and 8 in 2 years. Twelve of the 17 returning males (70.6%) bred on the same territory they held previously. Two of the dispersing males bred an additional 2 years at their new site. Males that did not return to their original territories dispersed 6.4-42.9 km from the territory where they had been banded (mean 14.98 km). Four of 30 females (13.3%) returned, 3 the year after banding and 1 the following year. Returning females dispersed a maximum of 2.6 km from their original territories. Most birds remained in the same location for the entire season. Only 1 male relocated after the nest failed and his mate disappeared. He moved 12.3 km, defended a territory at the new site, and was successful in attracting a mate (McKibbin and Bishop 2012b).

Limiting Factors

Eggs have been reported in Ontario nests from 2 June to 1 July (Peck and James 1998a). No information is available on how long it takes to build the nest or if there is an interval between nest completion and laying of the first egg. Eggs are laid at the rate of 1 a day. Incubation begins the night before the last egg is laid. The incubation period at 1 Ontario nest was at least 11 days and 2 District of Columbia nests had incubation periods of 11 days. Five Indiana nests had an average incubation period of 11.6 days (range 10.7-12.3 days). The eggs hatch within 24 hours of each other. The nestling period at District of Columbia nests was 8 days. The nestling period in Indiana averaged 8.9 days (range 7-10 days). In British Columbia, the time between fledging of the first brood and laying the first egg of the second clutch averaged 7.4 days. In a single third clutch, the first egg was laid 6 days after the second brood fledged (Eckerle and Thompson 2020; McKibbin and Bishop 2014; Peck and James 1987; Petrides 1938; Schadd and Ritchison 1998).

Based upon Ontario egg dates (Peck and James 1998a), it appears as though only a single brood is raised. The number of broods that the chat raises is difficult to ascertain because individuals may raise broods in disparate locations within a single year. In Indiana, some birds arrived later in the season that had apparently bred elsewhere (Thompson and Nolan 1973). Some birds arrive in Mexico in late July to nest and females have a brood patch indicating that they previously attempted to raise a brood. Stable isotope analyses revealed that these birds originated in the eastern United States (Rohwer et al. 2009). In Kentucky, the chat was double brooded (Schadd and Ritchison 1998), but all birds in Georgia and South Carolina were single brooded (Kilgo and Moorman 2003). It is possible that this area is partially the source of birds that breed later in Mexico. In British Columbia, 50 of 384 females (13.0%) had 2 broods. Nests for the second brood averaged 25.8 m from the first nest. One female attempted to raise 3 broods. Her first nest fledged 2 chats and 1 cowbird, the second nest fledged 3 chats and 1 cowbird, and the third clutch consisted of 3 chat eggs but failed to fledge any young. The third nest was 34 m from the second nest and 14 m from the first nest. The female that initiated 3 broods was one of the first to lay eggs in the spring (McKibbin and Bishop 2014). The chat may renest after nest failure; renesting was confirmed in Elgin County (Lancaster et al. 2004). In Indiana, 11 of 20 males (55%) and 11 of 22 females (50%) that lost their nests initiated a replacement nest. Ten of the females that did not renest disappeared from the study area. The other remained but did not renest. It is possible that those that disappeared initiated a replacement nest

elsewhere (Thompson and Nolan 1973). Clutches of 3-5 eggs have been reported in Ontario, with 4 eggs most frequent (mean 4.15 eggs; Peck and James 1998a). Throughout its range, the chat lays 3-6 eggs, but typically 3-5 eggs with 3 and 4 eggs most common. In Indiana, 78.9% of 4-egg clutches were laid in the first half of the laying period. Only 27.8% of 3-egg clutches were laid then. Average clutch sizes reported elsewhere include 4.09 in Illinois, 3.5 in Indiana, 3.5 and 3.75 in British Columbia, 3.36 in Arizona, 3.8 in New York, 4.0 in Pennsylvania and New Jersey, 3.84 in Tennessee, and 3.5 in Maryland (Bent 1953; Brand and Noon 2011; Campbell et al. 2001; Chapman 1907; Eckerle and Thompson 2020; Graber et al. 1983; McKibbin and Bishop 2014; Miño et al. 2011; Morgan et al. 2007; Petrides 1938; Thompson and Nolan 1973).

It appears as though all yearling females breed. Some yearling males may not be successful in defending a territory or attracting a mate (Eckerle and Thompson 2020; McKibbin and Bishop 2014). In Indiana, there was a surplus of birds. Some were transients that failed to establish a territory and others were territorial but failed to attract a mate. Of 10 males arriving later in the breeding season, only 3 bred after replacing nonbreeding territorial males that disappeared. Although 1 nonbreeding territorial male remained all season, most eventually left the area. When mated males disappeared or died, they were quickly replaced by other males (Thompson 1977; Thompson and Nolan 1973). It is unlikely that Ontario nesting areas support surplus birds due to its rarity. Some territorial males may not attract a female simply because none are available. Thompson and Nolan (1973) recognized 3 types of male mating systems: monogamy, successive monogamy, and polygyny. Successive monogamy occurred when a male mated with 2 or more females in sequence, but without any overlap in the timing of association with the females. Overall, 66.7% of males were monogamous with a single mate during the breeding season, 16.7% were successively monogamous, 4.2% (1 of 24) were polygynous, and the mating strategy of 12.5% of males was undetermined. Females may be monogamous or polyandrous, nesting with different successive males, and they may be in relationships with males that are either monogamous or polygynous. In the single case of polygyny in Indiana, the male initially bred with a female whose nest failed. She disappeared and 2 females appeared. The nesting cycle of these females was synchronous with the first egg laid on the same date in both nests; 1 nest failed and the other was successful. Because birds frequently moved within breeding seasons, the mating systems of some birds may have been more complicated than what was documented (Thompson and Nolan 1973). At a Virginia site, 2 broods were produced but only 2 males and 1 female were present. A male cared for the first brood and the female for the second. It was unknown if the female was polyandrous or if 1 male was unmated and both broods belonged to the other male (Dennis 1958). In Kentucky, 9 of 10 males were monogamous and 1 was bigamous (Eckerle and Thompson 2020). In British Columbia, 1 male defended 2 territories about 700 m apart and females were present in both territories. This male had the largest home range of all males (McKibbin and Bishop 2012a). Nest failure can have a profound effect on the stability of pair bonds. Pairs with successful nests tend to remain together throughout the season. Of 11 Indiana males that renested after the first nest failed, 6 retained their mate and 5 acquired a new mate. Of those obtaining a new mate, 1 paired with a female that had been mated to another male earlier in the season and the other 4 paired with females that had no previous breeding experience in the study area; all had brood patches (Thompson and Nolan 1973). In British Columbia, no mate fidelity was observed between breeding seasons (McKibbin and Bishop 2012b).

Extra-pair copulations are an important component of the mating strategy of the Yellow-breasted Chat. Both sexes solicit extra-pair copulations by making extra-territorial forays. In Kentucky, 65% of females and 50% of males made at least 1 foray into neighbouring territories. When females moved off territory, 96% of telemetry locations were less than 2 m from the ground, 3% were 2-5 m from the ground, and only 1 was 5-15 m from the ground. Females remained near the ground where vegetation was the densest. Females stayed lower than males, with 4.7 points less than 2 m from the ground per hour compared with 2.15 for males. Males followed their mates and, in 2 cases, attempted to herd them back to their own territory. Birds also move and sing at night, activities that are associated with extra-pair copulations. In Kentucky, 33% of 9 broods contained at least 1 extra-pair young and 17% of nestlings were not related to their social father. In British Columbia nests, 49.1% of nestlings were full siblings, 21.8% were half siblings, and 29.1% were unrelated. Four of 13 nestlings (30.7%) were not sired by the social father. The clustering of territories in some areas could facilitate extra-pair copulations (Dussourd and Ritchison 2003; Eckerle and Thompson 2020; Mays and Ritchison 2004; McKibbin and Bishop 2012a; Miño et al. 2011). Intraspecific parasitism is also a component of the mating system. In British Columbia, 3 of 13 nestlings (23.1%) were unrelated to the social mother (Miño et al. 2011).

During the breeding season in North Carolina, the Yellow-breasted Chat foraged 25.7% of the time in the canopy, 45.7% in low trees, 28.6% in shrubs, and 0% on the ground. Singing males occurred at heights of 2 m to more than 15 m (average 8.8 m). Nonsinging birds occurred at 0-15.8 m (average 4 m; Parnell 1969). The chat foraged primarily by gleaning insects from the foliage of shrubs (Whitmore 1977).

Nests where both sexes provision the young are more successful, fledging an average of 3.14 young compared with 1.52 young for nests fed by a single adult. In Kentucky, 56.7% of prey items brought to young consisted of adult insects; 43.3% were larvae. Small prey (equal to or shorter than the length of the adults' bill) accounted for 15.8% of prey items, medium-sized prey (bill length to 2 times the bill length) constituted 56.8% of prey items, and large prey (greater than 2 times bill length) comprised 27.4% of food items. In Washington, DC, the food of nestlings consisted almost entirely of soft-bodied orthopterans and caterpillars, and 2 half-grown praying mantises were consumed. Brown, almost hairless caterpillars were the most abundant food item; young were also fed locusts and grasshoppers. Young at a western nest were fed beetles, grasshoppers, and butterflies, but hairless caterpillars were the dominant food item. In British Columbia, males were the main providers to first broods while females initiated second broods (Bent 1953; Eckerle and Thompson 2020; McKibbin and Bishop 2014; Petrides 1938; Schadd and Ritchison 1998).

Adults eat a mix of small invertebrates (almost exclusively insects, but a few spiders and crustaceans) and fruit. Birds collected early in the breeding season had eaten approximately equal proportions of insects and fruit. Commonly consumed insects include beetles and weevils, bugs, ants, bees, wasps, mayflies, grasshoppers, adult and larval moths, caterpillars (including those of the tent caterpillar), and cicadas. The chat eats fruit of strawberries, mulberries, blackberries, raspberries, elderberries, grapes, blueberries, Japanese honeysuckle, and Saskatoon. A British Columbia female ate rose petals (Bent 1953; Eckerle and Thompson 2020; Holt 1918; McKibbin and Bishop 2014).

The Yellow-breasted Chat is parasitized by the Brown-headed Cowbird at moderate rates. Early publications suggested that the chat invariably deserted its nest in response to parasitism, but it is now known that is not the case. In Michigan, only 3 of 10 nests (30%) were abandoned after they were parasitized. The chat is typically considered an acceptor of cowbird eggs, but it occasionally ejects them. In Missouri, nests were artificially parasitized with 2 cowbird eggs: one normally coloured and the other painted white. Half of white eggs were ejected and 1 of 9 normal cowbird eggs was ejected. Chats may have difficulty distinguishing cowbird eggs from their own and eject only those that differ in maculation. The impact of parasitism on the chat is uncertain, but appears to be much lower than for many host species. In Indiana, 7% of eggs were removed by cowbirds; 81% of eggs were lost due to predation. Nestling chats appear to be able to successfully compete against cowbird nestlings. Many parasitized nests successfully fledge both species. Parasitized nests are more likely to be depredated than unparasitized nests; cowbird nestlings may attract more predators. In Missouri, nest patches with stems larger than 10 cm were more likely to contain parasitized nests because the larger stems provided perches for cowbirds. There were no differences in daily survival rates in parasitized and unparasitized nests. Four of 19 Ontario nests (21.1%) were parasitized. Parasitism rates are variable: 12 of 50 nests (24.0%) in Illinois, 3 of 5 nests (60.0%) in Saskatchewan, 10 of 11 nests (90.9%) in Michigan, 0 of 49 nests in Kentucky, 0 of 15 nests in Texas, 21 of 113 nests (18.6%) in Georgia and South Carolina, 31% of 42 nests in Missouri, 2 of 52 nests (3.8%) in Arkansas and Oklahoma, 4 of 127 nests (3.1%) in Mississippi, 17-20% of nests in Indiana, 5% of nests in Maryland, 11% of nests in Arizona, 0 of 10 nests in Pennsylvania, and 13%, 17.4%, 23.5%, and 49% of nests in 4 British Columbia studies. In British Columbia, the parasitism rate was 21.4% before 1978 and 54.7% 2012-14 despite a decrease in cowbird abundance of 80% (Alterman et al. 2005; Brand and Noon 2011; Burhans and Freeman 1977; Burhans and Thompson 1999; Cadman et al. 2011; Campbell et al. 2001; Eckerle and Thompson 2020; Forrester et al. 2020, 2023; Graber et al. 1983; Hackemack et al. 2016; Harrison 1984; Kilgo and Moorman 2003; Kirk and Pearce 2011; Nickell 1955; Novak et al. 2016; Peck and James 1998a; Ricketts and Ritchison 2000; Thompson and Nolan 1973).

Scarcity of suitable habitat and loss and degradation of existing habitat are the greatest limiting factors for the Yellow-breasted Chat. It is uncertain if it occurred in Ontario before European settlers deforested the landscape. The amount of suitable habitat probably peaked in the mid-20th century. The amount of shrubland began to decrease around this time due to removal of hedgerows to create bigger agricultural fields, road widening and right-of-way management to remove shrubs, reforestation of abandoned agricultural land, reductions in the amount of pasture, natural regeneration, and fire suppression. Shrublands are scarce in the province now and are often regarded as wastelands that are frequently converted to agricultural or urban land uses. Point Pelee and Pelee Island formerly supported the highest numbers of chats, but both have become marginal habitat as a result of natural succession. It appears to be adapted to inhabiting areas that are short-lived due to natural succession in the east by having low site fidelity and readily moving to new areas of suitable habitat. Remaining suitable patches may be too small and isolated from each other to provide continuing habitat for the chat in Ontario. There appear to be no data on the amount of shrublands within the province during different periods, but it has been estimated that more than 50% of suitable habitat has been lost in the Lower Great Lakes Physiographic Region since 1966. The

entire eastern population depends predominantly on anthropogenic early successional habitat that is being lost due to natural succession and other factors. Habitat loss was identified as a problem shortly after the turn of the 20th century and conditions have continued to deteriorate. The western subspecies appears to be stable in British Columbia despite the loss of 87% of riparian shrublands. It is increasing in Saskatchewan due to increased shrub coverage due to a reduction in grazing (Austen et al. 1994; Cadman et al. 2011; Chapman 1907; Curry 2006; Eckerle and Thompson 2020; Graber et al. 1983; Kirk and Pearce 2011; McKibbin and Bishop 2010).

Another major limiting factor is that the eastern subspecies of the Yellow-breasted Chat is at the extreme northern extent of its range in Ontario. When species decline, their range typically contracts from peripheral areas first. This subspecies is declining so that even suitable habitat may not be occupied. This appears to be happening in the Windsor and LaSalle area, an area typically occupied by the chat, but where none were found in 2010. Numbers declined on Pelee Island despite the persistence of suitable habitat. Declining populations south of Ontario means that there is unlikely to be recruitment to the province from areas further south (Cadman et al. 2011; Kirk and Pearce 2011).

Factors that change shrub density have an effect on habitat suitability for the Yellow-breasted Chat. Livestock grazing in the west adversely affects habitat and it declines in grazed areas. It has responded positively to fencing of riparian habitat to exclude livestock and to the lack of grazing by bison in the Prairie Provinces (Campbell et al. 2001; Eckerle and Thompson 2020; Kirk and Pearce 2011; McKibbin and Bishop 2012b). It responds favourably to clear-cuts, utility corridors, and openings created in forests provided that these are large enough (Alterman et al. 2005; Conner et al. 1983; Eckerle and Thompson 2020; Keller et al. 2003).

Morgan et al. (2007) examined the effects of fragmentation in riparian habitat in British Columbia. They compared clutch size and the number of fledglings produced in isolated patches smaller than 2 ha to fecundity in patches 15-70 ha in area and found no differences. There was no evidence that fragmentation reduced reproductive success or increased parasitism. Habitat fragmentation probably is an issue for the eastern subspecies. Most populations consist of a series of spatially separated subpopulations linked by extensive movements of individuals among short-lived patches of early successional habitat (Eckerle and Thompson 2020). As individual patches disappear, shrink, or succeed into unsuitable habitat, linkages become weaker and this may affect the viability of the larger population.

The Yellow-breasted Chat appears to be sensitive to human disturbance. Earlier researchers concluded that nests were invariably deserted if disturbed by a human. It has since been determined that nests disturbed late in the nesting cycle are not usually abandoned and birds may be fairly tolerant of humans. In Indiana, 10 of 78 nests (12.8%) were found during the nest-building stage and all were abandoned (Petrides 1938; Thompson and Nolan 1973). In British Columbia, it occurred only in areas of low development and appeared to avoid even gravel roads and buildings. No suitable habitat adjacent to high-traffic roads was occupied. Centres of territories were 5-1,600 m from the nearest gravel road (mean 287.6 m) and 50-1,500 m from the nearest building (mean 443.8 m). Most territories were at least 148 m from roads and 126 m from buildings. In Oregon, nests were in areas

of almost no human activity and at least 400 m from the nearest building (Campbell et al. 2001; McKibbin and Bishop 2010).

In North Carolina pine-oak forests, the chat occurred much more frequently in burned than unburned areas, but only after fires of high severity. It occurred less frequently as the time since the burn increased and was most common in areas that had burned 5-10 years previously. Rose and Simons (2016) concluded that it should benefit from large patches of high-severity burns.

In habitat near roads, the chat may be vulnerable to being struck by vehicles. McKibbin and Bishop (2010) observed 2 cases of road kills in British Columbia.

Several studies examined microhabitat features and other factors in relation to nesting success. In Kentucky, successful nests had significantly higher forb cover (57.5% compared with 31.1%) and lower shrub cover (30.1% compared with 51.2%) than unsuccessful nests. Successful territories had greater foliage cover below 1 m and less canopy cover (16.0% compared with 31.6%) than unsuccessful territories. There was no difference in daily survival rate of early and late nests (Ricketts and Ritchison 2000). In Arkansas and Missouri, nests closer to the ground, further from forest edge, and in areas with fewer large trees and small snags were more likely to be successful (Alterman et al. 2005). In Texas, nest survival was positively influenced by decreased shrub density and increased nest concealment above the nest at heights of 1.5-2 m. Survival was also affected by edge, with lower survival 50-100 m from edge than 0-50 m from edge or in core areas (Novak et al. 2016).

Price (2009) predicted that the breeding range of the chat might expand in southern Ontario if the average summer temperature increased by 2°C. Although climate change may be favourable for the chat, it is highly unlikely that warmer temperatures will result in an increase in its abundance or range. Warmer temperatures are unlikely to overcome significant limiting factors such as rarity of habitat and increasing loss of habitat.

Status

The first Yellow-breasted Chat record for Ontario was at Point Pelee in 1879 and by 1884 it had been confirmed breeding. Early breeding records were from the Point Pelee area, the northern shore of Lake Erie, and the Hamilton area (Austen et al. 1994; McIlwraith 1894; Saunders 1885). Baillie and Harrington (1937) reported that the chat rarely occurred north to Middlesex County and Peel Region, the most easterly record based upon the presence of a pair in Erindale in 1934. At that time, breeding had only been confirmed in Essex and Elgin counties. It apparently nested in the west Hamilton area in 1937 and summered there for 4 more decades at several sites that were almost contiguous. Breeding also occurred in Oakville, at Six Nations, at Aldershot, and in the Dundas Valley (Curry 2006). By 1954, it was a rare and irregular summer resident in Elgin County, with breeding records from Port Burwell and St. Thomas (Lancaster et al. 2004). In the 1960s, it was thought to be increasing and breeding regularly in the Niagara Peninsula (Austen et al. 1994). The largest concentrations of breeding chats have always been at Point Pelee and Pelee Island, where as much as 40% of the population occurs (Cadman et al. 2011; Kirk and Pearce 2011). Breeding first occurred at Rondeau in 1980 after a windstorm created suitable habitat within the forest, but nesting persisted there for only a few years (Austen et al. 1994). During the first atlas, it occurred predominantly in the Carolinian Forest Region, particularly in the extreme southwest and the Niagara and Hamilton areas. There were scattered records further north to Shelburne and the Kingston area, but these may have been

nonbreeding males. The population was estimated at 50 pairs, with more than 10 pairs at each of Point Pelee and Pelee Island (Eagles in Cadman et al. 1987). James (1991) considered the chat a rare to locally uncommon breeder in the Carolinian Forest Region north to Peel Region, with summer sightings in the Kingston area. By the late 1980s, 6-15 pairs were estimated on Pelee Island but only 2 pairs and 2 singing males were documented there in 1991. In 1982, 10 pairs were estimated at Point Pelee compared with 5-10 in 1994. In 1994, the population estimate for the province was 18-38 pairs (Austen et al. 1994; Kirk and Pearce 2011).

The second atlas revealed that the range of the chat had shrunk since the first atlas, with only 2 records north of the Carolinian Forest Region. Breeding was confirmed at only 4 locations within the province. Its probability of observation declined significantly between atlases. It was documented in 45 squares during the first atlas and 27 during the second atlas. It was estimated that there was a minimum of 42 pairs present during the second atlas (Eagles in Cadman et al. 2007). The population appears to have continued to decline since the second atlas. At Point Pelee, 3 pairs nested in 2008 but only 1 pair was present in 2009 and 2010. In 2008, there were 5-6 pairs nesting on Pelee Island but only 1 pair in 2010. None were found in 2010 in Windsor or LaSalle where it formerly nested annually. In the Hamilton area, it was documented in 3 squares during the second atlas but most of these sites have since been abandoned. Since the 1960s, there have been only 8 summer records in Elgin County and evidence of only 3 successful nests. By 2011, it was estimated that the chat probably occurred at fewer than 10 locations annually in the province (Cadman et al. 2011; Curry 2006; Kirk and Pearce 2011; Lancaster et al. 2004).

Too few chats are detected on the Breeding Bird Survey (BBS) to determine trends in Canada. Nonetheless, all evidence indicates that the Yellow-breasted Chat is declining in Ontario. In addition to declines documented by the atlases, it declined at an annual rate of 21% per year 1995-2008 on Forest Bird Monitoring Program surveys at Point Pelee. At the Long Point Bird Observatory, it declined significantly 3.5% per year in spring and 2.3% in autumn 1960-2010. From 2000 to 2010, it declined there at a rate of 6.0% per year in spring and 11.5% per year in autumn (Austen et al. 1994; Kirk and Pearce 2011).

The Ontario Yellow-breasted Chat population was designated special concern in 1994 and 2000 and endangered in 2011. The objective of the 5-year management plan prepared in 2011 was to maintain the population at its current level. It was considered unlikely that any rescue would occur from southern populations. BBS data indicate long-term declines in states bordering Ontario and the various atlases confirm these trends. The exception is Ohio, but the population there is concentrated in the southern portion of the state. It was also recognized in the management plan that population changes at the continental level could have significant effects on the chat's Canadian and Ontario populations (Cadman et al. 2011; Kirk and Pearce 2011). The objectives identified for Ontario in 2019 were to halt the decline within 10 years and provide enough suitable habitat to support at least 8 pairs. The long-term objective beyond 10 years was to achieve a stable population within its range (Brett 2019).

POSTFLEDGING PERIOD

After leaving the nest, young remain nearby until they are able to forage for themselves. After becoming independent, juveniles usually leave the territory and often the entire area. In Indiana,

young that were raised elsewhere began to arrive as those that were raised on site left. Newcomers often stayed for the remainder of the summer until autumn migration. In Virginia, about half the population was gone by the end of July. There was no general exodus, but small areas were deserted as family groups departed. Some families left before other birds had finished nesting (Dennis 1958; Eckerle and Thompson 2020; Thompson and Nolan 1973).

Both adults and juveniles have been detected in clear-cuts in deciduous forests during the postfledging period. In clear-cuts 4-7 years old in Ohio, 127 adults and 173 juveniles were captured. The Yellow-breasted Chat was the second-most abundant early successional species and was more abundant than any forest-breeding species (Vitz and Rodewald 2006). In a Missouri clear-cut, it was the third-most abundant early successional species and was sixth in abundance overall. Mist netting was undertaken 2-15 years after clear-cutting and it declined significantly with time. Peak numbers occurred 3-4 years after harvest with 64-75 captured; in years 11-15, only 1-7 were captured (Porneluzi et al. 2014). Habitat used during the postfledging period appears to be similar to breeding habitat and consists of dense deciduous shrubs, saplings, and vines.

In British Columbia, juveniles travelled as far as 15 km from their natal territories (Miño et al. 2011). Much longer distances are travelled by eastern juveniles. Some birds leave the breeding areas in July and August and travel northeastward, appearing in New England and occasionally Quebec and the Maritime Provinces in late August into late September or October. Most appear to be juvenile birds. Some remain north of the normal breeding range into early winter. Prior to 1949, the chat was only a casual visitor to the northeast, but this is now a regular occurrence that involves many birds. The presence of these birds later in the breeding season often confounds assessments of its breeding range, particularly near the northern extent of its range (Dennis 1958, 1967; Eckerle and Thompson 2020; Kirk and Pearce 2011).

MIGRATION

The Yellow-breasted Chat is a nocturnal migrant that probably travels singly or in small groups (Eckerle and Thompson 2001). Early arrivals at breeding areas sing nocturnally and these songs appear to be important cues to migrants that suitable habitat is present. Alessi et al. (2010) broadcast the nocturnal song at night in unsuitable habitat that consisted of 6 rows of apple trees with mowed grass between them. The nearest shrubland supporting chats was 16 km away. Fifteen chats were captured, but only on mornings following broadcasts, and 8 (53.3%) were captured in nets closest to the speakers. Both sexes responded to the broadcast and only 1 bird was recaptured in a subsequent day. Nocturnal songs of diurnally active birds occur chiefly in species that breed in patchy or ephemeral habitat. Males may sing nocturnally for as long as 6 days after spring arrival, potentially providing social cues to returning females.

Males migrate earlier than females and tend to arrive about a week before females, but females are occasionally among the early arrivals. Over 4 years in Indiana, males arrived 3, 6, 4, and 3 days earlier than females. Spring arrival of the sexes overlaps and there is no significant difference in the duration of migration for the sexes (Bent 1953; Thompson 1977; Thompson and Nolan 1973). One spring bird remained at a Texas stopover site for 9 days (Eckerle and Thompson 2020). In southern Ontario, birds arrive in early to mid-May but may arrive at Point Pelee in late April. Most are on the

breeding grounds before the end of May, but some may still be migrating until the first week of June (Black and Roy 2010; Curry 2006; Speirs 1985; Weir 2008).

Autumn migration begins after a moult by both juveniles and adults in August and September (Thompson and Nolan 1973). True timing of autumn migration is often difficult to determine. Some birds leave the breeding grounds early and raise another brood further south. Others wander north of the normal breeding range from August to October and remain until early winter. Birds that remain in a single area all breeding season probably leave in late August or September. Individuals seen 11 October in Algonquin Park (Tozer 2012) and near Huntsville on 16 August (Mills 1981) were probably examples of birds wandering during the postfledging period. In the south, birds reappear in autumn at the end of August. Migrants may occur until mid-October or even until mid-November. There are rare records in December and January (Black and Roy 2010; Curry 2006; Weir 2008). In Texas, 3 autumn migrants remained at a stopover site for more than 3 days (Eckerle and Thompson 2020).

In North Carolina, the numbers of chats observed in different habitats per hour during migration included 4.48 in dry thickets, 2.00 in wet thickets, 0.30 in pine-hardwood forests, 0.15 in floodplain forests, 0.11 in pine forests, and 0 in beech and oak-hickory forests (Parnell 1969). During spring migration in Illinois, it occurred mostly in forest edge and shrub habitats (Graber et al. 1983). On 2 islands in the Gulf of Mexico, autumn migrants were significantly more abundant on an island dominated by shrubs than a treed island (Suomala et al. 2010). During migration, it favours dense thickets of shrubs and vines. Occasionally it occurs in suburban habitat (Bent 1953; Eckerle and Thompson 2020). During migration in British Columbia, it inhabits the densest available habitat, mostly balsam poplar riparian forests where there is an understorey of willow, alder, maple, elderberry, and other shrubs. It occupies forest edge thickets where tangles of shrubs and forbs provide a dense understorey. Thickets of roses, blackberries, or snowberry in uncultivated corners of fields, orchards, and vineyards provide good migration habitat. Density of cover is more important than the plant species (Campbell et al. 2001).

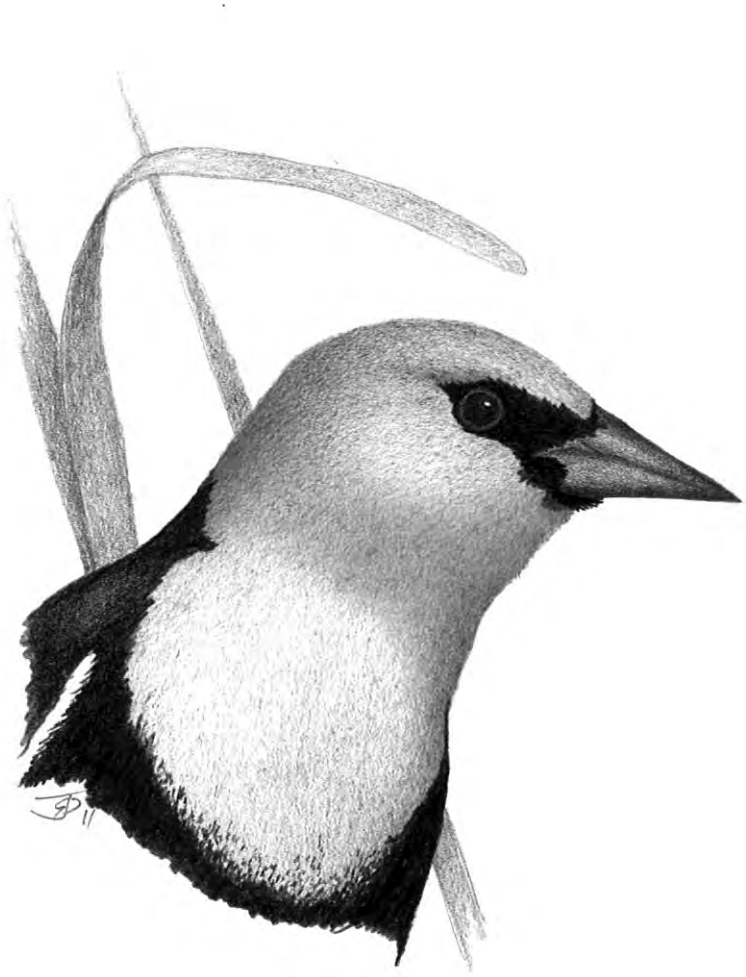
In North Carolina, foraging Yellow-breasted Chats during spring migration spent 22.9% of their time in the canopy, 36.8% in low trees, 40.5% in shrubs, and 0% on the ground (Parnell 1969). A bird in Virginia fed on small insects and Japanese honeysuckle berries in November (Kessler 1987).

The chat frequently collides with tall stationary objects during migration such as buildings, communication towers, and off-shore oil platforms. It becomes disoriented by bright ceilometers used at airports. Birds may fly around these until they are exhausted and fall to the ground (Eckerle and Thompson 2020).

James (1991) considered the Yellow-breasted Chat a rare migrant. There are both spring and autumn records far north of its breeding range, north of Lake Superior and in the southern James Bay area. Typically, only a single bird is seen at once but 12 were seen at Point Pelee on 12 May 1973 (Speirs 1985).

Yellow-headed Blackbird

Xanthocephalus xanthocephalus

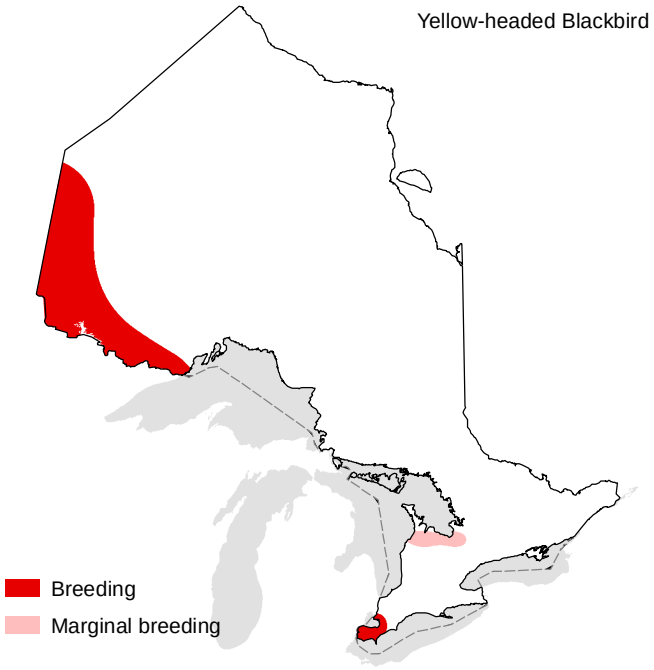


BREEDING SEASON

Habitat Requirements

Ontario Yellow-headed Blackbird nests were in both large and small marshes dominated by cattails, bulrushes, or common reed. Occupied marshes were in rivers or lakes (Peck and James 1987). At Mission Island in Thunder Bay, it nested in a marsh dominated by bur-reeds, bulrushes, and other emergent vegetation, with cattails lining the shore. The marsh contained a central area of open water and open pools were frequent (Harris 1989).

The Yellow-headed Blackbird is an obligate marsh-nesting species. It requires robust emergents to support its nest and is found most commonly in marshes dominated by cattails, bulrushes, and common reed, or a mix of these species. Less frequently, it nests in less robust emergents such as wild rice, bur-reeds, and sedges. It rarely nests in marshes with woody vegetation such as willows or



saltcedar. In Washington, a sparse population occurred in a wetland with many small trees. In British Columbia, all 750 nests were in wetlands with emergent vegetation; 97% of wetlands used for nesting had dense stands of cattails or bulrushes. The other wetlands that were used did not have these emergents but had willows growing over water or flooded willows. Most wetlands that are occupied are palustrine, either with no inflow or outflow, or limited outflow and no inflow. On lakes and rivers, it is restricted to shallow-water areas that support emergents. In addition to natural wetlands, potholes, and sloughs, it nests in constructed wetlands and sewage lagoons (Austen et al. 1994; Bent 1958; Campbell et al. 2001; Fautin 1940; Miller 1968; Picman and Isabelle 1995; Roberts 1909; Twedt and Crawford 2020; Weller and Spatcher 1965; Willson 1996b).

At the landscape level, the Yellow-headed Blackbird is associated with open areas. It is predominantly a western species associated with prairies and farmland. It also nests in the aspen parkland zone, margins of some of the larger lakes in the western mixed-wood zone of the boreal forest, mountain meadows, and in dry grasslands in arid regions. It avoids areas with trees around the margins of a wetland. A single tree that extends more than 30° above the horizon may occasionally be tolerated, but areas where tree stands extend this tall are avoided. Cliffs that extend this tall are also avoided. Treed areas are probably avoided because their shade reduces primary productivity in the marsh and therefore food availability, and they make the upland area less suitable for foraging. This blackbird is not particularly adept at capturing insects in trees. Its probability of occurrence in a given wetland is not affected by any other landscape attributes. It may nests in very small isolated wetlands where there are no other wetlands within 5 km (Beal 1900; M. Brown 1988; Campbell et al. 2001; Fairbairn and Dinsmore 2001b; Forcey et al. 2007; Miller 1968; Orians 1980; Twedt and Crawford 2020; Willson 1996b). In Minnesota, it was unaffected by the proportion of wetland cover at scales of 12.6, 50.3, and 4,000 ha. At the 12.6-ha and 4,000-ha scales, it was affected by the amount of agricultural cover and reached its greatest frequency of occupancy at 20-60% agricultural cover. It had a somewhat positive response to agricultural land, consistent with its use of pastures and crops for foraging. It was negatively influenced by the proportion of developed land at the 12.6-ha scale. Its frequency of occupancy was 70% at 0% developed land and dropped steadily to 10% at 100% developed land (Saunders et al. 2019).

Although marshes are relatively simple habitats, the Yellow-headed Blackbird has several habitat requirements that make it much more specialized than the Red-winged Blackbird, which is often present in the same marshes. Being a colonial nester, the Yellow-headed Blackbird tends to be

present in a marsh in numbers or completely absent, except perhaps at the periphery of its range. Critical habitat features include emergent vegetation sturdy enough to support nests, water at the base of the emergents supporting nests, a central area of open water in the marsh or openings among the emergents, and an abundant food source (Campbell et al. 2001; Miller 1968; Orians 1980; Twedt and Crawford 2020; Weller and Spatcher 1965). Absence of any of these factors makes the wetland unsuitable for nesting.

The most commonly used emergents for nesting include cattails, bulrushes, and common reed. These are tall, robust species that are capable of supporting a nest. The type of bulrush that is present is also important. In Saskatchewan and Iowa, the Yellow-headed Blackbird nested in hard-stemmed bulrush and river bulrush, but not in the less study soft-stemmed bulrush and American three-square. Other emergents that were present that were not used for nesting included rice cut-grass, arrowheads, spikerushes, sedges, bur-reeds, slough grass, sprangletop, and American manna grass (Miller 1968; Weller and Spatcher 1965). Height of emergents may be important. In a Utah marsh, a small area where the bulrushes had been burned and extended only 15-20 cm above the water was not occupied until all other available areas had been incorporated into territories (Fautin 1940). Nests higher above water are less vulnerable to flooding.

The Yellow-headed Blackbird will not nest in emergents that do not have water underneath them. Water provides aquatic insects that form the bulk of the diet and protection from land-based predators. Nests have been reported in emergents over mean water depths of 25-57 cm (range 15-120 cm). In Saskatchewan, the minimum water depth under a nest was 21.6 cm. It has been suggested that water depths as low as 15 cm are suitable (Bent 1958; Fautin 1940; Miller 1968; Picman and Isabelle 1995; Roberts 1909; Schroeder 1982b; Weller and Spatcher 1965; Willson 1966b).

Water levels are critical because they dictate the types of emergents that can grow and their density. Each species has a maximum water level that it can tolerate, and once water depths increase much over 1 m, all emergents begin to disappear. When the substrate is uneven and water depths are high, marshes tend to have openings among the emergents and an open-water centre. Under low water-level conditions, the entire marsh may consist of dense emergents. Ideal conditions for the Yellow-headed Blackbird consist of a central open-water area and robust emergents interspersed with patches of open water. The interface between deep open water and emergents is preferred habitat and territories are established there first in the season. Open water and openings among emergents allow sunlight to penetrate into the water column to the substrate. This increases local productivity of aquatic submergent plants and enhances the food supply for blackbirds. In many marshes, it is restricted to the central portion where the water is deeper. Areas nearer shore may be settled, but only where the water is deep and vegetation is sparse. Birds nesting near the centre of a marsh are more likely to fledge young than those nesting closer to edge and they also tend to fledge more young. A Wisconsin lake was completely covered with dense emergents and supported no Yellow-headed Blackbirds. Beavers built a dam and raised the water level, killing most of the cattails. Blackbirds colonized the marsh for 2 years until the cattails again closed in the lake. At a 160-ha marsh in Iowa, emergents covered 0-100% of the wetland over several years. It was absent when there was no open water and the number of pairs peaked at 70% open water. Another Iowa study determined that its presence was positively correlated with the amount of emergent

vegetation in the wetland and negatively correlated with open water and the wetland perimeter divided by the wetland area. The apparent disparity in its relationship to open water in the 2 studies may have been due the different scales of measurement that were used. The first study measured openings as small as 0.6 m within emergents. The second study measured only open water that was devoid of emergents (Fairbairn and Dinsmore 2001a, 2001b; Lederer et al. 1975; Miller 1968; Orians 1980; Picman and Isabelle 1995; Twedt and Crawford 2020; Weller and Fredrickson 1973; Weller and Spatcher 1965; Willson 1966b).

The Yellow-headed Blackbird may forage in both aquatic and terrestrial habitats, but the productivity of the aquatic habitat is the key factor in determining if a wetland is suitable for occupancy. Damselflies are an important component of the diet in most locations and the ability of a wetland to produce these insects determines whether it will be occupied. Even in terrestrial habitat, damselflies may be important in the diet. In British Columbia, it was restricted to nesting in wetlands where the conductivity was greater than 1,100 micromhos per cm. Reproductive success was much lower on a lake closer to the lower conductivity level than one much above it, with most nesting losses due to starvation. Traps captured 16.8 odonates per m along wetland edges and 15.0 per m^2 of emergent vegetation in areas with breeding Yellow-headed Blackbirds compared with 0.4 per m along edges and 0.1 per m^2 of emergents where breeders were absent. It is absent in western Washington where all lakes are low in dissolved nutrients and support few emerging aquatic insects. It was also absent in 1 highly productive British Columbia lake that lacked emergents robust enough to support nests (Orians 1980). Schroeder (1982b) concluded that the amount of submergent vegetation present in a wetland was the best measure of productivity and abundance of aquatic insects. Open water is essential for the presence of submergent vegetation and subsequent production of insects, so interspersed openings among emergents improve productivity. Dense emergents inhibit foraging by the blackbirds (Orians 1980).

In the Prairie Pothole Region of Canada, abundance of the Yellow-headed Blackbird was positively correlated with the amount of precipitation received the previous year, the annual temperature, and the amount of wetlands in the landscape. The first factor affects the amount of emergent vegetation and the amount of water under the emergents. Land-use parameters had no influence on its abundance (Forcey et al. 2007). In Iowa, there was no difference in its abundance in natural and restored prairie pothole wetlands. The difference between the 2 types of wetlands was that restored wetlands did not have low prairie or wet meadow zones between the emergent vegetation and upland habitats. This type of habitat is not used by this blackbird. Density of emergents was less on restored than natural wetlands, but this did not affect its abundance (Delphey and Dinsmore 1993).

Schroeder (1982b) prepared a habitat suitability index model for the Yellow-headed Blackbird. He considered wetlands with solid stands of emergents, those with no open water, and those with less than 15 cm of water underneath the emergents to be unsuitable. Suitability was 0 when no submergents were present and optimum when 80-100% of the wetland supported submergents. The amount of edge between open water and emergents was an important factor. All water depths of 15 cm or more were considered optimum, although excessive water depths will kill emergents. The percentage of emergents robust enough to support nests was another factor, with 100%

optimum and 0% unsuitable. Another important criterion that was not included in the model was wetland permanence. Most odonate nymphs require a year to develop into an adult, so they require permanent or semipermanent water bodies. Wetlands that regularly dry up are unsuitable for production of damselflies, one of the most important food items.

The Yellow-headed Blackbird and the Red-winged Blackbird frequently nest in the same marshes, but their territories rarely overlap. This is due in part to interspecific territoriality, but also because the Red-winged Blackbird is more of a habitat generalist. The Yellow-headed Blackbird is confined to robust emergents in deeper water and lower densities than areas used by the Red-winged Blackbird, and it requires wetlands to be more nutrient-rich. The Red-winged Blackbird nests in emergents with no standing water beneath them, in much less robust emergents, in trees and shrubs at margins of wetlands or on the upland shore, and also in grasslands and other non-wetland habitats. In the absence of the Yellow-headed Blackbird, the Red-winged Blackbird occupies the habitats that the Yellow-headed Blackbird uses (Campbell et al. 2001; Miller 1968; Orians 1980; Weller and Spatcher 1965).

The Yellow-headed Blackbird is not an area-sensitive species. In the core of its breeding range, it prefers smaller than large wetlands and even very small wetlands may support substantial colonies. In Washington, colonies occurred in wetlands 0.2-2.4 ha (Miller 1966). British Columbia colonies occur in sloughs, ponds, marshes, or small lakes 0.5-5 ha (Campbell et al. 2001). In Iowa, Brown and Dinsmore (1986) considered it area independent. It occurred in 67% of marshes smaller than 1 ha and in all larger wetlands. It is not confined to small wetlands, nesting in marshes 160 and 182 ha in Iowa (Brown and Dinsmore 1986; Weller and Fredrickson 1973). Highest densities often occur in the smallest wetlands: 30 pairs in a 0.4-ha marsh and 12 in a 0.25-ha marsh. In Iowa, it frequently nests in wetlands as small as 0.2 ha (M. Brown 1988; Schroeder 1982b).

At night, adults roost among emergent vegetation in their territories. During the day, they may loaf among wetland vegetation, in shrubby areas, and in small woodlots (Orians 1980; Twedt and Crawford 2020).

All Ontario nests were over water in emergent vegetation consisting of cattails, bulrushes, or common reed. The supporting vegetation was often dead growth from the previous year, but sometimes was living or a combination of the two. Nests were 0.2-1 m above water with most 0.3-0.7 m up (Peck and James 1987). Harris (1989) reported a nest in a dense stand of big bur-reed at Thunder Bay. It was approximately 20 m from shore where the water was 50 cm deep and was 30 cm above water.

All reported Yellow-headed Blackbird nests were over water, typically in robust herbaceous emergent plants but rarely in shrubs such as willow and saltcedar. The most common emergents used are cattails, bulrushes, and common reed. Only the larger and sturdier species of bulrushes are used such as river bulrush and hard-stemmed bulrush. It rarely nests in wild rice. The Thunder Bay nest appears to be the only one reported in bur-reeds. In a California marsh, some nests were in rushes and the weaker stems of these plants collapsed at 37% of nests. Early season nests are in dead vegetation from the previous year; cattails are preferred because they are less likely to be flattened by ice and snow. Later nests may be in green growth. Nests have been in water depths of 15-120 cm. Nests in shallower water are at risk of predation or desiccation underneath them; water deeper

than 120 cm may not support any emergent vegetation. Nests in emergents have been reported 0-90 cm above water, mostly 30-60 cm up. In shrubs, nests may be as high as 3.0 m above water. Reuse of nests is rare and occurs only within the same season after a predation event. In Washington, 7 of 1,161 nests (0.6%) were reused (Bent 1958; Campbell et al. 2001; Lederer et al. 1975; Miller 1968; Orians 1980; Picman and Isabelle 1995; Roberts 1909; Twedt and Crawford 2020; Weller and Spatcher 1965).

The Yellow-headed Blackbird typically nests colonially. Single nests are rare and usually occur at the fringes of its range or in suboptimal habitat. One Ontario colony contained 20 nests and as many as 600 nests have been reported at British Columbia colonies. In Iowa, the number of nesting pairs at 1 marsh was estimated at 5,000. Within a marsh, colonies are not always continuous and may be scattered in groups where the vegetation is most suitable for nesting. Breeding occurs in grouped territories when most food is obtained in the territory. It is loosely colonial when most food is obtained outside the territory (Bent 1958; Campbell et al. 2001; Peck and James 1987; Twedt and Crawford 2020; Weller and Fredrickson 1973). The primary function of colonial nesting appears to be to reduce predation. If a male leaves his territory, his neighbour temporarily assumes ownership of both territories and expels any intruding males or predators. Whenever any member of a colony emits an alarm call, all others immediately respond and often fly to where the alarm was sounded (Fautin 1940). Picman et al. (2002) studied a colony in Manitoba where predation accounted for 51% of nest losses, mostly by Marsh Wrens. They built experimental nests and placed eggs in them. Depredated nests were significantly further from an active blackbird nest and significantly closer to a wren nest than successful nests. Survival of experimental nests was significantly correlated with the number of nearby blackbird nests. Predation rates on nests placed outside colonies were significantly higher (almost 4 times greater) than at nests within colonies. Nests at the periphery of a colony suffered significantly higher predation rates than those in the centre of the colony. In colonies comprised entirely of artificial nests with no active blackbird nests, predation rates were similar near the edge and in the centre of the colony. Coloniality may facilitate certain aspects of the breeding strategy such as polygyny and extra-pair copulations. Some studies concluded that colonies act as information centres with members locating productive foraging areas by following successful foragers, especially neighbours. Other studies found no evidence to support this (Picman et al. 2002; Twedt and Crawford 2020). Gori (1988a) tested whether colonies acted as information centres for foraging Yellow-headed Blackbirds in Washington. He established artificial feeding sites that were superior to other areas used by the colony, 0.8-1.2 km from the colony. Recruitment rates to the enhanced foraging areas were significantly greater than expected. Birds departing the colony for the sites after provisioning were more likely to be followed than birds departing in different directions. Arrivals to the site were statistically clumped in time and disproportionately involved neighbours. He concluded that Yellow-headed Blackbirds can locate productive feeding areas by following successful colony members, especially neighbours.

Despite nesting colonially, the Yellow-headed Blackbird is highly territorial. Males establish territories almost immediately upon arrival but initially spend only the early morning and evening on the territory. Gradually the amount of time spent in the marsh increases with most of the day spent on the territory by the time females start to search for nest sites. Areas in the centre of the colony or at the outer interface between open water and emergents are settled first. These are the

most productive areas for aquatic insects and the safest from predators. For 2-4 weeks after territorial behaviour begins, vagrant males attempt to displace established males, usually unsuccessfully, or to establish territories between occupied areas. Most males defend their territories until they moult but some may abandon them as early as the beginning of June. When a territory is abandoned early, neighbours expand their boundaries to include it. Even at the height of the breeding season, males frequently feed outside the territory and may do so in small flocks with no aggressive behaviour (Fautin 1940; Willson 1966b). Females defend a radius of 0.6-0.9 m around the nest from other females. Intruders are expelled from the immediate vicinity of the nest but not necessarily out of the male's territory in which she is nesting. Females mated to the same male are intolerant of each other in the vicinity of the nest and frequently occupy opposite extremities of the territory. Females mated to polygynous males tend to maintain exclusive subterritories within the male's territory and frequently forage within their own areas. They do not forage on territories other than their own mate's (Fautin 1940; Willson 1966b). Lightbody and Weatherhead (1987) examined the relationships among females mated to the same polygynous males in a Manitoba marsh. Nests were neither clumped nor dispersed in time, with many females initiating their nests in the same territory on the same day. Females were least aggressive to each other during the laying stage and most aggressive during the nestling stage. There were no differences in the levels of aggression of primary, secondary, and tertiary females. It appeared as though females within polygynous relationships were not concerned with each other and did not nest either cooperatively or competitively. Male territory sizes are small but variable in size. Territory sizes of 8-5,899 m^2 (0.0008-0.59 ha) have been reported. Mean territory sizes from different areas range from 120 to 4,072 m^2 but a high proportion of territories are 100-400 m^2. Several factors may influence territory size. The most important is whether birds forage in the territory or in adjacent upland habitats. Territories where the adults forage within them are much larger than those where birds forage in terrestrial habitats. The quality of the emergent vegetation also influences territory size. Washington territories that averaged 4,072 m^2 were characterized by sparse scattered cattails that covered only 35% of the territories. Birds also foraged within these territories. Emergents in smaller territories tended to grow more sparsely or in a clumped fashion. Small territories had 55-79% coverage by emergents. Small territories supported as many females as large territories. Females on small territories fledged more young than those on larger territories. Another factor influencing territory size is breeding density. Areas with the highest population density have the smallest territories. Territories in productive marshes are smaller than those in less productive marshes (Fautin 1940; Lederer et al. 1975; Lightbody and Weatherhead 1987; Orians 1980; Schroeder 1982b; Twedt and Crawford 2020; Willson 1966b). Because of the small territory sizes and polygynous nesting, nests may be as close together as 2 m. In Manitoba, the distance between active nests was 2-33 m (averages 6.0 and 6.2 m in 2 years; Picman and Isabelle 1995). In California, mean internest distance in 2 years was 5.1 m and 8.3 m (Lederer et al. 1975). Twenty-five to 30 nests have been reported within an area of 21 m^2 (Bent 1958). Although the Yellow-headed Blackbird may have a small territory, its home range may be quite large. Those that forage outside the territory may fly 1.0-1.6 km to find food (Lederer et al. 1975; Shackford and Tyler 1987; Willson 1996b).

The Yellow-headed Blackbird defends its territory against the Red-winged Blackbird and Marsh Wren. The territories of the 2 blackbirds are mutually exclusive. Red-winged Blackbirds arrive earlier

in spring than Yellow-headed Blackbirds and often initiate territories throughout a marsh. Once Yellow-headed Blackbirds arrive, they evict Red-winged Blackbirds from the deep-water areas of the marsh and relegate them to shallow areas and areas of emergents that are not suitable nesting habitat for Yellow-headed Blackbirds. Aggression is common between the 2 species at this time. Red-winged Blackbirds frequently forage on newly established Yellow-headed Blackbird territories, but this stops once nesting begins. The Yellow-headed Blackbird is dominant to the Red-winged Blackbird at foraging areas outside breeding territories, but Red-winged Blackbirds are dominant at the periphery of marshes where their territories are established. Occasionally a Red-winged Blackbird will be able to maintain a territory within a Yellow-headed Blackbird colony. In these cases, there are usually minor habitat differences, such as the height or density of the vegetation, that make it more attractive to Red-winged rather than Yellow-headed blackbirds (Bent 1958; Fautin 1940; Miller 1968; Orians and Willson 1964; Voigts 1973; Weller and Spatcher 1965; Willson 1966b).

Marsh Wrens arrive before Yellow-headed Blackbirds. In some cases, they completely disappear once Yellow-headed Blackbirds arrive and reappear to breed once the blackbirds finish breeding. In other cases, the wrens remain but have highly compressed territories compared with when blackbirds are absent. When the 2 species remain for the breeding season, their territories are segregated. Yellow-headed Blackbirds occupy the deeper central portions of the marsh and the wrens are confined to the shallow perimeter of the marsh. Both species actively destroy the other's nests. Blackbird nests are most vulnerable in territories where females leave the nest to forage, thereby allowing wrens to sneak into the territory and destroy eggs or remove nestlings. Yellow-headed Blackbirds always challenge any Marsh Wrens they see. They may perch within 5 m of a singing wren and suddenly plunge headfirst at it, driving it into dense vegetation. They may also methodically follow a singing wren and occasionally perch above him, preventing him from singing from the top of emergents. Both males and females may perch on a wren's nest, preventing the female from returning to incubate the eggs. Rarely, male blackbirds may capture a wren and peck it vigorously. The Yellow-headed Blackbird responds aggressively to broadcast calls of the Marsh Wren indicating that it recognizes the wren as a threat (Bump 1986; Fautin 1940; Leonard and Picman 1986; Neudorf et al. 2011; Orians and Willson 1964; Picman and Isabelle 1995: Verner 1975). Yellow-headed Blackbirds spend more time attending their nests as Marsh Wren density increases (Behrens et al. 2019).

No information is available on natal philopatry. Males apparently do not breed in their first year, so it is unlikely that any breed for the first time in their natal area.

Adult male site fidelity varies depending upon the suitability of a given marsh. These wetland types may be quite dynamic with the amount of emergents and open water varying depending upon water levels. The Yellow-headed Blackbird is an excellent colonist and may appear at a marsh in the first year that the habitat becomes suitable. Occupied marshes may be abandoned if conditions become unsuitable, with blackbirds returning when the habitat improves. In 1 study, 30% of males breeding in 2 or more years skipped territory ownership in at least 1 year. Only 20% of those that skipped territory ownership were detected as floaters, indicating possible dispersal to other marshes. Over 5 years, 60% of breeding males changed marshes at least once. Males changed territories within the study area during 42.9% of between-year opportunities. There was no evidence

to suggest that males were more likely to move when territory density was low, likely to abandon territories that were deteriorating, or that they changed territories to improve reproductive success. Possible explanations for its low site fidelity are that it is a response to habitat deterioration and other factors causing population decline, migratory males make fresh settlement decisions each year when they arrive in the general vicinity of the previous year's territory, or it may be adapted to highly unstable habitats, moving frequently in response to changes in local site conditions. At 1 site, 51% of adult males and 19% of yearling males returned to breed the next year, often in the same territory. At Delta Marsh, Manitoba, 18 of 42 males (42.9%) returned in a subsequent year. Once a male established a territory there, he tended to return to the same marsh and usually to the same territory or very close to it. No information is available on adult female site fidelity (Beletsky and Orians 1994; M. Brown 1988; Picman and Isabelle 1995; Twedt and Crawford 2020; Weller and Fredrickson 1973; Weller and Spatcher 1965).

Limiting Factors

Eggs have been reported in Ontario nests from the end of May until the second week of July, with most present in the first 3 weeks of June (Peck and James 1998b). Upon arrival, females travel either singly or in small groups from territory to territory before selecting one. Nests are started as soon as the female selects a site, as early as 3 days after her arrival. The female builds the nest in 2-10 days, but mostly in 2-4 days. One to 5 days may elapse between nest completion and egg laying, but usually eggs are laid within 1-2 days of nest completion. Nesting within a colony tends to be highly synchronized. At a Manitoba marsh, 60% of nests were initiated within a 5-day period. Incubation usually begins with the laying of the second egg, but may vary from the first to fourth egg. The incubation period is 11-13 days, with most eggs hatching in 12-13 days. Hatching may be synchronous or asynchronous depending upon when incubation was initiated. Asynchronous hatching may be a strategy to allow brood reduction and ensure that some nestlings fledge during periods of scarce food supplies. Hatching of the first nestlings closely corresponds to the emergence dates of damselflies. After days 3-5, no brooding occurs. The nestling period is 7-14 days, mostly 9-12 days. Cold wet weather may prolong the nestling period; young may leave earlier if disturbed (Bent 1958; Campbell et al. 2001; Lederer et al. 1975; Miller 1968; Picman and Isabelle 1995; Roberts 1909; Twedt and Crawford 2020; Willson 1966b).

The Yellow-headed Blackbird raises a single brood in a season. Renesting may occur if a nest is lost, but few females attempt a replacement clutch. Over 2 years in Manitoba, 15% and 23% of females that lost a clutch renested. The replacement clutch is usually laid in a new nest at a different location within the territory. Only 0.6% of nests were reused for a replacement clutch. In some cases, the female may move to a different territory for her replacement clutch. Clutches of 3-5 eggs (average 3.73 eggs) have been reported in Ontario, with most containing 4 eggs. Overall, clutches of 2-5 eggs have been reported with 4-egg clutches most common. Clutch size declines with the season, with 4-egg clutches prevalent early in the season and 3-egg clutches predominating later. The decline in clutch size may be due to inexperienced yearlings nesting later or perhaps reduced food availability. Replacement clutches typically consist of 2 eggs (Arnold 1992; Bent 1958; Campbell et al. 2001; Lederer et al. 1975; Leonard and Picman 1986; Miller 1968; Orians 1980; Peck and James 1998b; Picman and Isabelle 1995; Roberts 1909; Twedt and Crawford 2020; Willson 1966b).

It is probable that all yearling females breed. Adult males vigorously challenge yearling males that enter a colony and eject them. Most studies concluded that yearling males do not breed and first initiate breeding when they are 2 years old (Bent 1958; Fautin 1940; Orians 1980; Twedt and Crawford 2020; Weller and Spatcher 1965; Willson 1966b). Yearling males occasionally breed, but are probably restricted to areas where there are no adult males, to suboptimal habitat, or areas at the extremes of the range. Sawyer and Dwyer (1968) reported a yearling male successfully breeding in the Lake St. Clair marsh in Ontario. Twedt and Crawford (2020) reported an annual return rate of 19% for yearling males, suggesting that these birds nested in their first year. Even after males begin breeding, they may occasionally skip breeding in some years and become nonterritorial floaters (Twedt and Crawford 2020).

Pair bonds are established after arrival on the breeding grounds and there is no evidence that they are maintained for more than 1 year. The mating system is predominantly polygynous. Some males are monogamous, but this is likely an indication of an inferior territory. Polygynous males may have 2-8 females nesting within their territories, but 2-5 is typical. In some cases, all females nest simultaneously on the territory but some females may settle later than others to nest. The number of females in a male's harem depends on the size of his territory, its location, and structure of the vegetation. In Washington, females were more abundant in territories with more edge. Four males had only a single mate and these had either very little edge or shallow water in their territories (Fautin 1940; Lightbody and Weatherhead 1987; Orians 1980; Picman and Isabelle 1995; Twedt and Crawford 2020; Willson 1966b). Some females move to a different territory to initiate a replacement nest, suggesting that some pair bonds may not persist for the entire season (Orians 1980). In Manitoba, half of 32 observed copulations were extra-pair, suggesting that extra-pair copulations may be a regular component of the mating system (Twedt and Crawford 2020). Roberts (1909) observed some differently coloured eggs in some nests suggesting that intraspecific parasitism may be a rare breeding strategy. In Washington, 13 of 1,161 nests (1.7%) were parasitized intraspecifically (Twedt and Crawford 2020).

Birds with small territories forage in upland areas or less frequently in undefended portions of the marsh or at a different wetland. In larger territories with open water, birds forage within the territory, but also in adjacent upland areas. Males wander much further than females from the territory and may travel to distant upland foraging areas in small groups. They do this from spring until well into the incubation period. Females may feed in areas of the marsh where emergent cover is too sparse to be suitable for nesting. Even those females that have productive territories for foraging tend to move to the shoreline or upland areas in early morning and evening to forage. In some areas, there appears to be no distinct foraging pattern, which probably depends upon behaviour of their insect prey. Preferred terrestrial foraging habitat is open and includes grassy meadows and alfalfa fields. In spring, the Yellow-headed Blackbird may follow plows to capture disturbed invertebrates. It is not very proficient at foraging in woody vegetation and tends to avoid shrubby and treed areas. An exception is at Delta marsh where birds fed on the abundant midges in a forested dune. Within wetlands, it forages predominantly near the water line by moving slowly around clumps of vegetation and searching on floating vegetation. During midday, damselflies emerge by ascending stalks of emergent vegetation and this is one of the dominant food items at most locations. It is not adept at capturing adult damselflies and relies upon recently emerged

tenerals that have not yet acquired the power of flight. It is capable of capturing some flying insects. In terrestrial habitat, it prefers to forage on the ground. It digs in the litter, sweeps with its bill, and double-scratches to uncover prey. It also uses its bill to flip over stones. When foraging in woody vegetation, it gleans mostly aquatic prey but also caterpillars. It preferentially forages near Forster's Tern nests, probably because they are in openings with a plentiful food source. Insects may be attracted to the nesting mounds by the heat of the incubating terns. Blackbirds frequently forage on and near tern nests without harming them. The terns benefit from the blackbirds' alarm calls and their displacement of Red-winged Blackbirds. When artificial feeders are provided in marshes, both sexes of the Yellow-headed Blackbird are attracted. Adult males displace females so they can access supplemental food only when males are absent. Red-winged Blackbirds and Brewer's Blackbirds are also displaced by male Yellow-headed Blackbirds (Arnold 1992; Bent 1958; Bump 1986; de Queiroz 2008; Fautin 1940; McNicholl 1981; Orians 1966, 1980; Picman and Isabelle 1995; Roberts 1909; Twedt and Crawford 2020; Voigts 1975; Willson 1996b). In Washington, Orians and Horn (1969) compared the foraging behaviours of the Yellow-headed, Red-winged, and Brewer's blackbirds and the Western Meadowlark. The Yellow-headed Blackbird foraged completely within the marsh at this study area, mostly by clinging to emergent vegetation. This behaviour was similar to that of the Red-winged Blackbird, which foraged in the same manner but mostly only during the morning. In the afternoon, it fed in adjacent uplands so there was no overlap in the foraging of these 2 blackbirds at that time. The meadowlark foraged solely in terrestrial habitat and the Brewer's Blackbird seldom fed in the marsh and was ill-adapted to clinging to stems of emergent vegetation. The Red-winged and Yellow-headed blackbirds fed predominantly on emerging damselflies. Although there was a broad overlap in their diet and foraging strategies, the damselflies were an abundant resource that was not limiting.

The female is mostly responsible for feeding the nestlings. Some monogamous males do not feed their nestlings; others do. Polygynous males tend to feed nestlings only at the primary nest, if they feed at all, but may feed nestlings at the secondary nest if the primary nest has a small brood. In Manitoba, only 7 of 67 males (10.4%) fed any of their nestlings; at some marshes, no males fed any of their nestlings. The probability of a male feeding young is much higher on unproductive than productive marshes. On productive marshes, males expend their energy on attracting additional females rather than assisting their existing mates. Males preferentially feed nestlings of females that have broods of 3 or more young aged 4 or 5 days rather than those in nests where broods have already been reduced due to starvation. Food is allocated to chicks based on their size, with larger nestlings fed more. This ensures that the largest chicks fledge but the youngest may starve if there is a shortage of food (Bent 1958; Cash and Johnson 1990; Gori 1988b, 1990; Picman and Isabelle 1995; Price and Ydenberg 1995; Roberts 1909; Twedt and Crawford 2020; Willson 1966b). In Washington, Willson (1966b) classified food items brought to nestlings as primary if they constituted 25% of all items and occurred in at least 50% of samples. Secondary food items constituted 10-24% of all items and occurred in 10-49% of samples. Tertiary items comprised less than 10% of all items but occurred in at least 10% of samples. Primary prey consisted of narrow-winged damselflies, flies, mayflies, soft-winged bugs, and lepidopterans. Secondary prey included flies, lepidopterans, other odonates, and true bugs. Tertiary prey included beetles, flies, caddisflies, mayflies, true bugs, spiders, lepidopterans, orthopterans, snails, and hymenopterans. The odonates were predominantly narrow-

winged damselflies but also included spread-winged damselflies, darners, and skimmers. The flies were mostly midges but included shore flies and house flies. The beetles were predominantly predaceous diving beetles and scarab beetles, the true bugs were water boatmen, the soft-winged bugs were aphids and spittle bugs, and the orthopterans were mostly short-horned grasshoppers. Some neuropterans and nematodes were consumed. The amount of damselflies fed to nestlings increased as they aged. There appeared to be no active selection for prey. Roberts (1909) reported a female feeding a leech to a nestling. In Iowa, the food provided to nestlings included narrow-winged damselflies, true bugs, treehoppers, aphids, ground beetles, owlet and snout moths, crane flies, midges, soldier flies, flower flies, shore flies, anthomyiid flies, spiders, and corn. Narrow-winged damselflies were the only food item that was important all day. The diet of nestlings changed as the season progressed. Before 20 June, the most important foods were narrow-winged damselflies, larval soldier flies, and adult midges. After 20 June, midges and soldier flies continued to be important, but aphids, anthomyiid flies, and flower flies from nearby hayfields became important. The overlap in diet between Yellow-headed and Red-winged blackbird nestlings was 46-49%. The 2 species selected much of the same food items, but at different times of the season. Differences in their habitat selection, foraging behaviour, and mutually exclusive territories further reduced competition for food (Voigts 1973). Orians (1966, 1980) analyzed the diet of nestling Yellow-headed Blackbirds in British Columbia and Washington. Odonates were most important in the diet at all lakes studied, predominantly narrow-winged damselflies. In 1 year when damselflies were scarce at a lake, females that continued to select for them raised fewer young than those that searched for alternate prey. Other important prey included long-horned beetles, caddisflies, and flies. Other food items included dragonfly nymphs and adults, spittle bugs, plant bugs, seed bugs, water striders, predaceous diving beetles, weevils, ground beetles, click beetles, water scavenger beetles, scarab beetles, lepidopterans, shore flies, flower flies, midges, biting midges, soldier flies, black flies, house flies, picture-winged flies, bristle flies, ants, ichneumonid wasps, braconid wasps, spiders, water mites, snails, mayflies, locusts, froghoppers, planthoppers, water boatmen, shore bugs, rove beetles, checkered beetles, snout moths, robber flies, fruit flies, amphipods, plant bugs, marsh beetles, crane flies, harvestmen, leaf beetles, and snipe flies. In 1 lake where damselflies were scarce, flies dominated the nestling diet. In Washington, Orians and Horn (1969) reported that the nestling diet consisted of 56% odonates, 1% orthopterans, 1% leafhoppers, 4% lepidopterans, 24% flies, 7% other insects, 4% spiders, and 3% other items. In Texas, nestlings were fed adult orthopterans, caterpillars, flies, and lesser quantities of beetles, odonates, spiders, and snails (Twedt and Crawford 2020). In Utah, the nestling diet was dominated by insects and spiders, with small insects provided initially and larger ones such as damselflies and grasshoppers supplied as the nestlings became older. In California, nestlings were fed snails and partially digested larvae on their first day; predigested and crushed insects devoid of wings, legs, and chitinous parts on their second day; and similar food on their third day but it was less digested and occasionally supplemented with fresh food (Bent 1958). Although the Yellow-headed Blackbird can survive where narrow-winged damselflies are scarce, they appear to be the most important food item in much of its range. Timing of egg laying or hatching of the first nestling are often timed to coincide with the emergence of damselflies (Miller 1968; Willson 1966b).

During the breeding season, adults eat mostly the same items that they provide to the nestlings. They have a high dependence on damselflies in most areas, but also capture terrestrial prey such as caterpillars, leafhoppers, grasshoppers, spiders, and probably most, if not all, of the items described in the nestling diet (Bent 1958; Orians 1980; Twedt and Crawford 2020; Willson 1966b). Fifteen stomachs collected in Utah contained 7 orthopterans (mostly grasshoppers), an ant-lion, 7 odonate nymphs, 2 true bugs, 96 beetles (including 13 ground beetles, 2 predaceous diving beetle larvae, 1 skin beetle, 1 lady beetle, 2 scarab beetles, 7 leaf beetles, and 18 weevils), 40 caterpillars (including 18 cutworms and armyworms), 13 flies that were mostly larvae plus an adult horse fly, and 10 hymenopterans (including 7 ants). They also contained 2 spiders, 109 weed seeds, 18 wheat kernels, and 6 barley kernels (Knowlton 1947). Arnold (1992) installed feeders in Manitoba wetlands and provided corn, layer diet for chickens, rabbit chow, oystershell, and grit. Both sexes visited the feeders and 1 female repeatedly fed her nestlings from the feeder. In all cases, birds selected corn, a species that otherwise is not available in southwestern Manitoba. The high-protein foods that were available were not used. From early spring through the postbreeding season and migration, the Yellow-headed Blackbird forages on agricultural crops such as sunflowers, corn, and small grains. Twedt et al. (1991) summarized its usage of these crops in the Prairie Pothole Region. Small grains (wheat, oats, barley, and rye) were the dominant crops in the provinces and North Dakota and corn dominated in Minnesota and South Dakota. The diet varied geographically and reflected the dominant crop species that were available. The diet of the sexes differed significantly. Males ate more sunflowers in North Dakota and Saskatchewan and more weed seeds in Manitoba, North Dakota, and Saskatchewan than females. Insects and, to a lesser extent, small grains and weed seeds were a large proportion of female diets in all geographic areas. The Yellow-headed Blackbird did not contribute much damage to sunflower crops. Beal (1900) summarized the contents of 138 stomachs collected in all seasons from 10 Mississippi Valley states, California, and Canada. The diet consisted of 33.7% animal matter and 66.3% vegetable matter. The diet was highly terrestrial, suggesting that most samples were collected outside the breeding season. The animal food consisted of 2.8% ground beetles, 5.0% other beetles, 4.6% caterpillars, 11.6% grasshoppers, and 9.7% other insects. The other insects were mostly ants and wasps with a few dragonflies and the occasional spider and snail. Almost two-thirds of the caterpillars were eaten in July when they formed 21.5% of the diet. Grasshoppers first appeared in the diet in May, with a peak in consumption in July and another significant increase in consumption in August. The vegetable matter consisted of 9.8% corn, 3.5% wheat, 25.6% oats, 27.1% weed seeds, and 0.3% other material. Oats were the most important grain, representing 63% of the October diet and 43.2% of the August diet. The seeds that it consumed included those of barnyard grass, panic grasses, and ragweed, with lesser amounts of smartweeds and docks. Seeds were most prominent in the diet in September when they comprised 64.4% of the diet. No fruit or garden produce was consumed.

The Yellow-headed Blackbird is rarely parasitized by the Brown-headed Cowbird, possibly because it is much larger. It readily accepts cowbird and other foreign eggs when added at an appropriate time. Eggs added 1-4 days after incubation is initiated are accepted, but those added 3 or more days before clutch initiation are rejected or abandoned. When real cowbird eggs were added to Colorado nests, there was no difference in the number of blackbirds fledged from parasitized and unparasitized nests. In most areas, cowbird parasitism is absent or very low.

Parasitism has not been documented in Ontario, no nests were parasitized in a Utah study, and 0 of 351 nests were parasitized in Colorado. In British Columbia, 2 of 357 nests (0.4%) were parasitized. The highest recorded incidence of parasitism was in Idaho where 12 of 62 nests (19.4%) were parasitized. There are no records of cowbirds fledging from Yellow-headed Blackbird nests. The cowbird has essentially no effect on this blackbird's populations (Bent 1958; Campbell et al. 2001; Dufty 1994; Fautin 1940; Ortega and Cruz 1988; Roberts 1909; Twedt and Crawford 2020).

Habitat loss probably is not a significant limiting factor for the Yellow-headed Blackbird in Ontario. In the core of its range, wetland drainage, conversion of wetlands to agricultural land, and forest encroachment on wetland edges have probably reduced populations (Twedt and Crawford 2020).

Weather significantly affects Yellow-headed Blackbirds, with precipitation dictating the quality of a marsh for it. The amount of precipitation received the previous year and prior to the current breeding season determines water depths in the marsh. Deeper water kills some emergents and tends to make marshes more suitable for this blackbird by creating open water. If water depth exceeds approximately 1.2 m, the marsh may become too open to be suitable. If water levels are low, the emergent vegetation may become too dense for nesting, or the water depth may drop below 15-20 cm in depth, becoming marginal for nesting. Nests built over water more than 52 cm deep have higher success rates than those over shallower water. In Iowa, variations in amounts of precipitation affected its habitat use. It tended to not settle and establish territories during dry years. Those that did nest failed to fledge any young. This was attributed to predation, which increased as water levels declined. Sudden changes in water levels during the nesting period are often detrimental. Rising waters may flood nests and nests may be abandoned or depredated if water beneath the nest becomes too shallow. Cold wet weather in spring may delay nesting and result in the nestling period being asynchronous with the peak emergence of damselflies. It may also delay plant maturation, resulting in fewer nest sites. This type of weather during the nestling period is more detrimental. Older nestlings are not brooded and may become chilled and die of exposure. Prey is less available during adverse weather, resulting in more runt nestlings and a higher rate of starvation. High winds may destroy nests because they are situated in more open areas of marshes (Bent 1958; M. Brown 1988; Campbell et al. 2001; Fautin 1940; Fletcher and Koford 2004; Lederer et al. 1975; Miller 1968; Orians 1966; Twedt and Crawford 2020; Willson 1966b).

Carp can destroy Yellow-headed Blackbird habitat. They stir up sediments and decrease the amount of submergent and emergent vegetation by uprooting it. This also decreases the abundance and diversity of aquatic insects. In some lakes, introduction of carp resulted in the elimination of Yellow-headed Blackbirds (Orians 1980; Schroeder 1982b).

Most marshes support muskrats and their presence may be positive or detrimental to the Yellow-headed Blackbird. The muskrat feeds on aquatic plants and small populations are beneficial. Their grazing creates openings among the emergents, enhancing habitat for this blackbird and emerging aquatic insects. The Yellow-headed Blackbird often uses their houses as singing perches and also for foraging. Muskrats occasionally cut off the emergents supporting a nest, resulting in its failure. High muskrat populations can eat almost all emergents in a marsh, rendering it unsuitable for this blackbird (Weller and Spatcher 1965).

The Yellow-headed Blackbird is frequently persecuted by humans because of its consumption of agricultural crops (Twedt and Crawford 2020). In addition to shooting, efforts are occasionally directed toward making its breeding habitat less suitable. In North Dakota, Linz et al. (1996) sprayed cattails with glyphosate to break up cattails to improve habitat for many marshland birds but make the area less favourable for blackbirds. Seventy percent of cattails were sprayed in 4 marshes and 90% on 4 other marshes. There was a slight but nonsignificant decline in Yellow-headed Blackbirds for 2 years after spraying. Their population rebounded once the cattails became re-established.

In most populations, the primary cause of nest failure is predation. This may be particularly severe in wetlands where the Marsh Wren is present. Despite the aggressive behaviour of Yellow-headed Blackbirds toward this wren, it may destroy in excess of 50% of nests (Picman and Isabelle 1995; Picman et al. 2002; Rutberg and Rohwer 1980).

In an effort to control mosquitoes, Hanowski et al. (1997a) sprayed wetlands with Bti and methoprene. There were no apparent effects on the Yellow-headed Blackbird as a result of the treatments.

There are 2 minor factors that may affect individual nests but not populations. Uneven growth of the emergents supporting nests may result in their contents being dumped into the marsh. Heavy mite infestations may contribute directly or indirectly to mortality (Twedt and Crawford 2020).

Status

The first record of the Yellow-headed Blackbird in Ontario was one near Toronto around 1885. Although the species was very rare in the province near the end of the 19th century, McIlwraith (1894) correctly predicted that it would eventually become a breeder. The first evidence of it breeding in Ontario was in 1931 when it was reported nesting near Quetico Park. Breeding was first confirmed in 1961 when 35 males were counted near the mouth of the Rainy River near Lake of the Woods; a nest with eggs was collected then. At that time, there were scattered summer records from other locations in southern Kenora and Thunder Bay districts, and in Essex, Chatham-Kent, Middlesex, Peel, Peterborough, Haliburton, and Frontenac. Breeding was not confirmed in any of these locations. In 1965, 3 territorial males were observed in the Lake St. Clair marsh complex. Two nests were found there in 1966 (Baillie 1961; Sawyer and Dyer 1968). Baillie (1967) and de Vos (1967) reported that the range of the Yellow-headed Blackbird had expanded eastward to include the Great Lakes area and Ontario, possibly due to forest clearing and damming of rivers (Austen et al. 1994). The first atlas indicated that it bred regularly in the Lake St. Clair and Rainy River areas. Nesting evidence was also obtained at Kenora and Dryden in the north and in Essex County. There was a possible breeding record from Tiny Marsh west of Barrie. Records of isolated birds were considered unlikely to represent long-term range expansions. Because it is a colonial species, sightings of individuals or even single pairs are not usually indicative of breeding (Flood in Cadman et al. 1987). Harris (1989) found a nest at Mission Island in Thunder Bay and presumed that another nest was present based on the presence of 2 females. James (1991) considered the Yellow-headed Blackbird locally uncommon at Rainy River, Atikokan, Essex County, and in Chatham-Kent; rare at Thunder Bay; and possibly occurring in Norfolk County. Summer records had been documented from Red Lake, Long Lac, and Simcoe County (Tiny Marsh) at that time. He concluded that it was slowly expanding in Ontario, with sight records north to Moosonee. Austen et al. (1994) estimated the Ontario

population at 25-56 pairs annually during the first atlas, but large colonies nesting in Lake of the Woods had been overlooked.

The second atlas revealed no significant changes in the range or probability of observation of the Yellow-headed Blackbird since the first atlas. It occurred in a few more areas in northwestern Ontario, north to the Pikangikum sewage lagoons. Small colonies previously reported at sewage lagoons at Amherstburg and Essex in Essex County and near Stoney Point on Lake St. Clair disappeared or declined between atlases. The population along the east shore of Lake St. Clair, excluding Walpole Island, was estimated at 75-100 birds (Dunn in Cadman et al. 2007).

Breeding Bird Survey data for Canada indicate annual increases of 0.841% 1970-2021 and 2.78% 2011-21. The long-term trend was highly reliable; the short-term trend was of medium reliability. There are no data for Ontario (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Upon leaving the nest, young move up the vegetation supporting it. When it bends over, they move to another stem and adeptly move about the marsh in this manner until they are capable of flight. They can fly 1-2 m 4-5 days after leaving the nest and are capable of 25-m flights by the time they are 3 weeks old. The young fledglings and female usually remain close to the nest for several days. At this time, the male may assist the female in feeding the fledglings. Eventually the female and fledglings make their way into other males' territories where they are not challenged. The male does not follow and the female assumes all responsibility for the fledglings (Bent 1958; Fautin 1940; Twedt and Crawford 2020; Willson 1966b).

Juveniles undergo a partial moult that begins in July. During this time, they and adults may congregate in large flocks where the growth of cattails or other emergents is the densest. If the natal marsh does not have dense stands of emergents, birds may begin to disperse from it by late June. While remaining in dense vegetation, flocks may segregate with males found in 1 part of the marsh and females and juveniles in another. Birds leave the marsh during the moult only in mornings and evenings to feed (Bent 1958; Picman and Isabelle 1995).

The moult is complete around the beginning of August. At this time, birds come out of hiding, spend the day foraging in fields, and roost in wetlands overnight. They leave the roost at sunrise in characteristic flight lines, often flying 10 or more km to suitable foraging areas. Near sunset, they typically follow the same flight lines to return, but may roost in different wetlands nightly (Bent 1958; Campbell et al. 2001; Twedt and Crawford 2020; Twedt et al. 1991).

Foraging flocks of Yellow-headed Blackbirds are often mixed with European Starlings, Red-winged Blackbirds, Brown-headed Cowbirds, and Common Grackles. They forage mostly in fields of small grains and corn, but often in landfills, floodplains, stubble fields, and bare, plowed, or fallow fields. They may also visit chicken runs, barnyards and manure piles, cattle feedlots, estuaries, marine beaches, lawns, and corn cribs (Beal 1900; Campbell et al. 2001; Cummings et al. 1989; Miller 1968; Twedt and Crawford 2020).

During the postfledging period, most foraging occurs in agricultural crops including wheat, oats, barley, millet, milo, sorghum, sunflowers, and corn. Once a suitable foraging site is found, flocks return to it repeatedly over several days until the crop is depleted or becomes too ripe for their

preferences. It prefers ripening grain and sunflower fields where the seed kernels are in the soft dough stage of development. After this seed stage is over, numbers of visiting birds decline rapidly. In unharvested fields, birds perch on the plants to feed on the seeds. Large foraging flocks roll over fields gleaning weed and grain seeds. Birds at the rear of the flock fly over birds foraging on the ground and land at the head of the advancing flock. Unripened grains may be milked from the hull and sunflowers are hulled before they are consumed. The conversion of vast areas of upland habitat from grasslands and forage crops to cultivation of small grains, corn, and sunflowers has created an immense food supply for postbreeders and has probably increased fledgling survival (Cummings et al. 1989; Twedt and Crawford 2020).

In some years, large numbers of juvenile birds appear in Massachusetts and on the Atlantic Coast, well away from the breeding areas. This appears to be long-distance postfledging dispersal. The numbers that occur each year on the east coast are linked to reproductive success. Large numbers on the coast coincide with years when large numbers of young are produced along the northern and eastern edges of the breeding areas, the portion of the breeding range that is closest to the coast (Veit 1997).

MIGRATION

The Yellow-headed Blackbird is a diurnal migrant that migrates in small flocks. Flocks tend to be composed almost exclusively of either adult males or females with juveniles. Flocks are often mixed with Red-winged Blackbirds, Common Grackles, Brewer's Blackbirds, and Brown-headed Cowbirds. These flocks congregate in staging areas and roost overnight in dense emergent vegetation in marshes, similar to the postfledging period. It is a rare and irregularly encountered autumn migrant throughout eastern Canada and the United States. Although it is distributed throughout this area in autumn, most records are from Atlantic Coast regions. It is a rare but increasing spring migrant in the east (Bent 1958; Twedt and Crawford 2020).

The Yellow-headed Blackbird appears to be cold intolerant and arrives in the spring later and departs in autumn earlier than the Red-winged Blackbird. The northward movement begins in the south in mid-March and continues through April, with most birds arriving on the breeding grounds by mid-May. At 1 Iowa marsh, there was little difference in the arrival times of adult males and females. In most areas, females arrive 1-2 weeks after the males. By then, males have established their territories and females can assess the quality of territories and males before selecting a site. Yearling males arrive 3-4 days after adult females and yearling females arrive about a week later. Autumn migration is usually underway by late August or early September (Bent 1958; Fautin 1940; Orians 1980; Picman and Isabelle 1995; Roberts 1909; Twedt and Crawford 2020; Weller and Spatcher 1965; Willson 1966b).

In southern Ontario, spring migrants arrive in late March and may continue to pass through until early June. Autumn migrants occur from mid-August to late October; some remain until December or January (Black and Roy 2010; Curry 2006; Speirs 1985; Weir 2008). Although some birds have been seen in winter, these appear to be late autumn migrants. There is no evidence that the Yellow-headed Blackbird has successfully overwintered in the province.

During migration, the Yellow-headed Blackbird is predominantly granivorous, eating small grains, corn, and weed seeds. The diet is similar to that of the postfledging season, particularly during

autumn migration. Preferred habitats for foraging include agricultural fields such as harvested grain fields, loose piles of hay around barnyards, cattle feedlots, along railways where there is spilled grain, in pastures and meadows, and in plowed fields. Less frequently, it may occur in wild rice stands and along roadsides and city streets. At night, it still requires marshes with dense emergents for roosting (Bent 1958; Campbell et al. 2001; Roberts 1909; Twedt and Crawford 2020).

Bobolink

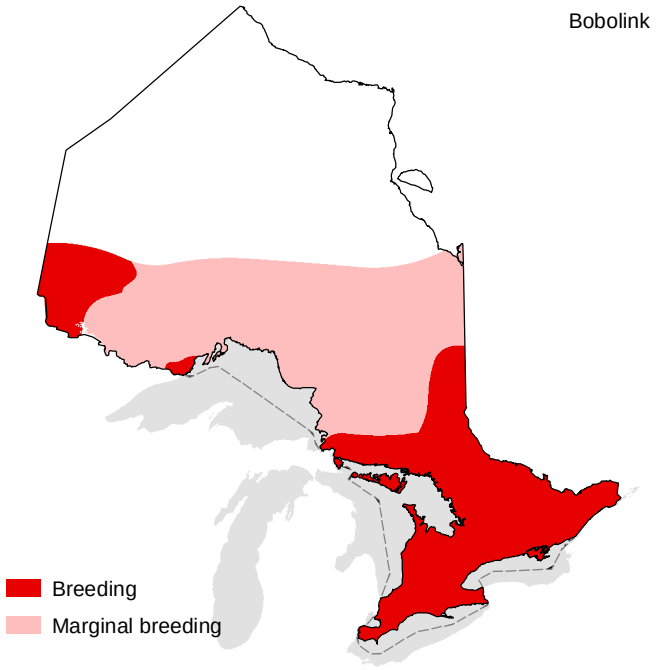
Dolichonyx oryzivorus

BREEDING SEASON

Habitat Requirements

All Ontario Bobolink nests were in open fields: 35.6% in hayfields, 35.6% in shrubby and weedy fields, 15.7% in pastures, 12.2% in marshy fields, and 0.9% in stubble fields (Peck and James 1987).

In Ontario, the Bobolink is an open-habitat species associated with agricultural landscapes with large areas of hayfields and pastures. It is an obligate grassland species that avoids areas dominated by shrubs or trees. It seldom nests in small-grain fields and avoids row crops such as corn and sorghum. Highest densities are associated with the highest densities of cattle and largest areas of hay and pasture. It still nests in some habitats that were used historically, such as remnant prairies, savannahs, and alvar grasslands. These habitats are now rare and support only a small proportion of the population. In landscapes that are extensively forested, it is confined to large openings such as blocks of agricultural land or bogs, fens, or beaver meadows dominated by grasses and sedges. It



does not nest in clear-cuts or burns. In some areas of southwestern Ontario where more suitable habitat is absent, it nests in fields of winter wheat that are at least 50 ha. It prefers fields where the grain crop is underseeded with clovers or alfalfa, or that are bisected by a wet grassy area (McCracken et al. 2013; Tozer 2012).

In Durham Region, the Bobolink showed a strong preference for old fields and hayfields with few nesting in pastures (Speirs and Orenstein 1967). At Luther Marsh, it nested in 4 habitats: monotypic reed canary grass or reed canary grass mixed with tufted vetch and bird's-foot trefoil; willow stands; mixed communities with Canada goldenrod, tufted vetch, bird's-foot trefoil, and grasses dominating; and ponds and vegetated mud mounds. Nests were placed where the vegetation, mostly Canada goldenrod, averaged 37.4 cm tall (range 33-41 cm). In addition to grasses, tufted vetch, bird's-foot trefoil, and common dandelion occurred near nests. In all cases, residual grass cover was used for nesting. Canada goldenrod was commonly used as a perch but did not appear to be an essential habitat component. The Bobolink also occurred in fields without goldenrods. It used fence posts, wire fencing, dead vegetation, and occasionally willow branches as perches, but preferred goldenrod (Joyner 1978).

The Bobolink was equally abundant on organic and conventional farms in southern Ontario. It was positively correlated with hedgerows, spring grain, hay, pastures, and habitat heterogeneity (Kirk et al. 2011).

Throughout its range, the Bobolink is restricted to grassland habitats. Where native grasslands persist, it is associated predominantly with tallgrass prairies and does not use shortgrass prairies or those containing a large proportion of shrubs. It is rare or absent in shrubsteppe communities. In native grasslands, it is most frequently associated with big bluestem and switchgrass, but it may inhabit other warm-weather grasses. Other natural habitats that it uses less frequently include graminoid fens and bogs and grassy margins of marshes (Askins et al. 2007; Norment et al. 2010; Robertson et al. 2012; Savignac 2010a; Swanson 1996). It is much more abundant in nonnative grasslands, particularly in hayfields and areas managed for waterfowl such as Conservation Reserve Program (CRP) lands in the United States and Dense Nesting Cover (DNR) in Canada. Hayfields are the largest source of nesting Bobolinks in the east; in New York, 74% nest in hayfields. In Massachusetts, 97% of territories were in hayfields that represented only 52% of available grasslands. In arid areas of the west, occupied grasslands tend to be near a source of water or be irrigated, but presence of water is not important in the east. Mesic fields are preferred to those that are dry or

flooded in the west, but drier habitat is acceptable in the east. Other grassy habitats it may use include lightly to moderately grazed pastures where shrubs are scarce, old fields and meadows, reclaimed surface mines, military bases, and airports. Less frequently used habitats include no-tillage croplands, fields of oats and winter wheat, grassy power-line rights-of-way that are at least 30 m wide and 500 m long and in rural rather than urban landscapes, and fields managed for blueberry production. Grass species that are characteristic or commonly found in fields used by Bobolinks include timothy, orchard grass, bluegrass, quack grass, and smooth brome. Other grass species that may occasionally be dominant in Bobolink habitat include reed canary grass, nonnative wheat grasses, fescues, Virginia wild rye, and meadow fox-tail. Some forbs within the grasses are desirable, especially red and white clover, bird's-foot trefoil, common dandelion, and American and tufted vetches. Many occupied fields contain alfalfa but those dominated by this species tend to be avoided. Other old-field species that are commonly present include buttercups, asters, goldenrods, and thistles (Askins et al. 2007; Banville and Gauthier in Gauthier and Aubry 1996; Beal 1900; Bollinger and Gavin 1991; Bollinger et al. 1988, 1990; Campbell et al. 2001; Dechant et al. 2001; Ells 1995b; Giroux et al. 2000; Graber and Graber 1963; Graves et al. 2010; Hartley 1994; Leston and Koper 2017; Nocera and Forbes 2010; Nocera et al. 2007b; Patterson and Best 1996; Renfrew and Ribic 2008; Renfrew et al. 2020; Renken and Dinsmore 1987; Savignac 2010a; Shustack et al. 2010; Swanson 1996; Vickery et al. 1994; Walk et al. 2010; Wiens 1969; Wittenberger 1978; Wootton et al. 1986).

The presence and abundance of the Bobolink are affected by several habitat features at the landscape level. These are related predominantly to the openness of the landscape and the abundance or proximity of forest cover. During the arrival and egg-laying periods in New York and Vermont, more birds occurred in fields where open habitats dominated the landscape within 2,500 m. During the incubation and early fledging periods, the amount of potential nesting habitat within 500 m became more important. The overall openness of the habitat was more important during settlement than the amount of habitat. This suggested that hayfields or pastures in landscapes with high proportions of row crops may provide suitable habitats. It was recommended that grassland reserves should be in mostly nonforested and undeveloped landscapes of 2,000 ha with subsets of areas of 80 ha with as much grassland and late-cut hay as possible (Shustack et al. 2010). In the same area, it avoided habitat that was not open, using open habitat more than expected even when only those nests within 50 m of edge were considered. Nest densities were reduced when the angle to the horizon was as low as 10° above horizontal; the minimum observed openness at a nest was 20° (Keyel et al. 2013). In Wisconsin, its abundance was associated predominantly with landscape characteristics. Densities were highest in landscapes with low cover diversity to a distance of 800 m. Low-diversity landscapes were characterized by large amounts of hay and grassland. Density was also higher where the area of woodlots was lower and where there were fewer wooded patches within 800 m. Density was lower when woody vegetation or larger wooded patches were closer to the transect (Ribic and Sample 2001). The amount of grassland within 1,200 m was important when Bobolinks were making settling decisions (Renfrew and Ribic 2008). In North Dakota, it reached its maximum probability of occurrence (more than 90%) in open, treeless grasslands; this declined to 40% at 10-25% woodland cover. The percent of woodland cover within 500 m was the most important predictor of its occurrence, which dropped to 0% at 40% woodland cover within this distance. Its probability of occurrence also declined with increasing coverage by tall shrubs. It was a

woodland-sensitive species that was negatively affected as woody plant height increased from brush to tall shrubs and trees. Even nominal increases in woody vegetation compromised the use of grasslands (Grant et al. 2004). In the Great Plains of the United States, the Bobolink's presence and abundance were positively correlated with grassland and herbaceous species, pastures, hayfields, CRP lands, alfalfa, and emergent herbaceous wetlands. It was negatively correlated with open water, forests, shrubs, and developed areas. Its probability of occurrence was high with 0-20% tree coverage in the landscape, moderate at 30% coverage, and 0 at 69% tree coverage (Niemuth et al. 2017). On Ohio reclaimed surface mines, the amount of woody vegetation within 100 m negatively affected its abundance (Graves et al. 2010). In Minnesota prairies, it was positively correlated with increasing grass extent at scales of 100, 500, and 1,000 m, plus litter depth and grass height. Density increased slightly with increasing visual obstruction. It was negatively associated with all woody vegetation including number of trees and shrubs within 50 m and percent tree cover within 100, 500, and 1,000 m. It was more strongly affected by the negative influence of woody vegetation than the positive effects of grass quality or quantity (Thompson et al. 2014). In North Dakota, it was restricted to landscapes with 0-13% tree cover (Cunningham and Johnson 2019).

Numerous studies examined microhabitat requirements of the Bobolink. It is associated with areas dominated by moderately dense and tall grasses with some forb coverage, a high grass-to-legume ratio, and moderately deep litter. In New York, it was most abundant in hayfields 8 or more years old. These fields were characterized by low amounts of total vegetative cover, low alfalfa cover, low legume cover, high litter cover, and a high grass-to-legume ratio. Most younger hayfields were planted to legumes or legume-grass mixtures, especially alfalfa. Alfalfa grows too densely and it usually avoids pure stands of it. Fields with the least amount of alfalfa had more than 15 times the density of Bobolinks than fields with the greatest amount of alfalfa. Maximum densities occurred at 55-64% total vegetation cover, 10% or less total legume cover and alfalfa cover, 26-50% litter cover, and a grass-to-legume ratio greater than 5. Densities were greatest in old hayfields followed by pastures, fallow fields, old fields, and young hayfields. It occurred at very low densities in heavily grazed pastures and brushy fields and was absent in oat fields. Densities declined by 50% 3 years after fields were abandoned due to the establishment of woody vegetation. Densities in hayfields were 3 times those in prairies. In old hayfields, densities were 4 times greater than in prairies (Bollinger and Gavin 1992; Bollinger et al. 1990). In Nova Scotia, abundance of males was positively correlated with percent coverage of vegetation and abundance of true bugs and orthopterans. Abundance was negatively correlated with alfalfa, forb coverage, and cordgrass. Vegetation height and density were the most important variables; average vegetation height was 36 cm (range 10-75 cm; Nocera and Forbes 2010; Nocera et al. 2007b). In New York, average habitat conditions were 13.6-15.2% grasses, 7.3-9.8% dandelions, 5.3-6.0% clovers in the genus *Trifolium*, 2.3-3.6% buttercups, 0.4-3.1% bird's-foot trefoil, and 43.3-48.1% coverage by all vegetation. Vegetation within the field was homogenous and there was no difference in vegetation within territories of bachelors or monogamous and polygynous males. Females appeared to settle randomly into high-quality habitat without being influenced by vegetation characteristics or food abundance (Wootton et al. 1986). In DNC near Montreal, accumulation of dead vegetation reduced the attractiveness of habitat to the extent that Bobolinks avoided it. Without periodic light grazing or mowing, this habitat gradually becomes unsuitable (Giroux et al. 2000). At Minnesota and North Dakota nest sites, habitat

consisted of 3.4% bare ground, 13.9% grasses, 6.0% forbs, 74.2% litter, and 0.7% shrubs with 67.1% vegetation coverage at the nest. Within the vicinity of the nest, cover included 0.3% bare ground, 35.3% grasses, 22.6% forbs, 38.6% litter, and 2.6% shrubs. Litter depth averaged 4.8 cm, mean vegetation height was 39.1 cm, visual obstruction was 20 cm, and the nest was an average of 4.7 m from the nearest shrub and 30.6 m from the nearest tree (Winter et al. 2004). Grass height should be above 25 cm at the start of the breeding season (McCracken et al. 2013). In North Dakota, Arnold and Higgins (1986) reduced shrub coverage by wolfberry and silverberry from 30-80% to 5%. Bobolinks were 5 times more abundant on the shrubless plots. Of 127 Wisconsin nests, 83.5% were beneath tall forbs, 11% were in sedge growth containing smaller forbs, 3.1% were beneath a woody overstorey, and 2.4% were arched over by dead vegetation. No nests were found where grass provided the major concealment despite 63.8% grass coverage. The vertical density was higher at nest sites than random areas and sun penetration was lower at nest sites (Renfrew et al. 2020). In shrubsteppe habitat, Rotenberry and Wiens (1980) found the Bobolink at only 1 site where its occurrence was correlated with percent litter cover. In Wisconsin, it preferred vegetation at the taller end of the spectrum in terms of grassland structure. Vegetation structure was an important predictor of its abundance and this changed annually in response to precipitation. It was least abundant in cool dry years when the vegetation was less dense, shorter, and had lower coverage by live vegetation (Renfrew and Ribic 2008). In North Dakota, it was most abundant in plots with a dense litter layer and taller, more lush vegetation that was often dominated by smooth brome, quack grass, and sweet clover (Grant et al. 2004). In Iowa CRP lands, its abundance was positively correlated with grasses and negatively with forbs. It tended to be more abundant where litter cover was higher, but not significantly. Density increased by 9.2 times over 3 years, probably because the grass-to-forb ratio increased from 2.5 to 4.4 (Patterson and Best 1996). Mean vegetation characteristics of nesting habitat in Wisconsin included 2% woody cover, 78% herbaceous cover, 16% litter cover, 5% bare ground, and 22 cm vegetation-height density (Swanson 1996). In Wisconsin, vegetative parameters at nest sites averaged 97% coverage by grasses, 20% coverage by forbs, 0% coverage by dead vegetation, 22% coverage by vegetation 10-20 cm tall, 10% coverage by vegetation 20-30 cm tall, 0% coverage by vegetation 30-40 and 40-50 cm tall, and 0% bare ground. The mean distance from territory boundaries to a woodlot was 100 m (range 40-220 m), 0 m to a fence line, and 59.4 m (range 0-170 m) from a cultivated field. All territories contained fence posts and fence lines, 50% contained trees, and 25% contained a bale or tangle of wire. Territories were nearly completely covered with grasses that were predominantly narrow and very narrow-leaved forms. Foraging occurred predominantly in cover 6-15 cm tall. It used tops of grasses for singing. Use of forbs was not high but heavy-stemmed species were important for singing and medium-stemmed species were used as lookouts. Posts and trees were used for singing and wires and posts were important as lookout perches. Maximum litter depth in territories was 9 cm, with areas of deeper litter avoided (Wiens 1969). In Illinois, its abundance was positively correlated with mean vegetation height, mean grass height, and mean number of vegetation contacts. It was negatively correlated with within-transect heterogeneity (Herkert 1994a). In North Dakota, its abundance was positively correlated with grass coverage, litter depth, density of low-growing shrubs, vegetation density, and plant communities dominated by Kentucky bluegrass, wiregrass, and grama grass. It was negatively correlated with clubmoss coverage, bare ground, and plant communities dominated solely by native grasses. The strongest predictors of its presence were

decreasing bare ground, increasing litter, and increasing vegetation density. In Nebraska CRP lands planted to cool-season grasses, it was positively correlated with percent litter cover and negatively with the vertical density of vegetation (Dechant et al. 2001).

Some studies compared the habitat characteristics of unoccupied areas and territories; of territories and nest sites; of bachelor, monogamous, and polygynous males; and identified where birds settled first at the beginning of the breeding season. In North Dakota, areas where the Bobolink was present had significantly deeper litter, taller vegetation, less live vegetation, fewer shrubs taller than 1 m, less open woodland within 100 and 500 m, and more smooth brome–quack grass community within 100 m than areas where it was absent. There were no differences in shrub coverage, amount of bluegrass, or amount of sweet clover within 100 m in occupied and unoccupied areas (Grant et al. 2004). In Wisconsin, occupied and unoccupied areas were generally similar but different in several manners. Forb coverage and density were similar but forb height was significantly greater in occupied areas. Grass cover was similar but very narrow-leaved forms dominated unoccupied areas. Vertical vegetation density was similar but the density of low (0-10 cm) vegetation was significantly greater in unoccupied areas. Litter depth was similar inside and outside territories. Litter coverage was 63% in territories, 66% in unoccupied areas, 58% within 1 m of a nest, and 100% at nests. Areas selected for nesting were markedly different from the rest of the territory. Forb coverage was somewhat less at nest sites and a higher proportion of grasses were of the narrow-leaved type. Forb heights were similar at nests and throughout the territory. Vertical vegetation density at nests was significantly greater both near the ground and over the entire height range than in the entire territory. Light penetration to lower levels was correspondingly reduced. Litter in areas about nests was more compact, deeper, and of greater coverage than in the remainder of the territory, and these differences were accentuated at the nest (Wiens 1969). In Oregon, territories of bachelors had significantly lower forb coverage than those of mated males. Forb cover differed significantly between territories of polygynous and monogamous males, but only in 1 of 3 years. Territories of polygynous males were in wetter areas than those of monogamous or unmated males and had higher coverage by sedges. Adjacent territories of polygynous and monogamous males often did not differ in vegetation characteristics and differed only in the number of females they attracted. Territories of polygynous males contained significantly higher densities of caterpillars from 31 May to 6 June and significantly more grasshoppers after 12 June than those of monogamous males. Polygyny occurred on territories containing high abundance of nestling food; unmated males had territories with low food abundance. Females selected territories based upon food resources and not vegetation characteristics (Wittenberger 1980a). In the same study area, males settled first in mesic habitats with low sedge coverage and high forb coverage. Later arrivals established territories in wet habitats with high forb cover and either high or low sedge cover. Flooded areas and dry areas distant from water were avoided. Female habitat preferences were less reliant on moisture condition and depended more upon food availability, so their settling pattern differed from those of males (Wittenberger 1978).

Other studies compared the Bobolink's habitat preferences to those of other grassland species. McCracken et al. (2013) compared the habitat requirements of the Bobolink and Eastern Meadowlark. In Ontario, habitat is often created with the objective of attracting both species, so it is important to be aware that their habitat requirements are not identical. Compared with the

meadowlark, the Bobolink prefers larger fields and tolerates or even prefers wetter portions of fields; the Bobolink tends to avoid field edges whereas the meadowlark does not; the Bobolink is associated more with hayfields and less with pastures than the meadowlark; the Bobolink prefers more forbs in fields (22.6% compared with 11-15% for the meadowlark); the Bobolink tends to nest in patches of denser and taller vegetation; and the Bobolink has a lower tolerance of woody vegetation (maximum of 25% coverage compared with 35% for the meadowlark). Winter et al. (2004) compared nest sites of the Bobolink and Clay-colored and Savannah sparrows in Minnesota and North Dakota. Clay-colored Sparrow nest sites differed significantly from the other 2 species, nesting most frequently in or near shrubs. The Bobolink and Savannah Sparrow nested most frequently within dense clumps of litter. Bobolink nests were in taller vegetation, had a lower percentage of cover at the nest, and less bare ground around the nest than those of the Savannah Sparrow. The authors concluded that, due to differences in habitat preferences, a single species cannot be used as an indicator species for the conservation of grassland birds. In Wisconsin, Wiens (1969) compared the habitat preferences of the Bobolink with those of the 2 species of meadowlarks and the Vesper, Savannah, Grasshopper, and Henslow's Sparrows. Density of forbs within 1 m of a Bobolink nest was considerably greater than for the other species. The height of forbs was somewhat taller than at Eastern Meadowlark nests, slightly lower than at Grasshopper Sparrow nests, and the same as at Savannah Sparrow nests. When entire territories were considered, height of forbs was significantly greater on Bobolink territories than in territories of all other species except for the Henslow's Sparrow, which occupied areas with significantly taller forbs. Density of forbs in Bobolink territories was higher than in Henslow's Sparrow territories; lower than in Vesper Sparrow, Grasshopper Sparrow, and Eastern Meadowlark territories; and considerably lower than in Western Meadowlark territories. Vertical vegetation density in Bobolink territories was significantly greater than in Vesper Sparrow territories, significantly less than in Henslow's Sparrow territories, and similar to that of other species. The mean vertical vegetation density 0-10 cm from the ground in Bobolink territories was significantly less than for all species except the Henslow's Sparrow. The mean effective height of vegetation in Bobolink territories was significantly less than in Henslow's Sparrow territories and significantly higher than in Vesper Sparrow, Savannah Sparrow, Grasshopper Sparrow, and Western Meadowlark territories. Coverage by low lawn-like vegetation with an effective height of less than 5 cm in Bobolink territories was the least of all species except the Henslow's Sparrow. Litter depth in Bobolink territories was shallower than in Henslow's Sparrow territories; deeper than in Vesper Sparrow, Eastern Meadowlark, and Western Meadowlark territories; and similar to the territories of other species. Bobolink territories were closer to woods than territories of all other species. The habitat continuum included sparse low vegetation for the Vesper Sparrow, dense low vegetation for the Western Meadowlark, and dense tall vegetation for the Bobolink and Henslow's Sparrow. The ranking of species based on increased richness of the habitat, including vegetation density and height and litter coverage and depth, was Western Meadowlark, Vesper Sparrow, Savannah Sparrow, Grasshopper Sparrow, Eastern Meadowlark, Bobolink, and Henslow's Sparrow. The range of differences among the rankings was low.

The Bobolink may avoid nesting near edges of grasslands, but this is not always the case. Whether it avoids edge may depend upon factors such as the amount of grassland in the landscape and the type of edge. Even where edge avoidance occurs, avoidance is manifested predominantly

by a lower density of nests near edge rather than by complete avoidance. In Wisconsin, Renfrew et al. (2005) found no relationship between nest density and distance to edge. The type of edge (wooded or nonwooded) was not a significant predictor of nest density within 50 or 100 m of edge. Nest density increased 50-200 m from edge, but not significantly. In Iowa, Fletcher and Koford (2003) examined the location of territories relative to edges created by row-crop agriculture, gravel roads with row-crop agriculture on the opposite side, and closed-canopy deciduous woodlands at least 30 m wide. Nest density increased with distance from edge and was 2 times greater near agricultural edges and 1.5 times greater near roads than near woodland edges. Habitat differed among edge types: litter depth was lowest near woodland edges and greatest near agricultural edges; total vegetation cover was greatest at agricultural edges and least at roads. Territory positioning was inconsistent with active avoidance of agricultural edges, marginally consistent with avoidance of roads but within the measurement error of the GPS used, and consistent with active avoidance of woodland edge. The Bobolink tended to settle closer to edges where territory densities were higher. One territory extended to within 10 m of a woodland edge. The authors concluded that the habitat differences among the edge types did not explain its distribution. Bollinger and Gavin (2004) studied 375 nests at 3 sites in New York and found that the Bobolink consistently avoided forest edges. Nest numbers within 25 m of forest edge were 0-8% of those expected based on field area. The degree of avoidance varied at sites beyond 25 m from edge. At 1 site, very few nests were 50-100 m from edge but at another site, the number of nests was 98% of those expected 25-50 m from edge. Wooded hedgerows were avoided at 1 site but not at another although the number of nests was lower than expected within 25 m of hedgerows. Road edges were avoided. At 1 site, nest densities were 0% of expected 0-15 m from roads, 57% of expected at 26-50 m, and 235% of expected 50-100 m from edge. At another site, road avoidance appeared to extend 100 m from edge, with nest numbers only 65% of expected 50-100 m from road edges. Old-field and pasture edges were not avoided with nest numbers 0-25 m and 26-50 m from these edges greater than expected. Daily nest survival within 50 m of forest edges was significantly lower than for areas more than 100 m from all edges. Survival was particularly low within 25 m of forest edge and was also lower within 50 m of wooded hedgerows. After nest failure, females tended to move further from forest edges but not hedgerows. Edge avoidance may contribute to area sensitivity in the Bobolink. Grasslands smaller than 10 ha may be poor habitat if they are near a wooded area. Larger fields may be poor habitat if they are bisected by wooded hedgerows. Fragmentation of grassland by agricultural crops, pastures, and old fields is not as detrimental as fragmentation by wooded habitats or roads. In Vermont and New York, it avoided both roads and wooded areas, including hedgerows (Keyel et al. 2013). Perkins et al. (2013) examined edges defined by agriculture, forests, hedgerows, human development, roads, and wetlands in the same area. Areas within 50 m of edge were used significantly less than expected: 60% of habitat was within 50 m of edge but only 17.0% of nests were within that band. Only 31% of habitat was 50-100 m from edge but this area contained 45.5% of nests. Nest survival and nestling mass were unaffected by distance to edge. The Bobolink nested closer to a forest edge more frequently than other edge types. The percent of nests nearest an edge type was 24% for wetlands, 21% for roads, 3% for human development, 1% for hedgerows (significantly less than expected), 42% for forests, and 9% for agriculture. Overall, 652 nests averaged 94.5 m from edge.

The Bobolink is usually considered an area-sensitive species, but this is not always the case. In some areas, it exhibits no sign of area sensitivity. In some regions, it may be area sensitive in some landscapes but not in others. The more grassland and open habitat there is in a landscape, the less likely it is to be area sensitive. In Massachusetts, Ells (1995b) found no evidence of area sensitivity, with it nesting in small scattered fields that were only 1.8-8.1 ha. As many as 30 occurred in a 1.2-ha field during the postfledging period. In Wisconsin, its abundance was positively correlated with the amount of field habitat 25 m from edge when there was a high percentage of tree cover in the landscape. When there was a low percentage of tree cover in the landscape, there was no relationship between field size and its abundance. Renfrew and Ribic (2008) concluded that patch size may be influential on the abundance of the Bobolink in fragmented landscapes. In another Wisconsin study, Ribic and Sample (2001) concluded that field size was not an important variable. In the Prairie Hardwood Transition Bird Conservation Region of the United States, Thogmartin et al. (2006) concluded that it was sensitive to grassland patch size at landscape scales of 800 ha and 8,000 ha. It was more abundant in grasslands surrounded by forest when grassland patches were large. In Minnesota and North Dakota, Winter et al. (2006) found no evidence of area sensitivity. The patches they examined were large with a mean size of 226.1 ha, so they may all have been larger than its minimum size requirements. Another study they completed using grasslands exclusively 65 ha or smaller also found no evidence of area sensitivity. In Ohio, grasslands occupied by the Bobolink averaged 12 ha (range 5-26 ha; Swanson 1996). In fields managed for blueberry production on Maine, its abundance was positively correlated with patch size. Many of the sites were unsuitable for it and Vickery et al. (1994) concluded that their results were probably not applicable to other grassland systems. Johnson and Igl (2001) examined grasslands 2.2-270.5 ha in Montana, North Dakota, and South Dakota. Bobolink abundance and presence was unrelated to size in 2 counties, was positively influenced by size in 4 counties, and negatively affected by size in 3 counties. They concluded that it generally favoured large patches and considered it area sensitive. In New York, its abundance increased exponentially with field size, but it occurred in fields as small as 1.5 ha, with maximum densities occurring in 30-ha fields, the largest examined (Bollinger and Gavin 1992). In Illinois, Herkert (1994a) studied native and restored grasslands 0.5-600 ha. It was significantly associated with larger grasslands, occurring in 88% of grasslands larger than 100 ha and 7% of grasslands smaller than 100 ha. The area at which its probability of occurrence was 50% of its maximum was 50 ha. The Bobolink occurred infrequently in this area, so birds may have occupied only the larger parcels. Seventy-four percent of transects in grasslands contained suitable habitat, but only 7% were occupied. He concluded that the Bobolink was area sensitive and most likely to occur in large grasslands. In Ontario, it is generally thought that the Bobolink prefers fields larger than 10 ha, and that fields as small as 5-10 ha in fragmented landscapes can provide suitable habitat, but the quality of the habitat is diminished if it is surrounded by forest (McCracken et al. 2013). Frei (2011) concluded that patches smaller than 4 ha were unlikely to attract the Bobolink. To compensate for lost Bobolink habitat in Ontario, it is recommended that created grasslands be a minimum of 4 ha with a minimum field width of at least 200 m. There have been no studies on area sensitivity of the Bobolink in Ontario and it is likely to vary geographically. It will probably use smaller patches in agricultural than forested or developed landscapes, and will probably require larger patches where it is less common.

Several studies provided recommendations for creating or managing Bobolink habitat. Habitat must be managed to prevent woody vegetation from invading fields. This may be accomplished by regular mowing outside the breeding season, periodic burning, or grazing at low to moderate intensities. In extensive grasslands, mowing, burning, and grazing should be done rotationally to provide a variety of successional stages. The periodicity of management should be site specific depending upon how quickly woody vegetation becomes established. Habitat should be dominated by grasses with scattered clovers (Bollinger and Gavin 1992; Dechant et al. 2001; McCracken et al. 2013).

During the nesting season, males roost on the ground at night and females remain on the nest until the young fledge (Renfrew et al. 2020).

Almost all (96.8%) Ontario nests were on the ground; 2 were 15 cm from the ground supported by grass stems and another was 30 cm up in vetch. Most were very well concealed under grasses, forbs, and sometimes shrubs, and were woven into surrounding grass and forb stalks; 3 nests were unconcealed. Some nests (13.8%) were in shallow depressions (Peck and James 1987).

Renfrew et al. (2020) stated that nests are always on the ground, but this is not the case. Three Ontario nests were elevated and Bent (1958) reported one 15 cm from the ground. The female selects a small depression for the nest site or scrapes one out. The nest is usually open but is occasionally under cover of heavy litter, usually where forbs are scarce and the litter is deep. New nests are built for replacement clutches; there is no evidence of nest reuse.

The Bobolink is territorial, but tends to nest in small groups of pairs. Single pairs may occur in small or marginal habitat patches. In Nova Scotia, males tended to strongly select territories based on the presence of conspecifics, and yearlings and older males tended to aggregate within their own age class. Presence of conspecifics appeared to be an indicator of habitat quality. The tendency to nest in groups may be a response to its mating systems that include polygyny and extra-pair copulations. Grouping may also explain its tendency to be area sensitive. Males establish territories soon after their arrival on the breeding grounds with territorial defence ending abruptly once the male begins feeding the nestlings. At this time, floater males may successfully establish territories and attract a mate. Territories are used for courtship, nesting, and the initial stages of fledgling rearing. Foraging may occur either on or off the territory. Territory boundaries may fluctuate throughout the season with no apparent relationships to singing perches, foraging sites, or any other features. Early arriving, usually older, males establish large territories but these become compressed as later arrivals squeeze among the established territories. The result is an area of contiguous non-overlapping territories. Females exhibit little aggression toward each other and do not defend a subterritory within the male's territory. Active nests have been found as close as 5 m together on the same male's territory (McCracken et al. 2013; Nocera and Forbes 2010; Renfrew et al. 2020; Savignac 2010a; Wiens 1969). Territory size varies depending upon habitat quality and density of nesting birds. Larger territories are associated with lower-quality habitat and lower nesting densities. Territory sizes of 0.33-4.90 ha have been reported with most averaging 0.4-0.75 ha. In Oregon, territories averaged 0.74 ha in good habitat and 1.46 ha in lower-quality habitat. In a lush Wisconsin field, territories averaged 0.45 ha. In low-quality fields, territories averaged 2.55 ha (range 1.09-4.90 ha). Territories in New York hayfields and pastures were 0.33-0.75 ha at 1 site and

averaged 0.4 ha at another. Territories were 0.45-0.69 ha in Wisconsin hayfields and averaged 0.43 ha in the St. Lawrence Valley of Quebec. Territories averaged 1.4 ha in a Michigan hayfield. In Washington, territories of polygynous males (1.2 ha) were significantly larger than those of monogamous males (0.95 ha). In Iowa, territory sizes increased near road edges, decreased near woodlands, and showed no changes along agricultural edges compared with territories distant from edge. Average territory sizes were similar along different types of edges: 0.34 ha at agricultural edges, 0.34 ha at roads, and 0.35 ha at woodlands (Bollinger and Gavin 1992; Dechant 2001; Fletcher and Koford 2003; Renfrew et al. 2020; Savignac 2010a; Wiens 1969; Wittenberger 1978; Wootton et al. 1986). Because adults often forage outside their territory, home ranges may encompass the territories of several males. The home range becomes even larger once the nestlings fledge (Renfrew et al. 2020).

Natal philopatry rates vary, with some birds returning to their natal area and others dispersing moderate to long distances. In Vermont, Perlut and Strong (2016) recaptured 83 of 759 nestlings (12.5%). Of these, 18 (21.7%) returned to their natal field. Mean and median dispersal distances were 1,267.2 and 1,037.1 m, respectively. Birds that fledged late in the season with below average body mass were most likely to return. Heavier birds that fledge earlier in the season have a longer period to disperse and may exhibit greater dispersal rates. In New York, 6 of 337 nestlings (1.8%) returned to breed (Renfrew et al. 2020). In Wisconsin, 7 nestlings returned to breed the next year; they were all females (Martin 1974). In Oregon, 1 of 8 yearling males (12.5%) established a territory within 1,000 m of its natal territory and 3 settled more than 2,000 m from the natal territory. Zero of 9 returning yearling females nested within 200 m of their natal territory but 6 (66.7%) nested within 1,000 m. Significantly fewer females than males dispersed further than 1,000 m from the natal territory. Females dispersed a mean distance of 810 m (range 290-2,200 m) compared with a mean of 1,610 m (range 120-3,350 m) for males (Wittenberger 1978, 1980a). In New York and Vermont, mean natal dispersal distance was 1,552 m (median 975 m, maximum 8,424 m). Approximately 30% of natal dispersal events resulted in birds breeding in the field in which they were hatched. Most dispersal was less than 300 m or more than 900 m. Birds either returned to their natal field or moved a substantial distance from it. There was no difference in dispersal distances of the sexes, with medians of 361 m for males and 1,033 m for females. Birds were most likely to disperse to a field with the same management practices as their natal field, but chose fields at random with respect to habitat quality. There was a high return rate of yearlings at this site and suitable habitat was patchily distributed so philopatry may have been unavoidable. Young did not make favourable decisions regarding habitat during natal dispersal. Fajardo et al. (2009) concluded that their data did not support the hypothesis that recently fledged young use the presence of conspecifics as a cue to assess potential breeding sites in subsequent years. Brewer et al. (2018) reported longer dispersal distances of juveniles banded in Ontario. Three banded in August at Mountsberg were recovered in a subsequent June in Newmarket, Carlisle, and Maine, having dispersed distances of 19-742 km. These birds were banded in August, so it is possible that they had already dispersed from the natal area.

Adult site fidelity is high and birds nesting in high-quality habitat usually return to the same area every year (Wittenberger 1978). Adult return rates may be influenced by the previous year's breeding success, with successful breeders remaining faithful. Birds that were unsuccessful tend to return to

high-quality habitat but may disperse from low-quality habitat. In New York, 22 of 56 females (39.3%) returned to nest. All settled significantly closer (67 m) to their previous year's nest than the expected distance of 217.3 m (Wootton et al. 1986). In Oregon, males often returned to the same territory but females usually did not. An average of 56.9% of males returned each year. Ninety-six percent of males and 92% of females settled within 1,000 m of where they had nested the previous year. Adult site fidelity was lower in years when areas that were inhabited the previous year dried out. Ten of 27 adult males (37.0%) established territories within 50 m of their previous year's territory. Males dispersed a mean of 205 m (range 0-1,450 m). Four of 13 adult females (30.8%) nested within 50 m of their previous year's nest, 9 (69.2%) within 200 m, and all but 1 within 2,000 m. Females dispersed a mean distance of 315 m (range 0-2,250 m; Wittenberger 1978, 1980a). In New York, significantly more males (44.1%) than females (25.4%) returned to breed in a subsequent year. Return rates were strongly influenced by the previous year's nesting success and by habitat quality. Significantly more returning males had been successful the previous year than birds that did not return, and returning males had significantly more mates the previous year than those that did not return. Females that returned hatched significantly more eggs and fledged more young than those that did not return. Five of 69 former residents (7.2%) that did not return settled 6 km away. Breeding success in the previous year influenced the choice of nesting sites by both sexes. Significantly more birds (70% of males, 49% of females) returned to a high-quality site than to lower-quality sites (44% of males, 25% of females). The return rate of birds that nested successfully the previous year did not differ between high- and low-quality sites. At low-quality sites, successful birds were 3-5 times more likely to return than unsuccessful birds. Unsuccessful birds were more likely to return if they had nested more than 1 year previously than were novice breeders. At high-quality sites, males dispersed a mean of 46 m, significantly less than for females (65 m). Birds dispersed significantly further at low-quality sites (93 m for males and 110 m for females). Unsuccessful birds were more likely to return to high-quality habitat. Females that lost their nests in poor habitat did not return. When birds dispersed between nesting seasons, they moved to higher-quality habitat and areas where the density of breeders was higher (Bollinger and Gavin 1989; Gavin and Bollinger 1988). In New York and Vermont, site fidelity also depended upon nesting success and habitat quality. Adults consistently returned to breed at the previous year's site and more than 80% nested in the same field. The mean dispersal distance was 370 m (maximum 10,637 m). There was no difference in the median dispersal distances of males (129 m) and females (108 m). When birds dispersed, they exhibited strong selection for sites with similar management practices as their previous year's site. Only 4 of 103 dispersal events (3.9%) involved a bird moving to a field with different management practices. Of birds that nested successfully, 93.7% returned to nest in the same field; 79.2% of unsuccessful nesters returned to the same field. Of those that moved, 86.2% made a favourable decision by remaining in or moving to higher-quality fields (Fajardo et al. 2009). In New York and Vermont, high-quality habitats produced more fledglings, had stable populations, and adults living in them survived longer and had higher site fidelity. Return rates in early cut hayfields were 43% for males and 27% for females compared with 63% for males and 46% for females in late-cut hayfields. There was a greater turnover of birds in more disturbed fields. Females that selected high-quality fields either returned or dispersed outside the study area. Some males appeared to disperse regardless of habitat and breeding success. First-time breeders and immigrants settled more frequently in low- and medium-quality fields than in high-quality fields. High-quality fields were at capacity and offered few open territories

(Perlut et al. 2008). In the same fields, the sex ratio of nestlings was 1:1 but male return rates were 35% higher than for females. This suggests that females have a lower survival rate or that a higher proportion of them disperse (Perlut et al. 2014). In Wisconsin, 62.8% of males and 33.9% of females returned. Unsuccessful females had a strong tendency to not return in the following year (Martin 1974). In Indiana, Scheiman et al. (2007) banded 143 males and monitored their movements within and between seasons. Thirty (21.0%) returned in a subsequent year and 24 (80%) were site faithful. Ten males (9.5% of the 105 that were resighted) moved as far as 14.2 km (mean 7.4 ha) to a different population from the one they were banded in, either within or between years. The probability of an individual dispersing from 1 habitat patch to another within a breeding season was 24%. Dispersal was frequent, which functionally linked the spatially separated groups of individuals into a single population.

Limiting Factors

Eggs have been found in Ontario nests from mid-May to mid-July, with most present in the first 2 weeks of June (Peck and James 1998b). In Algonquin Park, eggs and young occur in late June and dependent fledglings have been observed from mid- to late July (Tozer 2012). Egg laying typically begins during the last week of May in Ontario. Most eggs hatch in mid-June and most young have fledged by early July. Second nests hatch around 21-30 June with fledging occurring 1-12 July (McCracken et al. 2013).

Females returning to the same grassland patch often select a male within hours of returning. Females unfamiliar with the site move around the habitat for about 2 days before pairing. After the second day of courtship and by the first day of copulation, the male attempts to attract additional females. Pairing and other mating activities within a given field are highly synchronous. In an Oregon population over 3 years, all primary females selected mates over periods of 5, 7, and 10 days. Secondary females selected their mates later and did so over periods of 7, 10, and 10 days. Polygynous males obtain their second mate 3-8 days after the first. The female constructs the nest in 1 or 2 days and egg laying begins 1-2 days after the nest is complete. In Oregon, the average interval in 3 years between pair formation and laying of the first egg was 5.6, 6.1, and 7.3 days (range 2-17 days) for primary females. This interval averaged 5.8 days over the 3 years for secondary females (range 3-17 days). Early pairing females had longer intervals between pairing and egg laying. Eggs are laid at the rate of 1 a day. Incubation usually begins with the laying of the penultimate egg. The incubation period at 1 Ontario nest was 11 days. The incubation period is 10-13 days with most clutches hatching asynchronously; the last egg usually hatches 20-30 hours later than the others. In Ontario, more than 80% of clutches hatched asynchronously. Young usually leave the nest when they are 10 or 11 days old but may remain as long as 14 days. Young that are disturbed may leave when they are 8 days old, but mostly at age 9 days (Bent 1958; Bollinger and Gavin 1991; Gavin and Bollinger 1988; Martin 1974; Renfrew et al. 2020; Wiens 1969; Wittenberger 1978, 1980a).

The Bobolink typically raises a single brood each year, but there are confirmed records of second broods. At a New York site, 6 of 20 females (30.0%) laid a second clutch after successfully rearing a brood. None were successful in rearing their second brood. At a nearby site, 0 of 21 females were double-brooded. In Vermont, 58 of 798 females (7.2%) attempted a second nest after their first nest either fledged young or failed. One case of a double brood has been reported in Wisconsin. In

Vermont, 10 females attempted to raise a second brood and 6 were successful. Renesting may occur if the first brood is lost but most females do not attempt a replacement nest; 1 female attempted to renest after 2 failures. In a New York hayfield, 5 of 21 females (23.8%) attempted a second nest after the first one failed. After a nest is destroyed, females may disperse 10-15 km (range 0.5-60 km). Only 25-30% of females that disperse attempt to renest (Bent 1958; Bollinger and Gavin 1991; Bollinger et al. 1990; Gavin 1984; Gavin and Bollinger 1988; McCracken et al. 2013; Renfrew et al. 2020; Winter et al. 2004). Clutches of 3-7 eggs have been reported in Ontario, with most containing 5 eggs (average 4.95 eggs). Replacement nests have smaller clutches averaging 4 eggs. Clutches of 1-7 eggs have been reported with most containing 4-7 eggs; 5 eggs is the most frequent clutch size. Clutch size varies with the female's age, whether she is a primary or secondary female, whether it is a replacement clutch, and with the season. As a female ages, the number of eggs she lays increases from an average of 3.8 eggs in her first year to 5.9 eggs in her fourth year. Older females arrive earlier and become primary birds and lay more eggs than later-arriving and younger females that attain only secondary status. One female laid 7 eggs in her first year as a primary bird, became a secondary bird the next year and laid 5 eggs, and was once again a primary female the following year and laid 7 eggs. Secondary females may lay smaller clutches because they receive less or no assistance from the male in rearing the young. Females laying replacement clutches usually lay 1-2 fewer eggs than in their first nest and often become secondary females. Clutch size declines with the season. Mean clutch sizes reported elsewhere include 5.2 and 4.99 eggs in New York, 5.1 eggs in Wisconsin, and 4.7 eggs in Vermont (Bent 1958; Bollinger and Gavin 1991; Martin 1974; McCracken et al. 2013; Norment et al. 2010; Peck and James 1998b; Renfrew et al. 2020; Winter et al. 2004).

Both sexes are capable of breeding when they are 1 year old. It is probable that all yearling females breed, but some yearling males remain bachelors. Territories of unmated males may be drier than those of mated males, support lower densities of insects, or be inferior in other manners. Some unmated yearling males do not establish a territory and remain as floaters. In high-quality habitat in Oregon, only 2% of males were unmated; 27% were unmated in low-quality habitat. In Quebec, 26% of males failed to attract a mate and 8% did not establish a territory. Once a bird has bred, it probably breeds in all subsequent years (Giroux et al. 2000; Nocera and Forbes 2010; Renfrew et al. 2020; Wittenberger 1980a; Wootton et al. 1986).

The pair bond dissolves after the young reach independence. Females that renest may retain their mate or select a new one. When both members of a pair return the following year, they occasionally remate. In New York, 5 of 14 females (35.7%) whose previous mate returned paired with them again. They settled a mean of 31.5 m from their previous year's nest, significantly closer than the mean of 77.3 m for other returning females (Gavin and Bollinger 1988; Renfrew et al. 2020; Wootton et al. 1986).

The Bobolink is strongly polygynous. Polygynous males typically have 2 mates and rarely 3; 1 male had 4 mates. Although polygyny is the norm, monogamous and bachelor males also occur in populations. Polygyny is regulated by females who select territories, rather than males, based on habitat quality and abundance of insect prey. Primary females do not mate until territorial disputes among males are resolved. All males within a population are mated with a primary female before any mate with a secondary female. Females mated to the same male settle randomly with respect

to each other, with internest distances not varying from random, and exhibit little to no aggression toward each other. Females engaging in polygynous relationships do not settle asynchronously as is the case with many other polygynous species. When nests of females within a single territory are asynchronous, males might be more likely to assist at nests of secondary females if the primary nest was near completion. The rate of polygyny at a site is strongly governed by habitat quality. In Oregon, 43.7% of males were polygynous in high-quality habitat compared with 20.2% in lower-quality habitat. Overall, 28.8% of males were polygynous, 49.6% were monogamous, and 21.6% were unmated. Fewer males were polygynous in a dry year when habitat quality was lower. No yearling males attracted a second mate, possibly because their territories were not in the best habitat. Females choose to mate polygynously in high-quality habitat rather than monogamously in lower-quality habitat. The presence of high-quality habitat and more abundant food resources apparently outweigh the potential disadvantages of males contributing less to the rearing of nestlings in nests of secondary females (Bollinger and Gavin 1991; Martin 1974; Renfrew et al. 2020; Wittenberger 1978, 1980a; Wootton and Bollinger 1992; Wootton et al. 1986).

In New York, Gavin and Bollinger (1985) analyzed the nestlings in 7 nests genetically. In 2 nests, all nestlings were not sired by the attending male. Bollinger and Gavin (1991) collected DNA data for 840 nestlings from 191 families. Thirty-six nestlings (4.3%) exhibited genotypes that were consistent with extra-pair fertilizations. The frequency of extra-pair young was 36% for novice males, 10% for males that had nested at the site previously, 11% for novice females, and 22% for females that had nested previously. Frequency of extra-pair nestlings was highest when novice males were paired with experienced females and lowest when experienced males were paired with novice females. Frequencies were highest for primary females (24%), intermediate for monogamous females (12%), and lowest for secondary females (4%). For males, frequencies were similar for polygynous (16%) and monogamous (15%) birds. Bachelor, monogamous, and polygynous males sired extra-pair young at rates similar to their frequency in the population, but no nestlings were sired by nonterritorial floaters. Nearby residents sired most, if not all, the extra-pair young. It was uncertain if females solicited extra-pair copulations or if males actively pursued older primary females. Population density did not affect the rate of extra-pair copulations. As a result of extra-pair copulations, even unmated males may contribute to the population. In Vermont, 42% of 120 nestlings were sired by extra-pair males. Evidence of extra-pair paternity occurred in 57.5% of 40 nests. Extra-pair nestlings were more common in nests of polygynous males (49%) than those of monogamous males (33%), but not significantly (White et al. 2021).

At 4 New York nests, more adults than the parents fed the young. At 1 nest, 2 males and a female fed the nestlings. At 2 nests, 2 females and a male attended the young, and 3 males and a female attended the fourth nest. The reason for helpers at the nest was unclear (Beason and Trout 1984; Bollinger et al. 1986).

In New York, adults tended to forage outside the territory, frequently more than 150 m from the nest. Only 10 of 42 pairs (23.8%) foraged more than 60% of the time within their territories; 60.5% of foraging trips were to areas outside the territory (Wootton et al. 1986). In Wisconsin, adults foraged mostly in their territories early in the season. Later when they were feeding nestlings, most foraging occurred outside the territory, especially in adjacent oat and alfalfa fields and a marsh 1 km away.

Males travelled further for food for nestlings than females. When adults foraged within the territory, the sexes usually did so in different locations (Wiens 1969). In Oregon, both adults often foraged in flooded areas when provisioning the nestlings (Wittenberger 1980a). The Bobolink gleans arthropods from the mid-growth of vegetation and at bases of forbs, grasses, and sedges. It perches atop herbaceous plants interspersed within expanses of grasses or sedges, and eats their seeds. It occasionally forages for invertebrates in trees and shrubs near the nesting habitat. It feeds while walking very slowly on the ground or as it ascends into the lower levels of vegetation. It may jump from the ground to grasp dandelion seeds and those of other plants too limber to permit perching. During the breeding season, the Bobolink forages singly (Renfrew et al. 2020).

Females time their nesting activities and select their territory in relation to the availability of food for nestlings. In Oregon, secondary females showed no preference for areas based on densities of tiger moth caterpillars but settled preferentially in areas with higher owlet caterpillar densities. Females do not select territories until the abundance of caterpillars can be assessed. Primary females begin nesting shortly after caterpillars first emerge in the spring. The nestling period coincides well with peak caterpillar densities unless adverse weather interrupts their emergence. Caterpillar densities decline considerably by the time nestlings fledge (Wittenberger 1978, 1980a). In Nova Scotia, prey availability did not affect where Bobolinks settled, but its abundance was associated with bugs, particularly plant bugs, one of the top 4 prey groups fed to nestlings; spiders were also important prey (Nocera et al. 2007b). Most monogamous males help feed the nestlings but some do not. In Wisconsin, polygynous males fed nestlings at primary nests but not those at secondary nests. In Oregon, almost all polygynous males fed nestlings in secondary nests, often at the same rate as at primary nests. Females that receive male assistance spend more time brooding the young and less time feeding them than those without assistance. When food is scarce, males preferentially feed young in the primary nest and the larger chicks which are most likely to survive. Primary females spend more time feeding and less time brooding when food is scarce and the weather is good. When food is scarce and the weather is poor, primary females do not reduce the amount of time spent foraging but brood less. When food is scarce, males deliver food faster and bring more prey items and a higher biomass of food each trip. When food is scarce, brood reduction may occur with the youngest and smallest chicks starving. Brood reduction rates are higher in secondary than primary nests (Martin 1974; Wiens 1969; Wittenberger 1978, 1980a, 1980b, 1982; Wootton et al. 1986). Food items fed to nestlings in Wisconsin consisted of 57 geometer moth caterpillars, 46 other caterpillars, 17 dragonflies, 7 beetle larvae, 4 spiders, 4 damselflies, 3 adult beetles, 3 adult lepidopterans, and 2 harvestmen (Wiens 1969). The 1,575 food items fed to nestlings by 13 females in Oregon consisted of 44.4% caterpillars, 13.6% grasshoppers, 10.8% tiger moth caterpillars, and 4.1% owlet moth caterpillars. At a low-quality site, the 780 food items a female fed her nestlings consisted of 48.2% caterpillars, 29.0% grasshoppers, 10% owlet moth caterpillars, and 0.8% tiger moth caterpillars (Wittenberger 1980a). In another study in the same area, the major food items delivered to nestlings were lepidopterans and sawfly larvae, with males bringing a significantly higher proportion of each of these than females in every year. Small numbers of beetles, flies, spiders, bugs, adult hymenopterans, neuropterans, mayflies, odonates, and annelids were brought to nestlings. The proportion of caterpillars in the diet of nestlings varied annually and ranged from 54.2% to 65.6% (Wittenberger 1980b, 1982).

In Oregon, adults fed extensively on dandelion seeds in May and early June. In June, the Bobolink ate seeds of other forbs, but less frequently than earlier. These included seeds of cinquefoils, yarrow, Canada thistle, curly dock, and dwarf mallow, although these were not important components of the diet. Other forbs that were present whose seeds were not eaten included yellow sweet clover, hop clover, red clover, American vetch, groundsel, starry false solomon's-seal, and pepperweed. Most of these were host to sawfly larvae and caterpillars of tiger and owlet moths, and butterflies such as whites, sulphurs, common wood-nymph, ladies, and coppers that were fed to nestlings (Wittenberger 1978, 1980a). Bent (1958) reported that the diet of New England birds consisted of 70-90% insects in May, June, and July. In May, the Bobolink consumed a small but quickly dwindling amount of grain and more grain in July, with grain constituting 35% of the August and 3% of the September diets. Forb seeds constituted 8% of the diet in May, June, and July, but increased rapidly in August to 90% of the diet in September. Weevils were an important component of the diet, representing as much as 68% of food items at times. Beal (1900) reported that the Bobolink ate corn, grubs, caterpillars, beetles, grasshoppers, crickets, spiders, and seeds of wild rice, wheat, barley, and other grasses. He analyzed the contents of 291 stomachs. The diet consisted of 57.1% animal matter and 42.9% vegetable matter. The animal diet included 19% beetles (8.9% weevils plus some ground and June beetles), 13% caterpillars that were mostly cutworms (17.6% of the May diet and 28.1% of the June diet), and 11.5% grasshoppers (23.2% in June and 25.8% in July). It also consumed a few flies, bugs, mayflies, spiders, and millipedes. It began to switch to a vegetable diet in August, when oats constituted 31.4% of the diet. Rice was also commonly consumed; other grains such as wheat, barley, and buckwheat were eaten sparingly. In the north, wild rice is more important but cultivated rice is important in the south. It ate forb and grass seeds mostly in August when they represented 36.9% of the diet compared with 16.2% overall. Seeds that were most prevalent in the diet included those of barnyard grass, panic grass, smartweed, and ragweed.

The Bobolink is an occasional host for the parasitic Brown-headed Cowbird and readily accepts its eggs and raises cowbird nestlings. In Minnesota and North Dakota, clutches of parasitized nests were 0.5 egg smaller than unparasitized nests. The number of young fledged from parasitized nests was significantly lower than for unparasitized nests, averaging 1.4 fewer overall. Winter et al. (2004) concluded that the effect of parasitism was insignificant in these populations because the rate of parasitism was low. Cowbirds may destroy Bobolink eggs at nests that are both parasitized and unparasitized, and they may also kill nestlings in unparasitized nests. This may prompt the Bobolink to renest, potentially providing another opportunity for parasitism (Granfors et al. 2001). Habitat may affect parasitism rates. In Minnesota, nests within 45 m of wooded areas were parasitized at a greater rate than those further from edge (Renfrew et al. 2020). In predominantly grassland habitat in North Dakota, parasitism rates declined with increasing tree cover. For every 1% increase in tree cover within 2 km, the odds that Bobolink nests would be parasitized decreased by 5%. Odds of parasitism occurring were 35% at 0% tree cover within 2 km, 25% at 10% tree cover, 19% at 20% tree cover, 10% at 30% tree cover, and 8% at 40% tree cover. The availability of alternative hosts in woodland habitats may reduce the risk of parasitism. Bird densities are higher in woodlands and nests may be easier to find. Cowbirds are less likely to target grassland species in landscapes with sufficient tree cover to provide alternate hosts (Pietz et al. 2009). In Ontario, 8 of 149 nests (5.4%) were parasitized.

Parasitism rates are low in the east: 0 of 422, 0 of 81, and 1 of 375 nests (0.3%) in New York and 1 of 1,025 nests (0.1%) in Vermont; low to moderate in the Midwest: 0 of 57 and 1 of 62 nests (1.6%) in Illinois, 1 of 85 nests (1.2%) and 5-20% in Wisconsin; and higher in the west: 38 of 315 nests (12.1%) in Minnesota and North Dakota, 11 of 36 (30.6%) and 42 of 108 nests (38.9%) in North Dakota, 430 of 839 nests (51.3%) in Nebraska, and 0 of 11 nests in British Columbia (Bollinger and Gavin 2004; Campbell et al. 2001; Granfors et al. 2001; Norment et al. 2010; Peck and James 1998b; Renfrew et al. 2005, 2020; Winter et al. 2004).

The original clearing of forests to create agricultural land was highly beneficial for the Bobolink, resulting in large increases in its numbers and large range expansions. Modern agricultural practices coupled with other land-use changes now represent one of the greatest limiting factors for it. Reductions in habitat quantity and quality are the most significant threats. Based upon a literature review and modelling exercise, Ethier and Nudds (2017) concluded that habitat quantity better defined its population trend than habitat quality.

Habitat conditions were probably ideal for the Bobolink around the end of the 19th century. Prior to European settlement, there were only about 66,500 ha of grasslands in Ontario, mostly tallgrass prairie. There are only 300 ha of this habitat remaining in the province now. This habitat and much of the southern Ontario woodlands were converted to anthropogenic grasslands such as hayfields and pastures. The Bobolink readily adapted to this nonnative habitat. Subsequent habitat loss was related directly to a decrease in the number of livestock and consequently the requirement for hay and pasture. The amount of land planted to hay decreased strongly from 1930 to 1940, due the replacement of horses by tractors and other mechanized machinery. A second sharp decline occurred from 1965 to 1975 related to a decline in the number of cattle as farmers switched from raising livestock to planting crops such as corn and soybeans. The amount of improved and unimproved pasture decreased by 77% and 38% since 1966 and 1971, respectively (McCracken et al. 2013). The decline in the number of cattle, and therefore pastures and hayfields, continues. In 2001, there were 2.141 million cattle in Ontario but only 1.624 million in 2016 (Statistics Canada 2018), a decrease of almost 25%. In addition to changes in the crops grown, habitat was lost due to abandonment of farms, natural succession, tree planting, and conversion to urban areas and other land uses (Cadman et al. 2016; Ethier and Nudds 2017; Frei 2011; Savignac 2010a). Declines in the Carden Plain between the 2 atlases were related mostly to conversion of grasslands to row crops, but habitat in some fields changed from pasture or hayfield to shrublands and became unsuitable habitat (Merondun et al. 2024).

The remaining habitat is of lower quality than it was formerly due to the species that are planted for hay and the intensity of grazing. Hay originally consisted of timothy mixed with moderate amounts of clovers which provided ideal nesting habitat. This hay mix has been widely replaced by monocultures of alfalfa which grow too tall and dense to be attractive to Bobolinks. Until the 1950s and 1960s, most farmers had a few head of cattle, resulting in fairly low grazing intensity. Now limited numbers of farmers raise cattle and grazing intensity is much higher, usually making pastures unsuitable for nesting. The habitat trends that are occurring in Ontario are occurring in much of the Bobolink's range, particularly in the northeastern United States. It is anticipated that current habitat

trends will continue and Bobolink populations will continue to decline in the east (Askins et al. 2007; Bollinger and Gavin 1992; Bollinger et al. 1990).

Next to direct habitat loss, mowing of hayfields during the breeding season is the second most important limiting factor for the Bobolink. This is a direct result of conversion of most hayfields from grass-dominated forage crops to alfalfa crops. Hay is now cut 2-3 weeks earlier than formerly and usually 3 times a year instead of twice. The period between cuts must be 65 days or longer to provide enough time for vegetation to regrow and the Bobolink to complete a nesting cycle. This seldom occurs in alfalfa fields. Near Peterborough, typical hay management resulted in little to no reproductive success and early harvested sites were abandoned for the season. High reproductive success occurred in fields where the harvest was delayed until 14 July, but hay quality fell below ideal protein levels for most cattle before harvest. Delaying cutting from the last week of June until the end of the first week of July can increase fledging rates from 0 to 70%; cutting is rarely delayed this late in Ontario. Not all hayfields are cut every year or during the peak nesting period, and these contribute to the population (Cadman et al. 2016; Diemer 2014; Frei 2011; McCracken et al. 2013; Savignac 2010a). Tews et al. (2013) determined that the greatest losses of Bobolinks due to mowing in Canada occurred in the Carolinian Zone. Losses to the autumn flight due to the death of birds that would have fledged successfully in the absence of mowing were estimated at 321,000 annually in Canada, including 36,000 in the Great Lakes–St. Lawrence Forest Region and 154,000 in the Carolinian Zone of Ontario. Nest losses due to early mowing are high in other areas in the east, typically resulting in 80-100% mortality of eggs, nestlings, and young fledglings. Older fledglings occasionally survive if they are able to move to nearby uncut areas. Mortality occurs from 3 sources: the initial cutting of the hay; predation by gulls, corvids, and other predators on exposed nests and young fledglings; and by raking of the hay prior to baling. When a field is cut, all adults that were present abandon it and typically no birds colonize it later. These birds disperse and most do not attempt replacement nests; their entire reproductive effort for the year is lost (Bollinger and Gavin 1992; Bollinger et al. 1990; Ells 1995b; Fajardo et al. 2009; Nocera et al. 2007b; Perlut et al. 2006; Shustack et al. 2010). In New Jersey, the effects of leaving 5 uncut refugia of 0.25 ha in a 23-ha hayfield were studied. Bobolinks used the refugia more often than the cut areas. Their density increased only slightly in the refugia after mowing, with most differences in densities resulting from lowered densities within mowed areas. Birds completely abandoned fields that were entirely mowed. Although the refugia resulted in some birds remaining after harvest, there was no evidence of renesting (Allen et al. 2019). Mowing every few years later in the season is necessary in most fields to prevent them from becoming invaded by woody vegetation. Wolcott et al. (2023) recommended that grassland management be deferred until August to protect both nests and fledglings.

Light to moderate grazing or grazing on a rotational basis in areas of large pasturelands can be beneficial by preventing natural succession to woody vegetation. Heavily grazed areas where the grass is cropped close to the ground are unsuitable habitat. In most areas, ungrazed meadows support higher densities than those that are grazed. Its preference for moderate to tall vegetation means that grazing has to be low intensity in order to maintain habitat quality. In addition to altering the structure of the vegetation, cattle often trample nests and actively depredate them by feeding on the eggs and nestlings, possibly incidentally. Grazing may also expose nests, making them vulnerable to predation. Grazing appears to be beneficial only when stocking densities are less than

0.198 cows per ha per day. Average stocking density in Ontario is 7 times this rate (Ethier and Nudds 2017; Frei 2011; Giroux et al. 2000; Kim et al. 2008; McCracken et al. 2013; Perlut et al. 2006; Renken and Dinsmore 1987; Savignac 2010a; Swanson 1996). Campomizzi et al. (2019) studied the effects of rotational grazing of cattle on Bobolink breeding success in the Ottawa Valley of Ontario. Some fields were ungrazed in 1 of 2 years during the breeding season; they were grazed normally in the other year. In another experiment, some fields were grazed for 4-8 days between 21 May and 3 June at stocking rates of 31-40 cattle per ha per day and not again until the Bobolink breeding season was over. Over 2 years, 13% and 28% of nests were trampled by cattle; 77% of trampled nests were in fields with 50 or more cattle-days per ha. In the year when fields were ungrazed, young fledged from 54% of territories, significantly more than when the same fields were grazed (16%). In the light spring grazing experiment, 67% of territories fledged young. The probability of a territory fledging young decreased with grazing intensity: 53% at 0 cattle-days per ha and 4% at 174 cattle-days per ha. Fields that were rotationally grazed provided suitable Bobolink habitat and production of fledglings. Favourable conditions for Bobolinks include keeping fields ungrazed until 15 July or grazing fields lightly after territories are established. In Grey County, fields were rotationally grazed beginning in late May. Bobolink abundance decreased 73% after grazing and it was more abundant in ungrazed than grazed fields. It dispersed from grazed fields. Few remained after the first round of grazing and they remained in fields where the vegetation was taller than in grazed fields (Campomizzi and LeBrun-Southcott 2022).

Prescribed burning to reduce woody growth can be beneficial for the Bobolink, provided that it is done either after the breeding season or early enough in spring that vegetation can grow to a suitable height. In North Dakota, it was absent in unburned mixed prairie, reached its highest abundance 2 years after fire, and declined considerably by 5 years after fire. In Minnesota, it was most abundant 1 year postfire at 1 site and at the other site it was absent 1 year after fire but present 2 years postfire (Dechant et al. 2001; Madden et al. 1999).

In the west, abundance and survival of the Bobolink are strongly linked to weather factors such as precipitation and temperature. It is uncertain if these are important in Ontario. In most studies, it was less abundant in dry years. Its abundance was positively correlated with mean annual precipitation, the amount of precipitation in the previous year, and early spring moisture indices. It was negatively correlated with drought indices and the differential between the previous year's precipitation and the long-term average. An exception occurred at a Nebraska site where it was more abundant in dry than wet years. In that location, wet riparian wetlands may have provided a refuge from drought. Nest survival may be lower when June to August weather is wetter than usual. In the Great Plains of the United States, its abundance was positively correlated with maximum August temperatures. Nestling mortality may increase due to exposure to long-term rainstorms, hailstorms, and nights with temperatures near freezing. Adult return rates in Oregon were lower in a year when both sexes encountered both snow and rain storms before arrival, suggesting that these events increased mortality rates (Kim et al. 2008; Niemuth et al. 2008, 2017; Thogmartin et al. 2006; Wittenberger 1978, 1982; Zuckerberg et al. 2018).

Herbicides are unlikely to be a limiting factor for the Bobolink, but pesticides may have adverse effects. Neonicotinoids are a concern due to potential toxicity to pollinators and birds. High

concentrations in surface water have been linked to declines of local populations of farmland-breeding passerines and have negative impacts on nontarget invertebrates that may provide prey. The Bobolink is routinely exposed to pesticides on its wintering grounds in South America where it feeds in treated rice fields. It may be intentionally poisoned there and in the southeastern United States where it may significantly damage rice crops (Cadman et al. 2016; Frei 2011; McCracken et al. 2013; Renfrew et al. 2020).

At 1 Ontario wind farm, the Bobolink was among the top 10 species killed by turbines. It may be vulnerable to being struck by turbine blades because of its high aerial flight displays (McCracken et al. 2013). In North and South Dakota, Bobolinks were attracted to the area encompassing turbines and the area within 0.8 km of them in the first year. After 2-5 years, Bobolinks exhibited an avoidance reaction at 2 of the 3 sites. At 1 site, displacement occurred at all distance categories (0-100 m, 100-200 m, 200-300 m, and more than 300 m), but only within 200 m at the other site. The delayed response may have been due to site fidelity (Shaffer and Buhl 2015).

Grasslands planted for agrofuels have some potential to be beneficial, particularly if cornfields are converted to grasslands, but the high-density planting tends to favour habitat generalists only. Management of these fields to maximize biomass and homogenize vegetation structure is likely to reduce species richness and abundance of grassland birds (Robertson et al. 2012).

Fragmentation of grasslands by forests and other land uses has the potential to reduce nesting success. In Minnesota tallgrass prairies, nest parasitism and depredation decreased with distance from edge; similar results were obtained in Wisconsin. Productivity was greatest in nests more than 45 m from edge. Nest depredation rates were significantly lower on large (130-480 ha) than small (16-32 ha) grasslands (Dechant et al. 2001; Renfrew et al. 2005).

Human disturbance may have low to moderate effects on the Bobolink. Nests discovered early in construction are often abandoned immediately (Renfrew et al. 2020). In Wisconsin, Renfrew and Ribic (2003) placed video cameras at nests to study predation. Nests with cameras were abandoned more frequently than those without cameras. Nests with cameras were more likely to be trampled by cattle. In Massachusetts, Keyel et al. (2012) measured the flight-initiation distance when observers walked toward a male Bobolink. Males flushed at an average distance of 21.8 m and flew an average of 33.5 m. A buffer of 28 m would prevent 75% of males from flushing, 40 m would prevent 95% from flushing, and 59 m would prevent 99% from flushing.

Nixon et al. (2016) predicted the response of the Bobolink to climate change in Alberta. They concluded that 100% of the existing habitat would remain suitable and that there would be a 42% expansion in Bobolink habitat to the north based on more favourable climate in this area. They predicted a large increase in habitat by 2050 and even more suitable habitat in 2080. Price (2004) predicted that the breeding range of the Bobolink might contract in southern Ontario if the average summer temperature increased by 2°C. Unlike Alberta, its range cannot expand northward in Ontario because of the largely forested habitat on the Canadian Shield.

Status

Prior to European settlement, the Bobolink was probably rare in Ontario. Its primary range at that time consisted of the prairies and Great Plains where it was predominantly associated with tallgrass

prairies. It was not very common in this habitat, probably because the grass was taller than it prefers. It may have nested in Ontario in native prairies, savannahs, alvar grasslands, meadow marshes, beaver meadows, burns, and areas cleared for agriculture by First Nations. It was known to breed in natural meadows along the north shore of Lake Ontario in the early part of the 19th century. Settlers deforested large areas and converted them to pastures, hayfields, and other agricultural crops. They also converted most of the native grasslands to croplands and nonnative grasslands. The Bobolink responded positively and expanded its core range both eastward and westward into what had formerly been forested landscapes. The grasses that were planted in hayfields and pastures were an optimum height for it, and it became much more abundant in nonnative than native grasslands (Banville and Gauthier in Gauthier and Aubry 1996; Bent 1958; Cadman et al. 2016; de Vos 1964; Frei 2011; Mayfield 1988; Renfrew et al. 2020). Anecdotal declines were reported early in the 20th century with large declines beginning in the 1930s and 1940s due to changing agricultural practices (Frei 2011; McCracken et al. 2013).

In the Kingston area, the Bobolink was very common by the late 19th century, particularly on Wolfe, Simcoe, and Amherst islands which are agricultural habitats (Weir 2008). In Elgin County, it was a very common summer resident in 1891 and an abundant breeder in 1954; in 2000, it was locally common (Lancaster et al. 2004). In Niagara Region, Sheppard et al. (1936) considered it a common breeder that appeared to be increasing; Black and Roy (2010) considered it a local and uncommon breeder. In Algonquin Park, it formerly nested in old fields and extensive sedge meadows but decreased drastically beginning in the 1980s due to forest succession (Tozer 2012). Baillie and Harrington (1937) reported that it was a common summer resident in the south, breeding north to at least Sudbury and Ottawa. They concluded that it probably bred in Nipissing District and the Thunder Bay area. The first atlas revealed a somewhat broader range for the Bobolink, but confirmed that it was associated predominantly with agricultural lands. It was widespread south of the Canadian Shield; had a spotty distribution in the Shield portion of the Great Lakes–St. Lawrence Forest Region, including the area from Thunder Bay to Kenora; and occurred in the agricultural areas of the Clay Belt. It also probably bred along the James Bay coast north of Moosonee. It was most abundant south and east of the Shield. Within this area, it was less abundant southwest of Chatham-Kent (where hayfields and pastures were less common) and around Lake Ontario from Niagara Region to Prince Edward County (Weatherhead in Cadman et al. 1987). James (1991) considered the Bobolink a common breeder in southern agricultural areas, rare in the north to Dryden and Kapuskasing, and a vagrant north to Big Trout Lake and Moosonee.

The second atlas demonstrated that there had been no significant change in the range of the Bobolink since the first atlas. It was not detected north of Moosonee and in some of the more northern areas where it was observed during the first atlas. Its probability of observation declined significantly province-wide and in all regions. The greatest decline occurred in the Shield portion of the Great Lakes–St. Lawrence Forests Region, probably due to natural succession. Declines south of the Shield were probably due to continuing losses of hayfields and pastures and to increasing use of alfalfa for hay. It was most abundant in the Great Lakes–St. Lawrence Forest Region south of the Shield. Highest densities were in Grey and Bruce counties, around Peterborough and Kingston, and between the Ottawa and St. Lawrence rivers in southeastern Ontario. These areas were associated with lower-intensity farming practices and grazing of small herds of cattle was still common. Despite

its decline, the Bobolink remained a very common species in the agricultural south. On point counts, it was the 12th most abundant species in the Great Lakes–St. Lawrence Forest Region south of the Shield and 24th most abundant in the Carolinian Zone (Gahbauer in Cadman et al. 2007).

The Bobolink has declined significantly throughout its range. According to Breeding Bird Survey (BBS) data, it declined in North America at a rate of 1.7% per year 1966-2004 (McCracken 2005). For 1968-2008, the rate of decline was 5.2% in Canada and 2.6% in Ontario (Savignac 2010a). Ontario supports approximately 13% of the global population of the Bobolink. The sharpest declines in Canada since 2000 occurred in Ontario. Annual rates of decline in the province were 3.3% 1970-2010, 3.6% 1980-2010, 3.7% 1990-2010, and 4.0% 2000-2010 (Frei 2011; McCracken et al. 2013). BBS data indicated annual decreases of 3.06% in Canada and 3.08% in Ontario 1970-2021. The 2011-21 trends were annual decreases of 3.37% in Canada and 4.59% in Ontario. All results were highly reliable (A.C. Smith et al. 2023).

The Bobolink has been designated threatened in Canada (McCracken 2022) and Ontario. A strategy for its recovery in Ontario was prepared (McCracken et al. 2013). The long-term goal is to maintain stable self-sustaining populations. The goal for 2013-23 was to slow the annual population decline to an average of no more than 1.0% per year. The long-term goal is to achieve a stable population of approximately 90% of the 2013 population. Maintaining the 2013 population was not considered feasible due to existing trends in agriculture, urbanization, human population growth, and the changing dairy and beef production sectors.

Ethier and Nudds (2015) analyzed BBS data for southern Ontario for 1967-2011 and 1998-2011. Of 35 survey regions, only 5 had positive population trends and 6 had significant negative trends. These were mostly in the southwest and included Brant, Perth, Oxford, Middlesex, and Huron counties and an isolated area in the Kawartha Lakes region. They concluded that the trend estimates exceeded the goals of the recovery strategy and that the outlook for the Bobolink might be more optimistic than analyses obtained at broader scales indicated.

POSTFLEDGING PERIOD

Young are unable to fly when they leave the nest and remain in dense vegetation until they attain the power of flight about 13 days of age. Some fledglings remain near the nest for as long as 5 days. Others disperse as far as 70 m from the nest in the first day. In Oregon, a fledgling from a primary nest was found in one of the male's secondary nests 23 m away. The young and adults usually leave the territory within a week and interfamily flocks may begin to form as early as 6 days after the young fledge (Bent 1958; Renfrew et al. 2020; Wittenberger 1980a, 1980b; Wootton et al. 1986).

Brood division occurs a few days after the young fledge with each adult feeding half the brood. In Oregon, every male continued to feed its primary fledglings while attending secondary nestlings. Within interfamily flocks, adults continue to feed their own young for as long as 28 days after fledging (Renfrew et al. 2020; Wittenberger 1980b).

As soon as the fledglings are capable of flight, usually by mid-July, adults and young form flocks mixed with other families. These often disappear from the breeding fields and move to more secluded locations such as marshes, stream margins, and interfaces between wetlands and

agricultural lands. These flocks feed mostly on weed seeds, but also on grain and wild rice if it is available (Beal 1900; Bent 1958; Campbell et al. 2001; McCracken et al. 2013).

MIGRATION

The Bobolink migrates in flocks, mostly at night but some diurnal movements occur. In spring, flocks are composed of a single sex with flocks of males moving northward first. Autumn flocks contain both sexes as well as adults and juveniles. It makes one of the longest migratory flights of North American passerines, travelling 19,000-20,000 km during a round trip. The flight path is complex and includes transoceanic flights. The autumn migration is protracted and takes 3-4 months, although it may fly as far as 1,200 km a night while flying over the ocean. Some birds flew nonstop between North and South America. Spring migration is more rapid and takes 5-6 weeks (Bent 1958; Hamilton 1962; Perlut 2018; Renfrew et al. 2020).

Renfrew et al. (2019) analyzed the migration of the Bobolink using geolocators for 4 birds in Ontario, 1 in British Columbia, and 15 in the western United States. The Ontario birds were captured at Luther Marsh. Results indicated that most of the global population uses a single migration corridor. Individuals from eastern populations tended to stage more than 250 km from their breeding locations for 1-3 weeks before making consistent southbound flights. The duration of southbound migration was 20 weeks compared with 10 weeks for the northward flight. Two Ontario birds flew from the Colombia-Venezuela border 2,500-2,600 km to Florida within 2 days. A female from Ontario carried out her moult in western Brazil.

Males may initiate northward migration fairly synchronously and arrive on the breeding grounds in flocks. Female arrival is more diffuse. Females arrive 4-10 days after males, averaging about 10 days later in the Kingston area. Yearling females may arrive 1.5-2 weeks later than adult females. Yearling males arrive after adult males (Bent 1958; Martin 1974; Renfrew et al. 2020; Wittenberger 1980a, 1982). Most Bobolinks return to Ontario in the first 30 days of May (McCracken et al. 2013), but some arrive in the last week of April (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004).

Some Bobolinks leave the breeding grounds in late July and early August and congregate in freshwater or coastal marshes while they complete the moult. Others remain on the breeding grounds until mid-August. From mid-August to mid-September, large concentrations occur along the Atlantic Coast from Nova Scotia to Florida (Hamilton 1962; Renfrew et al. 2020). Based on banding at Long Point Bird Observatory, most autumn migration in Ontario occurs between mid-August and 20 September (McCracken et al. 2013). Most leave the southern Shield in late July or early August, but some may persist until mid-October (Mills 1981; Tozer 2012). Autumn migration is underway in southern Ontario by late July or early August with most birds gone by mid-September; birds rarely remain until early November. In Hamilton Harbour, individuals and flocks migrate westward along the Lake Ontario shoreline from the end of July through August and early September (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008).

During spring migration, birds may first appear on the breeding grounds in typical breeding habitat. The Bobolink may also occur in in grassy fields, oat fields, newly sown rice fields in the south, pastures, sorghum fields, idle fields, and margins of crop fields (McCracken et al. 2013; Meanley 1953). During autumn migration, it may spend several weeks in staging areas where it may

concentrate in large numbers. Certain staging areas are used traditionally and are important in its life cycle by providing abundant food resources for building energy reserves prior to transoceanic flight. Before European settlement, it probably congregated in autumn in wild rice stands along coastal shores and in large rivers in the southeast. These were largely replaced by cultivated rice and the Bobolink exploited this rich food resource. The creation of agricultural land has resulted in more suitable migration habitat. It has become more opportunistic and may concentrate wherever food is plentiful. This may include weedy fields, cornfields, small grain fields, grassy wetlands, and hayfields (Beal 1900; Meanley 1982; Renfrew et al. 2020; Savignac 2010a; Watts 1997).

The Bobolink may roost nocturnally in large numbers during autumn migration. In Virginia, approximately 6,000 roosted in a field of foxtails in scattered dense patches of amaranths 1.2-m tall (Meanley 1982). Two other autumn roosts in Virginia were in dense monocultures of common reed 31 and 70 ha in area. The smaller area was the primary roost, and most birds settled within an area smaller than 1 ha near the centre of the vegetation. Average density of birds within the roost was more than 5 per m^2, but sometimes reached densities several times that. Individuals appeared to roost at night and make most of their southward movements during early morning and late afternoon. Groups of a few to several hundred could be heard flying high and out over Chesapeake Bay, primarily in early morning hours (Watts 1997).

During migration, the Bobolink feeds in flocks. Sentinels sit atop plants while the remainder of the flock feeds, predominantly while they are on the ground. It may feed nocturnally on moonlit nights in rice fields while it is building fat reserves during autumn migration. During spring migration in Pennsylvania, 18 of 27 birds fed exclusively on beetles, larvae, ants, and a few earthworms; others fed on seeds. Historically, autumn migrants fed almost exclusively on wild and cultivated rice, eating the grain when it was still milky. It visits cornfields, tearing open the tops of the husks and eating the milky grain. It also eats large amounts of grass and weed seeds. At a Virginia roost site, seeds of foxtails and goosefoots were favoured foods. Thirty stomachs collected in autumn in an Arkansas rice field contained 76.0% rice, 14.3% paspalum grass seeds, 2.9% barnyard grass seeds, 2.4% panic grass seeds, 1.2% foxtail seeds, 0.5% ragweed seeds, 0.1% smartweed seeds, 2.7% beetles, and traces of soft-winged bugs, stink bugs, locusts, and weevils (Beal 1900; Bent 1958; Meanley 1953, 1982; Renfrew et al. 2020).

Habitat loss is occurring in migration habitat and particularly in wintering areas (Cadman et al. 2016; McCracken et al. 2013).

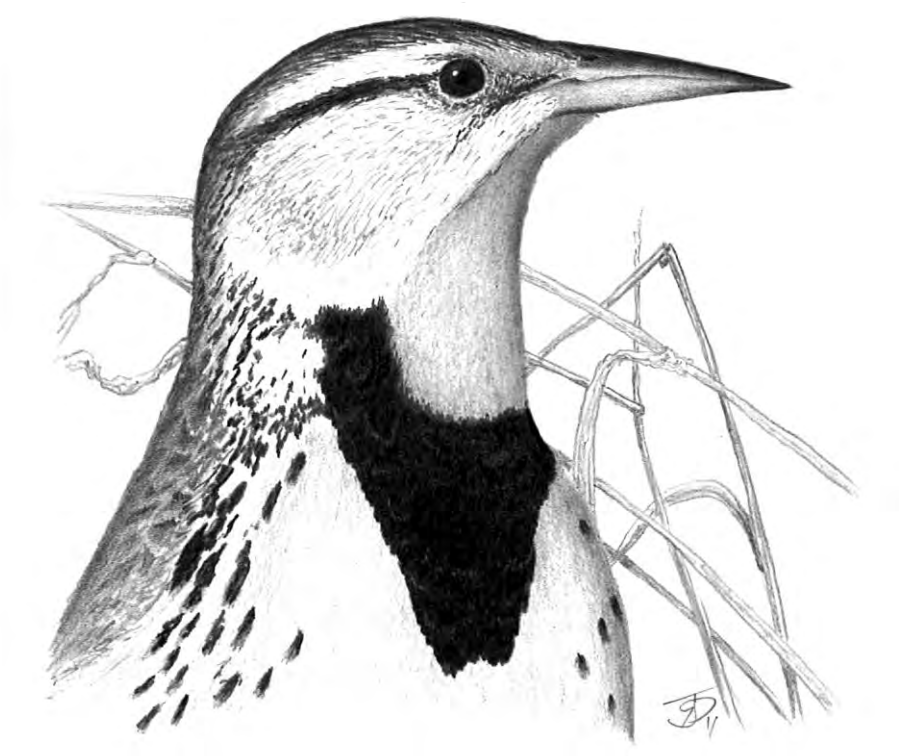
Human persecution during autumn migration was formerly a significant limiting factor. The Bobolink was highly esteemed for its flesh and vast numbers were killed by market hunters. Populations were thought to have been greatly reduced by this activity but numbers rebounded after proclamation of the *Migratory Birds Convention Act*. Bobolinks caused extensive damage to rice crops in the southeastern states and these were also killed in large numbers. There are records of individual landowners killing 45,000-60,000 in a single autumn. Some birds continue to be killed in the southeast, but at a fraction of former rates. Shooting and poisoning of Bobolinks on the wintering grounds still continues (Beal 1900; Bent 1958; McCracken et al. 2013).

During migration, the Bobolink occasionally strikes tall structures such as buildings, communication towers, and lighthouses. This does not appear to be a significant threat (McCracken et al. 2013). Weir (2008) reported that 33 were killed at the Lennox generating station chimneys and that an additional bird was killed by a car.

James (1991) considered the Bobolink a common to locally abundant migrant in Ontario.

Eastern Meadowlark

Sturnella magna

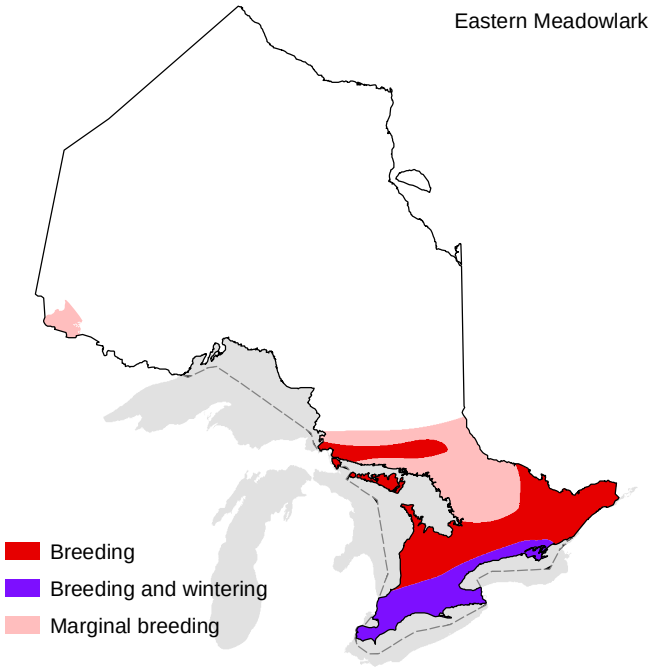


BREEDING SEASON

Habitat Requirements

Ontario Eastern Meadowlark nests were in open grassy fields, pastures, and occasionally golf courses (61.0% of nests); in shrubby and overgrown grassy fields, partially wooded city ravines and parks, young conifer plantations, and orchards (33.9% of nests); in treed sand-dune areas (4.7%); and on road allowances (0.4%). Areas of tall grasses were preferred to those with short grasses. Dry areas were selected more often than wet sites (Peck and James 1987).

The Eastern Meadowlark is an obligate grassland species. In Ontario, it still nests in native grasslands such as remnant prairies, savannahs, and alvar grasslands, but these habitats are rare in the province. It nests predominantly in anthropogenic grasslands, particularly in hayfields and pastures dominated by nonnative grasses such as timothy and Kentucky bluegrass and various



broad-leaved forbs such as clovers. It is most common in pastures followed by hayfields, native grasslands, and savannahs. It also nests in weedy meadows, young orchards, golf courses, grassy roadsides, young plantations, grain fields, herbaceous hedgerows, and grassy airports. It rarely nests in row crops such as corn and soybeans, except perhaps when grassed waterways are present. It is most abundant in agricultural landscapes in areas of high cattle density and with the largest amounts of pasture and hayfields (McCracken et al. 2013). McIlwraith (1894) reported that it nested in agricultural regions throughout the province and was associated with clover fields and freshly mowed hay. In Parry Sound and Muskoka districts, it is restricted to large open areas (Mills 1981). In Durham Region, it nested in a young pine plantation that was still dominated by shrub willows and meadowsweet; in an abandoned grassy field with scattered hawthorns and apple trees 1.2-m tall; in an old field dominated by grasses, goldenrods, and asters; and in hayfields of clover, timothy, and alfalfa (Speirs and Orenstein 1967, 1975). In Niagara Region, it nested in old fields dominated by grasses and in abandoned vineyards with grasses and forbs growing among rows of old posts and dead cultivated grape stalks. The fields were crossed by several old fence lines that were used as song perches (Knapton 1987, 1988b).

The Eastern Meadowlark was equally abundant on organic and conventional farms in southern Ontario. It was positively correlated with fences and negatively correlated with hedgerows, woods, spring grain, and road and utility rights-of-way (Kirk et al. 2011).

Throughout its range, the Eastern Meadowlark is associated with open grasslands. In the northeast, it uses a wide range of grassland types, often in association with the Bobolink. In addition to native grasslands, it nests in pastures and hayfields dominated by nonnative grasses. In the Midwestern and eastern states, it is common on reclaimed surface mines planted to grasses. In the central portion of the continent, it inhabits tallgrass prairies where it prefers vegetation of moderate height. It also nests in Conservation Reserve Program (CRP) fields. It tends to avoid short-grass prairies (Askins et al. 2007). A variety of nonnative grassy areas may be used for nesting. These include old fields and meadows, CRP lands, hayfields, young orchards, golf courses, restored surface mines, grassy roadsides, pastures, young plantations still dominated by grasses, grain fields, herbaceous fencerows, Dense Nesting Cover (DNC) established for waterfowl, grassy patches within plowed fields, fields of grain stubble, cranberry and blueberry fields, wet meadows, grassed waterways, farmstead shelterbelts, fallow fields, weedy borders of croplands, airports, shrubsteppe communities, grassy areas along railways, large woodland clearings, no-tillage corn and soybean

fields, and oak and pine barrens (Galligan et al. 2006; Granfors et al. 1996; Graves et al. 2010; Hull 2002; Jaster et al. 2020; Lanyon 1956a; Mossman et al. 1991; Norment et al. 2010; Roseberry and Klimstra 1970; Rotenberry and Wiens 1980; Savignac 2011b; Swanson 1996; Vickery et al. 1994). Native grasses that the Eastern Meadowlark nests in include big bluestem, little bluestem, grama grass, switchgrass, broomsedge, and Indian grass. Common forbs include sunflowers, milkweeds, and dense blazing star (Askins et al. 2007; McLaughlin et al. 2014; Shugart and James 1973; Winter and Faaborg 1999). It may use a variety of nonnative grasses for nesting: timothy, orchard grass, redtop, smooth brome, Kentucky bluegrass, quack grass, tall ryegrass, meadow fescue, and Virginia wild rye. Timothy, orchard grass, and bluegrasses tend to be the dominant grasses in northeastern areas. These fields may contain forbs such as thistles, clovers in the genus *Trifolium*, bird's-foot trefoil, alfalfa, wild carrot, and milkweeds (Norment et al. 2010; Renfrew and Ribic 2008).

The Eastern Meadowlark is less affected by habitat variables at the landscape scale than many other grassland species. In Quebec, it is associated with open agricultural landscapes and is patchy in distribution and rare in more northern forested landscapes (Rail in Gauthier and Aubry 1996). In Wisconsin, it was associated only with variables at 200 m and 400 m and not by characteristics of larger landscapes. There was a tendency for it to be more abundant where grasslands were more abundant within 200 m. Densities were higher further from woodlots or where overall hedgerow length was greater in the landscape. Densities were higher in areas with more hedgerows or where hedgerows were closer. Hedgerows were important because they were used as singing perches (Ribic and Sample 2001). In the same area, it was negatively correlated with the amount of woody cover within 200 and 1,200 m. Its abundance was affected by the amount of core grassland area more than 25 m from edge. When the percent coverage by grasslands within 200 m was low, its abundance increased with increasing core area. In landscapes with a high percentage of grassland within 200 m, the pattern was reversed. Interactions between microhabitat variables and landscapes were important only where grassland cover was low (Renfrew and Ribic 2008). In Nebraska and Kansas, its abundance and presence were positively correlated with grasslands, pastures, hayfields, CRP lands, emergent herbaceous wetlands, minimum temperatures, and long-term precipitation. It occurred mostly in moister portions. It was negatively correlated with forest cover and developed areas. As tree cover increased in the landscape, its occurrence declined. It had a high probability of occurrence at 0% tree cover, moderate at 30% tree cover, and low at 100% tree cover (Niemuth et al. 2017). In the Prairie Pothole Region of the United States, it was positively associated with grasslands, particularly at the 800-m scale. It had the highest niche breadth of all grassland species, indicating that it was a habitat generalist (Murray et al. 2008).

The Eastern Meadowlark exhibits distinct preferences for types of grasslands. It prefers grasslands with moderately tall vegetation with abundant litter cover, a high proportion of grass coverage, moderate to high forb density, and low coverage by woody vegetation. Nonnative grasslands are often preferred to native grasslands. Grasses in tallgrass prairies and other native grasslands may be taller than it prefers. In Missouri and Ohio CRP fields planted to switchgrass or nonnative grasses, it was more abundant in nonnative grasses probably due to their lower height. In Nebraska, it was found only in native grasslands and not in sorghum fields or CRP fields planted to either nonnative or native grasses. This was probably because CRP vegetation was tall and dense and did not provide adequate perch sites. In Oklahoma, densities were higher in moderately grazed

heterogeneous tallgrass habitats than in ungrazed homogeneous tallgrass. In Kansas, abundance was highest in CRP fields with the greatest abundance of forbs (Hull 2002). In Illinois, pasture was the preferred nesting habitat followed in order by hayfields, CRP fields, winter wheat fields, idle fields, and fallow areas. Alfalfa fields were the least preferred type of hayfield. Fully stocked alfalfa fields lacked sufficient grass cover at ground level to provide suitable nesting habitat and the vegetation was probably denser than it prefers. Grass-invaded fields of sparse alfalfa provided appropriate nesting cover. In hayfields, density was highest in mixes of orchard grass, meadow fescue, timothy, bluegrass, and downy brome. Few birds used dense uniform stands of meadow fescue with some orchard grass and bush-clover. Density was higher in this habitat where planted grasses had died out and were replaced by bush-clover, panic grasses, and other invading species. Fallow fields were seldom used because of an absence of sufficient grass cover. One to 2 years after termination of cultivation, there were still too few dead stems available for nesting. Idle lands received little usage because they supported numerous shrubs and small trees and a variety of forbs mixed in with the grasses. Areas with suitable ground cover for nesting were avoided if woody cover was extensive. Idle areas that received moderate use were recently idle and had a better cover of grasses than fallow areas, but supported little to no woody vegetation (Roseberry and Klimstra 1970). In North Carolina, Moorman et al. (2017) investigated a variety of field types, including wildlife fields planted to native grasses and forbs. It was absent in wildlife fields. They contained the dense litter and dense ground cover that it prefers but lacked the vertical structure of vegetation that it requires. It used both hayed and grazed native grasslands, but at lower densities than in fields of nonnative grasses. The height of the native grasses was too tall to be attractive. It was most abundant in grazed nonnative grasslands followed by hayed nonnative grasslands. The grazed nonnative grasslands were larger than other field types and this may have partially explained why density was highest in these fields. These grasslands had short grass heights, a moderately dense litter layer, no woody vegetation, and high coverage (50%) by forbs. In New York, nest survival was higher in hayfields and pastures than in fallow fields (Norment et al. 2010).

Numerous studies examined microhabitat preferences of the Eastern Meadowlark. It prefers vegetation 25-50 cm in height, but may use areas with vegetation 2.5-75 cm tall provided that other conditions are ideal. Best foraging habitat is 10-30 cm tall. Effective vegetation-height density of nesting habitat ranges from 6-30 cm and is mostly 20-30 cm. It avoids areas of very sparse or dense vegetation. Percent litter cover in occupied areas ranges from 7-70% and averages around 30%. Areas with sparse litter are avoided. Litter depth is typically 2-5 cm in territories. Very dense litter may inhibit movement and tends to be avoided. Ideally, grasses occupy 80% or more of the habitat; areas with less than 20% grass coverage are unsuitable. It may tolerate forb coverage as high as 50%, but prefers less than 20%. Areas completely dominated by grasses without forbs may provide excellent habitat. The coverage by bare soil within territories varies from 0% to 42%, but less than 8.5% appears optimum. Less than 5% woody vegetation is preferred and once woody cover exceeds 35% the habitat becomes marginal or unsuitable (Kerschner et al. 2004a; McCracken et al. 2013; Schroeder and Sousa 1982; Wiens 1969). In Ohio, Graves et al. (2010) studied the influence of woody cover on reclaimed surface mines on the Eastern Meadowlark. Its abundance was negatively correlated with woody cover. Daily nest survival was significantly negatively correlated with the amount of woody vegetation surrounding the nest. Woody vegetation may attract predators and reduce nest survival.

Mean vegetation parameters were 1.5% woody vegetation within 100 m, 1.9 woody patches within 100 m, and 201.8 m to the nearest woodland. Nest sites had 72 times less woody cover and fewer woody patches within 100 m than random locations. On reclaimed surface mines in West Virginia, it was more abundant on areas planted to grasses than shrubby areas, but not significantly (Margenau et al. 2019). In Illinois, presence of dead grass stems at ground level and absence of woody vegetation or numerous shrubs within the immediate vicinity appeared to be prerequisites for nesting. Cover height at 204 nests was 5-76 cm (average 37.8 cm); 66.6% of nests were in vegetation 25-50 cm tall. One nest was in the mowed portion of a golf course fairway. When it nested in gently rolling or moderately hilly terrain, it exhibited a definite affinity for slopes rather than flat crests or valleys. Most (75.8%) were in areas of good to excellent drainage where they would not be flooded or washed out except possibly under torrential conditions (Roseberry and Klimstra 1970). In Nebraska and Iowa, its occurrence was positively correlated with the total number of grass hits and negatively with mean vegetation height. Its probability of occurrence was 75% at vegetation heights of 15 cm, 60% at 20 cm, 30% at 25 cm, 20% at 30 cm, and 5% at 35 cm (McLaughlin et al. 2014). In Missouri, it was most abundant where the grass was 10-30 cm tall (Jaster et al. 2020). In Kansas tallgrass prairies, it selected nest sites with higher vertical vegetation density and greater litter depth, less bare ground, and sites further from patches of bare ground 1 m^2 or larger than random sites. In West Virginia, nests were associated with greater amounts of standing dead vegetation, deeper litter, and taller vegetation than random sites (Jaster et al. 2020). In shrubsteppe communities in the Midwest, there was a clear association between its abundance and variables describing tallgrass plots with dense grass and deep litter, but it was strongly negatively correlated with bare soil and increasing horizontal heterogeneity. It was positively correlated with grass cover, litter, total vegetation hits, the maximum dm interval containing hits, effective hits, the number of hits in the first dm, and litter depth. It was negatively correlated with percent coverage by bare soil or rock, the coefficient of variation of total hits, the coefficient of variation of litter depth, the coefficient of variation of maximum-minimum forb and shrub height, the total hits heterogeneity index, and the litter depth heterogeneity index (Rotenberry and Wiens 1980). Abundance of the Eastern Meadowlark in mixed-grass prairies was greatest when red cedar coverage was less than 10% and was consistently near 0 at 25% coverage. The presence of cedar appeared to override the influence of other cover features (Chapman et al. 2004). In Arkansas, it was common to abundant in open fields but absent in fields that had been invaded by shrubs and small trees (Shugart and James 1973). In Kansas, it occurred mostly in hayfields and prairies where the grass was fairly short. An area of dense grass with a heavy accumulation of dead vegetation on the ground was not occupied, but it nested in nearby grain fields. As the grain grew taller, it provided better nesting cover than the dense stand of smooth brome (Fitch 1958). In Maine blueberry fields, it was positively correlated with grass cover and shrubs 0-60 cm tall and negatively correlated with shrubs 0.6-2 m tall. It preferred areas of extensive grass cover (Vickery et al. 1994). In Wisconsin, occupied fields were large and grassy with some elevated singing perches and some litter present of variable depth and density. Occupied areas had 96% grass coverage: 17% at grass height of 10-20 cm, 11% at height 20-30 cm, 1% at height 30-40 cm, 0% at height 40-50 cm, and 1% at height above 50 cm. Other characteristics of occupied habitat included 3% bare ground, 41% effective vegetation height below 5 cm, litter depth 2 cm, forb height 20 cm, and effective vegetation 6 cm. Litter coverage was 61% in territories and 80% in unoccupied areas, but 92% at nests (Wiens 1969).

In Missouri CRP lands, it was negatively correlated with percent canopy coverage by dead vegetation and positively correlated with percent live grass canopy, length of pasture-hayfield edge, vertical obstruction, litter cover, and area of core (greater than 50 m from edge) hay and grassland. In Nebraska CRP fields planted to nonnative grasses, it was negatively correlated with litter depth (Hull 2002). In Wisconsin, its abundance was negatively correlated with the maximum vegetation height and vegetation height-density. It was positively correlated with percent litter cover, density of prostrate residual vegetation, and woody vegetation, although occupied areas were characterized by only 4% tree and shrub coverage. Mean vegetation characteristics included 74% vegetation coverage, 29% litter cover, 5% bare ground, 66 cm maximum vegetation height, and 20 cm vegetation height-density (Swanson 1996).

Perches may be an important habitat component for the Eastern Meadowlark. Although males occasionally sing from forbs, it prefers taller perches. These include shrubs, isolated trees, fence posts and wires, hedgerows, and edges of woodlots. In Wisconsin, 67% of territories contained posts, 67% contained a fence line, 33% a bale or tangle of wire, and 58% a tree that functioned as a singing perch. Other features that may be used as singing perches include power lines, mounds of earth, and farm implements. Territories may contain several perches. One is usually selected as a favourite and becomes the centre of the territory. This may be changed by polygyny when a male selects secondary perches nearer his mates (Gross in Bent 1958; Wiens 1969). In Missouri, areas at song perches had few woody stems less than 2.5 cm diameter at breast height (DBH) and 0 larger than 2.5 cm DBH, more than 90% ground coverage by vegetation, and more than 65% litter cover (Hull 2002). In Michigan, Harrison (1977) installed perches 1.5 and 2 m tall in an alfalfa field. In 34 of 40 observations, the taller perch was selected. Significantly more 2-m tall perches and significantly fewer 1.5-m perches were used than expected.

Several studies compared the habitat characteristics of territories with unoccupied areas and nest sites with the remainder of the territory. Others studied the effects of habitat features on nest survival. In Kansas, microhabitats at nests in CRP fields and grazed grasslands did not differ, indicating that the Eastern Meadowlark had the ability to find suitable nest sites despite large differences in habitat structure. The main difference between nests, areas within 5 m of a nest, and random sites was that litter within 5 m of the nest was finer in diameter than at the nest or random sites. Habitat was more homogeneous at nests than at other locations. Areas within 5 m of nests were more similar to nest sites than random areas for all parameters except the fineness of the litter. Successful nests had more grass and standing dead cover than unsuccessful nests (Granfors et al. 1996). In Kansas, the 0.25 m^2 around the nest had significantly less bare ground than the area 1-10 m from the nest. It selected nest sites with significantly greater litter cover and depth, a higher proportion of grass cover, and more structured homogeneity than was available in random areas (Hull 2002). In Illinois, there were no significantly different nest-site characteristics between successful, failed, and subsequent nest sites except that the maximum vegetation height was taller at successful initial nests. Females that failed during their first nesting attempt selected areas with similar nest-site characteristics for their second nesting attempt (Kerschner et al. 2004a). In Wisconsin, territories had lower coverage by dead forbs, medium- and heavy-stemmed forbs, and very narrow-leaved grasses than unoccupied areas. In unoccupied areas, forb density was somewhat lower but the forbs were taller. Vertical vegetation density and mean effective height were significantly lower in territories,

but vegetation density near the ground was greater. Coverage by low lawn-like vegetation was considerably greater in unoccupied areas than in territories. Litter in territories was significantly shallower, less extensive, and less compact than in unoccupied areas. In early spring, it selected areas where the litter was significantly deeper, more compact, and more continuous than in unoccupied areas. It also selected areas with more grass cover and less bare ground. Vegetation around nests was denser and taller than in the entire territory. Vertical vegetation density was significantly greater at nest sites than in territories but there was no difference in vegetation density near the ground. Light penetration to the ground was less at nests than within the entire territory. Litter was used to form the nest dome and was substantially deeper at nest sites than in the entire territory (Wiens 1969). In Indiana, nest survival was greatest in shrub savannah habitat and lowest in open and mixed grasslands. Nest survival increased with increasing distance to forest in shrub savannah habitat (Galligan et al. 2006).

Several studies compared the habitat preferences of the Eastern Meadowlark with those of other grassland-nesting birds. McCracken et al. (2013) compared the habitat preferences of it and the Bobolink. These are important to understand because there is often a requirement in Ontario to create habitat that is suitable for both species. This meadowlark may inhabit smaller fields than the Bobolink; it prefers to nest in drier areas and will nest along field margins whereas the Bobolink prefers damper areas away from edge; it is associated more with pastures and less with hayfields than the Bobolink; it prefers a lower proportion of forbs (11-15%) than the Bobolink (more than 20%); it tends to nest in less dense and shorter vegetation; it is tolerant of higher coverage by shrubs (35%) than the Bobolink (less than 25%); and it can withstand as much as 8.5% bare ground compared with 0.3% for the Bobolink. Lanyon (1956b) compared habitat preferences of Eastern and Western meadowlarks in the zone of overlap within the United States. The Eastern Meadowlark preferred tallgrass prairies. The Western Meadowlark was better adapted to short and mixed-grass prairies. In the western portion of the overlap zone where the Western Meadowlark is more abundant, it prefers extremely dry upland areas. The Eastern Meadowlark occurs in lowland areas with lush vegetation. The Eastern Meadowlark preferred smaller fields, taller vegetation, and damper soils. The Western Meadowlark preferred larger fields, shorter vegetation, and better drainage. Where the Eastern Meadowlark was more abundant, the Western Meadowlark nested on upland ridges of prairie surrounded by Eastern Meadowlarks in a variety of habitats. Vegetation was not a dominant factor in defining the 2 species' distributions. Soil moisture was the most important factor. The differences in vegetation at sites occupied by the 2 species were a direct consequence of soil drainage. Szijj (1960) found no differences in the habitats of Eastern and Western meadowlarks in Ontario. The species were not segregated by soil moisture and exhibited no apparent differences in habitat selection. In Midwest shrubsteppe communities, habitat of the Eastern Meadowlark was most similar to that of the Dickcissel, with a 90% niche overlap, and the Grasshopper Sparrow, with a 65% niche overlap. Of the species studied, the Eastern Meadowlark was the second most specialized species. The Bobolink tends to be more specialized but was not included in the analysis. The overlap between this meadowlark and the Dickcissel was 98% on a vegetation gradient that dealt mostly with grass and litter components (Rotenberry and Wiens 1980). In northern Illinois, density of the Eastern Meadowlark appeared to vary inversely with that of the Red-winged Blackbird. This was attributed to habitat preferences rather than interspecific territoriality (Graber and Graber 1963). It is

probable that the Red-winged Blackbird nested in areas that were wetter than this meadowlark prefers. Wiens (1969) compared habitat preferences of the Eastern Meadowlark with those of the Savannah Sparrow, Vesper Sparrow, Grasshopper Sparrow, Henslow's Sparrow, and Western Meadowlark in Wisconsin. Forb density and coverage of Eastern Meadowlark territories were intermediate among values for the species. Mean forb height in this meadowlark's territories was less than for the Bobolink and Henslow's Sparrow and greater than for the Western Meadowlark, Savannah Sparrow, and Vesper Sparrow. Vertical vegetation density was similar to most species but significantly less than in Henslow's Sparrow territories. Density of vegetation on the ground in Eastern Meadowlark territories was less in areas occupied by the Western Meadowlark and Vesper Sparrow and greater than in Bobolink and Henslow's Sparrow territories. Coverage by low vegetation (effective height 5 cm) was slightly greater than in Bobolink territories and similar to Savannah and Vesper sparrow territories. The mean effective height was less than that in Henslow's Sparrow territories but greater than in Western Meadowlark and Savannah, Grasshopper, and Vesper sparrow territories. Litter in Eastern Meadowlark territories was deeper than in Western Meadowlark and Vesper Sparrow territories and shallower than in Bobolink and Henslow's Sparrow territories. Eastern Meadowlark territories were closer to fence lines than other species and not far from cultivated fields and woods. Territories averaged 165.8 m from a woodlot (range 10-330 m), 11.6 m from a fence line (range 0-60 m), and 45.8 m from a cultivated field (range 0-180 m). In early spring, the Eastern Meadowlark occupied areas with greater grass cover and less bare soil than the Savannah Sparrow, but occurred where the overall vegetation height and litter depth were lower. Substrates used by this meadowlark for singing and perching included 50.0% grasses, 41.4% posts, 7.7% trees, and 0.9% in flight. Foraging substrates included 54.8% grass 0-5 cm tall, 36.4% grass 6-10 cm tall, and 8.7% grass 11-15 cm tall. It used grass cover more than any other species, predominantly for foraging in low grasses. Half of singing activity was in grass cover but forbs were also used for singing and perching. Litter depth at nests was greater than for the Bobolink and Savannah and Grasshopper sparrows. Forbs at this meadowlark's nests were of intermediate height and widely dispersed. Forb coverage at nests was the least compared with nests of Bobolinks and Savannah and Grasshopper sparrows. Species arranged in increasing order of vegetation richness (vegetation density and height, and litter coverage and depth) included Western Meadowlark, Vesper Sparrow, Savannah Sparrow, Grasshopper Sparrow, Eastern Meadowlark, Bobolink, and Henslow's Sparrow. There were many similarities in habitat occupancy of the species, especially among the Savannah Sparrow, Grasshopper Sparrow, and Eastern Meadowlark. The range in differences in the habitat ranking was low. Differences in patterns of foraging in grasses by the species may have been sufficient to bring them into contact with different types of food items.

The Eastern Meadowlark exhibits limited to no evidence of edge avoidance, although nests near forested edges may be subject to higher rates of predation and parasitism. In Wisconsin, Renfrew et al. (2005) pooled results for the 2 meadowlark species. Nest density was lower near edges, but not significantly. Nests within 50 m of a wooded edge tended to have higher predation rates than those the same distance from nonwooded edges, but not significantly. There were no differences in predation rates 100 m from wooded and nonwooded edges. Edges were bordered by fence lines and the Eastern Meadowlark may establish territories close to them so that they can use trees as singing perches. In Illinois, nests were a median of 80 m (range 3-400 m) from cropland edges and

a median of 400 m (13-1,000 m) from a wooded edge. Results suggested that it did not avoid cropland-grassland edges but may avoid wooded edges. Significantly fewer nests were found within 100 m of wooded edges. Proximity to edge had no effect on daily nest survival (Walk et al. 2010). In Kentucky and Tennessee, there were no differences in its abundance at roads or areas 300 and 600 m from roads (Lituma and Buehler 2016). In Kansas, meadowlarks that nested within 100 m of woodland edges experienced higher rates of nest parasitism. The mean distance of nests from agricultural edges was 44 m compared with 50 m from woodlands, suggesting no avoidance of either edge type (Hull 2002).

There is little evidence that the Eastern Meadowlark is area sensitive. In Illinois, Herkert (1994a) concluded that it was positively correlated with patch area. Eight-eight percent of transects in grasslands larger than 100 ha contained suitable habitat and 100% were occupied. All transects in smaller grasslands contained suitable habitat but only 77% were occupied. The probability of its occurrence was approximately 30% in 1-ha patches, 55% in 10-ha patches, 85% in 100-ha patches, and 98% in 1,000-ha patches. He concluded that the minimum patch size for the Eastern Meadowlark was 5 ha. This was the area at which its probability of occurrence reached 50% of the maximum. It occurred less than 50% of the time in grasslands smaller than 5 ha, about twice the size of a territory. In Maine blueberry fields, it was positively correlated with patch size, but it had a low rate of occurrence (40%) even in 500-ha patches reflecting the fact that many of the sites were unsuitable habitat. Vickery et al. (1994) concluded that size was an important factor in their study area but that their results were probably not applicable to other grassland systems. This study and the one by Herkert (1994a) are frequently cited as demonstrating that the Eastern Meadowlark is an area-sensitive species. It was only mildly area sensitive in Illinois, occurring in 50% of patches as small as 5 ha. Walk et al. (2010) and Walk and Warner (1999) found it in every grassland they studied, ranging from 3-142 ha. They concluded that there was no evidence of area sensitivity or that nest survival was related to patch size. Nest survival rates were higher in small than large grasslands. Even small grasslands were important from a conservation perspective. McLaughlin et al. (2014) concluded that patch size was not an important predictor of Eastern Meadowlark occurrence or density in Nebraska and Iowa. In New York, Norment et al. (2010) found it in fields 5-98 ha in size. Grassland area had little effect on nest survival in hayfields and pastures, but survival was lower in larger fallow agricultural fields. Their results were influenced by lower survival rates in 1 large fallow field. In Wisconsin, grassland size was not an important variable influencing its presence and abundance (Ribic and Sample 2001). In Missouri, there were no effects of grassland area on its density or nesting success. The smallest prairie that Winter and Faaborg (1999) sampled was 31 ha, so their patch sizes may have been too large to detect area sensitivity. In Ohio, 10 occupied fields averaged 14 ha and 24 occupied CRP lands averaged 10 ha (range 1-26 ha; Swanson 1996).

Swanson (1996) and Hull (2002) recommended management practices for maintaining habitat for the Eastern Meadowlark. Woody encroachment should be limited by mowing every 3-5 years. This also removes accumulations of dead vegetation that may make cover too dense to be suitable. Mowing should be done later in summer after young have fledged and left the area. Light grazing that leaves 40% or more vegetative cover at least 25 cm tall is beneficial because it results in vegetation of intermediate density and height; grazing also removes woody vegetation. Tallgrass prairie should not be grazed to below 25 cm during the breeding season. Burning in early spring

can be beneficial but it is desirable to maintain a complex of burned and unburned areas. No more than 50-60% of an area should be burned at once.

The Eastern Meadowlark roosts nocturnally on the ground, usually in dense grass (Jaster et al. 2020).

All Ontario nests were on the ground, often in a depression. Most nests (88.2%) were hidden in or under grass clumps, 5.1% were under clumps of other plant species, and 2.9% were at bases of shrubs or small trees. One nest each (total of 2.9%) was under pine branches and forbs, under manure and straw, under a piece of linoleum, and under a mound of sod. One nest was within 1 m of a paved road (Peck and James 1987).

Nests are almost always in a depression in the ground. These are usually scraped out by the female, but occasionally deeper depressions caused by cattle or horse tracks are used. Nests are occasionally built in rather deep bowls or natural depressions, allowing nesting in areas with very little cover and grass heights as low as 5 cm. Unused nests are commonly built or partially built early in the season when females may not have attained the full sexual and physiological conditions required for nesting. Of 388 Illinois nests, 126 (32.5%) were not used; 32.0% of these had no canopies and only 18.0% had full canopies. Of used nests, 17.3% had no canopies and 38.2% had full canopies. Some nests have obvious runways that may be as long as 1 m leading to the entrance. Of 377 Illinois nests, 19.1% were excellently concealed, 47.8% were well concealed, 28.9% were fairly well concealed, and 4.2% were poorly concealed. There was no relationship between nest concealment and fledging success. Nests are not used more than once (Gross in Bent 1958; Jaster et al. 2020; Roseberry and Klimstra 1970; Wiens 1969). Nest orientation is nonrandom, with most nest entrances facing north or east away from prevailing winds. In Kansas and Oklahoma, nests were oriented more to the east before the median date of nest construction and more northward later in the season. The prevailing winds were from the south and shifted significantly from the southwest to the southeast as the season progressed. Nest orientation in the opposite direction of the prevailing winds has thermoregulatory advantages by being out of the wind and providing shading from the sun. Orienting nests in the direction of wind-blown grasses might confer some structural advantages in constructing nest domes. In Kansas, nests were normally oriented east to northeast, but were oriented southward in a drought year. This may have diminished morning solar radiation and increased cooling due to the prevailing southerly winds. In Illinois, most nests on slopes faced downward but a few faced upslope. An Oklahoma nest on a steep slope faced downward. A nest within 2.7 m of a busy railway faced away from it. Nest locations do not appear to be correlated with any particular position in the territory or with singing perches (Corimanya et al. 2024; Gross in Bent 1958; Jaster et al. 2020; Long et al. 2009; Roseberry and Klimstra 1970; Shackford 1990; Wiens 1969).

Males are territorial and begin defending territories as early as 4 weeks prior to the arrival of females. Territory maintenance continues until young of the first brood fledge, but the intensity of defence varies with breeding stages. Defence is most intense preceding incubation of the first clutch with secondary peaks of lower intensity preceding each subsequent nesting attempt. Males defend against intruding resident and migrant males and migrant females. Females are not aggressive toward each other even when mated to the same male. They do not establish subterritories within the male's territory. Territory boundaries and size flux considerably as a result

of changes in population density, relocation of female activity centres, and changes in habitat availability and suitability. In 1 Wisconsin study area, territories were initially small and became larger; the opposite was true at another Wisconsin site. Initial shrinkage of larger territories is probably more common as new birds arrive and attempt to establish a territory. When a male disappears, his territory is absorbed by his neighbours. Males that are unsuccessful in attracting a mate either leave voluntarily or are forced out by their neighbours. During boundary disputes, males keep between their mate and the intruder, possibly to lessen the likelihood of extra-pair copulations (Lanyon 1956a; Jaster et al. 2020; Knapton 1987, 1988b; Wiens 1969). Territory sizes of 1.1-8.1 ha have been reported, with most 2-4 ha. In 1 Wisconsin area, territories ranged from 1.2 to 6.1 ha but most were 2.8-3.6 ha. At another Wisconsin site, territories averaged 2.3 ha (range 1.7-3.2 ha). Territory size varied inversely with population density at this site. When 6 territories were present, they averaged 2.59 ha (range 1.94-3.12 ha); when 12 territories were present, they averaged 2.33 ha (range 1.50-3.08 ha). Kansas territories were 1.2-4.8 ha. Large territories were in open grazed grassland with few trees and shrubs. Small territories were in open ungrazed grassland with lush ground cover and numerous scattered trees. In New York, 15 territories averaged 2.8 ha. Two other New York territories were 3.6 ha and 8.1 ha, but the area within them that was regularly used was the same: 2.4 ha. In Kansas, 1 pair had a territory of 1.1 ha. Another male defended an area of 0.57 ha but did not attract a mate and left the area (Fitch 1958; Gross in Bent 1958; Hull 2002; Jaster et al. 2020; Lanyon 1956a; Wiens 1969).

There is almost no interspecific aggression among the Eastern Meadowlark and most other grassland species. The exception is the Western Meadowlark. The 2 meadowlarks defend mutually exclusive territories and each is as aggressive to the other species as it is to conspecifics. Interspecific territorialism may serve to eliminate competition between these 2 closely related species with similar habitat and diet requirements (Lanyon 1956a; Wiens 1969). In Ontario, Eastern Meadowlarks responded aggressively to Western Meadowlark songs where the 2 species were in close contact, but did not recognize its song as a threat elsewhere (Falls 2000). In areas of contact, males of both species have more intense black and a larger black V on their breast and a brighter yellow glow on the breast, probably to increase interspecific communication. More fighting and greater intensity of fights occur in areas of contact, with males involved in interspecific territorial disputes suffering more wounds than those engaged only in intraspecific territoriality (Jaster et al. 2020; Rohwer 1973).

Natal philopatry rates are low. In Illinois, 1 of 343 juveniles (0.3%) returned in a subsequent year. Kerschner et al. (2004b) considered it unlikely that postfledging movements were used to locate future breeding sites or to establish navigational landmarks for future use during migration. In Wisconsin, 1 of 36 nestlings (2.2%) was found in the following year, 0.96 km from the natal site. One of 2 fledglings (50%) returned the next year to a site 0.48 km from where it was banded (Jaster et al. 2020).

Adult site tenacity appears to be high in both sexes. In Wisconsin, 8 of 14 males (57.1%) returned to breed in another year; 7 (87.5%) returned to their previous territory and 1 (12.5%) returned to an adjacent territory. Twelve of 22 females (54.5%) returned to breed and 9 (75%) returned to their former territory. Of the 3 that moved, 2 were forced to do so because there was no male on the territory (Jaster et al. 2020). Lanyon (1956a) stated that both sexes exhibited a strong homing behaviour that was directed toward their former territory rather than toward a particular mate. In

Illinois, densities in individual hayfields varied by as much as 2.5-fold annually, but the total number in all hayfields tended to remain constant. This supported the theory that there may have been considerable switching among habitats from 1 year to the next (Graber and Graber 1963).

Limiting Factors

Eggs have been reported in Ontario nests from the beginning of May until the first week of August, with most present from the last week of May until mid-June (Peck and James 1987). Pairing occurs immediately once the females arrive and nest building begins about a week later. First nests take 6-8 days to construct but later nests may be built within 3-4 days. Females may spend as long as 18 days nest building, but not all at the same nest. Multiple nests may be started and abandoned. It is unknown if there is an interval between nest completion and initiation of egg laying. Material may still be added to the nest after the first eggs are laid. Eggs are laid at the rate of 1 a day. Incubation usually begins with the laying of the last egg. Incubation of 5-egg clutches may begin with laying of the third, fourth, or fifth egg, but mostly with the fourth egg. Incubation takes 13-14 days, rarely as long as 15-16 days. Incubation periods of 12-13 days have been reported in Ontario. Hatching usually occurs on the same day, but may be spread over 2 days. The nestling period is 10-12 days but young may leave the nest when they are only 8 days old if they are disturbed (Gross in Bent 1958; Jaster et al. 2020; Peck and James 1987). In Illinois, the timing of spring initiation of nesting and the duration of nesting were important to overall nesting success, determining whether there was sufficient time to renest or raise a second brood. Only 3 of 129 nests (2.3%) were initiated after 7 July and the latest nest was begun on 23 July (Roseberry and Klimstra 1970).

The Eastern Meadowlark may raise 1 or 2 broods in a year, but never more than 2. Double broods are probable in Ontario but have not been confirmed. The frequency of double broods varies considerably geographically but the reasons for this are uncertain. In 1 area of Wisconsin, females that successfully raised a brood always attempted another one. In another Wisconsin area, single and double broods were equally common. In Illinois, no obvious peak in egg laying occurred that was indicative of second broods. If second broods were initiated, it was not until mid-May or later. At another Illinois site, 7 of 19 females (36.8%) that successfully reared their first brood attempted a second brood. Only 3 of 34 females (8.8%) successfully reared a second brood. Of the 19 females that initiated a second brood, 2 (10.5%) remained on site and ceased breeding and 10 (52.6%) emigrated from the study area. Many of these were found within 10 km of the nesting area within 3 weeks of emigration and there was no indication that they attempted another nest (Kerschner et al. 2004a; Lanyon 1956a; Roseberry and Klimstra 1970; Wiens 1969). It may be a persistent renester in some areas, making as many as 5 attempts to raise a brood. Replacement nests may be uncommon in other areas. In Illinois, 8 of 14 unsuccessful birds (57.1%) renested. Thirty-four females built a total of 52 nests (mean 1.34 per season, range 1-4). Females renested an average of 9.9 days after nest loss. Successful females did not initiate their second nest until 27.7 days after the young left the nest. At this site, individuals attempted relatively few clutches within a season; females seldom attempted more than 3 clutches. Birds ceased breeding with at least 2 months still available in the breeding season. Double brooding added little to the annual productivity because second nests were significantly less successful than early nests. In other areas, replacement nests were started 2-3 days after the first nest was lost. In Illinois, the distance between successful nests was 111.5 m, similar to the distance of 79.0 m between unsuccessful nests (Gross in Bent 1958; Jaster et al. 2020; Kerschner

et al. 2004a; Lanyon 1956a). Clutches of 3-6 eggs were reported in Ontario, plus an 8-egg clutch. The mean clutch size was 4.53 eggs and 5 eggs was the most frequent clutch size (Peck and James 1987). In the Region of Niagara, Knapton (1988b) reported clutches of 3-6 eggs; 5-egg clutches were most common. Seven of the 8 6-egg clutches (87.5%) were laid by females mated to a polygynous male. There were no significant differences in clutch sizes of females in polygynous (4.70 eggs) or monogamous (4.51 eggs) relationships. Overall, clutch sizes of 3-7 eggs have been reported, with 5-egg clutches most abundant. In Illinois, the mean size of 101 clutches was 4.16 eggs. Clutch size declined as the season progressed: 4.36 eggs for clutches initiated prior to 27 May and 4.03 eggs for later nests. In Kentucky and Tennessee, there was no evidence that clutch size declined significantly with the season. Clutch size increased initially, peaked in mid-season then gradually decreased with an overall mean of 4.6 eggs. In Illinois, there was no difference in clutch size, hatch rate, survival rate, and fledging success between initial and subsequent nesting attempts. Initial nests had a mean clutch size of 4.56 eggs compared with 4.22 eggs for subsequent nests. Females laid an average of 6.8 eggs per season. Mean clutch sizes reported elsewhere include 4.76 and 4.57 eggs in New York, 4.7 eggs in West Virginia, 4.81 eggs in Wisconsin, 4.8 eggs in Missouri, and 5.2 eggs in Kansas. Mean clutch sizes range from 4.1 to 5.2 eggs (overall mean 4.4 eggs). Clutch sizes tend to increase with latitude (Giocomo et al. 2008; Gross in Bent 1958; Jaster et al. 2020; Kerschner et al. 2004a; Norment et al. 2010; Roseberry and Klimstra 1970; Suedkamp Wells et al. 2008).

Both sexes are capable of breeding when they are 1 year old (Jaster et al. 2020). It is unknown what proportion of yearling males fail to defend a territory or attract a mate. It is probable that all yearling females breed. Females select territories where the male is singing conspecific songs and copulations all occur within territories. These factors are important in minimizing the rate of hybridization with the Western Meadowlark. Mate changes within a season occur only when the original male disappears or is displaced by another male. The pair bond is maintained until the female has completed parental duties or she aborts the first nesting attempt. Mate guarding by males is a successful barrier to extra-pair copulations. No successful stolen copulations were documented in a 4-year Wisconsin study (Jaster et al. 2020; Lanyon 1956a). The mating system is polygynous, with a higher proportion of males being polygynous than monogamous. Polygynous males typically have 2 mates, rarely 3. Later-arriving yearling females often become secondary females in polygynous relationships. Different arrival times of the year classes of females and often low nesting success frequently result in asynchronous nesting by the females of a polygynous male. This allows the male to care for both nests. In New York, 50% of males were polygynous; 70-80% were polygynous in Wisconsin (Gross in Bent 1958; Jaster et al. 2020; Lanyon 1956a; Wiens 1969). Knapton (1988b) studied the nesting strategy of the Eastern Meadowlark in Niagara Region. Polygyny occurred in all 4 years of the study, but its prevalence varied annually from 38% to 56% of males (average 50%). Females in polygynous relationships hatched a significantly higher proportion of their eggs and fledged a significantly higher proportion of their nestlings than females in monogamous relationships. There were no significant differences in growth rates and mass of nestlings or in food items and delivery rates to nestlings of females in polygynous and monogamous relationships. Starvation rarely occurred and was not an important factor, suggesting that male feeding contributions were not significantly different at nests of primary and secondary females and nests in monogamous relationships. Nests of females in monogamous relationships suffered higher

rates of predation. Polygynous males appeared to be high-quality older birds that provided better parental care in the form of predator protection. Six males that returned in subsequent years switched from being monogamous to being polygynous. One male was polygynous for the first 3 years and was monogamous in the fourth year when he switched territories.

The Eastern Meadowlark forages almost exclusively on the ground, both inside and outside the territory. It obtains food from the surface of the ground, by probing beneath the soil, and searching under clods of earth, manure, and other objects. It hunts for seeds and insects through grasses and forbs, gathering them from fallen or standing stalks. It forages in grasslands as well as in grain and soybean fields. When the wind is strong, it may fly to the lee side of a field and advance across it on foot into the wind (Gross in Bent 1958; Jaster et al. 2020; Kerschner et al. 2004a).

Young were fed cutworms, grasshopper nymphs, other small insects, and spiders. By the time they were 6 days old, they were fed grasshoppers, crickets, and ground beetles (Gross in Bent 1958). Ostrand and Bollinger (2012) used esophageal ligatures to collect 29 diet samples from nestlings in 19 Illinois nests. Spiders represented the greatest volume (44%) and frequency (53%) of food items. The spiders consisted of 80% wolf spiders, 10% jumping spiders, 4% crab spiders, 4% orb weavers, and 2% sac spiders. Orthopterans were second in volume (23%) and numbers (13.5%), with the orthopteran sample consisting of 46% crickets, 31% grasshoppers, and 23% katydids. Caterpillars constituted 18% of the volume and 14.6% of the numbers of food items, including 73% cutworms and 27% sulphur butterflies; no adult lepidopterans were consumed. Other taxa by volume and numbers respectively included 10.8% and 15.6% beetles (mostly ground and scarab beetles), 2.0% and 1.0% cicadas, and 1.9% and 2.1% stink bugs. Although spiders are occasionally identified in the diet of adults, they eat mostly orthopterans, beetles, and caterpillars. In this area, adults preferentially fed their young spiders, particularly wolf spiders. These are rather large and commonly occupy the surface of terrestrial habitats. Most were females carrying egg sacs and their larger size and presence of egg sacs may have made them more conspicuous. The spiders in the sample were suggestive of the invertebrate fauna of soybean fields. Soybean fields are not usually treated with insecticides and may have abundant food resources (Kerschner et al. 2004a).

Adults eat mostly insects in the summer, particularly cutworms and other caterpillars, beetles, and grasshoppers. Later in summer and in autumn and winter, the Eastern Meadowlark eats mostly seeds, including waste grain (corn, wheat, rye, and oats). In early spring, it may pull up and eat sprouting clover, corn, and oats. This occurs mostly in the southern states during spring migration. It rarely consumes vertebrates such as lizards (Beal et al. 1916; Gross in Bent 1958; Jaster et al. 2020). In Oklahoma, Wiens and Rotenberry (1979) analyzed its diet but pooled some results for both meadowlark species. In 3 years, the diet consisted of 30%, 40%, and 76% dry weight beetles; 20%, 40%, and 16% orthopterans; and 45%, 18%, and 2% lepidopterans. It was the most highly insectivorous species they studied, with seeds never comprising more than 5% of the diet and usually less than 1%. Ground beetles and, to a lesser extent, scarab beetles made major contributions to the diet. Crickets were the most important orthopterans in 2 years. Short-horned grasshoppers were most important in 1 year. Phytophagous arthropods were the most important prey, but it also ate large quantities of predaceous and omnivorous prey. Other prey it consumed included ants, other beetles (weevils, and long-horned, leaf, lady, and click beetles), stink bugs, leaf-footed bugs,

spiders, and traces of grass and legume seeds. The dietary niche overlap of the Eastern Meadowlark was 26% with the Upland Sandpiper, 68% with the Dickcissel, and 83% with the Grasshopper Sparrow. Its dietary overlap with the Dickcissel and Grasshopper Sparrow was high in 1 year, less in the next year, and quite low in the final year. The mean size of the Eastern Meadowlark's prey was 8.66 mm, 9.42 mm, and 10.52 mm in the 3 years, larger than for the Dickcissel and Grasshopper Sparrow but similar to that of the Upland Sandpiper. Beal et al. (1916) summarized the contents of 890 stomachs collected in the southeastern United States. The diet consisted of 78.12% animal food and 21.88% vegetable matter. Orthopterans were the most important food group, comprising 27% of the overall diet. These included all types of grasshoppers plus crickets. They constituted 9% of the January diet and increased rapidly until October when they represented 56% of the diet, then declined to 40% in November; 52.4% of all stomachs contained grasshoppers. Beetles were second in abundance in the diet, peaking in May at 28%. These were mostly dung beetles, but June beetles, ground beetles, and weevils were consistent components of the diet. It ate true bugs throughout the year but they constituted only 3% of the annual diet; they were mostly stink bugs. Caterpillars comprised about 13% of the diet, peaking in May at 28%. Spiders and millipedes represented 3% of the total diet. Other animal foods included flies, earwigs, cattle ticks, snails, and small crustaceans; 3 stomachs contained bones of frogs or toads. Vegetation eaten included fruit, grain, and weed seeds. Fruit constituted less than 2% of the diet and was predominantly wild fruit. Grain totalled 9% of the diet and consisted mainly of corn with lesser amounts of wheat and oats. Most grain was consumed in winter indicating that it was waste grain gathered from fields. Weed seeds represented 7% of the diet and were eaten predominantly in winter. Seeds commonly consumed included those of ragweed, barnyard grass, smartweeds, sorrels, mustards, amaranths, and gromwell; clover seeds were rarely eaten. Gross (in Bent 1958) reported that the diet consisted of 74% animal matter and 26% vegetable matter, with orthopterans, beetles, and caterpillars forming the bulk of the food. Additional animal foods included ants, wasps, scale insects, and adult moths and butterflies, which were rarely consumed. The vegetable matter eaten was essentially identical to what Beal et al. (1916) reported. The fruit eaten included those of cherries, strawberries, and blackberries.

Near Ottawa, Picman (1992) used cameras to identify predators at artificial nests containing quail eggs. Thirty-two of 144 egg predation events (27.2%) were by the Eastern Meadowlark. It was the second-most important predator after the striped skunk and could therefore affect the reproductive success of other grassland birds such as the Savannah Sparrow, Bobolink, and Red-winged Blackbird. It did not eat the egg contents suggesting that the motive for the egg destruction was to reduce competition for food resources.

The Eastern Meadowlark is an infrequent host of the Brown-headed Cowbird. The incidence of parasitism may be higher than reported because it is a partial rejecter of cowbird eggs. In Illinois, it rejected cowbird eggs at a rate of 37.5-40%. It is one of few species with intermediate levels of rejection suggesting that it may be evolving from an acceptor to a rejecter species. Other studies noted nest desertion after parasitism. In 1 case, a second nest was built over a cowbird egg (Gross in Bent 1958; Peer et al. 2000; Rothstein 1974). In Kansas, parasitized nests had an average of 1.4 fewer eggs per clutch. Parasitism rates are low in the east and south and higher in the west. Parasitism rates are higher where cowbird densities are higher and where cattle are more abundant. Parasitism is not considered a significant limiting factor. Eleven of 390 Ontario nests (2.8%) were

parasitized. Parasitism rates reported elsewhere include 1 of 51 nests (1.9%) in Quebec; 0 of 131 nests and 6 of 38 nests (15.8%) in Wisconsin; 0 of 87 nests in Kentucky and Tennessee; 0 of 131 nests in Indiana; 0 of 50 nests in New York and Oklahoma; 0 of 246 nests, 2 of 450 nests (0.4%), and 4 of 221 nests (1.8%) in Illinois; 0 of 25 nests in New York; 5 of 31 nests (16.1%) in Nebraska; 31 of 512 nests (6.1%) in Oklahoma; and 18 of 67 nests (26.9%) in Kansas (Galligan et al. 2006; Giocomo et al. 2008; Jaster et al. 2020; McCracken et al. 2013; Peck and James 1998b; Renfrew et al. 2005; Rivers et al. 2010; Roseberry and Klimstra 1970; Savignac 2011b; Verheijen et al. 2022; Walk et al. 2010).

Hybridization between the 2 meadowlark species is rare. Although males readily mate with females of either species, females preferentially select territories where males are singing conspecific songs. In addition, males copulate only within their territories and the 2 species defend mutually exclusive territories. These mating strategies coupled with interspecific territoriality function to minimize the potential for hybridization. In Wisconsin, 1 incomplete interspecific mating occurred across territorial boundaries but over 4 years there was no evidence of interbreeding in more than 100 pair bonds where both species were common (Lanyon 1956a). The isolating mechanisms may break down at the edge of the ranges where 1 species is rare and the other is common. In southwestern Ontario over a period of 4 years, there were 9 nests built by mismatched pairs consisting of a male Eastern Meadowlark and 2 female Western Meadowlarks. It appeared as though the females were unable to find a male Western Meadowlark on territory and had to settle on an Eastern Meadowlark territory. Hybridization is likely to occur only on the very eastern edge of the Western Meadowlark's range, with the Ontario hybridization events the first documented. The hybrid young were not very viable, with fewer than 50% of eggs hatching and only about 25% of young surviving. Vocalizations of the young were atypical of both species and they demonstrated no increase in the size of their gonads despite being injected with hormones. Young of matched pairs exhibited the proper gonadal responses. Hybridization is very infrequent and does not occur where both species are common. It is not a threat to the gene pool of either species because of the low viability of the hybrids (Szijj 1966). Hybridization of the 2 species has also been documented in Quebec where the Western Meadowlark is rare (Rail in Gauthier and Aubry 1996).

The most significant limiting factors for the Eastern Meadowlark are habitat loss and degradation, and these factors are affecting it range-wide. Habitat loss is due predominantly to changes in agricultural practices. It benefitted immensely from the initial conversion of forests into agricultural fields. Originally, much farmland was devoted to raising livestock so that pastures and hayfields were prevalent in the landscape. Two major changes in farming occurred that affected cropping systems. The first was the mechanization of machinery, with tractors and other motorized equipment reducing the need to keep horses and provide pastures and hayfields for them. The second was a switch from raising livestock to cash cropping, planting row crops such as corn, soybeans, and winter wheat. Because its abundance is directly linked to the amount of grassland, these changes resulted in declines in its population. The area of hayfields in Ontario decreased strongly from 1930 to 1940 and again in 1965-75 and 2006-11. The amount of improved pasture decreased by 77% 1966-2011. The amount of unimproved pasture decreased by 38% 1971-2011. The decline in hayfields is directly linked to changes in the livestock industry and declining numbers of cattle (Askins et al. 2007; McCracken et al. 2013; Savignac 2011b). Declines in the Carden Plain between the 2 atlases were due to conversion of pastures and hayfields to row crops (Merondun et

al. 2024). Although changes in agricultural practices have had the greatest effects, several other factors contributed to habitat loss. These include natural succession of abandoned farmland and other early successional habitats, tree planting, and urbanization (Jaster et al. 2020; McCracken et al. 2013; Rail in Gauthier and Aubry 1996; Savignac 2011b; Tozer 2012).

In Nebraska and Iowa, McLaughlin et al. (2014) studied the effects of nearby urban areas on Eastern Meadowlarks breeding in tallgrass prairies. They measured its occurrence and density along a rural to urban gradient. Urbanization had a strong negative effect on it. It exhibited the strongest response of the grassland species they studied. Adjacent urban habitat negatively affected both its probability of occurrence and density. Its probability of occurrence was 75% in areas of low and moderate urban intensity and 10% at high urban intensity. Urban intensities were defined as: low, 3.7% developed; moderate, 17.5%; and high, 50.2%.

Declines in habitat quality are related mostly to changes in agricultural practices. Hayfields were traditionally planted predominantly to grasses or grass-legume mixes, with the legumes being mostly clovers in the genus *Trifolium*. Many fields are now planted to pure crops of alfalfa or alfalfa with lesser amounts of grasses. The abundance of the Eastern Meadowlark declines with increasing amounts of alfalfa in hayfields. Pure stands of alfalfa are typically unsuitable habitat because the vegetation is too dense to attract it. Lightly or moderately grazed pastures may provide quality nesting habitat, but most Ontario pastures are now intensively grazed. Originally, most farms had a few head of cattle and grazing pressure on pastures was fairly low. Now most farmers do not have cattle and those that do tend to have large herds associated with beef and dairy production. Pastures associated with these herds are typically heavily grazed, with the grass cropped to the ground. These heavily grazed pastures do not have adequate vegetation coverage to support the Eastern Meadowlark.

The conversion of many hayfields to alfalfa has resulted in faster and denser growth of crops. The higher productivity in these fields allows them to be cut earlier in spring and more frequently, usually 3 times within a growing season. Earlier cutting of hayfields is another significant limiting factor to Eastern Meadowlark populations (Gross in Bent 1958; Hull 2002; McCracken et al. 2013; Savignac 2011b). In CRP fields in Kansas, mowing caused females to desert the area. Granfors et al. (1996) recommended that mowing be conducted after 15 July and that spot-mowing be conducted to control noxious plants because meadowlarks did not abandon territories if they were only partially mowed. In Arkansas, Luscier and Thompson (2009) examined nest survival and breeding density of the Eastern Meadowlark on early hayed (26-31 May), late hayed (17-26 June), and unhayed fields. The effects of late haying were trivial but early haying had a strong negative effect on nest survival rates. Over 80% of nests in early hayed fields were destroyed. Surviving nests were in unmowed corners of fields, so no nests survived haying. There was a more pronounced effect of haying in fields closer to residences because there may have been domestic cats associated with these fields. Delaying cutting by 2-3 weeks in early hayed fields would provide sufficient time to complete a nesting cycle. In Michigan, meadowlarks successfully fledged 1 brood before mowing occurred but ceased breeding after mowing (Hull 2002). Periodic mowing at 3-5-year intervals to remove excessive amounts of woody vegetation can be beneficial (Hull 2002; McCracken et al. 2013). In New Jersey, 0.25-ha refugia left in mowed fields were not beneficial for this meadowlark (Allen et

al. 2019). Wolcott et al. (2023) recommended that grassland management be deferred until August to protect both nests and fledglings.

The response of the Eastern Meadowlark to grazing varies depending upon the intensity of grazing and the type of grassland. Low- to moderate-intensity grazing that maintains grass heights of 10-30 cm can be beneficial. Grazing is particularly beneficial in tallgrass prairies habitats where the vegetation may be taller than it prefers. It responds negatively to heavy grazing, particularly in habitats with shorter grasses, but excessive grazing can make any habitat unsuitable. In Illinois pastures, there was an inverse relationship between grazing and use by this meadowlark. In 3 years, heavy grazing occurred in 1 pasture but grazing in it was less intense in the fourth year. Nest density was 3.7-5.5 times higher in the year of lighter grazing. Another field was heavily grazed in 2 years, with no nests present in one of those years. In the third year, grazing was less intense and it was reseeded and ungrazed in the fourth and fifth years. Nest density in the year of lighter grazing was 4.3 times higher than in the 1 year of heavy grazing that meadowlarks were present. In the 2 years when the field was not grazed, nest density was 13-13.7 times greater than in the year of heavy grazing and 3-3.2 times greater than in the year of lighter grazing. Heavy grazing resulted in grass 2.5-7.6 cm tall with scattered clumps of grasses and forbs 30 cm tall. In the year of lighter grazing, there was uniform distribution of grasses and forbs 12.5 cm tall (Granfors et al. 1996; Hull 2002; McCracken et al. 2013; Powell et al. 2008; Roseberry and Klimstra 1970). In Ontario, Ethier and Nudds (2017) concluded that grazing appeared to be beneficial for the Bobolink only when cattle stocking densities were less than 0.198 cows per ha per day. Current stocking rates average 7 times greater than this. It is probable that the Ontario stocking rates are also too high for the Eastern Meadowlark. In Grey County, rotational grazing did not affect the number of meadowlark territories. Pairs attempted to renest after failure. Some territories shifted and some were abandoned. About 6 weeks between grazing periods is required to allow young to fledge from renesting attempts (Campomizzi and LeBrun-Southcott 2022). Grazing has the potential to have other adverse effects. These include direct trampling of nests by livestock and cropping of cover near the nest by cattle can expose nests and make them more vulnerable to predation (Granfors et al. 1996; Hull 2002; Roseberry and Klimstra 1970). In Wisconsin, Nack and Ribic (2005) recorded cows removing both eggs and nestlings of Eastern Meadowlarks from nests and either eating them or carrying them off.

The effects of fire on the Eastern Meadowlark vary depending upon the initial quality of the habitat. Fires every 2-4 years may be beneficial in reducing excessive coverage by shrubs and dense litter accumulations. Different responses to burns have been reported with some studies finding no difference in burned and unburned areas. Other studies have found it either more or less abundant in burned than unburned areas. Under optimum conditions, fire should be infrequent enough to allow modest levels of litter to accumulate yet frequent enough to keep woody vegetation in check. The optimum frequency of burns will vary geographically and by how quickly litter and woody vegetation accumulate. In Kansas and Illinois, it was more abundant 1-3 years postfire than in the year of the burn. In Arizona, birds responded positively to burning, especially in the second year postfire. It avoided freshly burned fields and declined on unburned plots over a period of 7 years, probably due to invasion by shrubs. At another Kansas site, its abundance was unaffected by burning in wet years but was reduced in drought years. In another Arizona study, its abundance was significantly lower 1 year postfire than in unburned native grasses. There was no difference in its

abundance in nonnative grasses. In Kansas, it had higher nest survival in annually burned and ungrazed pastures than in pastures managed with patch-burn grazing (Askins et al. 2007; Bock and Bock 1992; Hull 2002; McCracken et al. 2013; Powell et al. 2008; Swanson 1996; Verheijen et al. 2022).

The Eastern Meadowlark has the potential to be adversely affected by chemicals used in the agriculture industry. Carbofurans probably contributed to its decline prior to their being taken off the market but these continue to be used in South America. The greatest numbers are killed in the southeastern United States where pesticides are used on specialty crops such as cotton and cranberries. Mortalities have been reported due to insecticides in Kansas and it decreased in Maine after lowbush blueberries were sprayed, although this may have been related to the resulting habitat changes. It may die after ingesting grain that has been poisoned for rodent or insect control. Insecticides may have indirect effects by reducing insect prey (Hull 2002; Jaster et al. 2020; McCracken et al. 2013; Savignac 2011b).

The Eastern Meadowlark is unusually sensitive to human disturbance at the nest. Females flushed even as late as the incubation stage may desert the nest. Disturbance during the nestling period is less likely to result in desertion, but adults become wary and secretive and delay visiting the nest (Jaster et al. 2020).

Late-spring snow or ice storms may make food unavailable and result in extensive mortality. In Colorado, many were killed during a hail storm (Gross in Bent 1958; Jaster et al. 2020).

Fragmentation of grassland habitat by wooded areas, roads, and other land uses may have adverse effects on the Eastern Meadowlark, although many studies found negligible effects due to edges and woody growth. Its productivity may be greater in grasslands larger than 10 ha, so reductions in field sizes may reduce densities. Other studies found no relationships between its density and field size. In the Midwest, daily predation rates increased with increasing field size. Some studies found that predation rates were higher 50-100 m from forest edge than further from edge; other studies found no difference in predation rates close to forests. Parasitism rates may be either higher or lower near forested edges. The woody vegetation may provide perches for cowbirds to search for nests or, alternatively, cowbirds may opt to parasitize the more frequent and diverse bird species within forests rather than in grasslands (Galligan et al. 2006; McCracken et al. 2013; Renfrew and Ribic 2003; Renfrew et al. 2005; Savignac 2011b).

In the United States, nesting success was depressed by increased rain in May and June to August and was lower when May temperatures were above or below average (Zuckerberg et al. 2018). In Quebec, abundance of the Eastern Meadowlark was correlated with the mean annual degree-days 10°C or higher in May, June, and July. It was associated with warm summers. DesGranges and Morneau (2010) considered it sensitive to climate change. Price (2004) predicted that the range of the Eastern Meadowlark might expand in southern Ontario if the average summer temperature increased by 2°C. Models that suggest that it may increase are unlikely to be correct. Habitat is the limiting factor for the Eastern Meadowlark and a more favourable climate will not improve or create habitat for it.

Status

The Eastern Meadowlark probably occupied much the same breeding range in Ontario prior to forest clearing by settlers as it does now. It would have been considerably less abundant with a much spottier distribution due to rarity of suitable habitat. It would have been restricted to habitats such as prairies (there were originally approximately 66,500 ha of this habitat), burns, and openings created by First Nations. Remains dating back to 1630-1650 have been found near Brantford and Bronte Creek in Halton Region. It was documented as being present in the province in the 1770s (Curry 2006; Falls 2000; McCracken et al. 2013; Savignac 2011b).

Deforestation by European settlers and conversion of forest cover to forage crops, pastures, and small grain fields created much more habitat for the Eastern Meadowlark in the east. The native grasslands were mostly destroyed, with only about 300 ha still remaining in Ontario. Replacement of tallgrass prairies with nonnative grasslands was beneficial because these grasses grew to optimum heights for it. Although its overall range may have been similar pre- and post-settlement, its distribution in the south became continuous rather than scattered. This phenomenon occurred throughout the east, and it expanded its range westward around the end of the 19th century. It became the dominant meadowlark in much of Illinois, Michigan, and Wisconsin and became much more abundant in its previous range (Gross in Bent 1958; Lanyon 1956b; McCracken et al. 2013; Savignac 2011b; Swanson 1996).

McIlwraith (1894) stated that the Eastern Meadowlark was found in all suitable areas in the province, particularly in the southwest. It occurred north to the Manitoba border where it was replaced by the Western Meadowlark. In both the Hamilton and Kingston areas, the Eastern Meadowlark was common during the late 19th and early 20th centuries (Curry 2006; Weir 2008). It arrived in Muskoka District around 1863 and was common at Port Sydney by 1901 (Mills 1981). It arrived later in the Clay Belt and from Thunder Bay to Rainy River District in the 1940s, by which time the Western Meadowlark was well established there (Falls 2000). Despite the Eastern Meadowlark's initial rapid increase, declines in its habitat began to occur as early as 1900 due to changes in habitat and agricultural practices (McCracken et al. 2013). The subsequent decline in its population was well documented in Elgin County: in 1891 and 1954, it was a common breeder but it was uncommon and local in 2000, with only a single pair present in some atlas squares (Lancaster et al. 2004). Baillie and Harrington (1937) reported that it was common in southern Ontario north to Lake Nipissing and further north to at least Englehart and the eastern end of Lake Superior. Notable declines began in the 1940s to 1950s and still continue (Black and Roy 2010; McCracken et al. 2013; Savignac 2011b). The first atlas determined that its range was concentrated from Sault Ste. Marie east to Sudbury and just north of Lake Nipissing south to the Great Lakes. There were a few breeding records for the Clay Belt and in the vicinity of Lake of the Woods. Its distribution was continuous south of the Shield, except that it was absent from a few squares in Essex and western Chatham-Kent. These areas are intensively farmed for cash crops and have limited grass cover. Its distribution in the Shield was spotty, where it was absent in forested landscapes. It was most abundant in mixed farmlands bounded by Listowel in the west, Flesherton in the north, Lindsay in the east, and Brantford in the south (Knapton in Cadman et al. 1987). James (1991) considered the Eastern Meadowlark common in the agricultural south and rare in the north to Thunder Bay and western Rainy River District and in the extreme east to the agricultural areas of the Clay Belt.

The second atlas demonstrated that there had been no change in the range of the Eastern Meadowlark since the first atlas. Its probability of observation declined significantly province-wide and in all regions except the more northern areas where it was too uncommon to conduct meaningful statistical analyses. It was most abundant south of the Shield, particularly in a band from Lake Simcoe to Kingston and in Grey, Bruce, and Dufferin counties. Other areas of higher densities included portions of southeastern Ontario and Haldimand County. These areas correspond with regions where there are the highest concentrations of livestock and consequently more hayfields and pastures (Leckie in Cadman et al. 2007). The area of highest density was different between the 2 atlases. A high proportion of farmers within the area of concentration during the first atlas changed their farming practices to grow mostly cash crops.

Breeding Bird Survey data indicate that the Eastern Meadowlark decreased at annual rates of 3.84% in Canada and 3.53% in Ontario 1970-2021 and at annual rates of 5.23% in Canada and 5.15% in Ontario 2011-21. All results were highly reliable (A.C. Smith et al. 2023).

The Eastern Meadowlark has been designated threatened in Canada and Ontario due to declines in its population and ongoing habitat loss and degradation. The long-term goal of the recovery strategy is to maintain stable self-sustaining populations. The short-term (2013-23) goal was to slow the annual rate of decline to no more than 1% per year. Thereafter, the long-term goal is to achieve population stability at 90% of the 2013 population. Stabilizing the population at the 2013 level was deemed impossible because of the nature and number of threats to it. Habitat loss is expected to continue (McCracken et al. 2013).

POSTFLEDGING PERIOD

Fledglings are incapable of flight when they leave the nest. For their first week they are immobile and hide cryptically in the vegetation. They can run quickly when flightless, but their survival is highly dependent upon their remaining still. Distance moved when flushed averaged 1.3 m the first day out of the nest and 35.6 m on the seventh day. They hopped through the grass on days 1-3 and graduated to short-distance flights and glides as they aged. They were capable of more extended flights after their first week. Daily movements increased then, although individuals seldom moved more than 125 m from the nest. By the second week, they remained within 200 m of the nest. Fledglings were usually independent by the end of the third week out of the nest. By then, few had travelled further than 0.5 km from the nest (Jaster et al. 2020; Kerschner et al. 2004b; Seudkamp Wells et al. 2007).

In Missouri, 30 of 107 fledglings (28.0%) died and 27 of the deaths (90.0%) occurred in the first week out of the nest. The average age of death was 5.3 days out of the nest. A 1% increase in body mass of fledglings resulted in a 2% reduction in the risk of death. Heavier nestlings obtained a higher proportion of food brought to the nest and fledged 1-2 days before their siblings. Heavier birds may have been more successful at avoiding predators. In addition to predation, primarily by snakes, fledglings appeared to succumb to heat when the temperature exceeded 35°C and the humidity was greater than 80% (Seudkamp Wells et al. 2007). The highest rate of mortality also occurred in the first week out of the nest in Illinois (Kerschner et al. 2004b).

In Missouri, juveniles had slow but consistently increasing rates of movement until they had been out of the nest for approximately 28 days. After that, they had slightly longer movements, with

3 isolated peaks of movements further than 600 m around days 40, 44, and 54. Peaks of large movements corresponded with altered periods of activity when juveniles began congregating with other juveniles in roving flocks. At this time, they frequently foraged or moved into adjacent lands outside the nest field. The mean age when daily movements exceeded 300 m was 20.1 days out of the nest, with larger juveniles moving further than 300 m more frequently than smaller juveniles (Seudkamp Wells et al. 2008). In 2 years in Illinois, juveniles travelled an average of 46.2 m (range 1-105 m) and 48.8 m (range 1-108 m). Independent juveniles dispersed from the nest site over time, with maximum dispersal distances ranging from 0.4-12.8 km. Eleven of 16 birds that dispersed from the study area were relocated, and they had moved a mean of 6.0 km (range 3.6-12.8 km). After dispersal, juveniles occurred in flocks (Kerschner et al. 2004b). In Wisconsin, 12 of 14 radiotracked juveniles (85.7%) remained in the study area. One moved from a CRP field to another CRP field 8.8 km away and the other moved from a prairie to a pasture 6.6 km away. Juveniles were 2 times more likely to remain in their natal field during the fledgling period than during the independent period. The average distance moved by juveniles that remained in the study area was 499 m (maximum 526 m). Once juveniles started to leave the natal field, 66.7% did not return. They usually remained in the nest field until they reached independence and then moved to other grassy habitats (CRP fields, prairies, pastures, or cropland). Juveniles made low use of croplands and were not observed using areas with woody cover (Guzy and Ribic 2007).

Over 3 years in Missouri, home ranges of juveniles were similar: 109.4 ha, 82.7 ha, and 70.7 ha (average 80.9 ha). The density of grass cover explained a large proportion of the annual variation in home range size. Soon after juveniles dispersed, they had larger daily movements and home ranges and were among conspecific flocks. Because of the large home ranges of juveniles, the landscape context around the nesting area may be equally important as the nesting habitat. In addition to inhabiting grasslands, juveniles often foraged in agricultural crops. A field of sweet clover more than 400 m from the nesting area was a preferred foraging area (Suedkamp Wells et al. 2008). In Illinois, juveniles also occurred in flocks in grasslands and croplands. Food is probably abundant and predators scarce in croplands (Kerschner et al. 2004b).

As soon as they are done their nesting duties, females begin foraging both within and outside their former breeding territory without the presence of the male. They begin to form flocks at this time and remain gregarious until the next nesting season (Jaster et al. 2020; Lanyon 1956a). In Missouri, females repeatedly travelled more than 500 m from the nest to forage in fields planted with sweet clover. Later, these same females led their broods to this food source (Suedkamp Wells et al. 2007). In Illinois, females spent more than 90% of their time during the postfledging period in row crops, habitat that was rarely used for breeding. They used soybean fields almost exclusively. These may have abundant food resources because they are typically not treated with insecticides (Kerschner et al. 2004a, 2004b). In Illinois, 15 of 22 females (68.2%) emigrated from the study area after breeding. Both successful and unsuccessful birds emigrated. Emigration occurred more frequently by successful than unsuccessful females. Failed females emigrated almost immediately after failure but successful females remained in the nest field significantly longer. Of 15 females that emigrated, 7 (46.6%) remained within 10 km for as long as 3 weeks after dispersing. The others were not relocated and may have moved further. Females that emigrated were found in agricultural fields and were constantly moving across the landscape. Females from the study area were rarely found

in the same area again after emigration occurred (Kerschner et al. 2004a). Guzy and Ribic (2007) radiotracked females in Wisconsin during the breeding and postbreeding periods. While nesting, 21 of 22 females (95.5%) stayed in the study area. One nested unsuccessfully and was found 53 days later in a CRP field 22 km away. During nesting, females were found in their nest field 58% of the time, and this did not differ for successful (63%) and unsuccessful (49%) nesters. After breeding, most females moved out of the nest field. The average distance moved was 590 m (maximum 662 m) with no difference in distances moved by successful and unsuccessful breeders. Once females left the nest field, 11 of 18 (61.1%) did not return. Females moved to CRP fields, pastures, and croplands.

MIGRATION

Most of the Eastern Meadowlark population is sedentary but those at the northern extent of the range, including Ontario, move southward for the winter. Birds migrate to the eastern and southeastern states. An adult banded in Agincourt, Ontario was recovered in winter in South Carolina, 1,021 km from the banding site. Of 2 juveniles banded in Minnesota, 1 wintered in Alabama and the other in Oklahoma, suggesting that migrants from a given population do not share the same winter range. Migration occurs during the day, with birds travelling together in loose flocks in both spring and autumn. During spring migration in Ohio, flocks containing as many as 60 individuals flew over Lake Erie. Near the shore, flocks of 5-100 flew short distances and began to feed. Those in the rear rose and flew over the flock, alighting in front of it to forage again. When they reached an obstruction such as a woodlot, marsh, or lake, they flew over it in a long loose column (Brewer et al. 2018; Gross in Bent 1958; Jaster et al. 2020).

Adult males arrive first in spring with females arriving 2 weeks or as many as 4 weeks later. Young birds continue to arrive throughout April and May and even into June or July (Gross in Bent 1958; Jaster et al. 2020). In southern Ontario, birds start to arrive in mid-March but migrants are most abundant in early April. Spring migration extends through much of May and birds may arrive as early as late February (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; McCracken et al. 2013; Mills 1981; Tozer 2012; Weir 2008).

In Muskoka District, migrants are most likely to move south in September with movement continuing well into October and stragglers remaining until mid-December (Mills 1981). In the south, migrants become obvious in mid-September. Peak movement occurs in late September and continues through October, with most birds leaving by early November (Curry 2006; LaForest 1993; Lancaster et al. 2004; McCracken et al. 2013; Weir 2008).

Migration habitat is similar to that used during the breeding and postfledging periods. In spring, this meadowlark inhabits mostly grasslands. First arrivals in Algonquin Park initially seek areas that are free of snow, including road margins, forest clearings, old fields, and abandoned sawmill sites. It may visit bird feeders at this time. Autumn migrants may visit croplands in addition to grasslands. Marsh habitats may be used in autumn and some birds visit margins of gravel roads. It exhibits no territoriality during migration and occurs almost exclusively in flocks (Gross in Bent 1958; Jaster et al. 2020; McCracken et al. 2013; Tozer 2012).

Robertson et al. (2012) stated that the Eastern Meadowlark may use fields dominated by switchgrass during migration. They concluded that fields planted to this grass for the purposes of agrofuel production would be less likely to support it than natural grasslands.

Because this meadowlark visits road margins during migration, it is vulnerable to being struck by vehicles. It is a diurnal migrant, so collisions with tall structures are not a limiting factor (Gross in Bent 1958; McCracken et al. 2013).

James (1991) considered the Eastern Meadowlark a common migrant in Ontario.

WINTER

The Eastern Meadowlark winters where the annual precipitation exceeds 61 cm. It avoids areas where the average minimum January temperature is below –9°C. Densest winter populations occur where the minimum January temperature is above –1°C. High densities of Western Meadowlarks appear to exclude the Eastern Meadowlark, but the opposite is not true (Root 1988).

In winter, the Eastern Meadowlark uses habitats similar to those used during the breeding season and migration, particularly grasslands and cultivated croplands. It may also inhabit feedlots, marshes with tall grasses, and salt marshes along the Atlantic coast. In Illinois, it preferred hand-picked cornfields in 1906-07 (a habitat that no longer exists), hayfields, fields of small-grain stubble, and mechanically picked cornfields. Elsewhere, it may use cotton fields and old fields grown up with weeds (Graber and Graber 1963; Gross in Bent 1958; Jaster et al. 2020; McCracken et al. 2013; Savignac 2011b). In Texas, Saalfield et al. (2016) examined the effects of management practices such as grazing, burning, and mowing on Eastern Meadowlarks wintering in prairie habitats. Fields where these activities occurred were characterized by short sparse vegetation with fewer shrubs and reduced litter coverage. Two or more years after management, sites had taller, denser vegetation and increased litter depth, and shrubs were more common. A mosaic of prairies in 2-4-year burn rotations provided suitable vegetation characteristics. It occurred equally frequently in disturbed sites as in other management regimes, with its density positively influenced by the percent coverage by flatsedge. In Arkansas, Mississippi, and Kansas, it was more abundant in fields with a buffer of native warm-weather grasses and forbs. There was no difference in its abundance in fields with buffers wider than 23 m and those with narrower buffers (Evans et al. 2015).

During winter, the Eastern Meadowlark may roost in hayfields and cropped fields. It may also roost in tall grasses in marshes and occasionally in trees with grackles (Gross in Bent 1958).

The Eastern Meadowlark is gregarious in winter. It exhibits no signs of territoriality and there is no evidence of dominance hierarchies within flocks (Jaster et al. 2020).

This meadowlark exhibits low site tenacity in winter. It may make short-distance movements in response to changes in food and habitat availability due to snow cover. It may also make random longer-distance movements. A bird banded in South Carolina was reported 350 km distant in Georgia 11 days later (Jaster et al. 2020).

In winter, the Eastern Meadowlark eats a mix of vegetable matter that is predominantly waste grain and weed seeds, and insects if they are available. During snow and ice storms, it may move into atypical habitats where it may scavenge food or even prey upon other bird species. Beal et al. (1916) examined 6 stomachs collected in the southeastern United States in winter. These birds had eaten mostly insects, including many species of beetles, true bugs, grasshoppers and crickets, and a few wasps, caterpillars, spiders, and millipedes. Other winter food items include corn, oats, cutworms, weed seeds, and earthworms. When snow or ice cover traditional food sources, it often

feeds at manure piles or fields where manure has been spread, in barnyards to feed alongside the livestock, and in vacant lots in towns where it forages with the House Sparrow and European Starling. It has been reported feeding in alleys during severe snowstorms. Almost all these features are now scarce and unlikely to be sufficient to support it during severe storms. More frequently, it visits shoulders of highways that have been cleared of snow and tracks through the snow cleared by vehicles. It has been documented eating the flesh of flickers, other meadowlarks, sparrows, Horned Larks, Mourning Doves, cotton rats, domestic cats, cottontails, and jack rabbits. One killed and ate 2 American Tree Sparrows (Gross in Bent 1958; Hubbard and Hubbard 1969; Krutzch 1950; McIlwraith 1894; Schorger 1954; Terres 1956; Tyler and Choate 1990). The Eastern Meadowlark is not a regular visitor to bird feeders, but may visit them in desperation when normal food sources are scarce or covered with ice or snow. It may use raised feeders in addition to feeding on the ground. Its favourite feeder food is black oil sunflowers but it occasionally eats mixed seeds and cracked corn. It has been documented killing and eating Pine Siskins and American Goldfinches at feeders (Dunn and Tessaglia-Hymes 1999; Tozer 2012; Waters 1990).

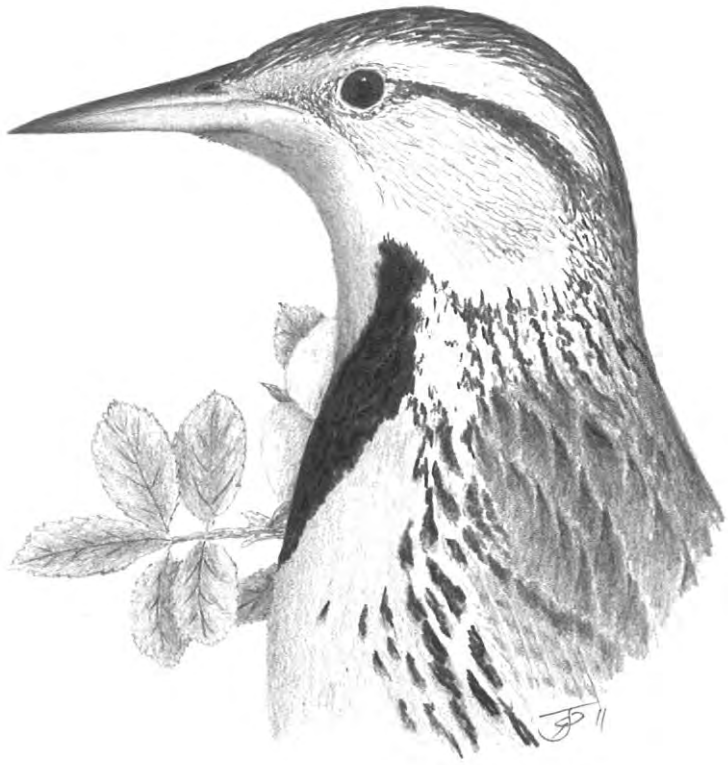
Severe winter weather can be a significant limiting factor for the Eastern Meadowlark. Widespread mortality may occur when snow covers food supplies for prolonged periods. Winter mortality is occasionally significant enough to result in drastic declines in breeding populations. Declines in populations in the late 1970s were partially attributed to severe winters in the southeastern United States during 1976-77 and 1977-78. Snowstorms force meadowlarks to visit roadsides. The birds quickly acclimatize to traffic and large numbers may be killed by vehicles. Over a 2-month period of prolonged sleet and snow in Kansas, birds foraging along roads were not obtaining adequate food. They became weakened and could scarcely fly 9 m. Each day, fewer remained and more dead birds were found (Gross in Bent 1958; Hubbard and Hubbard 1969; Jaster et al. 2020; Krutzch 1950; Robbins 1995; Tyler and Choate 1990).

Wintering habitat has declined over the past half century or more due to changing agricultural practices. In the southeastern states, the Eastern Meadowlark is among the most frequent visitors to rice fields. These are typically baited with an avicide that results in direct mortality (Gross in Bent 1958; McCracken et al. 2013).

James (1991) considered the Eastern Meadowlark a rare winter resident in the south to Kingston, with records of vagrants as far north as Dorion. In the Hamilton area, high numbers occurred in the 1950s and 1960s, with counts of 60 on 21 January and 44 on 2 February. Since the turn of the 21st century, only a few have been seen in winters with declines attributed to changing agricultural practices (Curry 2006). In Elgin County, flocks of 50 were common in the 1950s. It is now rare with usually only single birds seen (Lancaster et al. 2004).

Western Meadowlark

Sturnella neglecta

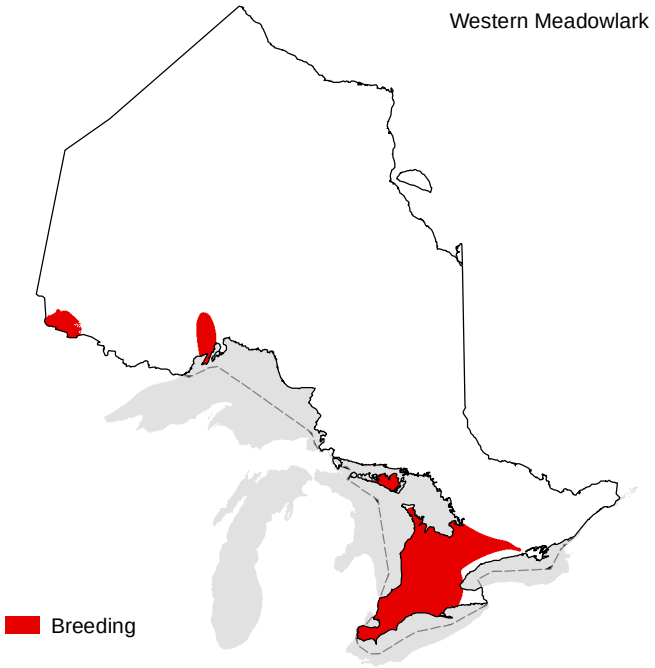


BREEDING SEASON

Habitat Requirements

Ontario Western Meadowlark nests were in grasslands, hayfields, and an orchard (Peck and James 1987). It was more abundant in southern Ontario in the drier climatic strip north of Lake Erie and Lake Ontario in the late 1950s and early 1960s. Within this area, it was found mostly in rough pastures (Falls 2000).

The Western Meadowlark is an obligate grassland species, with presence of grass an essential habitat component. It occupies a variety of grassland types including native and planted grasses. In native grasslands, it prefers short-grass and mixed-grass prairies to tallgrass prairies. It nests less frequently in shrubsteppe habitat. It inhabits undisturbed and grazed native grasslands. Nonnative grasslands that it regularly inhabits include pastures, hayfields, Conservation Reserve Program (CRP)



lands, Dense Nesting Cover (DNC) planted as waterfowl nesting habitat, meadows, and old fields. Less frequently, it nests in grassy and weedy roadsides, no-tillage cropland, weedy borders of agricultural fields, orchards, alfalfa fields, pine and oak barrens, wheat fields, airports, golf courses, large urban parks, open forests and aspen parkland areas with a grassy understorey, montane meadows, wetlands with grass or sedge cover, sand dunes, hydro corridors at least 30 m wide with reaches at least 500 m long of grassland, oak savannahs with a grassy understorey, and grassed waterways in agricultural fields. It formerly nested on vacant lots in towns and villages (Askins et al. 2007; Bent 1958; Camp and Best 1994; Campbell et al. 2001; Dancey 1990; Davis and Lanyon 2020; Dechant et al. 2002j; Earnst et al. 2009; Jones and Bock 2002; Jones et al. 2010; Leighton et al. 2002; Leston and Koper 2017; Mossman et al. 1991; Renken and Dinsmore 1987; Rotenberry and Wiens 1980; Sutter and Brigham 1998; Swanson 1996; Wood et al. 2013). Native grasses it is associated with include Mexican feathergrass, June grass, wheat grasses, grama grass, fescues, mountain bunch grass, and little bluestem (Camp and Best 1994; Davis 2003; Owens and Myers 1973; Pylypec 1991; Rotenberry 1980; Wilson and Belcher 1989). It is commonly associated with nonnative grasses including timothy, orchard grass, downy brome, smooth brome, quack grass, redtop, Kentucky and Canada bluegrasses, panic grasses, foxtails, and crested wheat grass (Dancey 1990; Davis et al. 2016; Dickinson et al. 1987; Earnst et al. 2009; Sutter and Brigham 1988; Wilson and Belcher 1989). In no-tillage croplands, it prefers fields where corn was planted into sod residue to fields where corn or soybeans were planted into corn residue (Dechant et al. 2002j).

Some studies considered Western Meadowlark habitat at the landscape scale. Its occurrence is positively correlated with the amount of grassland in the landscape and negatively correlated with tree and wooded cover. In South Dakota, its density increased but its occurrence decreased with the amount of grassland within 3,200 m. The study area was in a landscape averaging 70% coverage by grasslands. Its probability of occurrence decreased when there was woody vegetation adjacent to a plot. Its probability of occurrence was 70% where there were no wooded patches at the edge of a grassland but dropped to 20% when woody vegetation occupied 70% of the patch edge. It was negatively correlated with nonnative grasses. Its probability of occurrence was 80% when less than 5% of the grassland was covered by introduced grasses and declined below 50% where introduced grass coverage was greater than 80%. Greer et al. (2016) concluded that it was selecting for large expanses of grasslands rather than individual large patches. In Minnesota, its abundance was affected by the amount of grassland in the landscape, increasing by an average of 12 birds per

Breeding Bird Survey (BBS) route for each 10% increase in the amount of grassland in the landscape (Davis and Lanyon 2020). In Washington, its abundance was positively correlated with the amount of shrubsteppe habitat within 1 km. This was the most important variable explaining its abundance (Vander Haegen et al. 2015). In Saskatchewan, its abundance was influenced by the amount of cropland within 400 m. It was most abundant in grasslands where the surrounding landscape was composed of 40-50% cropland. Its abundance at this level of cropland was 5 times greater than where the surrounding area contained 0% or 100% cropland (Davis et al. 2016). In North Dakota, Grant et al. (2004) considered it sensitive to the presence of woodlands. Its occurrence was 50% where there was 0% woodland cover within 500 m, less than 10% at 20% woodland cover, and 0% at 40% woodland cover. In Manitoba, the amount of grassland within 100 m was an important determinant for presence of the Western Meadowlark. Its probability of occurrence decreased with the amount of woodland and urban cover within 100 m (Leston and Koper 2017). In the Prairie Pothole Region of Canada, its abundance was positively correlated with the amount of native and nonnative grasslands and wetlands within 3,200 m, but it was negatively correlated with coverage by trees and shrubs at this scale (Fedy et al. 2018). In Colorado, it was less abundant in grasslands at urban edges than in grassland interior (Jones and Bock 2002). In North Dakota, its probability of occurrence was 18% at 0-10% tree cover, dropping off quickly to 8% at 20% tree cover and almost 0% at 40% tree cover. Its favoured range of tree coverage was 0-13% (Cunningham and Johnson 2019).

The Western Meadowlark exhibits preferences for grassland types, although this may vary geographically. In native grasslands, short-grass and mixed-grass prairies are highly preferred to tallgrass prairies (Askins et al. 2007; Dechant et al. 2002j; Rotenberry and Wiens 1980). Many studies concluded that it prefers taller grasses, but this is within the context of grasses that are short compared with those in tallgrass prairies and in many nonnative grasslands. It prefers native to nonnative grasslands. This is probably because native grasslands tend to have shorter grass and the vegetation is often less dense with greater heterogeneity than nonnative grasses. In Saskatchewan, its abundance was positively correlated with vegetation height in both native prairies and nonnative grasslands. There was no significant difference in vegetation height in the 2 grassland types and both were short, averaging 18.9 and 20.5 cm. It was twice as abundant in native grasslands than planted grasslands (Davis et al. 2016). In Saskatchewan, it occurred in 66.7% of idle native grasslands, 6.3% of DNC fields, and 5.3% of wheat fields (Hartley 1994). In Manitoba, it was positively correlated with native vegetation. It was twice as abundant in native prairie than in nonnative grasslands (Wilson and Belcher 1989). In Washington, Vander Haegen et al. (2015) compared the Western Meadowlark's abundance in native shrubsteppe habitat and old and new CRP lands. Old CRP lands were planted in the 1980s with a mix of native and nonnative grasses and forbs. It was significantly more abundant in shrubsteppe habitat than either type of CRP habitat. Shrubsteppe differed significant from the CRP lands, having more shrub cover (15.8% compared with 5.0% and 2.0%) and taller shrubs (103.0 cm compared with 64.7 cm and 29.5 cm). Shrubsteppe habitat had significantly shorter grasses (42.5 cm) than new CRP lands (56.8 cm) and visual obstruction was significantly greater in shrubsteppe than in old CRP lands (11.1 compared with 5.4). In Alberta landscapes dominated by prairies and nonnative grasslands, it was more abundant in native grasslands and

prairies but differences were not significant from nonnative habitats. Fallow fields and row crops were unsuitable habitat (Owens and Myers 1987).

Several studies examined microhabitat preferences of the Western Meadowlark. It is strongly associated with grass cover, prefers dense cover near the ground and sparser cover at greater heights, low to moderate litter cover, moderate amounts of forbs, and little or no woody cover. It prefers open treeless areas (Davis and Lanyon 2020; Dechant et al. 2002j). In California, it occurred in 79% of oak savannahs with a grassy understorey, significantly different from 10% in savannahs with a shrubby understorey and 2% in montane hardwoods (Wood et al. 2013). In Wisconsin, it selected areas with less than 1% woody cover (Swanson 1996). In North Dakota, its abundance decreased significantly as coverage by shrubs increased (Grant et al. 2004). In grassland habitats becoming invaded by eastern red cedar in Oklahoma, it was less abundant in areas with greater cedar canopy cover (Chapman et al. 2004). Rotenberry and Wiens (1980) concluded that the Western Meadowlark had the broadest ecological niche of species inhabiting shrubsteppe areas. Nonetheless, it was negatively correlated with forb and shrub height but positively correlated with vegetation density. In Montana, it was the only species that avoided nest patches with high forb coverage (Dieni and Jones 2003). In Saskatchewan introduced grasses, its abundance was positively correlated with litter depth, the number of plant contacts below 10 cm, high grass and sedge coverage, and vegetation height. In native prairies, it was positively correlated with grass and sedge coverage but negatively correlated with the number of plant contacts below 10 cm and vegetation height. In both habitats, it was associated with dense vegetation. In short-grass prairies in Colorado, it was associated with taller grasses interspersed with forbs and low shrubs (Conrey et al. 2016). In Montana shrubsteppe habitat, it was significantly more abundant in areas without rock outcrops. Outcrops supported a plant community of more mesic shrub species that was unattractive to the Western Meadowlark (Rumble 1987). In a Wisconsin territory, grass coverage was high, especially by very narrow-leaved species, vegetation was about 15 cm tall, coverage by litter was low and of loose composition, and the vegetation resulted in little reduction in sun cover even at ground level (Wiens 1969). In Iowa, it was negatively correlated with vertical vegetation cover but positively correlated with vertical patchiness. It responded favourably to sites with a wide range of vertical vegetation densities (vertical patchiness) because it is within these plots that it can find the shorter vegetation it prefers (Patterson and Best 1996). Swanson (1996) reported that it was negatively correlated with coverage by legumes and summarized a Wisconsin study that stated its mean vegetation characteristics included less than 1% woody cover, 81% coverage by grasses and forbs, 14% litter coverage, 5% bare ground, and 8 cm vegetation height-density. It was positively correlated with coverage by prostrate residual vegetation and negatively correlated with the maximum height and density of vegetation. In mixed-grass prairie pastures in Saskatchewan, nest sites were significantly correlated with density of live grasses shorter than 30 cm, density of dead vegetation less than 30 cm tall, density of shrubs and forbs 20-39 cm tall, and density of forbs 50 cm or taller. It was also associated with increased litter depth and decreasing coverage by bare soil, but not significantly (Davis 2005). In North Dakota mixed-grass prairies, its abundance was positively correlated with percent grass cover, litter depth, density of low-growing shrubs such as snowberry and silverberry, and maximum and average vegetation heights (Dechant et al. 2002j). In Colorado, it was most abundant in grasslands with multilayered vegetation containing a fine-scale mixture of mid-height grasses that

provided tall vegetation structure, abundant dead vegetation from previous years, and a short-grass understorey (Davis et al. 2021).

Perches may be an important habitat component for the Western Meadowlark. It prefers to sing from an elevated perch but occasionally sings from the ground. Trees are not as important to it for perches as they are for the Eastern Meadowlark. Often Western Meadowlark territories do not include any trees. It frequently uses sturdy forb stems, shrubs, and fence posts as perches (Dancey 1990; Wiens 1969).

In Wisconsin, there were significant differences in vegetation between territories and unoccupied sites. In territories, the mean effective height of vegetation was lower, forbs were shorter, and the litter was not as deep as in unoccupied areas. Vertical vegetation density was similar in occupied and unoccupied areas, but the density at low levels was significant greater in territories (Wiens 1969). In North Dakota, occupied areas had deeper litter, less aspen woodland within 100 m, taller vegetation, shorter shrubs, more Kentucky bluegrass within 100 m, and higher coverage by legumes within 100 m than unoccupied areas (Grant et al. 2004). In Montana, it selected nest patches with greater visual obstruction, vertical vegetation density and height, grass cover, and litter cover and depth than random sites. It avoided areas with significant coverage by clubmosses (Dieni and Jones 2003).

Other studies compared the habitat preferences of the Western Meadowlark to those of other species. Lanyon (1956b) compared the habitat preferences of the 2 meadowlark species in their zone of overlap in the United States. Where they are both common, the Western Meadowlark preferred larger fields, shorter vegetation, and well-drained upland areas. The Eastern Meadowlark was more common in lowland areas in stream valleys, marshy areas, and poorly drained areas. The Western Meadowlark preferred short- and mixed-grass areas. The Eastern Meadowlark preferred tallgrass areas. Both species had a wide tolerance for varying habitat conditions and the Western Meadowlark occupied the lush lowland grasslands that the Eastern Meadowlark preferred when the other species was absent. Despite these different habitat preferences, the 2 species often nest in the same field. In Ontario, Szijj (1966) could find no differences in the habitats of the 2 meadowlark species. There were no differences in their habitat selection according to vegetation or moisture gradient. In Montana, the Western Meadowlark occurred in areas with more herbaceous and grass cover and with more widely dispersed shrubs than the Lark Sparrow (Walcheck 1970). In Wisconsin, Wiens (1969) compared the habitats of the 2 meadowlark species, Bobolink, and Vesper, Savannah, Grasshopper, and Henslow's sparrows. Coverage and density of forbs was highest for the Western Meadowlark of any species, but the mean height of forbs was significantly less than in areas occupied by other species. Coverage by broad-leaved forbs was high but heavy-stemmed forbs were sparse. Vertical vegetation density differed significantly only from that of the Henslow's Sparrow, which preferred denser areas, but density in the 0-10 cm height interval was significantly greater in Western Meadowlark territories than in areas occupied by all other species; coverage by vegetation less than 5 cm tall was the highest of all species. Its mean effective height of vegetation was significantly lower than for all other species except the Vesper Sparrow. Litter depth was significant less in Western Meadowlark territories than for all species except for the Savannah, Grasshopper, and Vesper sparrow. Species in order of increasing habitat richness based on

vegetation density and height and litter coverage and depth were Western Meadowlark, Vesper Sparrow, Savannah Sparrow, Grasshopper Sparrow, Eastern Meadowlark, Bobolink, and Henslow's Sparrow. The range of differences within the ranking was small with many similarities in habitat occupancy by the species. In Saskatchewan mixed-grass prairie, Davis (2005) compared the habitat preferences of the Western Meadowlark with those of the Sprague's Pipit, Chestnut-collared Longspur, Savannah Sparrow, and Baird's Sparrow. The Western Meadowlark was the only species strongly associated with the highest densities of tall shrubs and forbs, and it preferred tall dense vegetation. It selected the tallest and densest vegetation of all species.

The Western Meadowlark does not exhibit a strong aversion to edges and may be attracted to some edge types. An exception was in Colorado where it was significantly more abundant on plots 200 m from edges between suburban development or upland and lowland habitat than on plots closer to edge (Dechant et al. 2002j). In Wisconsin, nest density was lower near edges, but not significantly. The type of edge (wooded or nonwooded) was not a significant predictor of density within 50 or 100 m of edge and there were no differences in predation rates relative to distance from edge. Nests within 50 m of a nonwooded edge tended to have lower predation rates than those within 50 m of a wooded edge, but not significantly (Renfrew et al. 2005). In South Dakota, its density was influenced by patch shape and decreased with the complexity of patch shape as the edge-to-area ratio increased (Greer et al. 2016). In Alberta, the Western Meadowlark exhibited no response to roads. It decreased with increasing distances from wetlands and croplands indicating that it was attracted to wetlands and possibly to croplands (Sliwinski and Koper 2012).

The Western Meadowlark does not appear to be area sensitive. In Nebraska, the minimum patch size it was found in was 5 ha and territory sizes may occasionally be larger than this. In Idaho shrubsteppe, there was no relationship between its occupancy and patch size (Dechant et al. 2002j). In South Dakota, patch size was not a significant predictor of its occurrence or abundance (Greer et al. 2016). In Saskatchewan, it appeared to be area insensitive and showed some signs of inverse area sensitivity. It tended to occur more often in smaller patches, but not significantly (Davis 2004; Davis et al. 2006). Johnson and Igl (2001) studied its area sensitivity in Michigan, North and South Dakota, and Minnesota. Their results were inconclusive with no overall evidence for area sensitivity. Davis and Lanyon (2020) stated that the evidence for area sensitivity was weak and no effect of habitat size on occurrence of the Western Meadowlark had been determined. They noted that, in 1 Wisconsin study, it was not found on any lowland pastures smaller than 20 ha, but concluded that this was a function of habitat and not size. Swanson (1996) stated that it was considered mildly area sensitive in Illinois because it did not reach 50% occurrence until grasslands were at least 5 ha in size. Because some territories may be larger than that, this is not a valid indicator of area sensitivity.

Some studies provided recommendations for creating or managing habitat for the Western Meadowlark. Dechant et al. (2002j) concluded that keys to its management included providing a variety of grassland types and heights, sparse woody cover, and high coverage by grasses and forbs. They recommended avoiding burning, mowing, grazing, tilling, and chemical spraying during the breeding season, but spraying weeds on a spot-by-spot basis. Large tracts of grasslands should be provided and native grasslands and wet meadows should be protected from conversion to cropland. Management (burning, grazing, and mowing) should be done on a rotational basis to

provide a variety of habitats in different stages of succession. Mixed-grass prairie should be burned at varying intervals (2-3 years, 4-7 years, or 8-10 years) and tallgrass prairie and CRP lands should be burned every 4-5 years. Grazing can be used to improve habitat of tallgrass habitats and CRP lands. Dry short-grass prairies should be protected from grazing but wet short-grass prairies may be grazed. Patterson and Best (1996) recommended spot mowing on CRP lands in Iowa to open up dense vegetation and increase its use of this habitat.

The Western Meadowlark roosts on the ground in dense grass (Davis and Lanyon 2020), often under clumps of grass; as many as 12 may roost together (Bent 1958).

Ontario nests were all on the ground, hidden under grasses and other vegetation. They had a domed tunnel to the nest entrance (Peck and James 1987).

The Western Meadowlark invariably nests on the ground. The female excavates a depression in the ground as the first step in nest construction. Existing depressions may be used; 1 nest was in a hole in the ground 20 cm deep. In Manitoba, nests initiated before 10 May were in significantly deeper (6.0 cm) depressions than later nests (4.2 cm). Nests of primary females were in deeper depressions than those of secondary females. Many nests have a grass dome over them and some appear to be a round ball of grass. Some have tunnels constructed through the vegetation into the nest entrance; these may be as long as 75 cm. Most nests are well concealed beside a clump of vegetation or among tall grasses. They may also be at the base of a tree or beside a rock. One nest was in a plowed field with sparse oats, and the female was visible sitting on it from a distance of 30 m. In Manitoba, there was no consistent relationship between nest orientation and the direction of the prevailing winds. Nest orientation appeared to be such that it provided the most direct access through the vegetation. In Wisconsin, nests faced north or east. The prevailing winds during rain and sleet storms depressed the vegetation in these directions. Nests deteriorate rapidly and are not reused (Bent 1958; Campbell et al. 2001; Dancey 1990; Davis and Lanyon 2020; Dickinson et al. 1987; Wiens 1969).

Males establish territories as soon as they arrive, long before any females are present. They vigorously defend their territories against resident and migrant males and migrant females. Defence is most intense preceding incubation of the first clutch with secondary peaks of lesser intensity preceding each subsequent nesting attempt. Territories are defended until the last brood fledges. Although it has been stated that females are nonterritorial, females respond aggressively to the female rattle call. This response is strongest before incubation begins and declines rapidly thereafter, suggesting that this may be an attempt to delay the male's acquisition of another mate. Aggression by resident females may result in some high-quality territories not reaching their potential to support 2 females (Davis and Lanyon 2020; Dickinson et al. 1987; Lanyon 1956a). Territorial boundaries change considerably over the breeding season. Prior to the arrival of females, boundaries are dictated by the pressures of neighbouring males. Initial territories decrease in size with the subsequent arrival of additional males and an increase in density. If a bird disappears, boundaries change because neighbours annex the territory. Late in the season, the nest site and locations of females have a major influence on territorial boundaries. Males are flexible enough to alter territorial boundaries to ensure that they encompass the nests and female activity centres (Lanyon 1956a). Territory sizes are variable, with breeding density and habitat quality being major

factors influencing size. Territories in Indiana were 4-6 ha (Dancey 1990). Four Iowa territories were 4-13 ha (Davis and Lanyon 2020) and territories averaged 3.4 ha in Iowa alfalfa fields (Frawley and Best 1991). Two Wisconsin studies reported territory sizes of 1.2-6.1 ha, with most 2.8-3.1 ha (Lanyon 1956a) and 1.8-3.4 ha (mean 2.4 ha; Wiens 1969). In Manitoba, territories averaged 7 ha (Schaeff and Picman 1988). Dechant et al. (2002j) reported territory sizes of 3-13 ha in tallgrass prairies, 2-7 ha in short- and mixed-grass prairies, 3 ha in Iowa hayfields, 2.2 ha in idle shrubsteppe, 2.3 ha in shrubsteppe pastures, and 1.2 ha in Colorado. Bent (1958) reported territory sizes of 4, 8.5, 9.7, and 12.9 ha.

The Western Meadowlark tolerates most other grassland species and its territories may overlap broadly with theirs. The exception is the Eastern Meadowlark. Both species respond equally aggressively to the songs of both species. Territorial males challenge all male meadowlarks regardless of their species. This results in the 2 meadowlark species having mutually exclusive territories (Falls 2000; Lanyon 1956a; Rohwer 1973; Wiens 1969). In the main area of regular sympatry, the 2 meadowlarks have evolved to change their behaviour and body morphology. The incidence of fighting among males is much higher in the area of sympatry, and more serious wounds are inflicted. Male, but not female, Western Meadowlarks have larger and darker Vs on their chests. Female Eastern Meadowlarks showed a decrease in the size of the V but there was no change for males. Male Western Meadowlarks had brighter yellow chests and were significantly larger in areas of sympatry than where the Eastern Meadowlark was absent (Rohwer 1973).

Natal philopatry rates are low. In Wisconsin, 0 of 51 nestlings were found in a subsequent year within a radius of 1.6 km around the natal area. Three of 19 juveniles (15.8%) were observed in the following year 0.32-0.65 km from the banding sites (Davis and Lanyon 2020).

Adults appear to exhibit high site fidelity. In Wisconsin, both sexes showed strong site fidelity to their previous year's territory rather than toward a particular mate. Twelve of 21 males (57.1%) and 10 of 19 females (52.6%) returned. Only 1 male and 1 female failed to return to their former territory (Dechant et al. 2002j; Lanyon 1956a).

Limiting Factors

Eggs are likely to be present in Ontario nests from mid-May until the first week of July (Peck and James 1987). Pairing occurs almost immediately after the females arrive. It may take as long as 6 days to build early nests. Late nests may be built in a single day. Females may begin egg laying as soon as the nest lining is complete. Eggs are laid at the rate of 1 per day. Incubation begins with the laying of the penultimate or last egg. In Montana, the incubation period averaged 12.9 days (range 8-15 days). Elsewhere, incubation periods of 13-16 days were reported, with longer periods associated with long spells of cold wet weather. Hatching occurs over a 1- or 2-day period. In Montana, the average nestling period was 12.7 days (range 9-16 days). Others reported a nestling period of 10-12 days. Young may fledge as early as 8 days if they are disturbed (Bent 1958; Davis and Lanyon 2020; Dickinson et al. 1987; Jones et al. 2010; Lanyon 1956a).

Double broods have been reported in Ontario. In 1 Wisconsin study, all females that successfully raised a first brood attempted a second brood. A later study at the same site found that females laying 1 and 2 broods were equally abundant. It is likely that only females that initiate nesting early in the season raise a second brood. No more than 2 broods are raised in a season (Bent 1958; Davis

and Lanyon 2020; Jones et al. 2010; Lanyon 1956a; Peck and James 1987; Wiens 1969). The Western Meadowlark may be a persistent renester if initial nests fail. In Wisconsin, 5 females built at least 3 nests in a season and one built 6 nests in each of 2 successive years. Only birds that initiate nesting early in the season are likely to fledge young from a replacement nest (Davis and Lanyon 2020; Dickinson et al. 1987; Lanyon 1956a). Clutches of 4 and 5 eggs have been reported in Ontario (mean 4.42 eggs), although the sample size was only 7 nests (Peck and James 1987). Elsewhere, clutches of 3-7 eggs were reported, mostly 5 eggs. In Saskatchewan, mean clutch size was 5.1 eggs for unparasitized nests. Mean clutch size in Montana was 4.4 eggs, but this included parasitized nests that contained 0 meadowlark eggs. In Alberta, mean clutch size was 5.4 eggs (range 3-7 eggs, mode 6). In Saskatchewan, mean clutch sizes were 4.6 eggs in native pasture, 5.1 eggs in planted pasture, and 4.7 eggs in hayfields; in British Columbia, 58% of clutches contained 5 eggs (Bent 1958; Campbell et al. 2001; Davis 2003; Davis and Lanyon 2020; Davis et al. 2016; Gaudet et al. 2020; Jones et al. 2010; Ludlow et al. 2014). In Montana and Saskatchewan, clutch size decreased as the season progressed (Davis 2003; Jones et al. 2010), but it remained constant in Alberta (Ludlow et al. 2014). In Manitoba, clutches initiated before 1 May were smaller (5.10 eggs) than those initiated 1-10 May (5.77 eggs), with clutch size dropping to 5.00 after 10 May. Resources for egg production may be limited early in the season and may have prevented females from nesting earlier. Because secondary females began nesting when clutch size was higher, some were able to raise as many or more young than females that nested earlier. Clutches of secondary females were slightly larger (5.60 eggs) than those of primary females (5.29 eggs). Those that nest earlier may have the opportunity to raise a second brood or renest, but this increases the likelihood that their males will attract another mate (Dickinson et al. 1987).

Both sexes are capable of breeding when they are 1 year old and it is probable that all yearling females breed. Some males are unsuccessful in attracting a mate, and it is likely that these are yearlings. In a Manitoba population, 3 of 33 males (9.1%) failed to attract a mate. Males that remain unmated abandon their territories or are displaced (Davis and Lanyon 2020; Dickinson et al. 1987; Lanyon 1956a).

The mating system is polygynous, with polygynous males typically having 2 mates, rarely 3. Of 33 males in Manitoba, 10 were monogamous (30.3%), 9 mated with 2 females sequentially (27.3%), and 11 paired with females that had overlapping nest cycles (33.3%). Males' success in obtaining a second mate was related to the date when their primary females began nesting. All males that mated before 1 May subsequently mated with a second female and most of their females nested simultaneously. Most males whose females began nesting after 10 May mated with a single female; those that mated with a second female did so sequentially. Most secondary females became active on the territory after the primary female had begun incubation or fledged her young. Secondary females that were attracted while the first female was still nesting were more frequently recruited during the second half of incubation than during the first half. The staggered arrival of females may be a result of younger birds returning later than experienced females. Some females may become available if their first mate is abandoned or disappears. Unmated males were present, so some females chose to mate with an already mated male rather than entering into a monogamous relationship. When a primary female lost her nest, there was a high probability of the secondary female improving her status to become the primary female. Primary females fledged slightly more

young than secondary females, but the difference was not significant. There was no great disincentive to being a secondary female. Bigamous males had significantly higher reproductive success and were significantly less likely to produce no young than monogamous males. Selection should strongly favour behaviour that increases the likelihood of attracting a second female (Dickinson et al. 1987). The female selects the territory in which she wishes to breed and the male that is defending it. In Wisconsin, no female undertook a pairing with another male while her first mate successfully defended his territory. Within-season mate changes occurred only when the first male disappeared or was displaced (Lanyon 1956a). One nest contained 10 eggs suggesting intraspecific parasitism; it was subsequently abandoned (Davis and Lanyon 2020).

The Western Meadowlark forages on the ground in open areas, typically on arthropods but also on seeds. When feeding on sprouting grain, it occasionally eats the kernel but usually crushes it in the bill to obtain the milk and then discards it (Davis and Lanyon 2020). During a late spring snowstorm in Wyoming, it scavenged dead birds along a road, and attacked and killed others. It consumed 35 Horned Lark, 4 Western Meadowlark, 2 longspur, 2 robin, and 2 Dark-eyed Junco carcasses. It preyed upon live Horned Larks and juncos. It approached them from behind, seized the back of the skull in its beak, pinned them down, and pecked them until they were dead. In all predation events, it ate only the eyes and brain of the other bird. When muscles or internal organs were exposed in carcasses, it also ate them. This suggests that it is an effective predator during severe weather. It is possible that it is predatory at other times (Porter and Behl 2016). Scavenging and predation of other birds has been reported during severe winter snowstorms for both species of meadowlarks (Hubbard and Hubbard 1969; Krutzch 1950; Tyler and Choate 1990; Waters 1970).

Both adults feed the nestlings and assistance by the male is important in ensuring that nestlings do not starve. In Manitoba, 22 of 34 males (64.7%) were observed carrying food during the nestling period. Each fed nestlings of the primary female and 6 also fed the nestlings of the secondary female, but only after the primary female's young fledged or the nest failed. Eleven of 20 broods (55.0%) experienced some nestling starvation. These were always nestlings that hatched a day after the others. In each case when primary and secondary females were feeding their nestlings at the same time, the secondary female lost over half her brood to starvation. Larger nestlings were preferentially fed over younger, smaller nestlings so those that did fledge were in good condition. Two secondary females that were feeding their nestlings when the primary female lost her nest successfully reared all their brood with the assistance of the male. Primary females that are forced to share a territory may experience competition for food for their nestlings, reduced male vigilance for predators, and the possibility of losing primary status if their nest fails (Dickinson et al. 1987). Nestlings are fed invertebrates almost exclusively, predominantly caterpillars, beetles, and grasshoppers, plus ants, cutworms, and spiders. Some wheat has been reported in nestlings' stomachs and a few contained weed seeds (Bent 1958; Davis and Lanyon 2020). In Washington, food items collected from the esophagus of nestlings included 50 short-horned grasshoppers, 42 beetles, 36 spiders, 32 long-horned grasshoppers, 22 hymenopterans, 16 stink bugs, 15 flies, 4 crickets, 4 snails, 3 true bugs, 2 mayflies, 2 mosquitoes, 2 skippers (butterflies), 2 scorpions, and 1 each of assassin bug, shield bug, robber fly, and predaceous diving beetle (Orians and Horn 1969). In Saskatchewan, an adult fed a 2.5-cm-long frog to one of its nestlings (Ranford 1972).

The adult diet consists mostly of insects, with orthopterans, beetles, and caterpillars the most abundant prey. Ninety-one stomachs collected in California contained 70% animal matter and 30% vegetation. Beetles constituted 27% of the diet, particularly ground beetles. The remainder of the animal food consisted of 15% caterpillars, 6% wasps and ants, 12% grasshoppers (42% of the August diet), 4% bugs, and lesser amounts of crickets, crane flies, spiders, isopods, and snails. The vegetable food was mostly grain, including oats, wheat, barley, and corn. Two percent of the diet consisted of weed seeds and 1 bird had eaten fruit. Another California study examined nearly 2,000 stomachs which contained 63.3% animal food and 36.7% vegetation. The animal food consisted of 21.3% beetles (mostly ground beetles and click beetle larvae), 20.3% grasshoppers and crickets, 12.2% caterpillars, 5.6% hymenopterans (mostly ants), 1.7% bugs (mostly stink bugs), 0.1% flies, 0.2% spiders, and 1.9% miscellaneous insects. The Western Meadowlark often consumed cricket and locust eggs. The vegetation consisted of 30.8% grain, 5.3% weed seeds, and 0.6% miscellaneous plant material (Bent 1958). In Saskatchewan, the most common prey in 185 stomachs included ants, beetles, grasshoppers, and caterpillars; 9 orders of insects were documented in the diet. These were mostly beetles early in the breeding season, hymenopterans in June, and orthopterans from July to September. Thirteen percent of stomachs contained seeds, with 25% occurrence in spring and less than 1% in summer. In December, Wisconsin birds ate mostly corn and oats. One bird had eaten weevils, true bugs, and caterpillars (Davis and Lanyon 2020). Wiens and Rotenberry (1979) studied the diet of meadowlarks in shrubsteppe vegetation in Oklahoma, Texas, South Dakota, and Washington. In some states, the diet of the 2 meadowlarks was combined in the results, but they were separated in the west where only the Western Meadowlark occurred. The meadowlarks were the most highly carnivorous of the species studied. Over 3 years, the diet consisted of 18-45% beetles, 15-42% orthopterans, and 15-55% caterpillars. The diet over the years and sites ranged from 95.7-100% animal matter and 0-4.3% vegetable matter. The most important beetles in the diet included weevils and ground, scarab, leaf, and darkling beetles. It also consumed solder, long-horned, click, and clown beetles. Crickets were the most important orthopterans but it also ate long-horned and short-horned grasshoppers. Other prey items included hymenopterans (bees, ants, sweat bees, ichneumonid wasps, and thread-waisted wasps), odonates, millipedes, true bugs (leaf-footed, seed, squash, stink, ambush, and jewel bugs), soft-winged bugs (leafhoppers, cicadas, and scale insects), caterpillars, flies, snakeflies, spiders and sun jumping spiders, and snails. Seeds consumed included those of goosefoots, mustards, grasses, and legumes. The functional groups of prey were similar among all sites, but there was considerable variation in the orders of prey consumed among sites and years. Variations among sites were greater than those among years at a given site. It had a large niche breadth because it exploited both large and small prey items, consuming prey 1-32 mm in length with a peak at 4-16 mm. The mean prey size by location and year ranged from 7.54-14.13 mm. The diet overlap of the Western Meadowlark was 11-86% with the Horned Lark over 3 years and 67-83% with the Grasshopper Sparrow. At 1 site, the mean prey size consumed by the meadowlark and Horned Lark was significantly different. The authors concluded that food was not a limiting resource and that the Western Meadowlark exploited these resources in an opportunistic manner resulting in considerable individual, between-year, and between-location variation in diet composition and interspecific overlap. In the same Washington shrubsteppe habitat, Rotenberry (1980) compared the diets of the Horned Lark, Sagebrush Sparrow, and Western Meadowlark. All were highly insectivorous during the breeding season. The most

common prey of the Western Meadowlark early in the season was beetles, particularly weevils and larvae. Ants, wasps, caterpillars, small spiders, true bugs, and grasshopper nymphs occurred consistently in the diet, but contributed less to the diet combined than beetles. There was an abrupt shift in June and August when grasshoppers became much more abundant in the diet, often constituting more than 50% of the food. The average length of prey consumed was 7.66-8.23 mm in May in 2 years, 14.62 mm in June, and 12.51 mm in August. Each individual bird was likely to have eaten about 50% of the total taxa reported for the species, and individual dietary diversity was nearly 80% of that eaten by the entire population. There was a great deal of similarity in the diets of the 3 species and a substantial overlap in the size of prey consumed. In spring, the meadowlark ate a higher proportion of ground and darkling beetles than the other species, with a dietary overlap of 51%. When food items were categorized into groups of goosefoot seeds, orthopterans, grass seeds, scarab beetles, mustard seeds, caterpillars, and weevils, most individuals regardless of species were eating the same things at any given time. There was no apparent niche separation on the basis of food type. From June to August, this meadowlark ate more large items than the other 2 species, which ate more and smaller seeds. When only invertebrates were considered, the meadowlark consumed significantly larger prey than the other 2 species during this period. Animal food of the Western Meadowlark comprised 100% of the May diet, 97.3% of the June diet, and 95.2% of the August diet. Animal prey included spiders, beetles (weevils and darkling, scarab, and ground beetles), ants and wasps, caterpillars, robber flies, neuropterans, true bugs, orthopterans, and leafhoppers. Vegetable food consisted of grass seeds and miscellaneous forb seeds. Food was not limiting and all species were opportunistic foragers. In Nebraska, Kaspari and Joern (1993) compared the diets of the Western Meadowlark and Lark and Grasshopper sparrows. The meadowlark was largely carnivorous, consuming no more than 5% seeds in its diet. The diets of the Lark and Grasshopper sparrows consisted of 61% and 33% seeds, respectively. The most abundant items in the meadowlark's diet included 42% short-horned grasshoppers, 22% adult beetles, and 15% caterpillars. It consumed lesser amounts of long-horned grasshoppers, spiders, hymenopterans, true bugs, flies, beetle larvae, leafhoppers, and froghoppers. It preferred larger prey and exclusively consumed the largest sizes of 5 taxa and beetle larvae 5-14.9 mm in length. It uniformly avoided prey in all taxa groups that were shorter than 5 mm and 5-15.9 mm (except beetle larvae), preferred prey 15-35 mm long, and exhibited an increased preference for prey 35-45 mm in length over the other 2 species. It consumed 97% of the arthropod species that were collected in sweep samples. It selected short-horned grasshoppers, more so than the more abundant leafhoppers and froghoppers. It avoided small prey even though they were much more abundant. Small prey may be more difficult to find but, more importantly, have a higher proportion of chitin per unit of weight. Consequently, they may fill up the gut with less nutritional food. These authors concluded that their results did not support the conclusions of Wiens and Rotenberry (1980) that the Western Meadowlark was a dietary opportunist.

In Manitoba and Colorado, the Western Meadowlark punctured eggs in other species' nests and attacked nestlings. It does not appear to eat either the egg contents or young and may depredate nests to minimize competition (Creighton and Porter 1974; Schaeff and Picman 1988).

The Western Meadowlark is a fairly common host of the Brown-headed Cowbird, particularly in the Great Plains where this parasite is most abundant. In Illinois, Peer et al. (2000) artificially

parasitized nests with eggs painted similar to those of a cowbird and with nonmimetic eggs. It regularly rejected both types of eggs within 24 hours of parasitism: 77.8% of mimetic eggs and 100% of nonmimetic eggs. A real cowbird egg was accepted at the only naturally parasitized nest. Spots on the real cowbird egg were larger and resembled meadowlark eggs more closely than the artificial eggs. In Saskatchewan, parasitism rates were negatively correlated with grassland size but unrelated to distance to perches for cowbirds and amount of concealment at the nest (Dechant et al. 2002j). Parasitism significantly affected meadowlark clutch size and fledging success in Saskatchewan. Clutch size of parasitized nests averaged 4.0 eggs compared with 5.1 eggs in unparasitized nests. Successful parasitized nests fledged an average of 2.4 young compared with 3.7 for unparasitized nests (Davis 2003). Fledging success was also lower for parasitized nests in Manitoba: 0.6 young per parasitized nest and 1.1 per unparasitized nest (Davis and Lanyon 2020). The cowbird may adversely affect nests that are not parasitized by puncturing the eggs. This may prompt the female to renest, thereby offering another opportunity to parasitize (Granfors et al. 2001). No cases of parasitism have been documented in Ontario. Parasitism rates reported elsewhere are variable and may vary significantly annually at a given location. In Saskatchewan, 26 of 103 nests (25.2%) were parasitized over a 4-year period. Rates were 42% and 45% in 2 years and 0% in the other 2 years (Davis 2003). Other reported parasitism rates in Saskatchewan include 2 of 29 nests (6.9%) and 11 of 24 nests (45.8%; Dechant et al. 2002j). Other parasitism rates include 2 of 139 nests (1.4%) in British Columbia (Campbell et al. 2001); 4 of 26 nests (15.4%) in Alberta (Ludlow et al. 2014); 0 of 17 nests in Saskatchewan (Gaudet et al. 2020); 28 of 65 nests (43.1%) in Manitoba; 0 of 45 nests in Washington (Vander Haegen et al. 2015); 5 of 26 nests (19.2%), 5 of 39 nests (12.8%), 47% of nests, and 4 of 26 nests (15.4%) in North Dakota; 26% of nests and 32 of 118 nests (27.1%) in Montana; 2 of 29 nests (6.9%) in Kansas; 5 of 31 nests (16.1%) in Nebraska; and 14 of 76 nests (18.4%) in Minnesota (Davis and Lanyon 2020; Jones et al. 2010).

Hybridization of the 2 meadowlarks rarely occurs, and only in the extreme eastern portion of the Western Meadowlark's range. Hybridization has been documented in Ontario and Quebec (Bannon in Gauthier and Aubry 1996; Szijj 1966). Over 4 years, Szijj (1966) found 9 nests belonging to mismatched pairs in southwestern Ontario. Most Western Meadowlark populations in Ontario consist of isolated groups of 2 or 3 pairs, or even solitary pairs, surrounded by breeding Eastern Meadowlarks. Mixed pairs consisted of a male Eastern Meadowlark and 1 or 2 Western Meadowlark females. Females typically select a territory where the male is singing conspecific songs. All copulations occur within the territory, so these 2 factors usually inhibit hybridization. Hybridization has not been documented where both species are common in the zone of overlap. Where Western Meadowlarks are rare, females may not be able to find a conspecific mate. In Ontario, only 46.6% of eggs in nests of mismatched pairs hatched. Survivorship of fledglings was also poor. Only 2 of 5 young (40.0%) taken from nests were raised successfully compared with 5 of 7 pure young (71.4%). In 3 of the 9 nests, young were found dead in or around the nest. The overall breeding success of mismatched pairs was no higher than 25%. Fledglings that survive initially do not appear to fully develop. One young was considerably smaller than normal, failed to acquire adult plumage, and subsequently died for no apparent reason. Another was larger than normal and gained full adult plumage, but its gonads failed to develop despite receiving hormone injections. Hybridization is unlikely to affect the gene pool of either meadowlark species because it is a rare occurrence and the

resulting young are unlikely to survive or develop physically enough to mate with other birds (Lanyon 1956a; Szijj 1966).

The most significant limiting factor for the Western Meadowlark is habitat loss and degradation. Habitat loss is due predominantly to conversion of hayfields and pastures into row crops. Losses also occur due to natural succession of abandoned fields, tree planting, and conversion of agricultural land into urban areas or other land uses. These types of losses occur rangewide and are not confined to Ontario. In the core of its range, extensive habitat degradation has occurred by converting native grasslands to planted grasslands. Nonnative grasslands are inferior habitat and support lower densities than prairies. Nonnative grasslands also promote the growth of nonnative forb species, such as sweet clover, that may greatly reduce habitat suitability. In the east, conversion of hayfields dominated by grasses and clovers in the genus *Trifolium* to those planted to alfalfa has been detrimental. Alfalfa fields grow much denser than it prefers and do not provide the grasses that it requires to construct its nest. In Ontario, there is much less pastureland available than when the Western Meadowlark was more common. The remaining pastures are grazed at a much higher intensity than previously and the resulting short-cropped grass does not provide suitable habitat (Campbell et al. 2001; Falls 2000; Greer et al. 2016; Swanson 1996; Walk et al 2010).

Mowing may be detrimental or beneficial for the Western Meadowlark depending on the timing of mowing and the original density of grasses. Mowing of hayfields during the breeding season typically results in the loss of all nests and fledglings. In Iowa, densities of meadowlarks were the same before and after mowing an alfalfa field. Results were inconclusive because territories were large and extended into unmowed areas. In dense grasses in CRP lands, spot mowing creates patches of shorter grasses that improve habitat. In North Dakota native grasslands, density was highest in hayfields mowed the previous year compared with those grazed. Emergency mowing of CRP lands in the Midwest due to drought increased coverage by herbaceous species and the proportion of grasses in the cover the following year. This resulted in an increase in its population. In Saskatchewan, it occurred consistently in hayfields that were mowed annually and was occasional in periodically mowed fields, but was most abundant in idle native grasslands. Mowing or spot mowing after the breeding season may be an important management practice in dense or tall grasslands. Mowing during the breeding season and in short, sparse grasslands may be detrimental (Davis and Lanyon 2020; Dechant et al. 2002j; Frawley and Best 1990; Patterson and Best 1996). Wolcott et al. (2023) recommended that grassland management be deferred until August to protect both nests and fledglings.

Prescribed burning is a regular management practice in western grasslands. Without periodic burning, shrub density eventually reduces habitat quality. The general response of the Western Meadowlark is a decline in numbers immediately following fire, an increase for a few years postburn due to recovery of grasses and herbaceous species and a lack of shrubs, and a subsequent decline when shrubs reinvade. In North Dakota, grass cover increased after fire but its density decreased as did coverage by shrubs. It was absent in unburned areas and responded positively to the extent and frequency of fire. It reached its highest abundance in areas that were burned 4 times within 15 years, with the last fire occurring 2 years previously. It was most common 2-5 years postfire and declined starting about 5 years postfire (Madden et al. 1999). In Saskatchewan, Pylypec (1991) studied the

effects of an October fire. It was adversely affected by fire the first 2 years following the burn, but densities were similar in burned and unburned areas 3 years after fire. Its recovery was related to the recovery of the grassland community. In Texas, there was no difference in its abundance on burned and unburned plots after a 3,600-km^2 wild fire (Roberts et al. 2012). Earnst et al. (2009) reported its response to a wild fire in shrubsteppe habitat in Washington. Its population was declining prior to the fire. After the fire, it stabilized but at a lower population level. There was a substantial loss of vegetation after the fire and shrubs showed little sign of recovery 4 years later. There are some differences between prescribed and wild fires that may result in different habitat regimes. Prescribed burns tend to be of uniform low or moderate intensity and usually result in an even burn over an area. Wild fires tend to have varying intensities in different areas and isolated patches may escape without being burned. In North Dakota, it was absent from unburned mixed-grass sites but present in areas subject to repeated burning at 3-year intervals. It was absent in prairies that had not been burned for more than 80 years. Meadowlark density peaked 1-3 years postburn. In South Dakota, its use of native pastures burned in spring increased in June and July. Its abundance in burned areas was significantly higher in July than in June. In July it was more abundant in burned than unburned areas. In Idaho shrubsteppe, densities were higher 1-3 years postburn than prior to the burn; densities levelled off 4 years postburn. In Montana, it was more abundant in burned than unburned shrubsteppe. Occupied areas within burns contained significantly less grass and herbaceous cover than random areas within the burn (Dechant et al. 2002j).

The Western Meadowlark responds positively to light to moderate grazing and negatively to heavy grazing. In some cases, it exhibits no response to grazing. Harrison et al. (2010) studied its response to grazing in short-grass habitat in British Columbia. Some sites were ungrazed; others were lightly, moderately, or heavily grazed. Vegetation characteristics were significantly different in grazed and ungrazed plots, but vegetation was similar in plots with different intensities of grazing. Grazed plots had 46% less coverage by native grasses and 400% higher coverage by Kentucky bluegrass. There was a weak indication that it was more abundant where there was less bare ground and where vegetation was taller. It appeared to find suitable nesting patches even in grazed areas. In Nebraska, grazing had no effect on it (Kim et al. 2008). In 1 Saskatchewan study, it was 3 times more abundant in ungrazed than grazed grassland, although it was abundant in both habitats. In another Saskatchewan study, it was equally abundant in grazed and ungrazed areas. In Alberta, it was equally common in different grazing systems but more abundant in idle mixed-grass prairies than continuously grazed prairies. In short-grass prairies in Colorado, it nested in lightly to moderately summer- or winter-grazed pastures and heavily grazed winter pastures but avoided heavily grazed summer pastures. In Oklahoma, it nested more frequently in moderately grazed tallgrass prairies than in undisturbed prairies. In Wisconsin, it was equally abundant in rotationally grazed pastures, continually grazed pastures, and ungrazed pastures. In short-grass prairies in Arizona, it was absent in pastures heavily grazed by sheep and common in moderately grazed pastures. In North Dakota, its density was higher in grazed native prairies than in DNC planted to alfalfa and wheat grass. It also occurred in formerly grazed fields that had been idle for a year. In South Dakota, a 20-year drought and a year of grazing on restored fields caused a decrease in plant height and vertical and horizontal density. This resulted in an increase in this meadowlark (Dechant et al. 2002j).

In extensive grasslands in the core of its range, habitat fragmentation by woody vegetation may adversely affect the Western Meadowlark. In Minnesota tallgrass prairies, nest depredation and parasitism decreased with distance from a woody edge, and predation rates were lower on large (130-486 ha) than small (16-32 ha) grasslands. On large patches, the probability of finding nests was highest near forest edges but nest productivity was highest distant from edge (Dechant et al. 2002j). Zuckerberg et al. (2018) concluded that large patches appeared to moderate the effects of weather on this meadowlark. The positive effects of precipitation in the preceding year were strongest on small patches and had little effect on large patches. Warm temperatures reduced nesting success in small patches and increased it in large patches.

The Western Meadowlark population may be affected by drought and weather conditions, particularly in the core of its range. It appears to respond negatively to extreme drought or very wet conditions. In Wisconsin, its abundance was strongly correlated with the amount of spring precipitation but unrelated to summer precipitation (Lanyon 1956a). In Nebraska, it experienced the most erratic patterns of any species in response to drought severity levels. Its abundance declined significantly as conditions changed from mild drought to very wet conditions (Kim et al. 2008). Within nesting seasons, Ludlow et al. (2014) found that weather had no effects on nest survival. Gorzo et al. (2016) analyzed 45 years of BBS data for the United States prairie and badlands area to determine effects of extreme weather events. Its abundance did not respond to significant weather events related to temperature or precipitation. Single-year extreme weather events did not result in abundance declines in the following year. Nests were abandoned in mid-June in 1 year, but this did not result in lower abundance the next year. In short-grass prairies in Colorado, nest survival was lower after very hot days, after dry days, and on stormy days during both the incubation and nestling phases. Survival rates were lower during warmer and drier breeding seasons. They modelled the projected effects of climate change assuming a 2-3°C increase in daily maximum temperature and 1-2 additional dry days experienced by each nest. This suggested a decline of 5% in daily nest survival in the most conservative scenario and 8-10% in the least conservative. Increasing dryness had a greater effect than increasing temperatures. The combined effects of increasing temperatures and dryness could result in a 50% decline in overall nest success. In North Dakota, abundance of the Western Meadowlark was positively correlated with the number of ponds present in May in the current and previous years combined, but not by the number of ponds in the current year on its own or by drought indices (Niemuth et al. 2008). In the United States, higher amounts of precipitation in the preceding year were associated with higher nesting success, but wetter conditions during the breeding season reduced success. Extremely hot or cold conditions early in the breeding season were associated with lower nest success rates (Zuckerberg et al. 2018).

Agricultural chemicals may have adverse effects on the Western Meadowlark. It may die from eating poisoned grain designed to kill rodents (Bent 1958). In Oklahoma, several died after eating grain treated with insecticides. These were known to bioaccumulate and be toxic to vertebrates (Griffin 1959). The effects of grasshopper control methods (malathion, carbyl in oil, carbyl bait, and another bait) were evaluated in Colorado, Idaho, North Dakota, Utah, and Wyoming. Its density declined 10 and 21 days post treatment due to a reduction in insect prey. In Colorado and New Mexico, it suffered mortality where toxaphene was applied. No effects on brain levels of

acetocholinesterase were detected due to carbyl. Fenitrothion has been reported causing declines and diazinon caused mortality and significant declines in Wyoming (Dechant et al. 2002j).

Shaffer and Buhl (2015) studied the effects of 3 wind-energy facilities on the Western Meadowlark in North and South Dakota. Immediate displacement occurred in 1 year at 1 site overall and within 100 m of wind turbines. Long-term displacement (2-5 years after installation) occurred at the same site but not the other two. Delayed displacement may have been due to site fidelity. Sustained displacement mostly occurred within 100 m of turbines. The inconsistent response across study areas probably resulted from habitat differences. The site where the response occurred may have been a cumulative effect of conversion of adjacent grasslands to croplands. There were few other disturbances at the other 2 wind farms.

Ludlow et al. (2015) studied the effects of oil and gas development facilities in extensive tracts of mixed-grass prairie in Alberta on the Western Meadowlark. The proportion of nests within 100 m of a well was significantly higher than expected. Nest density was lower than expected within 100 m of a gravel road. Road avoidance may be due to presence of unsuitable habitat, increased predation risk, or disturbance by vehicles. Wells may provide singing perches for territorial males and therefore attract birds. In Alberta, it was less abundant within 805 m of gas wells. Noise did not appear to be a factor. Results were similar at quiet gas wells and noisy oil wells (Daniel and Koper 2019).

The Western Meadowlark may be affected by human disturbance. It is sensitive to the presence of humans in its territory. Females flushed during laying or early incubation often abandon the nest (Davis and Lanyon 2020). In Colorado, it was significantly more abundant along control transects than along recreational trails in mixed-grass prairies (Dechant et al. 2002j). During spring snowstorms, it may be attracted to bare areas along roadsides. These birds may be lethargic due to food scarcity. In Wyoming, hundreds were killed by vehicles during such an event (Porter and Bell 2016).

Nixon et al. (2016) projected the response of the Western Meadowlark to climate change in Alberta. They projected a 29% expansion in the area of suitable climate: 150% by 2050 and 200% by 2080, and that all existing habitat would remain climatically suitable. They predicted a 20% increase in the amount of suitable habitat by 2050 and 25% by 2080. The area of suitability shifted northward with projected climate change.

Status

Prior to European settlement, the range of the Western Meadowlark extended eastward only to the edge of forest coverage in Missouri, Illinois, and Wisconsin. After the clear-cutting of forests and their conversion to agricultural lands, it extended its range northeast. It was almost unknown in Michigan in the 1930s but about 20 years later it occurred in all counties. In Wisconsin, it was originally confined to isolated patches of prairies surrounded by Eastern Meadowlarks, but the Western Meadowlark is now widespread in that state. It now occurs in Indiana and reached Ohio in 1930. No significant eastward expansion occurred in the south in Missouri, Kansas, Oklahoma, or Texas (Davis and Lanyon 2020; Lanyon 1956b; Swanson 1996).

The Western Meadowlark extended its range into Ontario from the west with the first specimens collected at Ottawa in 1900, Thunder Bay in 1917, and Sault Ste. Marie in 1921. Breeding was first confirmed at Emo in Rainy River District in 1929. At that time, it was fairly common in the farmland between Fort Francis and Rainy River. Widely scattered populations occurred around the Lakehead by 1934 and a nest was found there that year. By 1940, it was a common resident in that area in agricultural lands. The first record south of Lake Nipissing was at Franks Bay in Parry Sound District in 1932 and one was present in Elgin County in 1935. From then until 1960, it occurred in increasing frequency over a wider area of southern Ontario from Lake Huron east to at least Peterborough and Northumberland counties. It was documented in the Ottawa area in 1954 and 1955. By then, it was a regular breeder east of Lake Superior and on the Clay Belt (Baillie 1939, 1960, 1967; de Vos 1964). It was first seen in the Hamilton area in 1940, and bred intermittently in old fields south of the city from about 1945-60. A nest was found there in 1947. From 1953 onwards for about 4 decades, one to several occurred on territory annually. A colony of 5 occurred in prairie-like pasture near Hagersville (Curry 2006). The first record for Niagara Region was in 1953 at Port Colborne and there were numerous records there until 1966. A decline was apparent after that, with only 5 observations 1966-76 and only 2 in the following 30 years. A nest was found in Wainfleet Bog in 1966 (Black and Roy 2010). From 1958 to 1962, 33 nesting sites were documented in southern Ontario ranging from Essex County to Oshawa. In many years, what was reported as a single singing male turned out to be a small colony of 2-8 individuals surrounded by Eastern Meadowlarks (Falls 2000). The Western Meadowlark first reached Kingston in 1969 with an invasion occurring for several years before it began to decline after 1974. By the late 1970s, it was difficult to find more than a half dozen birds in the southwest (Austen et al. 1994; Falls 2000; Weir 2008). By the time of the first atlas, the population had declined considerably. The first atlas indicated that the Western Meadowlark occurred in the Thunder Bay and Rainy River areas and in scattered locations in southern Ontario, including Manitoulin Island and southwestern Ontario east to the Peterborough area. Highest concentrations in the south were in Bruce County. It was most abundant in the Rainy River area where it was more common than the Eastern Meadowlark. It was reported from 84 squares with 69 of them in the south. It was doubtful that it nested in all these squares and it was concluded that the distribution map overestimated its abundance. It was estimated that fewer than 100 pairs nested in the southern portion of the province, but that the northwestern population might be higher (Eagles in Cadman et al. 1987). James (1991) considered the Western Meadowlark a common summer resident in western Rainy River District, rare in the Thunder Bay area, and rare to locally uncommon in the south in agricultural land, mostly west of Toronto.

Falls (2000) noted further declines in the Western Meadowlark before the second atlas was initiated. BBS data for 1966-96 indicated that it had declined in Ontario at a rate of 5.7% per year in Ontario. In the last 2 years of this period, none were reported. The breeding population in the northwest was still extant, but it appeared to have declined over the 15 years since the atlas. It also declined in the Great Lakes states suggesting that sources for Ontario birds are dwindling.

The second atlas indicated no change in the range of the Western Meadowlark, but its probability of occurrence declined significantly province-wide and in all regions where it occurred. It was observed in only 34 squares in the entire province, with almost all losses occurring in the southwest. Most squares in the southwest were occupied by a single pair and often only for 1 or 2

years. There were only 2 squares in the south that were occupied during both atlases. The population in the Rainy River area was still present but it was less common than during the first atlas (Leckie in Cadman et al. 2007). In the Hamilton area, the decline in the Western Meadowlark was obvious after the mid-1980s and there were only 2 records in the decade prior to 2006 (Curry 2006).

BBS data indicate that the Western Meadowlark decreased at annual rates of 1.5% in Canada and 3.61% in Ontario 1970-2021. Trends for 2011-21 were annual increases of 1.28% in Canada and 1.03% in Ontario. All results were highly reliable except that the short-term trend for Ontario was of low reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Fledglings are incapable of fight when they leave the nest and spend their first week crawling and hopping among the vegetation. During their second week they make short flights and are capable of sustained flight in the third week. They remain with their parents and are dependent upon them for the first 2 weeks out of the nest (Bent 1958; Davis and Lanyon 2020; Giovanni et al. 2015). In Nebraska, Giovanni et al. (2015) radiotracked 28 fledglings from 12 nests on a 500-ha meadow dominated by smooth brome, redtop, timothy, wheat grass, quack grass, Kentucky bluegrass, and reed canary grass with some native grasses, sedges, spikerushes, and clovers. As young aged, they moved greater distances from their nest and between sequential sites. They began dispersing further than 0.5 km from nest sites during their fourth week postfledging. They selected sites with shallower litter, taller vegetation, and less cover by grasses and sedges than occurred at random sites. The amount of bare ground and cover by forbs appeared to have no influence on habitat selection. The probability of a habitat being selected by a 30-day-old fledgling decreased with litter depth and increased with vegetation height. Seventy-day-old fledglings selected areas with increasing litter depth and lower vegetation height. Habitat selection varied with ambient temperature. At 39°C, they selected areas with increased litter depth, lower vegetation, and lower coverage by grasses and sedges. At 19°C, they selected areas with taller vegetation, decreased litter depth, and lower coverage by grasses and sedges. Selecting areas with taller vegetation and shallower litter may have allowed fledglings to maximize thermoregulation and minimize caloric expenditure on movement respectively. Twenty-two of 23 mortalities (95.7%) occurred during the first week postfledging. Survival increased with age and ambient temperature and decreased with litter depth. The probability of habitat use was 22% when litter depth was 0 cm and near 0% at 12 cm; 15% at 0-cm vegetation height, 20% at 40-cm vegetation height, 30% at 60 cm, 40% at 95 cm, and 55% at 100 cm; and 60% at 0% cover by grasses and sedges, 40% at 20% coverage, 30% at 40% coverage, 20% at 60% coverage, and 10% at 80% coverage.

Fledglings have roosted at night in low shrubs with other juveniles (Bent 1958).

In Saskatchewan, juveniles consumed 8 orders of insects and had a diet similar to that of adults, although they ate more grasshoppers in July and August than adults. Beetles and hymenopterans were also important prey (Davis and Lanyon 2020).

Once young are capable of strong flight, they amalgamate into flocks and are joined by adults after the last broods fledge. Birds remain in flocks until next spring when breeding is initiated again. Where they coexist, flocks may contain both Western and Eastern meadowlarks (Bent 1958; Campbell et al. 2001; Davis and Lanyon 2020).

MIGRATION

The Western Meadowlark is a diurnal migrant that may travel in loose flocks of 15 or more birds (Davis and Lanyon 2020). Three recoveries have been made of birds banded in Ontario. One banded in June in Blenheim was recovered in March in North Carolina (a distance of 783 km), 1 banded in Nilestown in June was recovered in January in South Carolina (1,066 km), and 1 banded in Sandhill in June was recovered in December in Mississippi (1,398 km). The first 2 records are noteworthy because these birds wintered outside the known wintering range and within the wintering range of the Eastern Meadowlark (Brewer et al. 2018).

Migrant Western Meadowlarks return to their breeding grounds in March and April and leave in mid-October, with some staying into November. Females arrive in spring 1-4 weeks after males and yearlings presumably arrive even later (Dancey 1990; Davis and Lanyon 2020). In Ontario, spring migrants have been observed from mid-March until the first week of June. Most autumn records are in October, but birds may tarry until early January (Curry 2006; Lancaster et al. 2004; Tozer 2012; Weir 2008).

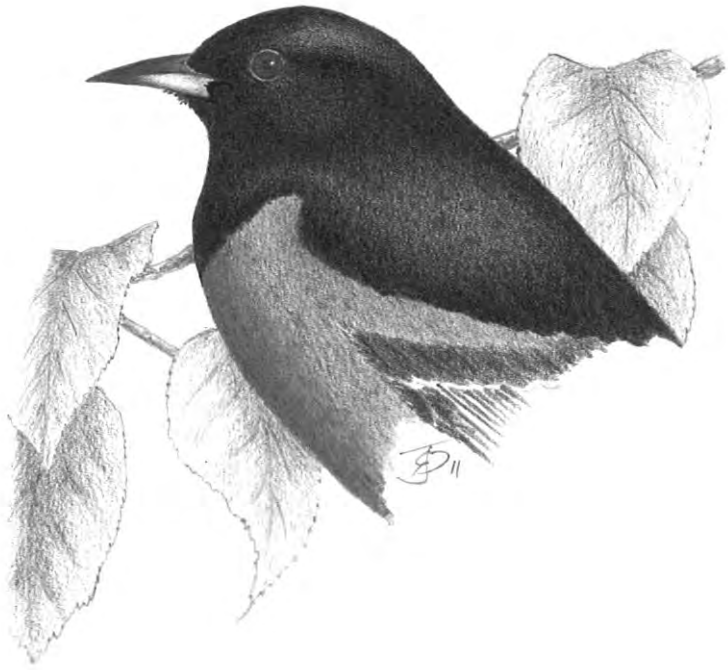
In Manitoba, Murphy-Klassen et al. (2005) found no change in the Western Meadowlark's spring arrival dates in response to climate change over the period 1939-2001.

The Western Meadowlark uses habitat during migration that is similar to its breeding habitat. It occurs predominantly in grasslands but may visit agricultural fields (Davis and Lanyon 2020).

James (1991) considered the Western Meadowlark a rare migrant in Ontario. It occasionally wanders north to Sandy Lake and Moosonee.

Orchard Oriole

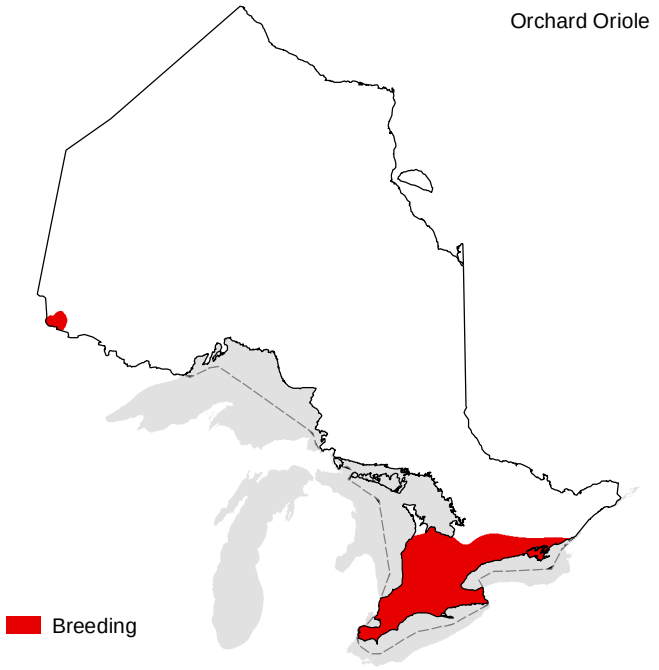
Icterus spurius



BREEDING SEASON

Habitat Requirements

Ontario Orchard Oriole nests were in rural areas in orchards, shrubby fields, and rural gardens (42.9% of nests); in open parkland areas such as campgrounds, picnic areas, and near buildings (34.3% of nests); in urban gardens (20.0%); and along woodland edges (2.9%). Breeding habitats were characteristically open with little or no understorey (Peck and James 1987). Nearly every orchard along the Lake Erie shoreline in Elgin County supported a pair in the early 1950s (Lancaster et al. 2004). It often breeds in orchards or farmyards, suburban areas, campgrounds, nurseries, hedgerows, roadsides, open second-growth woodlands, lightly wooded river shores, and open fields with scattered trees (Austen et al. 1994). In Peel Region, a pair nested in a damp depression regenerating



with 3-m tall trembling aspens with an understory of red-osier dogwood. The patch was 0.28 ha in a 4.8-ha meadow (personal observation).

The Orchard Oriole avoids large forests and grasslands without scattered shrubs or trees or small patches of trees. It exhibits a strong preference for riparian zones bordered by narrow strips of trees, floodplains, marshes, and shorelines of large rivers and lakes. It often nests in shade trees and open shrublands and thrives in habitats with low-density human intrusion such as farms and parklands. It frequently nests in orchards. Trees along roads and scattered shade trees around dwellings are favoured habitats. Where orchards are uncommon, it may nest in nurseries and other habitats with an abundance of trees and shrubs within open habitats (Bent 1958; Scharf and Kren 2022). In Manitoba, it nested in a narrow 2-km long sand dune ridge separating Delta Marsh and Lake Manitoba. The area was treed with peach-leaved willow, Manitoba maple, cottonwood, and green ash with a shrub layer comprised of sandbar willow, red elderberry, and red-osier dogwood (Sealy 1980a). In Illinois in a mosaic of old fields, camp sites, and woodlots, it nested in isolated trees in second-growth fields and along hedgerows and woodland borders (Enstrom 1993). Graber and Graber (1963) concluded that hedgerows and edge shrubs were probably the best habitat in Illinois, but densities were highest in orchards. It occurred in pastures, fallow fields, residential areas, and forests, but these were not preferred habitats. Fallow fields, mixed hayfields, clover fields, and wheat fields were visited for foraging but were not used for breeding. In Wisconsin, it was rare overall in pine and oak barrens but uncommon in oak savannahs (Mossman et al. 1991). McCabe (1948) reported it nesting in a university arboretum in Wisconsin. It was widespread in Louisiana but seldom found in forests and swamps. It was most abundant along ditches, bayous, and canals; in open marshes; and on grassy and shrubby islands along the coast (Kopman 1915). In the same state, Dennis (1948) reported very high nesting densities in a wildlife sanctuary where there were 10 buildings, lawns, 78 shade trees, and numerous shrubs and ornamental plantings within an area of 2.8 ha. There appeared to be similar densities nesting in willow shrubs along the Mississippi River and larger backwaters. Low densities of nests occurred in extensive common reed marshes as far as 8 km from the nearest trees. All nests were on the outer edge of the common reeds overlooking a body of water. It also appeared to nest in dense mangroves and wax myrtle on an island 16 km offshore. In Arkansas, a colony nested in a deciduous woodlot dissected by streams (Thomas 1946b). In Kansas, it nested in forests dominated by hackberry, green ash, black walnut, white elm, and oaks bordering low-lying streams (Verheijen et al. 2017). Most trees used for nesting in the Great Plains grew in linear stands along streams (Schaefer 1976). Zimmerman (1989) also

reported this for Kansas with birds also nesting in isolated trees beside ponds. In South Dakota, it nested in strips of green ash woodland that were mostly 30 m or less in width. Canopy closure and shrub density within the wooded areas had no effect on its density (Rumble and Gobeille 1989). In the same state, it nested both in upland woodlots 3 ha or smaller and in large contiguous riparian woodlands (Gentry et al. 2006). In South Dakota, it nested in shelterbelts with 3 common vegetative features: a tree layer, shrub rows at the edge, and an interior grass layer. It nested in willow shrubs within cattail marshes in Nebraska. Typical habitat there was eastern cottonwood, common hackberry, and ashes where it nested colonially. It nested singly in marginal habitat in willows and junipers. It was strongly associated with riparian woodlands and islands in rivers (Scharf and Kren 2022)

In North Dakota, the Orchard Oriole preferred areas with 7-30% tree cover at the 200-m and 1,200-m scales (Cunningham and Johnson 2019).

Some studies identified microhabitat preferences of the Orchard Oriole or compared its usage of different habitats. In Nebraska, 41% of nests were within 15 m of water and 68% were within 15 m of a road (Scharf and Kren 2022). In Maryland and Delaware, there were no significant differences in its probability of detection in riparian forests 50, 100, 200, or 300 m wide, but it was significantly less likely to be detected in forests 800 m wide (Keller et al. 1993). In Mississippi, it was equally abundant in mature and recently clear-cut forests but absent in 4-year-old regenerating stands with hardwood saplings evenly distributed throughout them (Hurst and Bourland 1996). In the same state, Conover et al. (2009) compared its abundance in fields with no, narrow (7.3-8.5 m), or wide (38.8-44.3 m) borders around them. The borders were native grasses and forbs between agricultural lands and wooded hedgerows. It was absent in fields with no and wide borders and occurred in low density in fields with narrow borders.

Scharf and Kren (2022) compared the habitat requirements of Orchard and Baltimore orioles. The Orchard Oriole preferred smaller-diameter shorter trees that were more densely spaced than the Baltimore Oriole. They were also separated by the distance of the nest to the tree perimeter (2.14 m for the Orchard Oriole and 4.04 m for the Baltimore Oriole), more trees 7.6-15.2 cm diameter at breast height within a 0.04-ha circle around Orchard Oriole nests, and more tree species within this area for the Orchard Oriole. The niche overlap of the 2 species is further ameliorated by later nesting of the Orchard Oriole and it also feeds lower in trees than the Baltimore Oriole.

All Ontario nests were elevated in trees, shrubs, and vines. Deciduous species (77.1% of nests in 12 species) were preferred to coniferous species (22.9% of nests in 3 species). The most frequently used trees were apple (9 nests), maples (4 nests), spruces (4 nests), and pear (3 nests). Nests were usually suspended in forks near ends of horizontal branches and positioned randomly from near the top to the lower portions of trees. They were sometimes well concealed in foliage. There was a pronounced tendency for nests to be built in the same vicinity in successive years. A pair used the same tree for 3 successive years and another nest was built 5 m from the previous year's nest. Nests were 1.8-20 m above ground, with most 3.7-6 m up (Peck and James 1987, 1998b). Lancaster et al. (2004) reported 4 nests in Elgin County: 2 in red pine and 2 in white spruce.

Nests are typically in trees and shrubs, with a strong preference for nesting in deciduous species. The Orchard Oriole occasionally nests in tall conifers planted around buildings. Species it has nested

in include Manitoba maple, green and other ashes, cottonwood, sandbar and other willows, hawthorn, crabapple, spruces, red cedar, elm, white pine, ornamental shrubs, elderberries, apple, pear, oaks, hickories, sycamore, peach, and privet. Most nests are woven around outer forks of branches. Nests tend to be well concealed yet be situated where they receive the greatest amount of sunshine. In Florida, it often nests among Spanish moss where the nest is attached to the moss rather than to twigs. In Louisiana, it nests in common reed marshes. Nests were woven around several stems of common reed in these cases. Nests have been reported in cattail marshes with scattered willows in Nebraska. A nest in a pine was lodged among needles near the top of the tree. Nests have been reported 0.8-20 m from the ground. In Manitoba, mean nest height was 8.8 m in trees that averaged 11.7 m in height. In Nebraska, mean nest height was 3.6 m in willows and 7.9 m in cottonwoods. All Louisiana nests in common reed were 2.1 m above water (Bent 1958; Dennis 1948; Leighton et al. 2002; McCabe 1948; Scharf and Kren 2022; Sealy 1980a). Nest orientation is random. There is no evidence of nest reuse, but 1 pair used an old Baltimore Oriole nest. Although nests do not appear to be reused, the same tree is frequently used for nesting in multiple years (Bent 1958; Dennis 1948; Schaefer 1976; Scharf and Kren 2022).

Other species may influence where the Orchard Oriole nests. It preferentially nests near nests of Eastern and Western kingbirds. In Kansas, Orchard Oriole nests were as close as 0.9 m to an Eastern Kingbird nest and in Louisiana, as many as 4 Orchard Orioles nested in a tree that supported an Eastern Kingbird nest. The aggressive nature of kingbirds in defending their nests may deter predators and benefit nesting orioles. In Wisconsin, 1 oriole nest may have been abandoned because of persistent harassment by a pair of Eastern Kingbirds (Bent 1958; Dennis 1948; McCabe 1948; Scharf and Kren 2022). In Louisiana, Boat-tailed Grackles and Orchard Orioles nested in the same trees. The grackles occupied the uppermost parts of the trees. After the grackles finished nesting, the orioles spread into areas formerly occupied by grackles and built a large proportion of their nests in the central and upper portions of trees (Dennis 1948).

The Orchard Oriole exhibits some territoriality, but is often semicolonial in prime habitat. Some authors never observed any signs of aggression, others stated that a small area is defended around the nest, and others noted intense aggression. Little aggression occurs among birds. Aggression may occur at rich food resources such as a feeder or other sites suggesting that there may be some defence of foraging areas regardless of how close nests are together. In optimum habitat, 4-8 nests may occur in a single tree and 20 nests were reported in an oak tree. Nests are occasionally as close together as 1.2 m. In most cases, nests are more scattered and single isolated pairs are common. In Manitoba, distances between nests ranged from 95 to 610 m. No information is available on home range size (Dennis 1948; Enstrom 1993; Kopman 1915; Scharf and Kren 2022; Sealy 1980a; Thomas 1946b).

Natal philopatry rates are low. In Arkansas, 8 of 127 juveniles (6.2%) returned and 1 returned in 3 consecutive years. Three returned as yearlings but 2 did not return until they were in mature plumage (Thomas 1946b). In Manitoba, 0 of 13 young returned (Sealy 1980a). Scharf and Kren (2022) reported that 22 of 682 young (3.2%) were recaptured in Nebraska.

Adult site fidelity is fairly low. Outside areas where it is very abundant, individual sites may support birds for 2-3 years and then they disappear. In Arkansas, 9 of 26 mature males (34.6%)

returned. One was present in 6 consecutive years, 1 in 4 of 6 years, 1 for 3 consecutive years, 2 for 2 of 3 years, and 4 for 2 consecutive years. Zero of 14 yearling males were recovered, suggesting that they moved to a different nesting area or suffered mortality. Mature males may force yearling males to nest in suboptimal habitat and they may move to better habitat the following year once they attain adult plumage (Thomas 1946b). In Manitoba, 0 of 8 females returned. In 1 year, all 4 nests that were attended by adult males had nested successfully the year before, 2 as adults and 2 as subadults (Sealy 1980a). In Maryland, 25 of 71 birds (35.2%) returned (Dowling and Omland 2009). In Kansas, 1 of 42 males (2.4%) and 1 of 55 females (1.8%) returned (Verheijen et al. 2017). In Nebraska, 1 yearling returned to breed 1 km from where it was banded and bred there each year for 9 years. At 2 sites over 13 years, 123 of 975 birds (12.6%) returned (Scharf and Kren 2022).

Limiting Factors

Eggs have been reported in Ontario nests from the last week of May until mid-July, with most present in the first 3 weeks of June (Peck and James 1998b). In Louisiana, mating began about 1 week after the females arrived and nest building began after another 2 weeks. It is likely that these intervals are shortened at higher latitudes. Nests take 3-7 days to complete. After 1 nest was blown down by the wind, a replacement nest was finished within a week. Eggs are laid at the rate of 1 a day, often starting 3-7 days after the nest is finished. No information is available on when incubation is initiated, but hatching asynchrony suggests that this may occur as early as the laying of the first or second egg. The incubation period is 12-15 days (mean 13.9 days in Louisiana). The first-laid egg hatches first and the others follow in sequence about a day apart. The nestling period is 10-14 days (mean 12.5 days in Louisiana). Nestlings leave the nest in order of age over a 1-3-day period, but all may leave the nest at once if they are disturbed (Bent 1958; Dennis 1948; Scharf and Kren 2022; Sealy 1980a).

Until recently, it was believed that the Orchard Oriole raised a single brood. This is still true in much of its range where it usually leaves the breeding grounds shortly after the fledglings become proficient fliers. Ligi and Omland (2008) documented the first cases of double brooding in 2004 in Maryland. Eight of 24 pairs (33.3%) had a second brood. Sixteen of the first nests were successful and half these females attempted a second brood. Seven of the 8 (87.5%) successfully reared a second brood. Most double-brooded females initiated construction of their second nest within 5 days of fledging their first brood. One pair remained mated the following year and raised 2 broods in each of the years. Double broods have also been confirmed in Georgia (Scharf and Kren 2022). Ontario egg dates indicate that only a single brood is raised (Peck and James 1998b) and only single broods occurred in Manitoba (Sealy 1980a). Rohwer et al. (2009, 2012) presented evidence that some birds raised a second brood in Mexico after breeding in Canada or the United States. Stable isotope analyses supported this theory. Several females that initiated nesting in Mexico had regressed brood patches indicating that they had bred earlier. There was no evidence of recently fledged young suggesting that they had not bred there. Rohwer and Wood (2013) later determined that Mexican birds had bred unsuccessfully prior to initiating a replacement clutch, refuting the post-migration-breeding hypothesis. The Orchard Oriole may renest if the first nest is lost. In Manitoba, 3 of 4 unsuccessful females renested but only one was successful in rearing a brood. Replacement nests were 10-520 m from the original nest. One renested in the same species of tree and the other 2 switched tree species (Sealy 1980a). Clutches of 1-5 eggs have been reported in Ontario, with 4-egg

clutches most common (mean 4.54 eggs; Peck and James 1998b). Elsewhere, clutches of 2-7 eggs have been reported, with most containing 4 or 5 eggs. Mean clutch sizes were 3.6 in Manitoba, 4.1 in Kansas and Nebraska, and 3.80 in Louisiana (Bent 1958; Dennis 1948; Scharf and Kren 2022; Sealy 1980a).

Both sexes are capable of breeding when they are 1 year old (Kopman 1915; Scharf and Kren 2022), and it is probable that most females do so. Yearling males maintain a distinctive subadult plumage which is a significant disadvantage. Adult males are more intensively aggressive toward yearling- than adult-plumaged males. Females select mates rather than territories and move frequently among displaying males before choosing one as a mate. Females display significantly more to adult than subadult males. In Illinois over 2 years, 97% and 100% of adult males and 18% and 11% of subadult males were mated (Enstrom 1993). In Manitoba, 55% of nesting males were adults and 45% were yearlings. There was no different in the nesting success of the 2 age classes (Sealy 1980a).

The mating system consists of season-long monogamy (Enstrom 1993; Scharf and Kren 2022; Sealy 1980a). The pair bond is usually maintained through the season even if renesting or double brooding occurs. In Maryland, mate switching occurred in 1 of 8 cases (12.5%) of double broods. A male paired with a second female for his second nest (Ligi and Omland 2007; Sealy 1980a). It was thought that pair bonds are not maintained between years (Enstrom 1993), but some cases of mate fidelity in subsequent years have been documented. In Maryland, both members of a pair returned in only 2 cases. One of the 2 returning pairs remated and the members of the other pair changed mates. Because of the low site fidelity of adults, there may be limited opportunities for pairs to remate (Dowling and Omland 2009). In Maryland, 1 of 24 pairs (4.2%) returned and reunited, raising 2 broods in each year (Ligi and Omland 2007).

The Orchard Oriole regularly feeds on nectar of flowering trumpet creepers and other flowers and visits hummingbird feeders for sugar water. It has taken grain from gardens and eaten stamens of fruit blossoms. It gleans arthropods from twigs and leaves, pecks ripe fruit with its bill, holds grapes with its foot against a perch while pecking them, forages for grasshoppers in forbs 0.5-2 m tall in open areas, seldom forages on the ground, aerially chases dragonflies and moths, forages for seeds in lawns, gleans arthropods from sweet clover and alfalfa when they are in bloom, and feeds on insects in agricultural fields. During late autumn in northern Ontario, one fed on the ground in dead grasses, in patches of fireweed, in mountain-ash and white birch, and in red elderberry. It selects only ripe fruit for consumption and exhibits a significant preference for mature flowers with the highest nectar content (Bent 1958; Dennis 1948; Graber and Graber 1963; Leck 1974; Lohrer 1977; Scharf and Kren 1997, 2022; Thomas 1946b; Wormington and Lamond 1987). Both sexes forage away from the area that is defended around the nest (Enstrom 1993). When adult males are foraging, they chase away subadult males, and male-female chases may occur. These usually take place in mid-May early in the breeding season. It is uncertain if this behaviour represents defence of foraging territories or is related to defence of territories while selecting nest sites (Scharf and Kren 2022).

Nestlings are fed mostly insects and possibly spiders. In Louisiana, adults chased dragonflies and moths and carried them and other types of insects to their young. Dennis (1948) also found

fragments of oyster shells, crustaceans, and snails in nests. Bent (1958) stated that young were fed mostly katydids.

Early in spring, the Orchard Oriole frequently feeds on nectar and insects. During the breeding season, its diet consists predominantly of insects and spiders but it consumes mostly ripe fruit later in the season, usually after the young fledge. During spring arrival following transgulf migration, hundreds have been observed feeding in black locusts, presumably obtaining nectar. In Kansas, it fed on flower buds of Kentucky coffee-trees and has eaten mulberries in April in Alabama. It often visits hummingbird feeders in spring and early summer until the weather becomes hot. Eleven stomachs collected in Maryland contained 91% animal material and 9% vegetation. The animal matter consisted of 27% mayflies, 14% beetles, 13% grasshoppers and crickets, 13% spiders, 12% caterpillars, 5% bugs, 4% ants, 2% parasitic wasps, and 1% flies. The vegetation consumed was entirely mulberry fruit. In a Texas orchard infested with cankerworms, 80% of the diet consisted of cankerworms. Other caterpillars constituted 17% of the diet. In Texas cotton fields, cotton boll weevils comprised a third of the diet. In samples collected in the 1890s, the Orchard Oriole was documented eating small beetles, aphids, flies, hairless caterpillars, bugs, and a variety of larvae. In Louisiana, it ate bur clover in lawns and highly preferred mulberries (Bent 1958; Dennis 1948; Fitch 1958; Holt 1918; Scharf and Kren 2022). In Nebraska, 116 Orchard Orioles had eaten 30.3% orthopterans, 20.2% spiders, 19.3% beetles, 9.9% fruit pulp, 4.8% lepidopterans, 4.6% true bugs, 2.5% aphids, 2.1% book lice, 1.7% mites, 1.7% flies, 1.5% hymenopterans, 1.2% odonates, and 0.4% soft-winged bugs. The diet consisted of 90.1% arthropods and 9.9% fruit. All spiders that it consumed were less than 4 mm in length and many of the beetles were weevils less than 2.5 mm long. All the true bugs were plant bugs. Some of the hymenopterans were cuckoo wasps. The mites that it consumed were northern fowl mites. It was uncertain if they were ingested incidentally or in an attempt to eliminate them from the nest. Fruit consumed included those of mulberries, chokecherries, and bittersweet nightshade. It shifted from consuming mostly arthropods to fruit in the third week of July, but the timing of this depended upon weather conditions, when fruit ripened, and nestling development. The foraging niche became broader during the brooding period, probably due to the increasing food demands of the nestlings (Scharf and Kren 1997).

The Orchard Oriole is a common host of the Brown-headed Cowbird. It mostly accepts parasitic eggs, but occasionally abandons parasitized nests. In 1 study, parasitized nests fledged 1.5 orioles compared with 3.0 in unparasitized nests. In Ontario, 10 of 32 nests (31.3%) were parasitized. Parasitism rates in other areas include 7 of 7 nests, 6 of 13 nests (46.2%), and 8 of 15 nests (53.3%) in Kansas; 20 of 71 nests (28.2%) in Louisiana; 1 of 6 nests in Manitoba (16.7%); 8 of 13 nests (61.5%) in Nebraska; 1 of 15 nests (6.7%) in Kansas, Nebraska, and Missouri; and 6 of 83 nests (7.2%) reported to the Western Foundation of Vertebrate Zoology. Parasitism by the Brown-headed Cowbird may be a significant limiting factor (Peck and James 1998b; Rivers et al. 2010; Scharf and Kren 2022; Sealy 1980a).

Although the range of the Orchard Oriole is expanding and its population is increasing, it is declining in some local areas due to habitat loss. Natural succession that results in closing of forest gaps and reforestation to coniferous plantations degrade habitat and result in some direct habitat loss. Largest declines appear to be related to the decrease in area covered by orchards, a preferred

habitat. Many early farms had small orchards that provided optimum habitat. These have mostly been removed and replaced with larger, more commercial orchards that are manicured and routinely sprayed with pesticides that reduce food supplies. Loss of orchards and small woodlots has been identified as a significant limiting factor rangewide and specifically in Niagara Region and Norfolk and Haldimand counties in Ontario, and in Illinois. In Illinois, it was common in residential areas 1907-09, but considerably less abundant in this habitat 1957-59. Over time, residential lots became smaller, were less treed, and were more highly manicured. It is even less common in residential areas now as these trends continue (Austen et al. 1994; Graber and Graber 1963; Scharf and Kren 2022).

There are a number of miscellaneous factors that affect the Orchard Oriole. Grazing that destroys shrub habitat has a negative effect. A snowstorm in Nebraska resulted in high egg mortality and probably some starvation. It frequently nests along roads and is struck by vehicles (Scharf and Kren 2022). In Saskatchewan, mortality occurred due to spraying for grasshopper control (Leighton et al. 2002).

Price (2004) predicted that the breeding range of the Orchard Oriole would increase in Ontario if the average summer temperature increased by 2°C.

Status

The first Ontario record of the Orchard Oriole was an immature male in 1865 in Hamilton. It was not observed again in that area again until 1883 when it was found breeding at several locations. At that time, it bred in considerable numbers in the London area and further west along the north shore of Lake Erie near Dunnville (McIlwraith 1894). More recently in the Hamilton area, breeding occurred at Van Wagner's Beach 1937-39 and others were seen in the general area after which it was not observed again until 1954. Nesting has been regular since 1967, with it becoming more common in the 1990s (Curry 2006). In 1891 in Elgin County, it was a very rare breeder until a few years before that time when it became quite common. Nests were found in the St. Thomas area in 1887. By 1954, it was quite common along the Lake Erie shoreline but less common inland. In 2000, it was a rare breeder that was also cyclical, nesting in an area for a couple of years, then disappearing. Most nesting in that county occurs within 2 km of Lake Erie (Lancaster et al. 2004). In Toronto, Fleming (1907) considered it a very rare breeder where nesting was confirmed in 1900. In Niagara Region, it bred at Vineland from 1923 to 1945 then deserted the area (Curry 2006; Sheppard et al. 1936). In the Kingston area, it was first recorded in the summers of 1922-25, with no more records until 1961. After 1971, it was documented in 36 of 37 spring seasons (Weir 2008). It was first recorded in northern Simcoe County at Waubauschene in 1976 (Mills 1981). Baillie and Harrington (1937) reported that it was fairly common in some places along Lake Erie but rare elsewhere. It was confined to the south, breeding north to Lambton and Middlesex counties and east to at least Durham Region. The most northerly records were from Huron County, but these may have been nonbreeders. It has slowly continued to expand its range eastward along Lake Ontario and northward away from the Great Lakes (Austen et al. 1994). During the first atlas, the breeding range included the shorelines of extreme southern Lake Huron, Lake Erie, and Lake Ontario eastward to Kingston. Records were obtained north to Lindsay and northern Grey County. The highest concentrations of records were along the shoreline of Lake Erie with inland extensions in Elgin, Norfolk, Haldimand, and Brant

counties, and in the Hamilton and Toronto areas (Flood in Cadman et al. 1987). James (1991) considered the Orchard Oriole an uncommon summer resident in the Carolinian Forest Region and rare north to Georgian Bay and Kingston.

The second atlas revealed that the distribution of the Orchard Oriole was essentially the same as during the first atlas, but 2 breeding records were obtained from the Lake of the Woods area. Its probability of occurrence increased significantly province-wide since the first atlas. Increases were most dramatic in the Carolinian Forest Region but significant increases also occurred in the Great Lakes–St. Lawrence Forest Region south of the Shield. It continued to be most abundant along the north shore of Lake Erie, with greatest concentrations in the extreme southwest and in the Long Point area. Lower abundance occurred along the Lake Ontario shoreline east to Prince Edward County and along the Lake Huron shoreline north to the base of the Bruce Peninsula. Outside the Carolinian Forest Region, many records were of isolated unmated males. It may be quite frequent in some years and absent in others (Woodliffe in Cadman et al. 2007).

Since about the 1980s, the Orchard Oriole has extended its range to the north, south, and west. Its population has increased within the past 40-50 years (Scharf and Kren 2022). In Ontario, it increased at an annual rate of 5.1% 1983-2013, the 12th largest increase of any species in the province (Cadman et al. 2016). Breeding Bird Survey data indicate that it increased at annual rates of 2.84% in Canada and 1.81% in Ontario 1970-2021. Trends for 2011-21 were an annual decrease of 0.434% in Canada and an annual increase of 4.05% in Ontario. The long-term trend for Canada and the short-term trend for Ontario were highly reliable; the other trends were of medium reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Brood division occurs, with each adult caring for half the brood, even though all brood members are occasionally together. Presumably the male cares for all the first brood if the female initiates a second brood. In Manitoba, fledglings spent their first week out of the nest in dense cover within 20-30 m of the nest. The family unit then moved away from the nest. Once fledglings are proficient fliers, they gather in flocks of 5-12, travelling with adults. Yearlings and older males frequently initiate migration as early as mid- to late July. Flocks of females and fledglings of both sexes remain to forage together for another 4-6 weeks before migrating. In some cases, both yearling and older males may stay longer into August and adults continue to split parental duties for half the fledglings. In Arkansas, young that fledged in mid-June stayed until mid-or late July. Those that fledged in July left as soon as they could fly strongly. In Manitoba, family groups moved off the territories, but remained together until autumn migration (Bent 1948; Kopman 1915; Scharf and Kren 2022; Sealy 1980a; Thomas 1946b).

Habitat used during the postfledging period is similar to the breeding habitat. In Arkansas, juveniles foraged on blackberries in openings in wooded areas. Flocks feed on wild cherries, wild grapes, and other wild fruits, and sometimes visit orchards (Bent 1958; Thomas 1946b). In Missouri, Porneluzi et al. (2014) reported Orchard Orioles in clear-cuts in oak-hickory-pine forests during the postfledging period. They captured a total of 6: 4 2 years after clear-cutting, 2 3 years after harvesting, and 0 4-14 years after harvest.

MIGRATION

The Orchard Oriole is a complete migrant in North America, with the entire population moving south of the United States to winter. Migration is nocturnal (Bent 1958; Ligi and Omland 2007; Scharf and Kren 2022).

In Louisiana, adult males arrived first in spring, yearling males arrived a few days later, and females arrived another week later. In Manitoba, both age classes of males arrived at the same time (Dennis 1948; Enstrom 1993; Scharf and Kren 2022; Sealy 1980a). In Ontario, most Orchard Orioles arrive in early to mid-May, with the earliest migrants in mid- to late April (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008).

The Orchard Oriole is one of the earliest passerine species to migrate in autumn. It leaves the breeding territories in late July to early August and some birds arrive in the wintering areas as early as mid-July (Scharf and Kren 2022). Wormington and Lamond (1987) reported a vagrant at Terrace Bay Township in northern Ontario on 25 September, well north of its breeding range. In the Hamilton area, it is seldom seen after the young fledge. Families leave the breeding areas in late June, but it has been observed in autumn from late August to mid-November (Curry 2006). In most of southern Ontario, it disappears suddenly in early to mid-August (Black and Roy 2010; Lancaster et al. 2004; Weir 2008).

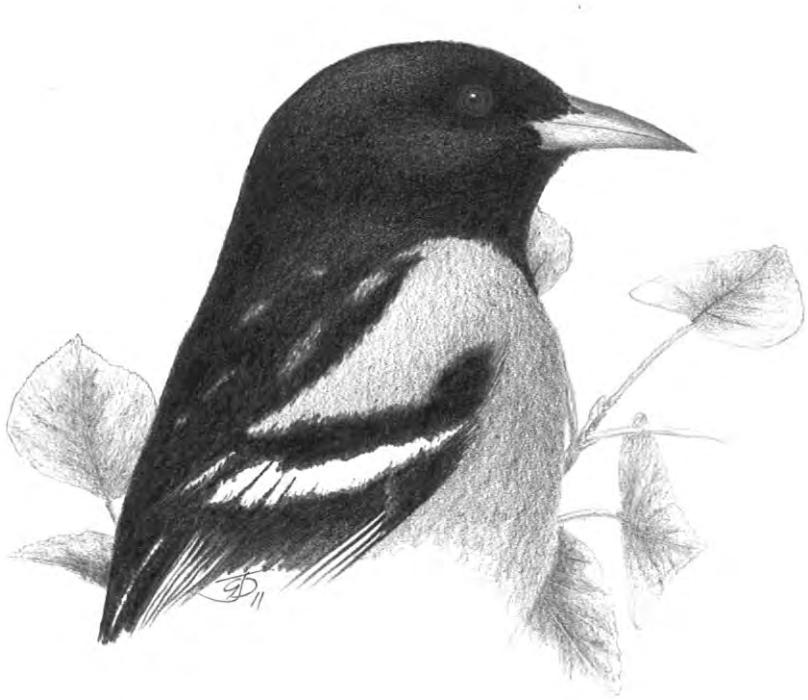
During migration, the Orchard Oriole occurs in wooded margins and parks, gardens, ranches, and farmlands where flowering trees and plants provide nectar (Scharf and Kren 2022). It is often conspicuous in cold springs because it visits hummingbird feeders at rural residences (Lancaster et al. 2004). It is also attracted to grape jelly at feeders (Scharf and Kren 2022).

Some fatalities occur during migration as a result of striking buildings and communication towers (Scharf and Kren 2022).

James (1991) considered the Orchard Oriole an uncommon migrant in Ontario.

Baltimore Oriole

Icterus galbula



BREEDING SEASON

Habitat Requirements

In Ontario, the Baltimore Oriole nested in wooded areas that were usually deciduous but occasionally mixed or coniferous with a few deciduous species present (30.2% of nests); in rural and residential gardens (19.8%); at shorelines of rivers, lakes, marshes, and swamps (17.3%); along roadsides (14.8%); in fields with shade trees and overgrown hedgerows (9.4%); in parks, schoolyards, and playing fields (4.1%); in orchards (3.5%); and tamarack bogs (0.9%; Peck and James 1987).

In Parry Sound and Muskoka districts, the Baltimore Oriole occurred mostly in rural and residential areas (Mills 1981).

The Baltimore Oriole occurred in a variety of habitats in Durham Region. These included young forest with an open canopy, a black spruce bog surrounded by a red maple–poplar swamp, a wet

open forest, a sugar maple stand with numerous openings, a mature maple-oak stand with sparse canopy on rocky ridges, a mature beech–sugar maple woodlot, and a beech woodlot (Speirs and Orenstein 1975).

In the Carolinian Forest Region, it was more common in the Hamilton area in ornamental trees in parks than in the country (McIlwraith 1894). In the same area, it was formerly an abundant nester in elms along roads, but has since adapted to nesting in cottonwoods and ashes (Curry 2006). In Niagara Region, it was a common resident, nesting in tall elms and maples in older residential areas of Niagara Falls, St. Catharines, and Welland, as well as in towns and villages and along roads (Sheppard et al. 1936). It occurred in both urban and rural settings in Elgin County (Lancaster et al. 2004). At Point Pelee, it inhabited open forests dominated by ash (Dodds and Otis 2009).

In Ontario south of the Canadian Shield, the Baltimore Oriole was positively correlated with the amount of forest cover 100 m or further from edge and negatively correlated with woodlot size, amount of forest cover within 2 km, and amount of regional forest cover. All relationships were nonsignificant (Austen et al. 2001).

The Baltimore Oriole prefers fairly open habitat with tall trees, especially deciduous species. Historically, it was probably confined to woodland edges, open riparian areas, savannahs, burns, and natural forest openings. It is now well adapted to nesting in human-altered landscapes. These include urban parks; shade trees in residential areas; tall trees along roadsides, hedgerows, and in regenerating old fields; isolated tall trees; university campuses; edges of fragmented woodlands; narrow strips of trees along watercourses and water bodies; grasslands with scattered trees; forested ridges between lake and marsh habitat in Manitoba; shelterbelts; open farmlands; orchards; pastures with some tree cover; oak savannahs; upland and swamp deciduous forests; regenerating strip mines; clear-cuts and burns; and pine and oak barrens. It may also nest in mixed forests and rarely in coniferous forests and plantations (Bielefeldt and Rosenfield 1994; Brush 1987; Campbell et al. 2001; Faanes 1987; Golet et al. 2001; Graf and Greeley 1976; Hurst and Bourland 1996; Keller et al. 2003; Leighton et al. 2002; Ligi and Omland 2007; Mossman 1988; Mossman and Hoffman 1989; Mossman et al. 1991; Packard 1948; Perreault and Aubry in Gauthier and Aubry 1996; Pleasants 1979; Rising and Flood 2020; Rumble and Gobeille 1988; Sealy 1980b; Suthers 1988; Zimmerman 1989). Substrates beneath nests may include herbaceous or shrub cover, lawns, uncut grass, forest understorey, grazed pastures, road shoulders, gravel and paved roads, and cultivated fields (Graf and Greeley 1976). In the Great Plains, it prefers small or narrow strips of green ash woodlands. It prefers

trembling aspen stands further west and in the aspen parklands. It may also inhabit balsam poplar stands (Campbell et al. 2001; Faanes 1987; Faanes and Andrew 1983; Grant and Berkey 1999; Johns 1993; Rumble and Gobeille 1998).

The Baltimore Oriole tends to avoid heavily forested landscapes. In Pennsylvania, Keller and Yahner (2007) detected it more frequently in fragmented than unfragmented landscapes. In the mid-Atlantic states, its abundance was negatively correlated with the amount of forest cover within 2 km (Robbins et al. 1989). In North Dakota in 400-m landscapes with 30% or less forest cover, its probability of occurrence increased from 5% with 0-30% tree cover within 100 m to 15% at 70% tree coverage. In wooded landscapes, its probability of occurrence was 0-5% with 0-70% tree cover within 100 m. It preferred landscapes that were 48-75% forested; no areas were more than 75% forested (Cunningham and Johnson 2016, 2019). Erskine (1977) considered the Baltimore Oriole characteristic of the prairie-forest ecotone.

Several studies examined microhabitat requirements of the Baltimore Oriole. In regenerating old fields in New Jersey, Suthers (1988) detected it in 20-year-old fields but not in those 10 or 40 years old. Fields 10 years old did not support large enough trees for nesting and 40-year-old fields were completely overgrown with trees. In Illinois, Karr (1968) found it on reclaimed strip mines only in late shrub habitat where the oldest trees were 37 years old. It was absent in areas of bare soils and in early shrub habitat where the oldest trees were 10 years old. It was present in bottomland deciduous forests but not in upland maple-oak forests. In California, Nevada, Utah, and Oklahoma, tree density at nesting areas was 5-116 trees per ha (Pleasants 1979). In Michigan in large contiguous riparian forests that sloped up from a river to upland habitat, it was most abundant near the river and its density tended to decrease toward the upland (Inman et al. 2002). In northeastern hardwoods, it was more abundant in disturbed and successional forests than in mature undisturbed forests (Noon et al. 1979). In Iowa, it was specialized in its selection of nest trees, with all nests in deciduous trees. Stauffer and Best (1980) considered it tolerant of a wide range of habitat and observed it in herbaceous areas, savannahs, scrub, wooded edges, and floodplain and upland forests. It was positively correlated with tree size and negatively correlated with the vertical patchiness of vegetation, slope, and forbs. In Maryland suburbs, it occurred in 45.0% of plots. It was well adapted to suburban areas. Its habitat typically contained deciduous shrub coverage and coniferous and deciduous trees. Its abundance was positively correlated with deciduous shrub volume 0-1.5 m from the ground, coniferous tree volume 7.9-9.1 m from the ground, and deciduous tree volume 1.8-3.0 m and 6.4-7.6 m from the ground. It was negatively correlated with children, dogs, mowed lawns, and building density, suggesting that it preferred quieter, older, and more established neighbourhoods (Thomas et al. 1977).

Most researchers consider the Baltimore Oriole a forest edge or obligate forest edge species (Austen et al. 1994; Freemark and Collins 1992; Golet et al. 2001; Grant and Berkey 1999: Keller and Yahner 2007; Keller et al. 2004; Suthers 1988). Faanes (1987) considered it a forest-interior species nesting in wooded draws in North Dakota. Most of these were narrow strips of forest, so it is unlikely that orioles nested very far from edges.

Freemark and Collins (1992), Golet et al. (2001), Grant and Berkey (1999), Keller and Yahner (2007), and Stauffer and Best (1980) concluded that the Baltimore Oriole was not area sensitive.

Johns (1993) considered it area sensitive in Saskatchewan trembling aspen stands. He examined stands 0.04-36.7 ha in size and found it in stands 1.2 ha and larger.

All Ontario nests were elevated in trees and shrubs, and all but 2 were living. Deciduous trees and shrubs (19 species, 94.3% of nests) were preferred to conifers (6 species, 5.7% of nests). The most frequently used species for nesting were elms (122 nests), maples (71 nests), poplars (56 nests), willows (33 nests), birches (28 nests), and oaks (14 nests). Most nests were suspended at ends of branches with only a few at the centre of the tree (4 nests were near the trunk). They almost invariably hung from branches where they were attached by their rims. One nest was not suspended and 2 were in the crotch of limbs. Old nests were sometimes reused in the following year. Nests were 1.2-30.5 m from the ground, with most 5.5-10.7 m up (Peck and James 1987). In Muskoka and Parry Sound districts, white birch and poplars were favoured nest trees, but 1 nest was in a pine. Nests were 5.5-17.7 m from the ground (Mills 1981). In the Kingston area, nests were in elms, poplars, birches, and tall lilacs (Weir 2008). In Elgin County, nests were in a willow tree and a white spruce (Lancaster et al. 2004). In Oxford County, Dance (2008) reported a nest in a black alder.

Throughout its range, the Baltimore Oriole nests in trees and tall shrubs, highly selecting for deciduous species. Elms are highly preferred for nesting, often used significantly more than their relative abundance. Nest trees are selected based on their height and size, with the habitat beneath the nest of no importance. Since the demise of most elm trees due to Dutch elm disease, it has adapted to nesting in other tall trees such as sycamores and cottonwoods. Nests have been reported in sugar and red maples, white and black oaks, apple, pear, shagbark hickory, weeping and black willows, trembling aspen, balsam and black poplars, locusts, Norway spruce, hemlock, horse chestnut, and birches. Most are near the tip of a branch distant from the trunk, attached to slender twigs. Nesting high in trees at tips of branches may be an adaptation to deter predation by squirrels. Less frequently, nests may be close to the trunk and supported in forks of larger branches. One nest was in a limb that had broken off but was still attached to the tree by Virginia creeper. The nest subsequently fell and the replacement nest was built in the remains of the Virginia creeper. It usually builds a new nest for each nesting attempt but occasionally refurbishes an old nest. Old nests from the previous year may be torn apart and the material incorporated into the new nest. Replacement nests and those built in subsequent years are often very close to earlier nests. In some areas, nests are oriented randomly but in others they are on the leeward side of trees. Nests have been reported 2-22 m above ground, with average nest heights ranging from 7.6 to 13.0 m. In Massachusetts, nests in white elm averaged 10.6 m from the ground. Those in sugar maples averaged 13.0 m from the ground (Campbell et al. 2001; Graf and Greeley 1976; Leighton et al. 2002; Mousley 1916a; Pleasants 1979; Rising and Flood 2020; Schaefer 1976; Stauffer and Best 1980; Tyler in Bent 1958). Schaefer (1976) examined 516 nests in winter near Campbellville and Pickering in Ontario, and in Quebec and the Great Plains region. At Campbellville, nests averaged 8.9 m from the ground, were 3.0 m from the top of the tree, 0.6 m from the perimeter of the tree, 2.3 m from the trunk, and on branches 1.6 cm in diameter. At Pickering, nests averaged 9.6 m from the ground, were 2.6 m from the top of the tree, 0.4 m from the perimeter of the tree, 0.7 m from the trunk, and on branches 1.7 cm in diameter. Pickering nests were oriented randomly but Campbellville birds tended to face their nests away from the east. Nests in Ontario and Quebec were in taller trees, closer to the perimeter of the trees, on thinner branches, and were less firmly attached than those in the Great Plains. Nest trees in

Ontario and Quebec were larger than those in the Great Plains. Nests in the latter region may experience greater wind stress and therefore be attached more firmly. Most nests were at least 1 m above the understorey and toward the periphery of the tree. In Ontario, most nests were in trembling aspen and maples. In Manitoba, Mackenzie et al. (1982) compared Baltimore Oriole nests with those of 2 other high-nesting species: Western Kingbird and Eastern Warbling-Vireo. The Western Kingbird nested exclusively in green ash and peach-leaved willow. Fifteen percent of Baltimore Oriole nests and 17.6% of warbling-vireo nests were in cottonwoods, which had a clumped distribution and represented only 0.9% of available trees. Nests sites of these 2 species were not significantly different from each other, with their habitat characterized by large trees with little or no understorey. Although the 2 species were very different in their nest construction and placement, these differences may not be sufficient to preclude competition for nest sites. Rising and Flood (2020) compared Baltimore and Orchard oriole nests in Nebraska. The Baltimore Oriole preferred larger, taller, and more openly spaced trees than the Orchard Oriole. Baltimore Oriole nests were in trees with larger crowns and closer to the tree trunk, but there was no difference in the height of nests above the ground for the 2 species.

Upon arrival, the male defends a large territory. Once nesting begins, the territory shrinks to a radius of approximately 5 m around the nest. Territories are defended against other males, and females also defend the territory against other females. Males frequently intrude into territories to seek extra-pair copulations. In Colorado, all intruding males were paired and both yearling and adult males trespassed into other male's territories. Those that were detected by the resident male were immediately chased out of the territory (Edinger 1988; Rising and Flood 2020; Sealy 1980b). As many as 3 nests have been reported in a single tree, but these are typically large trees where nests can be 7-10 m apart either horizontally or vertically. Usually 1 nest is well established before a second pair initiates a close nest, and these nests are usually attended by a yearling male. Average nearest-neighbour distances of nests vary considerably annually, with nests closer in years of higher nesting densities. Nearest-neighbour distances may range from 12.7 to 59.5 m (Graf and Greeley 1976; Pleasants 1979; Rising and Flood 2020; Sealy 1980b). Some feeding may occur on territories, but most foraging occurs 50-100 m from the territory. Feeding areas are not defended during the breeding season, and home ranges may overlap by 47.5% without any aggression. In narrow strips of treed habitat in extensive grasslands, nests sites may be limited but food in lands adjacent to the nesting habitat may be abundant. The amount of foraging that occurs in the nesting territory ranges from 16% to 81%, with lowest in-territory foraging rates occurring at higher densities. In extreme cases, this may lead to semicolonial nesting, but not for the usual reasons of highly clumped or unpredictable food supplies. In Nebraska, the average home range size of yearling males was 1.74 ha (range 0.41-1.86 ha). Older males had average home range sizes of 0.63 (range 0.15-1.68 ha; Pleasants 1979; Rising and Flood 2020; Sealy 1980b).

The Baltimore Oriole may defend food resources from other species, particularly in winter, but also during migration and the breeding season. Packard (1948) found a Baltimore Oriole and an Eastern Kingbird nesting in the same tree. There was a large web of tent caterpillars between the nests and both species fed from it and fed their young the caterpillars. Both species spent considerable time chasing the other from this food source. A male oriole that was feeding on caragana blossoms killed a Ruby-throated Hummingbird that ventured within 30 cm (Wright 1962).

In Costa Rice, orioles regularly defended 8-12 nectar-producing flower heads, each with approximately 50 flowers. Orioles aggressively hopped toward intruders and expelled them. Aggression was most common toward hummingbirds but was also directed toward wrens, tanagers, other oriole species, and Yellow Warblers (Schemske 1975).

The Baltimore Oriole often nests near the Eastern Kingbird (Packard 1948; Peck and James 1987; Tyler in Bent 1958). The kingbird is particularly aggressive in defending its nest from predators. Nesting near a kingbird may reduce the probability of an oriole's nest being depredated.

Natal philopatry rates are low. Zero of 51 nestlings returned in Massachusetts (Rising and Flood 2020). In Manitoba, 17 of 96 nestlings and 416 fledglings (3.3%) returned to nest in 1 year. In another year, 2 of 199 nestlings and 140 fledglings (0.6%) returned (Sealy 1980b).

Adult site fidelity rates are fairly low. In Maryland, 16 of 42 adults (38.1%) returned (Dowling and Omland 2009). In Kansas, 2 of 41 males (4.9%) and 2 of 64 females (3.1%) returned (Verheijen et al. 2017). Another Kansas study reported that 9 of 28 adult males (32.1%), 17 of 35 yearling males (48.6%), and 13 of 33 females (39.4%) returned (Rising and Flood 2020). In Manitoba, older males returned to the vicinity of their previous nest but most females paired with a different male than in the previous year (Sealy 1980b).

Limiting Factors

Eggs have been found in Ontario nests from mid-May until the third week of June, with most present in the first 2 weeks of June (Peck and James 1998b). In Algonquin Park, dependent fledglings have been seen from mid-July to late August (Tozer 2012).

Immediately upon arrival, older males and some yearlings start to defend a territory. When females arrive, they are vigorously courted as they forage within territories. Females may move among territories until they finally settle on one. Pairs form 1-7 days after the females arrive and most females begin nest building within 10 days of their arrival (range 1-14 days). In Colorado, the outer shell was woven in 4 or 5 days and another 4-6 days were required to add the lining. Other reports stated that it takes 4.5, less than 6, 5-8, or 15 days to build the nest. Most nests are built within a week. It is unknown if there is a delay between nest completion and the initiation of egg laying. Eggs are laid at the rate of 1 per day. Incubation begins with the laying of the penultimate or last egg. The incubation period at 1 Ontario nest was 14 days. Incubation periods of 11-14 days have been reported elsewhere (average 11 days). Hatching occurs over 2-3 days, but may take as long as 5 days during inclement weather. The nestling period is 11-14 days but mostly 12-13 days. Nestlings that leave the nest when they are less than 10 days old as a result of disturbance or other factors usually do not survive. One or 2 days before fledging, the young often cling to the outside of the nest and clamber in and out of it (Edinger 1988; Leighton et al. 2002; Peck and James 1998b; Rising and Flood 2020; Tyler in Bent 1958).

A single brood is raised in a season, but renesting may occur if the first nest fails. Clutches of 3-6 eggs were reported in Ontario, with most containing 4 or 5 eggs (mode 5 eggs, mean 4.54 eggs). Clutches of 3-7 eggs have been reported elsewhere, with 4- and 5-egg clutches most common (Ligi and Omland 2007; Peck and James 1998b; Rising and Flood 2020; Tyler in Bent 1958). In Manitoba, clutch size was 3-6, mostly 5 eggs. Mean clutch size over 3 years was 5.06-5.33 eggs (Sealy 1980b).

Mean clutch sizes reported elsewhere include 4.5 in Vermont, 4.7 in Massachusetts, 5.1 in Colorado, and 4.7 in Kansas (Rising and Flood 2020). In Kansas, Labedz (1984) reported a mean clutch size of 4.5 eggs. In 2 years, nests with yearling males had significantly smaller clutches (2.3 and 3.0 eggs) than those of older males (5.1 and 4.9 eggs). Nests with yearling males were initiated later than those with older males. More than half of young from nests with old males fledged before the first nestling from a nest with a yearling male fledged. In another Kansas study, nests attended by yearling males fledged significantly later than those attended by older males in only 1 of 2 years. In this population, there were no significant differences in clutch size and breeding success between male age classes (Flood 1984).

Both sexes are capable of breeding when they are 1 year old (Flood 1984; Rising and Flood 2020). All adult males and all females breed each year, but some yearling males fail to attract a mate. Over 2 years in a Kansas study, 58.2% and 71.0% of yearling males did not breed, suggesting that females were a limited resource. For yearling males that did breed, there were no significant differences in their territory quality, breeding success, or parental quality compared with older males. Yearling males have a plumage that is intermediate in colour between females and older males. This colouration is effective in reducing the amount of aggression elicited from older males and elicits less aggression from females than the plumage of the dullest females (Flood 1984). In Manitoba, 1 yearling male bred in a year during the beginning of a tent caterpillar invasion, 27 bred in the following year at the height of the outbreak, and 0 bred in the year following the outbreak (Sealy 1980b).

The mating system is typically monogamous. In Kansas, a mated male also mated with a neighbouring female whose mate had been removed, suggesting that the Baltimore Oriole may be an opportunistic polygynist (Flood 1985; Rising and Flood 2020). The pair bond typically lasts for a single breeding season. If a female loses her mate prior to egg laying, she may mate with another male. These are usually yearling males that were previously unmated (Flood 1985). In Maryland, both sexes of 4 pairs returned in a subsequent year. In 1 case, the pair reunited but in the other 3 cases, each bird mated with a different bird in the second year (Dowling and Omland 2009). Males frequently intrude into other territories, with older males seeking extra-pair copulations and yearlings possibly prospecting for territories in the following year. Intrusions occur most frequently when the resident female is building the nest, but may occur from prenesting to feeding of the nestlings. In some cases, the intruder chases the female from the nest and may force it to the ground and copulate with it. One female copulated with an intruding male after he displayed to her. In Colorado, intruding males had territories 110-280 m from the resident female's nest. Their females were also fertile when extra-pair copulations were attempted. Males attempt to avoid cuckoldry by guarding their females by following them, driving them away from neighbouring males, spending considerable time foraging or perching near the nest, and copulating with their mate very rapidly (Edinger 1988; Flood 1985; Rising and Flood 2020).

Upon spring arrival, the Baltimore Oriole often visits feeders to feed on sugar water, orange sections, and bananas. Blossoming apple trees are a strong attractant, where it gleans insects and possibly feeds on nectar. During the breeding season, it forages solitarily in trees and less frequently on the ground, in shrubs, or in alfalfa and sagebrush. In Manitoba, it usually foraged high in the

canopy but lower during windy weather. In Colorado, 80% of its foraging time was spent in cottonwoods and the remainder of the time was spent on the bark of these trees, in willows and currants, and on forbs. Sixty percent of foraging was at heights of 7-12 m, 30% below 7 m, and 10% above 12 m. Most foraging occurred on branches 0.3-1.0 cm in diameter. It hunts insects and spiders by gleaning or probing, usually in trees and shrubs and rarely on the ground. It picks insects from spider webs and tears open webs to prey upon tent caterpillars. It rarely captures flies, moths, and dragonflies in the air. It often feeds by gaping, thrusting the closed bill into a fruit then opening the bill, allowing the tongue to swallow the juice and perhaps some of the pulp. It sometimes opens rolled leaves to access the insects inside. It may pick peas from plants and fruits from trees, shrubs, and vines (Beal 1897a; Lancaster et al. 2004; Perreault and Aubry in Gauthier and Aubry 1996; Rising and Flood 2020; Sealy 1980b; Tyler in Bent 1958). In Illinois, there were no differences in foraging manoeuvres between forest and savannah habitats: 65-75% gleaning, 2-12% hanging, 1-20% flycatching, 4-7% hovering, 0-1% sallying, and 2-7% other techniques. The same foraging heights were preferred in the 2 habitats. The area 0-5 m from the ground was strongly avoided, heights of 6-10 and 11-15 m were strongly preferred, and areas above 16 m were used relative to their abundance. It foraged significantly more in black locust and hackberry than their availability. The preference for hackberry may have been because of the high density of leafroller caterpillars. It was not observed foraging in sugar maple or red elm. Sugar maple was a dominant species in the forest but did not provide suitable foraging conditions (Hartung and Brawn 2005). Pleasants (1979) concluded that the abundance of undergrowth in small forest patches was a good indicator of food abundance that potentially influenced nesting density.

Females that lose their mate are capable of rearing nestlings on their own. Nestlings are initially fed by regurgitation but all food is supplied fresh once they reach the age of 4 days (Flood 1984, 1985; Tyler in Bent 1958). Regurgitated food fed to nestlings includes soft parts of grasshoppers and dragonflies plus caterpillars and other insect larvae. Tent caterpillars are frequently fed to nestlings and they may be fed mulberries, cherries, and other fruits later in the season (Packard 1948; Rising and Flood 2020; Sealy 1980b; Tyler in Bent 1958). In Manitoba, Sealy (1980b) analyzed nestling diet in a year when tent caterpillars were extremely abundant and in the next year when they were scarce. In most years, nestlings were fed predominantly midges. Food fed to nestlings in the years when tent caterpillars were abundant and scarce, respectively, consisted of: mayflies, 0% and 14.9%; odonates, 0% and 0.6%; beetles, 0% and 0.6%; moths, 2.0% and 25.4%; geometer moth caterpillars, 8.7% and 1.6%; owlet moth caterpillars, 0% and 5.0%; tent caterpillars and pupae, 63.3% and 0%; midges, 26.5% and 41.4%; and red elderberry fruit, 0% and 0.6%.

In most years in Manitoba, adult Baltimore Orioles subsisted predominantly on midges. In a year when tent caterpillars were abundant, they preyed on most life stages of the tent caterpillar despite the presence of the usual midge population. The nesting density doubled in the second year of the outbreak. Productivity of individual pairs decreased during the second year of the outbreak (with fewer young fledged per nest) but productivity as a whole increased as a result of more pairs nesting (Sealy 1980b). Beal (1897a) analyzed the contents of 113 stomachs. The diet was comprised of 84% animal matter and 16% vegetable matter. Caterpillars were the most important food item, constituting 34% of the diet. They were consumed throughout the breeding season, with fewest eaten in July when some fruit was consumed. Other insects consumed included beetles (mostly

click beetles), bugs (aphids and book lice), ants, wasps, and grasshoppers plus some spiders. Ants were eaten mostly in spring, grasshoppers in July and August, and wasps and spiders were eaten in considerable numbers throughout the season. Vegetable matter included blackberries, cherries, wild fruits, a few peas, and some miscellaneous seeds. Many of the caterpillars it consumes are hairy. In addition to tent caterpillars, these include those of the fall webworm, mourning cloak butterfly, gypsy moth, and tussock moths. Other animal food items include parasitic wasps, snails, treehoppers, lace bugs, scale insects, shining leaf chafers, June beetles, metallic wood-boring beetles, long-horned beetles, leaf beetles, weevils, sawfly larvae, potato beetles, carpenter bees, and pine needleminer moths. It also ate sycamore and hollyhock seeds and aspen leaves, and drilled into grapes, apples, and pears (Tyler in Bent 1958). Prey items in Colorado included 58% leafroller moth caterpillars, 10% sphinx moths, 15% other lepidopterans, 5% ants, 5% aphids, 2% leaf beetles, 1% crickets and grasshoppers, and 4% miscellaneous. In Manitoba on 25 and 26 May, the diet consisted of 57% beetles, 8.5% midge larvae, 7% small midges, 7% small caterpillars, and 20% other insects and spiders. On 8 and 9 June, the diet consisted of 93% large midges. On 20 and 21 June, the diet consisted of 50% large midges, 12.5% medium-sized caterpillars, 6.5% small beetles, 6% spiders, 6% large caterpillars, and 19% other insects. On 1-3 July, the diet consisted of 42% midges; 77% of the food items on 13 and 14 July were midges. The study was repeated 2 years later with similar results except that 42% of the 12 June diet consisted of leafhoppers. It did some damage in Niagara Region to cultivated grapes, usually in late August (Rising and Flood 2020). There are 2 cases of it eating tartarian and Morrow's honeysuckle berries in Ontario. These berries contain rhondoxanthin and impart a reddish colour to the orioles' plumage (Derbyshire and Flinn 2007; Hudon et al. 2013).

The Baltimore Oriole is an ejector of Brown-headed Cowbird eggs, so the rate of parasitism is underestimated. Both sexes eject eggs, often within minutes of the parasitic event. In 2 separate experiments where nests were artificially parasitized with either real or plaster cowbird eggs, all parasitic eggs were ejected. Eggs are spiked with the bill and usually carried away where the contents are often eaten. Occasionally the parasitic egg is simply dropped to the ground below the nest. Orioles can distinguish between their own and cowbird eggs and have not been documented ejecting their own eggs. Cowbird eggs are unusually thick for their size and occasionally the oriole's bill deflects off the cowbird egg and damages one of its own eggs. In Manitoba, 0.38 eggs were broken or damaged for every cowbird egg ejected, so parasitism has a cost even if no cowbird eggs hatch (Rohwer et al. 1989; Rothstein 1977; Sealy and Neudorf 1995; T.S. Smith 1972). One Manitoba nest had a cowbird egg buried in the lining, the only known case of this occurring. The nest was new and contained no oriole eggs, so it is unknown if this was a response to parasitism or simply continuation of nest building. Egg burial may be more prevalent because it is necessary to dissect the nest to find buried eggs (Hobson and Sealy 1987b). Schaefer (1976) found no buried eggs in almost 300 nests from Ontario, Quebec, and the Great Plains. In Ontario, 10 of 181 nests (5.5%) were parasitized (Peck and James 1998b). In Manitoba, 3 of 136 nests (2.1%) were parasitized. At 1 nest, both orioles and cowbirds fledged, representing one of few records where a cowbird successfully fledged from a Baltimore Oriole nest (Hobson and Sealy 1987b). In the same area, 5 of 153 nests (3.3%) were parasitized (Sealy and Neudorf 1995). In 2 Kansas studies, 1 of 17 (5.9%) and 2 of 61 nests (3.3%) were parasitized. Four of 283 nests (1.4%) in the collection of the Western Foundation of

Vertebrate Zoology were parasitized. Oriole nestlings in parasitized nests may be malnourished (Rising and Flood 2020).

Forest fragmentation as a result of clearing for agriculture and urban areas was beneficial for the Baltimore Oriole (Perreault and Aubry in Gauthier and Aubry 1996; Rising and Flood 2020). Friesen et al. (1995) studied the effects of residential development in Waterloo Region. They examined small (3-4 ha), medium (8-15 ha), and large (20-50 ha) woodlots with no development, low development (1-3 houses), medium development (8-15 houses), and high development (25 or more houses) within 100 m. They concluded that the Baltimore Oriole tended to avoid high density housing. Older residential areas were once good habitat, but this habitat has deteriorated and new urban habitat is unsuitable. The large elms that once lined streets died and were removed in the 1960s and 1970s. Many other large trees have become hazardous and have been removed. Many municipalities conducted widespread planting of ash trees as shade trees and these are now dying and being removed. Lots in new subdivisions are too small to support a large tree.

The Baltimore Oriole responds positively to forest management or other factors that open up the forest canopy. In mixed sugar maple stands in southern Ontario, it was most abundant in stands that had experienced heavy diameter-limit cuts, with lesser numbers in stands that had been selectively harvested and those that had not been cut. It was significantly negatively correlated with the basal area of trees (Holmes et al. 2004). In deciduous forests in Pennsylvania, it was 2.7 times more abundant where 50% of 4-ha blocks had been clear-cut than it was in uncut blocks. It was absent where 75% of the block was cut (Yahner 1993). In New York, it was absent or occurred at very low abundance in clear-cuts in northern hardwoods 2-4 years after cutting, gradually increasing with stand age and reaching maximum abundance 55-120 years after cutting (Keller et al. 2003). In Pennsylvania and New Jersey over a 15-year period, hemlock declined from 56% of the total basal area to 46% due to the hemlock woolly adelgid, resulting in increased deciduous understorey. It increased over this period, probably in response to the more fragmented canopy (Toenies et al. 2018).

Inclement weather during the breeding season may delay breeding, reduce the Baltimore Oriole's abundance, or cause females to suspend nest building or abandon the nest. Nests initiated later in the season are more likely to fail or be abandoned (Rising and Flood 2020).

Declines in Baltimore Oriole populations have been documented as a result of gypsy moth control and spraying of DDT. It is occasionally killed by vehicles, but this is not a significant limiting factor (Rising and Flood 2020).

Price (2004) concluded that the breeding range of the Baltimore Oriole might contract in southern Ontario if the average summer temperature increased by 2°C. In southern Quebec, DesGranges and Morneau (2010) considered it very sensitive to climate change. It was associated with warm summers and the mean number of annual degree-days 10°C or more in May, June, and July. They concluded that it may be limited by the number of degree-days.

Status

The Baltimore Oriole is probably more common now than before European settlers cleared much of the forest cover in the south. In Elgin County, it was a common breeder in 1891, 1954, and 2000 (Lancaster et al. 2004). It was common in the Kingston area in 1859, 1909, 1965, 1973, 1989, and 2008

(Weir 2008). Baillie and Harrington (1937) considered it a common breeder in southern Ontario north to Parry Sound District and Ottawa. It was common in the Lake of the Woods area but apparently did not occur between there and Parry Sound District. The first atlas revealed that the range of the Baltimore Oriole was more extensive. It bred in the Kenora area east to the Thunder Bay area, and from the northeast shore of Lake Superior east to the Lake Abitibi area south to the southern boundary of the province. There were gaps in its distribution in the Algonquin Highlands and other extensively forested areas. In more northern areas, it is limited by the dense forest and scarcity of the deciduous trees that it prefers. It was most abundant south of the Canadian Shield, where it was documented in every square, and was widespread in the southern Shield south of the Algonquin Highlands (Flood in Cadman et al. 1987). James (1991) considered it a common summer resident north to Georgian Bay and Ottawa; uncommon north to Kenora, Thunder Bay, and Sudbury; and occasional and rare to Red Lake, Hearst, and Timiskaming District.

The second atlas revealed that the Baltimore Oriole had withdrawn from its more northerly range since the first atlas. It was not detected between Kenora and Thunder Bay or near the northern portion of Lake Superior, and was absent in many squares in the Sudbury–North Bay area where it was present during the first atlas. Its probability of occurrence declined significantly province-wide and in the Great Lakes–St. Lawrence Forest Region, most notably in the Canadian Shield. It was almost completely absent in the Algonquin Park area and declined steadily in the Haliburton area despite the presence of optimum habitat. Declines were consistent with the increase in forest cover and reduction in the amount of open and edge habitat. Most of the population bred south of the Canadian Shield. Highest densities occurred in the Kingston area and much of the Carolinian Forest Region except for the intensively farmed areas of Essex and Lambton counties and Chatham-Kent. High densities occurred in the urban areas of Toronto where it nested in wooded ravines, parks, and residential areas with mature trees. The ecotone along the southern edge of the Shield also supported high densities. This area is characterized by marginal farmlands with numerous hedgerows and tall trees (Cadman in Cadman et al. 2007).

Breeding Bird Survey data indicate that the Baltimore Oriole decreased at annual rates of 1.4% in Canada and 1.15% in Ontario 1970-2021. The trends were annual increases of 2.39% in Canada and 0.712% in Ontario 2011-21. All results were highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Young can only fly short distances when they first leave the nest but can fly reasonably well 2-3 days after fledging. They follow their parents for approximately 2 weeks and are fed by them during this period (Rising and Flood 2020; Tyler in Bent 1958). Sealy (1980b) described the postfledging period in Manitoba. Brood division occurs, with each adult caring for half the brood. Females abandon their portion of the brood before the male does and begin to move more widely during the last few days of June. Fledglings do not begin moving through the habitat until they have been out of the nest for about 10 days. At this time, they are capable of sustained flight and are presumably independent of the male. In early to mid-July, many males are followed by 3-4 young with few young still with females. Females begin to moult almost immediately after they leave their brood and may move 1-2 km from the nesting territory within 1 or 2 days. Males moult later than females because they remain with the broods longer and remain in their territories until they leave the breeding grounds,

usually in late August. By mid-July when the moult is well underway, females and older males withdraw into dense cover where they are silent, secretive, and essentially cease moving. These birds forage mostly in morning-glories and common hop vines in sandbar willows during this period. Yearling males begin their moult at about the same time as females and begin moving southward early in their moult. One banded on 20 June was found on 10 July 245 km southeast of the banding location. Tyler (in Bent 1958) reported that flocks of juveniles or birds in female plumage frequently occur until birds start to leave in late August. No males were ever seen in these flocks.

Habitat used during the postfledging period is similar to breeding habitat. Flocks of young and adults may occur in these habitats as well as in shrubby pastures (Tyler in Bent 1958). The Baltimore Oriole also inhabits clear-cuts during the postfledging period. In Pennsylvania, Stoleson (2013) netted birds in 3-6-year-old clear-cuts and in adjacent mature deciduous forests 90-100 years old. He captured 12 adult and 3 juvenile orioles in clear-cuts and 0 in mature forests. He considered it a forest edge species. In Ohio, Vitz and Rodewald (2006) netted in clear-cuts 4-7 years old and caught 21 adults and 55 juveniles.

In Kansas, Fitch (1958) observed a pair that arrived in late August with dependent fledglings and remained into early September. During this period, the family group remained within an area of 0.85 ha.

MIGRATION

The Baltimore Oriole is a complete migrant, travelling medium to long distances between the breeding and wintering grounds. Most migration is nocturnal but some diurnal migration occurs. Many appear to migrate at dusk or dawn, and migration continues after dawn. During migration, it may occur in flocks of all age and sex classes (Rising and Flood 2020). Tuck et al. (2018) observed autumn morning departures in Ohio along the southern shore of Lake Erie. Orientation of flights was west to northwest, following the lakeshore. Orioles avoided crossing the lake. Two birds banded in Ontario were recovered in New Jersey and Guatemala 618 km and 3,554 km, respectively, from the banding site. A bird recovered in Ontario had been banded in Honduras 3,298 km away (Brewer et al. 2018).

In Manitoba and Massachusetts, adult males and females arrive simultaneously in spring and yearling males arrive later (Baubock et al. 2012; Sealy 1980b). In most areas, adult males arrive before females by 1-10 days with considerable variation annually at individual sites. Some females arrive before yearling males (Campbell et al. 2001; Edinger 1988; Flood 1984; Leighton et al. 2002; Rising and Flood 2020; Tyler in Bent 1958). At Long Point, mean capture dates were 13.4 May for older males, 17.4 May for yearling males, and 18.2 May for males of unknown age (Stewart et al. 2002).

The Baltimore Oriole arrives in numbers in southern Ontario in early May but birds may appear as early as mid-April (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008). In the southern Shield, it arrives in mid-May with some appearing in early May (Mills 1981; Tozer 2012). Over 22 years at Deep River, peak numbers were recorded 13-30 May (Rising and Flood 2020).

Several studies examined spring arrival dates over time to determine the Baltimore Oriole's response to increasing temperatures due to climate change. In New York, Zelt et al. (2017) used first sighting dates for 1888-1939 and 1964-2013. First arrival date decreased significantly at a rate of 0.26

days for all long-distance migrants for 1987-2012. Evidence for longer breeding seasons was weak and nonsignificant. In Manitoba, it arrived significantly earlier over a 63-year period in response to increasing temperatures (Murphy-Klassen et al. 2005). In Massachusetts, the average first sighting was 8 May 1851-1973 and 6 May 1988-2007. The correlation between arrival date and temperature was not quite significant (Ellwood et al. 2010). In Massachusetts, Bauböck et al. (2012) compared mean arrival dates over a 32-year period and reported no change in response to climate change. Its arrival date was associated with temperatures of the current or previous year, with more females in years with higher temperatures. The timing of migration may respond to climate change in different manners in different locations.

Yearling males leave the breeding grounds first before completing their moult. Adult males tend to migrate before females, although flocks of mixed sex and age classes occur. The peak of autumn migration at Deep River was 26 July to 30 August (Rising and Flood 2020). In the southern Shield, most migrants are seen in August with most gone by the end of August, although some remain into early to mid-September (Mills 1981; Tozer 2012). In the south, migration is underway in early August and continues into early September. Most are gone by the end of September, but stragglers may persist into early winter (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008).

Migration habitat is similar to breeding habitat. The Baltimore Oriole occurs in a variety of habitats but prefers open woodlands, forest edges, and urban parks (Campbell et al. 2001; Rising and Flood 2020). Smith and Hatch (2017) compared its abundance during spring migration in Pennsylvania before and after the viburnum leaf beetle killed most southern arrowwoods, the dominant shrub. Fewer were captured after most of the shrub cover disappeared, but the difference in capture rates was not significant. In Pennsylvania, it was 7 times more abundant in shrubland than forest habitat during spring migration (Smith and Hatch 2008). Suomala et al. (2012) compared its abundance on 2 islands in the Gulf of Maine during autumn migration. One island was predominantly shrubby and the other was more treed. More Baltimore Orioles were captured on the treed than shrubby island. Birds lost mass on the shrubby island and gained mass on the treed island. During spring migration in Wisconsin and Minnesota, Kirsch et al. (2013) compared its abundance in riparian and upland forests. Riparian forests consisted of maple-elm-ash communities; upland forests were steeply wooded hillsides. They did not detect it in upland forests and considered it a riparian species. In Ohio, it was 1 of only 2 species that was significantly more abundant in upland than riparian forests. Upland forests had significantly more shrub cover and less canopy cover than riparian forests (Rodewald and Matthews 2005). It is probable that forest structure is more important than whether the forest is in riparian or upland landscapes.

The Baltimore Oriole is often killed at communication towers and other tall structures during migration (Rising and Flood 2020).

James (1991) considered the Baltimore Oriole a common migrant in Ontario, occasionally wandering north to Moosonee.

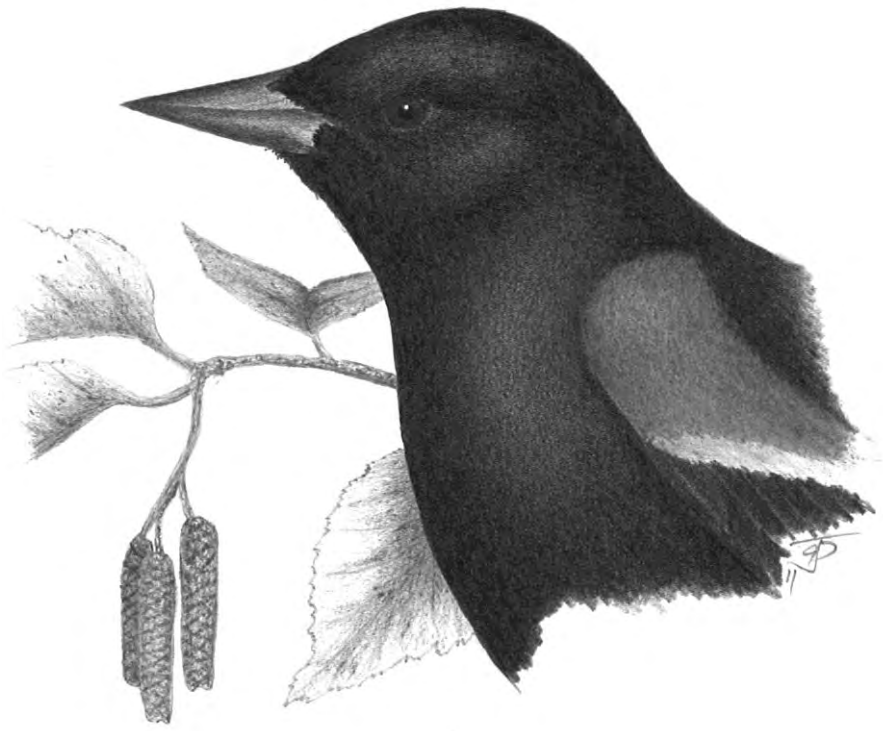
Captures of the Baltimore Oriole at the Long Point Bird Observatory declined at a nonsignificant rate of 0.3% per year 1961-88. Annual trends by period included: 1961-70, +1.0%; 1970-79, –8.2%; and 1979-88, –7.9% (Hussell et al. 1992).

WINTER

James (1991) considered the Baltimore Oriole a rare winter visitor in the south, north to Sault Ste. Marie and Kingston. It is probable that most do not survive the winter. One visited a feeder in Burlington from 3 January to 17 April 1983 where it survived by feeding on oranges (Curry 2006).

Red-winged Blackbird

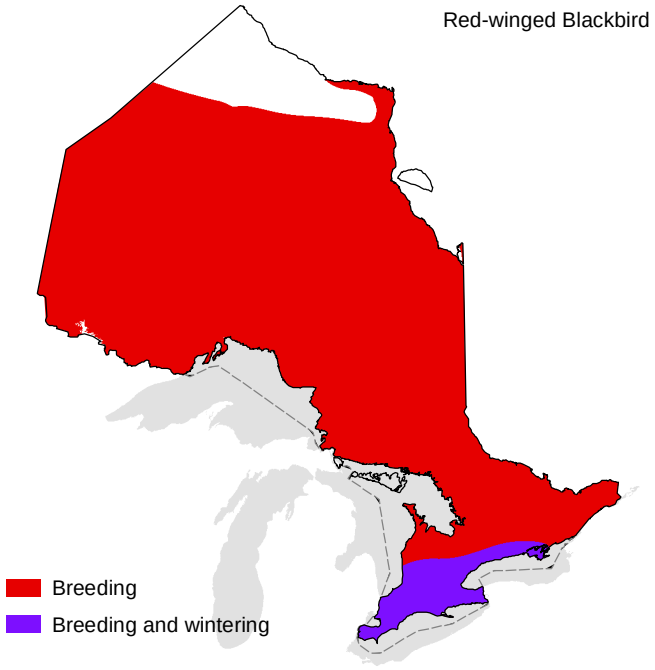
Agelaius phoeniceus



BREEDING SEASON

Habitat Requirements

Ontario Red-winged Blackbird nests were in freshwater marshes (31.5% of nests); in fields, abandoned pastures, river floodplains, and gravel pits (26.0%); in plantations and orchards (16.6%); in roadside ditches, railway rights-of-way, and at shorelines of lakes and rivers (8.2%); in treed swamps and beaver ponds (6.8%); in bogs and fens (4.1%); in gardens and parks (3.6%); on rocky islands (2.0%); and in sand dune areas (1.7%). Marshes that were used were mostly homogeneous cattail stands (90.4% of nests), 4.8% of nests were in mixed shrubs and cattails, 1.6% were in sedges, 1.1% were in rushes, 1.1% were in common reed, and 1.1% were in mixed marsh vegetation. Wooded habitats that it used were usually open and nests were at edges or in clearings. It preferred deciduous stands (65.3% of nests); 27.4% of nests were in coniferous stands and plantations and 7.4% were in mixed stands. Most occupied fields were open but some had limited shrub growth. It preferred wet fields with 57.6% of nests in this habitat (Peck and James 1987).



In the Boreal Forest Region, the Red-winged Blackbird nested in a 3-year-old clear-cut in lowland coniferous forest (Welsh and Fillman 1980).

In the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region, the Red-winged Blackbird nested in open bogs, small marshes, and damp meadows in Parry Sound and Muskoka districts (Mills 1981). In Algonquin Park, it occurred in wet and dry bogs with shrubs and snags. It occurred from ground level to a height of 9 m which represented the tops of dead snags outside the treeline (Martin 1960). It also nested in cattail and sedge marshes, lakeshores, beaver ponds and meadows, and wet shrubby clearings (Tozer 2012). North of Kingston, it nested in cattail and cattail-willow marshes surrounded by forest cover and in small (50-100 m^2) patches of cattails adjacent to highways (Shutler and Weatherhead 1991, 1994; Weatherhead 2005).

Near Ottawa in the Great Lakes–St. Lawrence Forest Region south of the Shield, the Red-winged Blackbird nested in uniform stands of cattails (Pribl and Picman 1996) and in 30-100-m-wide grassland strips bordered by a road on 1 side and fields on the other. These territories were covered by short grasses dominated by redtop with scattered small patches of tall vegetation consisting of reed canary grass, Canada goldenrod, and purple loosestrife. Redtop was present at 71.5% of sampling sites but supported only 11.5% of nests. Reed canary grass was present at 15.0% of sites and supported 48.1% of nests; Canada goldenrod occurred at 7.5% of sites and supported 15.4% of nests; and purple loosestrife occurred at 1.9% of sites and supported 5.8% of nests. Common vetch, lesser burdock, and raspberries occurred at 4.17% of sites and supported 19.2% of nests. Nests were in tall vegetation more than expected and in short vegetation less than expected. The distribution of nests was 0% in vegetation 0-25 cm tall, 30% in vegetation 26-50 cm tall (48% availability), 26% in vegetation 51-75 cm tall (equal or greater than availability), and 42% in vegetation taller than 76 cm (only 15% availability). Nests were more frequent in sparse and less frequent in dense vegetation than expected. Ninety-two percent of nests were in vegetation density of 0-10 stems per 0.04 m^2 (30% availability), with the remainder in density of 11-20 stems (less than availability) and 0% in densities of 21-20 or more than 30 stems per 0.04 m^2. Stem thickness was significantly greater at nests than random areas, with 55% of nests in plants with stems more than 3 mm thick (less than 10% availability). Only 1% were in plants with stems 0-1 mm thick. Patch size diameter was significantly less at nests than random sites. Fifty-nine percent of nests were in patches 0-1 m in diameter (1% availability), 30% in patches 2-10 m in diameter (greater than availability), and the remainder were in patches more than 10 m in diameter (less than availability). As patch size decreased, plant height and thickness of their stems increased but plant density decreased. Nest

success was not related to any vegetative features. In eastern Ontario, it nested in beaver ponds and municipal sewage lagoons. Cattails were the dominant vegetation at both habitats, but formed only a narrow band around the perimeters of lagoons (Zimmerling and Ankney 2005). At Luther Marsh in old-field habitat, all nests were in monotypic stands of reed canary grass. Sizes of patches of reed canary grass that it used averaged 1.2 m^2 (range 0.13-5.3 m^2). Twelve ha of the field did not support this grass and were avoided. It was probably attracted to reed canary grass because of its height and density. A second important habitat feature was presence of fence posts that were used as singing perches by males and lookouts by both sexes. Stands of reed canary grass lacking fence posts were unused. The presence of water influenced its distribution. Ten of 12 males were located near 2 ponds in the study area and the other 2 inhabited reed canary grass adjacent to a ditch containing water. Less than 2.9 ha of the 15.4 ha contained all the reed canary grass, fence posts, and water, and only this area was used. Other plant species such as common vetch, bird's-foot trefoil, willow, and Canada goldenrod had little influence on nest placement but became important later because they were a source of caterpillars to feed nestlings (Joyner 1978). In Durham Region, it nested in old fields with bluegrasses and other grasses, asters, and goldenrods with some raspberries and dogwoods; a very young pine plantation still dominated by willow shrubs and meadowsweet; and open forests with standing or running water (Speirs and Orenstein 1967, 1975). McNicholl (1987b) found it nesting in downtown Toronto on the University of Toronto campus. This is a highly urbanized area, but much of the campus consists of well-watered lawns with shrubby plantings.

In the Carolinian Forest Region in Elgin County, the Red-winged Blackbird nests in grassy roadside ditches and winter wheat fields in addition to marshes (Lancaster et al. 2004). In the Hamilton area, it bred almost exclusively in marshes until the 1950s. Since then, it has adapted to nesting in pastures, hayfields, grain fields, and suburban parks (Curry 2006).

In coastal Great Lakes wetlands, the Red-winged Blackbird was positively correlated with wetland cover and the amount of urban and agricultural land in the watershed. It was not correlated with water levels (Tozer et al. 2024).

In Ontario south of the Canadian Shield, it was significantly negatively associated with the amount of forest cover more than 100 m from edge, woodlot size, amount of forest cover within 2 km, and regional forest cover (Austen et al. 2001). It was equally abundant on organic and conventional farms. It was positively correlated with spring grain, hedgerows, hay, rights-of-way, woods, and row crops and negatively correlated with pastures, fences, streams, and trees (Kirk et al. 2011).

Originally, the Red-winged Blackbird was somewhat of a habitat specialist, nesting almost exclusively in wetlands with emergent vegetation. Beal (1897a, 1900) stated that it nested only in swamps and marshes and was absent from large tracts of lands without these features. The same was true in Ontario around this period (McIlwraith 1894). Beginning in the 1950s and 1960s, it adapted to nesting in upland grassy areas and other habitats altered by humans. At that time, it continued to be most abundant in wetlands. Bent (1958) stated that presence of water, or at least its proximity, was essential, but acknowledged that nests were often found in dry uplands a considerable distance from water. In Illinois, its density in mixed hayfields increased by 9.3 times from 1907-08 to 1957-58 (Graber and Graber 1963). In Washington, Orians (1980) observed that it

had recently spread rapidly as a breeder in upland pastures and crops. Dolbeer (1976) stated that most of the Red-winged Blackbird population nested in upland habitat in the Midwestern United States. In British Columbia, most nests continue to be in wetlands. In more boreal areas, it nests in small ponds and muskeg habitats where the traditional emergent aquatic plants it prefers may be absent (Campbell et al. 2001). In the Yukon where upland anthropogenic habitat is scarce, it is not known to nest in upland habitats (Sinclair et al. 2003). In the Boreal Forest Region, it was confined to deep and fertile marshes, wet areas dominated by sedges and low shrubs such as sweet gale and willows, and bogs and fens (Erskine 1977).

The Red-winged Blackbird nests in a variety of natural and anthropogenic wetlands. Marshes are highly preferred over other wetland types. Emergent vegetation must be present to provide nest sites. Open ponds and lakes are unsuitable nesting habitat. Shrub thicket swamps, especially those dominated by willows, alders, and buttonbush that have standing water are also favoured nesting sites. It inhabits bogs and fens at a low density, and some tall isolated shrubs, trees, or snags are usually present in occupied sites. Bogs and fens with some open water may be somewhat more attractive. Treed swamps are unused unless the canopy is very open and standing water is present. To be suitable for breeding, a wetland must have vegetation strong enough to support the nest and provide or be surrounded by suitable foraging habitat. Traditional nesting habitat consists of marshes with robust emergents in ponds, sloughs, beaver ponds and meadows, margins of lakes and rivers, and along sluggish streams. Freshwater, brackish, and salt-water marshes are all used. Wet meadow marshes also provide suitable habitat. Marshes that have bordering shrubs and trees, or woody vegetation close by may be preferred because these provide suitable singing perches, but scattered woody vegetation is preferred to adjacent woodlands. It also nests in sewage lagoons, rice paddies, natural and restored prairie potholes, roadside ditches, and agricultural drains (Bent 1958; Caccamise 1977; Campbell et al. 2001; Delphey and Dinsmore 1993; Hoffman 1989b; Jobin and Gauthier in Gauthier and Aubry 1996; Moulton 1981; Nero 1956a; Orians 1961a; Picman 1980a; Schmidlin and King 1986; Sinclair et al. 2003; Yasukawa and Searcy 2020).

The Red-winged Blackbird nests in several upland habitats. Its only requirement is that there is a small patch of tall grasses or forbs for nest placement, although it may use shrubs and even trees as nest sites. The most commonly inhabited upland sites are old fields and meadows dominated by grasses and forbs such as goldenrods and asters, pastures, and hayfields. It also nests in fields of cereal grains, hedgerows, weedy and shrubby patches, along interstate highways and other roads, tallgrass prairies, grain stubble, field borders with grasses and forbs, surface coal mines, sedge meadows, woodland openings, small woodlands, and forest edges. Conservation Reserve Program (CRP) and Dense Nesting Cover (DNC) lands planted for waterfowl production, clear-cuts in bottomland and northern hardwoods, on or in between sand dunes and beach ridges, orchards, farm shelterbelts, utility rights-of-way, pine and oak barrens, various urban and suburban habitats, and around human habitation and farmsteads may be inhabited. It rarely nests in forests except on edges but may nest in those where the canopy has been opened significantly due to timber management or other disturbances (Albers 1978; Askins et al. 2007; Bent 1958; Camp and Best 1994; Campbell et al. 2001; Conover et al. 2009; Dolbeer 1976; Galligan et al. 2006; Graber and Graber 1963; Hartley 1994; Holcomb 1974a; Hurst and Bourland 1994; Jobin and Gauthier in Gauthier and Aubry 1996; Kerr 1968; Leighton et al. 2002; Mossman 1988; Mossman and Hoffman 1989; Mossman et al.

1991; Noon et al. 1979; Orians 1961a; Paruk 1992; Patterson and Best 1996; Taylor and Taylor 1979; Webb et al. 1977; Yasukawa and Searcy 2020). In Illinois, Walk et al. (2011) reported it in every habitat they surveyed except upland forests and low-density and high-density developed areas.

At the landscape level, the Red-winged Blackbird avoids heavily forested areas where it is restricted to wetlands and other openings within the forest matrix. It is most abundant in grassland and agricultural landscapes, particularly those that have wetlands. In the St. Lawrence River valley, males exhibited a consistent preference for wetlands and avoided forested areas. A preference for hayfields was detected in 1 year. It preferred wetlands and hayfields, fields were used in proportion to their availability, and areas of human occupation, cropland, and forests were avoided. Densities in wetlands varied little over the years with greatest changes in densities occurring in less suitable habitats such as fields and human-occupied areas. Some birds held territories in lower-quality habitat even when the population was low and high-quality habitat was not saturated (Clark and Weatherhead 1987).

Although the Red-winged Blackbird nests both in wetlands and uplands, it prefers its original wetland habitat. Densities and reproductive success tend to be higher in wetlands. In North Dakota, males nesting in wetlands produced significantly more fledglings (5.22) than those nesting in uplands (1.73). Males in wetlands attracted significantly more females which contributed to their higher success rate. These females produced 2.0 times more fledglings than those in upland habitats (Besser et al. 1987). In Connecticut, nesting success was consistently significantly higher in marshes than upland habitats, but the number of young fledged per successful nest was similar. Differences in success were due to factors that resulted in total nest destruction rather than partial brood reduction. Birds in marshes nested in high density, nesting was highly synchronized, and nests had low predation rates. Those nesting in upland habitats nested in low densities, nesting was asynchronous, and predation rates were high. Water beneath nests in marshes deters most predators. Upland nests are accessible to all predators (Robertson 1972). In Illinois, densities were consistently higher in marshes than in upland habitats (Graber and Graber 1963; Walk et al. 2011). In British Columbia, 92% of nests were in wetlands such as marshes, sloughs, lake edges, swamps, and beaver ponds where cattails, bulrushes, sedges or tall grasses grew. Most occupied wetlands were bordered by shrubs, especially willow, but also by sweet gale and steeplebush. Four percent of nests were in upland habitats, including shrubs and deciduous trees along forest edges; 2% were in anthropogenic areas such as ditches, field borders, and orchards (Campbell et al. 2001).

Numerous studies identified the Red-winged Blackbird's habitat preferences and microhabitat requirements in wetlands. Marshes are highly preferred over other wetland types. Marshes with tall robust emergents such as cattails, bulrushes, cordgrass, or broad-leaved sedges are preferred over those with shorter or less robust emergents. Cattails appear to be the overall preferred emergent for nesting. In North Dakota, 23.5% of nests were in cattails. Females nesting in cattails produced an average of 1.13 fledglings per nest compared with 0.88 for all other plant taxa. Higher success rates were also reported in cattails in Connecticut. It will nest in a variety of emergents if the preferred species are not available. These include American three-square bulrush, common reed, bur-reeds, smartweeds, reed canary grass, rushes, arrowheads, rice cutgrass, and horsetails. Marshes with scattered shrubs and trees provide suitable habitat. In North Dakota, nests in American three-square

bulrush, sedges, and common reed produced above average numbers of fledglings. In Michigan marshes, it consistently selected areas with cattails and, to a lesser extent, broad-leaved sedges. It avoided narrow-leaved sedges, reed canary grass, Canada bluejoint, and forbs as nesting substrates (Albers 1978; Bent 1958; Besser et al. 1987; Campbell et al. 2001; Robertson 1972; Sinclair et al. 2003). It prefers edges of marshes to areas distant from shore. Areas with open water dispersed among the emergents are preferred to dense stands of emergents. Even the least preferred areas of a marsh may be occupied, but usually only after the optimum areas have been claimed. Dense stands of emergents preclude sunlight from reaching the substrate of the marsh. These areas typically support no submerged aquatic vegetation and few aquatic insects that could provide a source of food. In a habitat suitability index (HSI) model for the Red-winged Blackbird, suitability was considered 1.0 (optimum) if the wetland had a mix of emergents and open water, 0.3 if the wetland was covered by dense emergents, and 0.1 if the wetland consisted of open water with a few patches of emergents. In 1 cattail marsh, areas where cattails had been burned down to charred stubs were selected over areas where there were dense stands of old cattails (Albers 1978; Devine 1975a; Nero 1984; Orians 1961a; Short 1985). Areas with the tallest vegetation are preferred and are settled first early in the breeding season. In Great Lakes coastal wetlands, it was positively correlated with grass height and density, total vegetation density, submergent vegetation, and presence of open water. It was negatively correlated with bulrushes and shrub density. In New York, it nested in tall emergents and foraged in short emergents and at edges of open water. Presence of residual vegetation early in the spring is important in providing nest sites (Albers 1978; Devine 1975a; Riffell et al. 2001; Short 1985). Permanent wetlands are preferred to those that dry out at some period of the year. This is because most odonates, a preferred prey in many areas, need a year to develop from aquatic nymphs into terrestrial adults. The HSI model considered habitat to be ideal (1.0) if the water is permanent but only 0.1 if the wetland is usually dry at some period of the year. Suitability was 1.0 if the wetland supported odonates and 0.1 if it did not. Nesting occurs in semipermanent wetlands, but birds in this habitat tend to forage more in adjacent upland habitats rather than in the wetland (Short 1985). In a small Kansas pond with emergents around its margins, nesting occurred only in years when the pond retained water (Fitch 1958). In Iowa, its density was significantly higher at natural than restored potholes. This was attributed to the absence of adjacent wet meadows or prairies at restored potholes. This was probably important foraging habitat (Delphey and Dinsmore 1993).

The Red-winged Blackbird also exhibits habitat preferences and has microhabitat requirements in upland habitats. In Michigan upland habitats, it preferred hayfields, pastures, and old fields and occurred infrequently in mowed fields, fallow fields, woodlots, wheat and oat fields, soybeans, edge vegetation (roadsides, field edges, fencerows, and ditches), anthropogenic features (roads, homes, barnyards, and open ponds), and areas of tilled soils. New hayfields were occupied before old hayfields and old fields. In early spring, it had a slight preference for old fields and grasses such as timothy, orchard grass, bluegrasses, fescues, and bromes. It selected areas with the tallest and densest vegetation that restricted visibility. Erect residual vegetation is important early in the season. Although old alfalfa was partially upright in early spring, it was not preferred as consistently as old grass. As the season progressed, vegetation became less important and it also used forbs for nesting. Territories became established in less preferred areas later in the season. Early in the season, field

edges were preferred, but entire fields were used later (Albers 1978). In Illinois, forest edge shrubs, sweet clover, and mixed hay were preferred upland nesting habitats (Graber and Graber 1963). In Iowa, it occurred most frequently in herbaceous vegetation followed by scrub and wooded edges with low frequency in floodplain woodlands, savannahs, and upland woodlands. It was positively correlated with grass-like vegetation and negatively correlated with trees and saplings (Stauffer and Best 1980). In North Dakota, nests in common milkweed produced more fledglings per nest than average. Those in docks, brome grass, and alfalfa produced fewer than average numbers of fledglings. Nest success was lowest in alfalfa (Besser et al. 1987). In Maryland, plots planted to uniform redtop without any woody vegetation that could provide perches supported significantly fewer Red-winged Blackbirds than plots that were not planted to redtop but contained herbaceous vegetation and some trees and shrubs. It preferred areas with tall vegetation and dense grass (Burhans et al. 2010; Furey and Burhans 2006). In Mississippi, Conover et al. (2009) studied its response to field borders planted to native grasses and a variety of forb species. It was the most common species in fields, occurring in 30% of fields. It was significantly more abundant in fields with than without borders and in fields with wide (39-44 m) than narrow (7.3-8.5 m) borders. On restored surface mines in Indiana, it was the most abundant grassland species present. The height of vegetation where the nest was placed was positively correlated with nest success, but only in mixed habitats of grassland with a few areas of shrub or savannah habitat. Vegetation height had no effect on nesting success in open grasslands or shrub-savannah habitats (Gallingan et al. 2006). In Iowa, Camp and Best (1994) studied the Red-winged Blackbird in roadsides adjacent to croplands. Roadsides were 6 m wide with a foreslope descending 1.8 m to the bottom, then rising to a fence. It occurred in all these areas. Nests were positively correlated with coverage by reed canary grass and vegetation height and density. Nest sites had taller, denser vegetation and more forbs than occurred overall. In New Jersey in a shrub transitional area between upland and salt-marsh habitats, hatching success was negatively correlated with the height of the nest and the height of the shrub the nest was in (Caccamise 1977).

Although the Red-winged Blackbird will nest in uniform stands without distinct perch sites, it greatly prefers perches that are elevated above the emergents for singing and territorial defence. Shrubs and trees are highly preferred for perching and linear extensions may be made to territories to include suitable perches. Trees outside territories may be shared by territorial males. If a stick is shoved into the substrate within a marsh with homogeneous cover of emergents, it is immediately used as a perch. It readily uses shrubs 2-4 m tall and trees 10-15 m tall as perches. Artificial perches 1.5 and 2.0 m tall were provided in alfalfa fields. It exhibited no height preference and used both perch types in proportion to their availability. It may use anthropogenic objects as perches such as vertical exhaust pipes of parked trucks, light standards, and utility poles and wires (Albers 1978; Harrison 1977; Nero 1956a, 1984; Schmidlin and King 1986; Weller and Spatcher 1965).

The Red-winged Blackbird is not an area-sensitive species regardless of whether it nests in marsh, grassland, or forested habitat. It will nest anywhere large enough to support a single territory. In Iowa, it nested in 100% of marshes in all size categories (less than 1 ha to more than 20 ha). Brown and Dinsmore (1986) concluded that it was area insensitive. In Illinois grasslands, Herkert (1994a) recorded it on 93% of transects, the most of any species. Its occurrence was significantly negatively correlated with grassland area. Johnson and Igl (2001) studied its area sensitivity in grasslands in

Montana, South Dakota, North Dakota, and Minnesota. Their results were inconsistent and nonsignificant. In Maryland and Delaware, its probability of detection declined significantly as riparian forest width increased, from 46% in 50-m wide forests to 1% in 800-m wide forests (Keller et al. 1993). In Iowa, Fairbairn and Dinsmore (2001a, 2001b) found it in all wetlands they sampled. Its abundance was positively correlated with wetland area. It would be expected that larger wetlands would provide more habitat and support more blackbirds. It was positively correlated with the wetland perimeter to area ratio and area of weak-stemmed wetland meadow vegetation. It was negatively correlated with the percentage of wetland that was open water.

Communal roosts are an important habitat component year-round, but are least important during the breeding season. Very early in spring, flocks of males roost together in marshes, but these may be migrant birds that tend to move on rather than remaining to breed. Arriving resident males do not associate with these flocks and roost on their territories. Members of a pair also tend to roost on the territory. In New York, adults roosted during the breeding season in a small white pine forest on a college campus (Allen 1914; Bent 1958; Orians 1980; Yasukawa and Searcy 2020).

Most Ontario nests (58.3%) were at low heights in dead or living cattails, sedges, rushes, or other nonwoody plants over water or land; 38.6% were in shrubs, trees, or vines; and 3.2% were on or very near the ground. One nest was in a deep cavity in an elm tree, 1 was supported by a fence among cattails, and 2 were on tops of stumps in water. Nests were in 27 species of nonwoody plants; 37 species of deciduous shrubs, trees, and vines; and 6 species of coniferous shrubs and trees. Common nest substrates included cattails (131 nests), willows (51), grasses (40), hawthorns (24), pines (16), dogwoods (16), spiraeas (15), white cedar (15), goldenrods (14), and maples (14). Most nests were attached or woven to several upright stalks or branches of herbaceous or graminoid species, shrubs, and trees; some were in forbs or in crotches; others were suspended from branches or stalks; and a few were on horizontal limbs. Ground nests were in clumps of vegetation and 2 were at bases of shrubs or trees. Nests in cattails and other nonwoody plants were 0.1-1.4 m above water or ground, with most 0.3-0.6 m up. Nests in shrubs and trees were 0.2-11.6 m above water or ground with most 0.8-1.8 m up. One nest was built on top of an old Red-winged Blackbird nest and one incorporated part of an old Baltimore Oriole nest (Peck and James 1987). At Luther Marsh, nests were at a mean height of 15.0 cm (range 10-20 cm) in dead stems of reed canary grass from the previous year's growth that averaged 58.4 cm in height (range 51-71 cm; Joyner 1978). Near Kingston, 64% of nests were in cattails, but nests in cattails were fourth in nest success behind those in purple loosestrife, grasses, and alder-willows (Weatherhead and Robertson 1977a).

Throughout its range, the Red-winged Blackbird preferentially builds its nest in elevated locations in emergent marsh vegetation, but it also uses shrubs as a nesting substrate in wetlands. In upland habitats, it nests near or on the ground in grasses or forbs or higher up in shrubs and trees. Cattails are universally preferred as a nesting substrate, although a variety of emergents may be used in aquatic habitats. Cattails are particularly preferred early in spring because they become less flattened by winter snow than other emergents. As the season progresses, other vegetation becomes sufficiently developed to support nests, and they may be placed in sedges, bur-reeds, horsetails, docks, arrow arum, or other emergents. Softer vegetation such as docks and smartweeds may be preferred later (Allen 1914; Orians 1980). In British Columbia where most nests were in

wetlands, 67% were in emergent aquatic vegetation, including cattails (34%), bulrushes (19%), and reeds (14%). Other nest sites included shrubs (19%), deciduous trees (5%), and grasses and sedges (1.4%; Campbell et al. 2001). In Manitoba, nests were in cattails, common reed, sedges, and willows in shallow water and in patches of snowberry in pastures adjacent to creeks and ponds without emergents (Bird and Smith 1964). In Ohio marshes, 87.9% of nests were in cattails, 7.6% were in gray dogwood, 6.1% were in common elderberry, and 1.5% were in willows. In Michigan marshes, 47.3% of nests were in cattails, 12.5% were in common elderberry, 9.8% were in willows, 8.9% were in rushes, 8.0% were in red-osier dogwood, 3.6% were in gray dogwood, 2.7% were in honeysuckle, 2.7% were in red raspberry, 1.8% were in swamp birch, 0.9% were in shrubby cinquefoil, 0.9% were in white elm, and 0.9% were in dead shrubs (Holcomb and Twiest 1968). In Louisiana, nests were in 30 plant species with 47.1% in buttonbush. Bulrushes were the next most commonly used plant. Nests in buttonbush had higher nest success, probably because buttonbush was sturdier and better at resisting severe weather. Other important nest plants included willows, rushes, cattails, alder, sweet gum, dock, and grasses. Less frequently used species included pine, privet, peach, horse chestnut, oak, common lilac, ironweed, hawthorn, rose, sassafras, blackberry, sumac, boneset, and gray dogwood (Brown and Goertz 1978). In North Dakota, Besser et al. (1987) found 908 nests in 36 plant species: 23.5% in common cattail, 9.4% in American three-square bulrush, 9.4% in alfalfa, 7.9% in dock, 6.4% in sedges, 5.6% in brome grass, 5.1% in common reed, 3.7% in snowberry, 3.6% in big bur-reed, 3.6% in cordgrass, 3.5% in sweet clover, 3.0% in fescues, 2.3% in smartweeds, 2.2% in soft-stemmed bulrush, 2.0% in reed canary grass, 1.8% in willow, 1.4% in wormwood, and less than 1% each in common milkweed, wheat grass, rushes, barnyard grass, squirrel-tail grass, green ash, honeysuckle, Russian thistle, common ragweed, manna grass, daisy fleabane, broad-leaved arrowhead, hybrid cattail, rice cutgrass, prairie rose, stinging nettle, needle grass, Johnson grass, and Canada thistle. Twenty-seven nests were attached to fences for additional support and 8 were attached to 2 plant species. In Iowa, 88% of nests had water under them, 86% were in robust emergents, 75% had open water near the nest, and 75% were in open landscapes (Weller and Spatcher 1965). In upland interstate highway rights-of-way, 61.8% of 358 nests were in woody vegetation and 38.2% were in herbaceous vegetation (Paruk 1992). In upland habitat in Ohio, 39.7% of nests were in goldenrods, 12.8% were in gray dogwood, 10.3% were in white elm, 10.3% were in raspberries, 5.1% were in grapevines, 3.8% were in honeysuckles, 3.8% were in Manitoba maple, 2.6% were in willows, 2.6% were in common elderberry, and 1.3% each were in beech, staghorn sumac, chokecherry, rose, bur oak, meadowsweet, and ash (Holcomb and Twiest 1968). Along roadsides in Iowa, 32.9% of nests were in wire fences, 21.1% were in reed canary grass, 18.4% were in field horsetail, 13.2% were in forbs, 9.2% were in other grass species, and 5.3% were in shrubs (Camp and Best 1994). In upland habitat in Iowa, 20% of nests were in forbs, 48% were in grasses, 19% were in shrubs, 10% were in deciduous saplings, and 3% were in deciduous trees (Stauffer and Best 1980). Other upland species that the Red-winged Blackbird has nested in include poison oak, plum, bayberry, blueberry, cherry, wild currant, gooseberry, white spruce, white cedar, vetch, and peach (Allen 1914; Bent 1958; Devine 1975b; Miller 1968; Orians 1961a). Nests have been reported 0-10 m above ground or water. Nests in aquatic emergents tend to be 20-80 cm above water. In a Michigan wetland, nests were 20-25 cm above water in mid-April and averaged 62.5 cm above water by mid-June as the height of emergents increased. Nests in upland grasses and herbaceous vegetation may be 0-100 cm above ground and average 40-60 cm up. Nests in woody vegetation may be as high as

10 m above ground. In British Columbia, nests were 0-8.0 m above the substrate with 70% 0.3-0.9 m up (Allen 1914; Bent 1958; Campbell et al. 2001; Holcomb and Twiest 1968; Miller 1968; Yasukawa and Searcy 2020). Nest success increases with increasing height above the substrate. Nests over water less than 15 cm deep have lower success than those over deeper water (Brown and Goertz 1978; Holcomb and Twiest 1968). Near Kingston, nests over deeper water had lower incidence of predation; nests 0-40 cm above water were more successful than higher nests. Nests in open areas were more successful than those in dense vegetation (Weatherhead and Robertson 1977a). There are at least 2 records of the Red-winged Blackbird nesting in tree cavities and one of it nesting in a nest box (Nero 1956b; Yasukawa and Searcy 2020).

The Red-winged Blackbird is not known to reuse nests but there is 1 record of a nest being built on top of an old nest. In Washington, one relined an old Baltimore Oriole nest and successfully fledged young (Allen 1914; Bent 1958; Holcomb and Twiest 1968; Miller 1968; Nero 1984; Orians 1980; Yasukawa and Searcy 2020). In Washington, Erckmann et al. (1990) added old nests to experimental plots to determine if females were attracted to areas supporting old nests from the previous season. Females nested preferentially in these plots in 1 year but not in another; results were inconclusive.

The Red-winged Blackbird is often considered colonial because it nests in very high densities in marshes. The fact that it is polygynous can result in large numbers concentrated in a small area. It is not colonial in the traditional sense, with all suitable wetland habitat occupied. The size of the population is determined by the size of the marsh and secondarily by the nature of the surrounding vegetation. Its distribution appears to be the result of nesting habitat distribution rather than gregariousness. In upland habitats, there is no evidence of clumping of territories and solitary territories are common (Orians 1961b; Yasukawa and Searcy 2020).

Males are highly territorial. Territory size and song rate are significantly correlated. A large repertoire of song types is more effective in deterring trespassers than a single song type. The red epaulets of males are important in displays and maintaining boundaries. Males that had their epaulets experimentally blackened often lost their territories to an intruder and these all suffered wounds due to physical combat. Females preferred males with epaulets reddened slightly above the normal range. Chasing is another common method of territorial defence. One Ontario male killed another male by pecking him repeatedly and forcing him under water several times until he died. Males exclude other males from their territory and are particularly aggressive toward yearling males. They also exclude migrating flocks of females, any females that are not their mates, and fledglings of other pairs. Long-term residents know their territory boundaries and respect those of their neighbours. In these cases, there is very little dispute over territorial rights. Boundaries between territories are sharp and can be determined within 30 cm (Nero 1956a, 1980; Nero and Emlen 1951; Orians 1961a; Sabean and Sabean 2017; Yasukawa 1981; Yasukawa and Searcy 2020; Yasukawa et al. 2009).

Females exhibit aggression toward each other, particularly early in the season when they are first settling on territories. When the initial female arrives, she attempts to defend the entire male's territory. When a new female intrudes, the resident female usually vocalizes at it and chases it out of the territory. When the male is present, he often intervenes and courts the intruder and may chase

the resident female away. This may continue for as long as 10 days until the resident female is no longer able to exclude the intruding female who settles in another part of the male's territory and begins nesting. The 2 females subsequently avoid each other, and similar behaviour occurs when new females arrive. Although females are aggressive toward each other, their display perches overlap considerably and nests have been found less than 1 m apart. Females tend to be more aggressive toward harem mates but are also aggressive toward strange females and fledglings. Aggression is strongest early in the season during nest building and egg laying and more prevalent in smaller territories because there is less space to share. Later, females are aggressive only in a small area around the nest (Beletsky and Orians 1991; Blakley 1976; Hurly and Robertson 1984; Nero 1956a, 1956c, 1984; Nero and Emlen 1951; Orians 1980; Yasukawa and Searcy 2020). Whether the aggressive behaviour of females is consistent with territoriality is inconclusive. In Wisconsin, nests of primary females were significantly over-dispersed demonstrating that male territoriality results in over-dispersion. When all nests were considered, they were randomly distributed in 2 years and clumped in 1 year. Results were not consistent with female territoriality (Yasukawa et al. 1992). Near Kingston, females appeared to exhibit territoriality. Female territories were contiguous, aggressive behaviour occurred at boundaries, and trespassers were seldom tolerated. Females appeared to act competitively rather than cooperatively. The purpose of aggression may be to attempt to keep the harem size small, which could result in increased attentiveness of males to females already established within his territory (Hurly and Robertson 1984). Keeping the harem size small may be important in eastern populations where males frequently feed nestlings, but less important in the west where males contribute little to the raising of the young. All females were removed from experimental territories near Kingston. Eleven new nests were initiated in experimental territories compared with 3 in control territories, a significant difference. Hurly and Robertson (1985) concluded that presence of females in a territory inhibited settlement by other females. Early in the season, females respect male territorial boundaries and seldom cross them. They are typically expelled if they trespass onto a neighbouring male's territory. In Wisconsin, nests were experimentally moved into adjacent territories. The male did not alter his territorial boundaries to include these nests. Females readily accepted the new nest locations but became subordinate to both sexes in the other territory. Nests were more important to females than specific locations (Hurly and Robertson 1984; Nero 1984; Nero and Emlen 1951). Roberts and Searcy (1988) placed feeders in males' territories to determine which females within harems were dominant. The earliest female to settle on the territory was dominant in 82.6% of tests. Proximity to a nest at the encounter site was a significant factor in determining dominance. In 66.7% of contests, the female whose nest was closest to the feeder was dominant. When feeders were moved, different females became dominant. Nesting stage and female size and age did not affect dominance.

Upon arrival, males immediately establish territories but spend most of the day foraging away from the territory. They are usually present in the territory only early in the morning and prior to sunset. Gradually they spend more time in the territory until they are there all day. This usually occurs 1-3 weeks before the females arrive and territorial defence is intense at that time. Migratory males may temporarily defend tree perches for a few hours before moving on, but do not attempt to do this in marsh habitat. Territorial defence by resident males typically ceases once their fledglings leave the territory, and the intensity of defence declines before this (Allen 1914; Devine 1975a; Dickinson

and Lein 1989; Hurly and Robertson 1984; Nero 1956a, 1980; Orians 1961a). Boundaries fluctuate considerably early in the season, with early arrivals attempting to hold large territories and withdrawing from parts of them as new birds arrive. Those that previously held small territories usually attempt to enlarge their holdings and frequently succeed. In most areas, territories shrink as the season progresses but in a Michigan area they increased. This may have been due to some birds abandoning their territories, allowing neighbours to expand their territories. Later arrivals at this site may have been relegated to suboptimal habitat where larger territories were required. Some birds attempt to acquire a territory by forcing themselves in between existing territories. Those that are successful alter the boundaries of the neighbours' territories. There are constant attempts to take over territories and birds that die or disappear from their territories are quickly replaced. Birds that are experimentally removed from their territories lose them to other males and few are successful in regaining them after their release. Near Kingston, males defended all nests within their territory equally and did not give preferential treatment to nests of primary females (Albers 1978; Beletsky and Orians 1989; Dickson and Lein 1987; Nero 1956a, 1984; Orians 1961a; Picman 1987; Weatherhead 1990).

High-quality males that sing more frequently and have larger song repertoires have larger territories and males that previously bred in the same territory tend to have larger territories. Territories in high-quality habitat with open water dispersed among emergents are smaller than lower-quality stands of solid emergents. The proportion of food that is obtained in the territory affects its size. Territories are small where all food is obtained outside the territory and large where all food is obtained within the territory. Territories in upland habitat tend to be 1.5-3 times larger than those in marshes because all food is obtained in upland territories and little to none is collected within wetland territories. Territories on highly productive lakes tend to be smaller than those on less productive lakes due to a greater abundance of prey. Territory size may vary annually with changes in male densities, with territory sizes decreasing as densities increase. New territories created by birds inserting themselves between existing territories or by subdividing an existing territory are smaller than territories of displaced males. In Washington, territories were 3 times larger on lakes where Yellow-headed Blackbirds occupied the best habitat. In Michigan, upland territory size was not significantly correlated with landscape or vegetation features. Wetland territory size decreased as the proportion of broad-leaved monocots increased and as vegetation height increased, and increased as the proportion of narrow-leaved monocots increased and vegetation height decreased (Albers 1978; Dickinson and Lein 1987; Nero 1956a; Orians 1961a, 1980; Picman 1987). A large range in territory sizes has been reported, from 46 to 16,932 m^2. In western North America, mean territory sizes in 24 locations ranged from 234 to 2,361 m^2; the overall mean territory size was approximately 2,000 m^2. Largest territory sizes (mean 9,080 m^2) were in a brackish cattail marsh in British Columbia. Other mean territory sizes include 140-160 m^2 in Washington, 233-1,275 m^2 at other Washington sites, 330 m^2 in Wisconsin, 2,936 m^2 in Utah, 384 m^2 in Alberta, 4,000 m^2 in upland habitat in New York, and 771-2,310 m^2 in Manitoba. Territory sizes at a given site vary considerably due to changes in blackbird density and water levels that may affect the distribution and interspersion of emergent vegetation (Beletsky and Orians 1991; Blakley 1976; Dickinson and Lein 1987; Furey and Buchans 2006; Nero 1956a; Orians 1961a, 1980; Orians and Collier 1963; Picman 1980a, 1987; Shutler and Weatherhead 1991; Yasukawa 1981; Yasukawa and Searcy 2020).

The Red-winged Blackbird and Yellow-headed Blackbird are interspecifically territorial and have mutually exclusive territories. The Red-winged Blackbird arrives in marshes first and typically occupies all areas of emergent vegetation. When the Yellow-headed Blackbird arrives, it evicts the Red-winged Blackbird from its preferred habitat. This consists of emergents interspersed with scattered open water and especially the centre of the marsh at the interface between open water and emergents. Red-winged Blackbirds are forced to nest in the periphery of marshes and areas of dense emergents without any open water. Occasionally isolated Red-winged Blackbird territories occur within colonies of Yellow-headed Blackbirds where the microhabitat is not suitable for Yellow-headed Blackbirds. Although the Yellow-headed Blackbird is dominant in deep-water areas of marshes, the Red-winged Blackbird is dominant at the periphery of marshes. The Yellow-headed Blackbird avoids nesting in emergents adjacent to trees, so the Red-winged Blackbird inhabits these areas. The Yellow-headed Blackbird is dominant to the Red-winged Blackbird in upland foraging areas and displaces it from feeders (Miller 1968; Orians and Willson 1964; Weller and Spatcher 1965). In Washington, mean nest height of the Red-winged Blackbird was 22.6 cm compared with 30.8 cm for the Yellow-headed Blackbird (Miller 1968; Orians 1980).

Both sexes of the Red-winged Blackbird, but especially males, are aggressive toward the Marsh Wren. These 2 species commonly occur together in marshes and their territories overlap widely. Blackbird aggression toward the Marsh Wren may represent partial interspecific territoriality. Blackbirds often place their nest nonrandomly so they are as far as possible from a wren nest (Picman 1980b, 1983).

The Common Grackle seldom nests in marshes, but the Red-winged Blackbird is aggressive toward it when it does. The grackle defends a radius of only 0.6-0.9 m around its nest rather than the more expansive territories of the Red-winged Blackbird. Most interactions between the species were initiated by the Red-winged Blackbird as a result of grackles trespassing on their territories, most often in connection with courtship and their attempts to reach their nests or feed fledglings. Grackles that moved more than 3 m into a Red-winged Blackbird territory always elicited a response. Grackles modified their behaviour to conduct courtship displays at Red-winged Blackbird territorial edges and areas of poorly defined territories. Grackle nests were usually at the periphery of Red-winged Blackbird territories but some were well within territories as a result of boundary shifts. Grackles returning to their nests and their fledglings were usually ignored. Grackles were not aggressive to Red-winged Blackbirds unless they approached too close to the nest. The presence of grackles had no effect on Red-winged Blackbird reproductive success. It could not be determined if true interspecific territoriality existed between the 2 species because of the very small and vaguely defined territories of the grackle. Interspecific territorial aggression occurred by both species and even partial territorial exclusion between the species might contribute to successful cohabitation. Grackle nests were usually in somewhat denser cattail clumps and lower than Red-winged Blackbird nests (average 50.8 cm compared with 60.2 cm). Red-winged Blackbird nests were usually exposed and well lit; grackle nests were only somewhat exposed (Wiens 1965).

Natal philopatry rates appear to be quite low. Yasukawa and Searcy (2020) stated that 8% of male and 3% of female nestlings returned to the same series of marshes in Washington to breed. Near Kingston, Shutler and Weatherhead (1994) reported a return rate of nestlings of just over 2% in

marshes along roadsides and less than 1% in marshes surrounded by woodlands. Most fledglings dispersed from the area and were not seen again. Two of 10 fledglings (20%) from roadside wetlands returned in a subsequent year and 11 of 142 (7.7%) from marshes within woodlands returned. Floater birds had low return rates that were approximately the same as for fledglings. Eighty-nine percent of floaters were never seen again. The high rate of floater dispersal may be a mechanism to prevent inbreeding. Of floaters that subsequently acquired a territory, 5 of 14 (35.7%) returned the following year in woodland marshes and 1 of 8 (12.5%) returned to roadside marshes. Dolbeer (1978, 1982) analyzed banding returns of juveniles recovered in subsequent years. Distances between banding and recovery sites were greater than for birds banded in their second or later years. One nestling banded in the Great Plains was recovered more than 1,000 km away.

Adult site fidelity rates tend to be high and males may defend the same territory for several years. Females have high return rates but are more likely to switch territories or even marshes within and between seasons. At a Wisconsin marsh, 28 of 50 adult males (56.0%) returned and 27 of 48 females (56.3%) returned. Of 16 males, 10 returned in 4 years, 3 in 5 years, and 3 in 6 years. Of 16 females, 9 returned for 3 seasons, 4 for 4 seasons, and 1 for 5 seasons (Nero 1956a, 1956c). In British Columbia, 23 of 61 males (37.7%) returned in at least 1 year and 34 returned over the years. Only 2 of the 34 (5.9%) abandoned their original territory to establish a new one. One settled in the adjacent territory and the other established a new territory 600 m away. For 79% of returning males, the overlap between new and previous territories was at least 61% (mean 78%). Most males that returned in consecutive years exhibited strong site tenacity that resulted in similar territory boundaries. Changes in the location of territories were unrelated to the number of young raised, the number of fledglings per female, or harem size. The tendency for males to return to the same territories continues throughout their lives. Yasukawa and Searcy (2020) reported that 87-94% of males return to their same or a neighbouring territory. Meyers et al. (1990) reported return rates of females of 44.2% and 56.0% over 2 years. In British Columbia, 53 of 85 females (62.4%) returned to their original territory the following year in an area defended by their original mate, 26 (30.6%) nested in a territory of a neighbour, and 6 (7.1%) nested in a more distant territory. Seventy-five of 90 females that renested (83.3%) remained in the same territory with their original mate, 14 (15.6%) nested in 2 different territories and were members of 2 different harems, and 1 (1.1%) nested in 3 different territories. The mean distance between previous nests was significantly less within (46.9 m) than between (77.0 m) seasons (Picman 1980a). Albers (1978) concluded that females had strong habitat fidelity within seasons in Michigan. Those that were displaced from upland sites by mowing were reluctant to use a different habitat type. In marsh habitats, females often moved between territories or even marshes in the same or different year. Females may nest repeatedly in the same territory despite successive nest failures, but are more likely to change territories between years following an unsuccessful nesting (Yasukawa and Searcy 2020). In Wisconsin, female movements between years were primarily due to females switching mates because males remained in the same territory. Seven females moved an average of 29.9 m between years (range 4.9-73.2 m). One female was on a territory for 2 weeks then moved to another territory to nest. One nested unsuccessfully twice in 1 territory, then moved to another territory 68.6 m away where she nested successfully and returned the following year. Another deserted a completed nest and renested successfully in an adjacent territory while retaining her original mate (Nero 1956a). In upland habitat in Ohio, females

switched territories in 3 of 27 nesting attempts (11.1%) and another was seen feeding fledglings 220 m from the field. It was hypothesized that the incidence of movement of females in and out of territories was substantial and that females commonly switched territories, perhaps moving considerable distances (Dolbeer 1976). In Washington, Beletsky and Orians (1991) studied 8 marshes that were close enough together that a female could fly between them in a few minutes. Over a 12-year period, 49.2% of renesting females changed breeding territories within seasons and 20.1% changed marshes between breeding attempts. Twenty-two percent changed marshes between their final breeding in 1 year and their first breeding in the next year. Most moves of less than 10 m were within-territory moves, moves of 15-20 m were to adjacent territories, and moves of more than 100 m were associated with marsh changes. Between years, females moved significantly further if their last nest in the previous year was unsuccessful. Females tended to remain on the same marsh for their first and second nesting attempts regardless of their success. Females also tended to return to the same marsh as the previous year for their first nesting attempt. Significantly more females that had been successful the previous year (83.9%) stayed on the same marsh than those that had been unsuccessful (72.5%). The number of familiar males in a marsh appeared to influence whether a female remained. The breeding group may be more important than the individual territory owner. Females may select male breeding neighbourhoods in which they nest for the entire season and copulate with, feed among, and receive cooperative defence from these males. Almost half of females bred on territories other than those of their first mate. Dolbeer (1978, 1982) analyzed recoveries of banded birds. The mean distance between banding sites and recovery sites in a subsequent year was 31 km for males and 34 km for females. Results indicated that most adults were faithful to the general location of their previous breeding areas.

Limiting Factors

Eggs have been found in Ontario nests from the last week of April until the first week of August, with most present from the last week of May until mid-June (Peck and James 1987). In Algonquin Park, nests are under construction from mid-May to mid-June, eggs are present from late May to early July, nestlings occur from early June to late July, and dependent fledglings have been observed from mid-June to mid-August (Tozer 2012). North of Kingston, females arrive in early April at which time they select nest sites but spend very little time in the marsh. Most arrive in late April and begin to build nests shortly thereafter (Hurly and Robertson 1984).

Females arrive in small flocks and males have well established territories by then. Females tend to select territories or neighbourhoods of males over individual males. Yearling females and those new to an area may visit several territories in rapid succession before selecting one. Females familiar with an area may settle on a territory immediately. The pair bond is usually established within an hour of the female's arrival. Once the female has selected a territory, she remains in the territory except to feed in adjacent uplands. Nest building may start immediately or be delayed as long as 2-3 weeks. In Alberta, females spent an average of 4.6 days on a male's territory before building a nest. In Ohio and Michigan, the mean time spent building a nest was 3.1 days; often as long as 6 days is required to build the nest. One to 10 days may elapse between nest completion and egg laying. Eggs are laid at the rate of 1 day (Allen 1914; Bent 1958; Devine 1975b; Dickinson and Lein 1987; Holcomb and Twiest 1968; Miller 1968; Nero 1956c, 1984; Orians 1961a, 1980; Yasukawa and Searcy 2020). Incubation usually begins with the laying of the penultimate egg, but the onset of incubation

is variable, sometimes occurring with the laying of the second egg or not until 1-2 days after clutch completion. In Nebraska, incubation began on the first day of egg laying and the constancy of incubation increased each day. Nocturnal incubation usually began the night after the penultimate egg was laid, with effective incubation beginning with the laying of the last or penultimate egg. Commencement of nocturnal incubation before the clutch is complete results in asynchronous hatching. Nests with earlier onset of incubation are significantly less likely to be parasitized by the Brown-headed Cowbird. The incubation period at 28 Ontario nests was 10-13 days (mean 11.25 days). In eastern Ontario, the incubation period was longer by 0.2 and 0.8 day over 2 years at beaver ponds where prey were less abundant and blackbirds had to forage outside their territories than at sewage lagoons. Elsewhere, incubation periods of 10-13 days have been reported, but most eggs hatch in 11-12 days. Depending upon when incubation was initiated, hatching may occur over a 1-3-day period. The nestling period is 9-12 days, mostly 10-11 days (Allen 1914; Beletsky and Orians 1990; Bent 1958; Brown and Goertz 1978; Campbell et al. 2001; Clotfelter and Yasukawa 1999a; Holcomb 1974a; Miller 1968; Nero 1984; Peck and James 1987; Yasukawa and Searcy 2020; Zimmerling and Ankney 2005).

The Red-winged Blackbird is capable of raising 2 broods in a season and has done so in Ontario and many other areas. Most females raise only a single brood. In Wisconsin, only 3 birds raised more than 1 brood over a 6-year period. In 1 year, 20 females successfully reared their first brood and 0 attempted a second. In Maryland, 3 of 7 females (42.9%) that successfully raised their first brood attempted a second and one was successful. All females that attempted a second brood were adults. In Ohio, 3 of 132 females (2.3%) attempted a second brood and 2 were successful. In Washington, 5.9% of females raised 2 broods. In British Columbia, 108 of 120 females (90%) that nested successfully raised only a single brood; 12 (10%) raised 2 broods. Females may begin building the second nest before the first brood fledges. A Wisconsin female laid the first egg of her second clutch 9 days after the first brood fledged. Nests for second broods are usually close to the first nest, often within 3 m. Usually the same mate is retained (Allen 1914; Dolbeer 1976; Fankhauser 1964; Moulton 1981; Nero 1956b, 1956c, 1984; Picman 1981; Yasukawa and Searcy 2020). The Red-winged Blackbird readily renests if the first nest is unsuccessful. Females may make as many as 5 nesting attempts to try and raise a brood. In British Columbia, 86% of females whose nest failed renested (Picman 1981). In Washington marshes, 45.2% of 1,570 females built 1 nest in a season, 40.7% built 2, 11.1% built 3, 2.4% built 4, and 0.6% built 5 nests. The median distance between successive nests was 10.0 m (Beletsky and Orians 1991). In Maryland, second nests were built within 45 m of the first nest. One female successfully reared a brood in a hayfield and attempted a second. When it was destroyed by mowing, she initiated another nest 550 m away in a marsh (Fankhauser 1964). In Minnesota, 50% of females that renested switched territories and moved considerable distances between successive nests. This type of movement may be common (Moulton 1981). In Ohio, females whose nest failed in early May had the greatest probability of renesting; 0 of 10 females whose nests were lost after 21 May renested (Dolbeer 1976). Peck and James (1987) reported that some replacement clutches were laid in the original nest. Clutches of 2-6 eggs were reported in Ontario and a single 1-egg clutch appeared to be complete. A 7-egg clutch was documented but the eggs had 2 distinct colour patterns and were assumed to have been laid by 2 females. Four-egg clutches were most frequent, followed by 3-egg clutches (mean 3.59 eggs; Peck and James 1987,

1998b). Elsewhere, clutches of 1-6 eggs have been reported, with 2-5 eggs typical. In most areas, 4-egg clutches are most abundant followed by 3-egg clutches. In some areas, 3-egg clutches are most frequent and these are usually in upland habitat. A 7-egg clutch was documented in British Columbia. Mean clutch sizes typically range from 3.38-3.82 eggs, although there is 1 record of a mean clutch size as low as 2.43 eggs. Mean clutch sizes in Alaska were 4.3 and 4.4 eggs. In Ohio, clutch size declined significantly with the season, averaging 3.56 eggs before 10 June and 3.17 eggs later (Allen 1914; Bent 1958; Besser et al. 1987; Brown and Goertz 1978; Campbell et al. 2001; Dolbeer 1976; Ewald and Rohwer 1982; Francis 1975; McGuire 1986; Miller 1968; Moulton 1981; Orians 1961a, 1980; Robertson 1972; Yasukawa and Searcy 2020).

Both sexes are capable of breeding when they are 1 year old. It is probable that all yearling females breed, but few yearling males do. Yearling males are at a disadvantage because most adult males have already established territories by the time they arrive, their testes do not develop fully until about 3 weeks later than adults and they are not as large, and mated females do not display to yearling males. Some yearling males are successful in establishing a territory and mating, usually by nesting in inferior habitat that is unattractive to older males or by taking over a territory when the original owner disappears. Yearling males are occasionally successful in copulating with a paired female, but it is uncertain if these extra-pair copulations result in them actually siring young. Yearling males may initially attempt to hold a territory and subsequently abandon it. One Minnesota yearling male abandoned his original territory and successfully established another 1.4 km away. In Iowa, yearling females began nesting 15 days later than adult females. Yearlings had significantly smaller clutch sizes (3.40 compared with 4.11 eggs) and raised significantly fewer fledglings (0.73 compared with 1.63) than older females. Once a bird breeds, it usually continues to do so for the remainder of its life. Birds as old as 10 years have been documented breeding (Beletsky and Orians 1991; Besser et al. 1987; Crawford 1977; Holcomb 1974b; Moulton 1981; Nero 1956a, 1984; Orians 1961a, 1980; Yasukawa and Searcy 2020).

Most populations include a subpopulation of nonbreeding floater males. These are mostly yearlings, but also include some older birds. These birds try all breeding season to acquire a territory and some are successful in copulating with mated females. Several studies conducted near Kingston involved removal of male territory holders to determine if floaters were successful in acquiring their territories. The first replacement birds were older and only when they were removed did yearlings acquire a territory. In marshes surrounded by woodlands, all original territory holders were older birds and 83% of 410 floaters were yearlings. In roadside marshes, 89 of 90 territory owners (98.9%) were older birds. Only 15% of floaters that claimed a territory after the owner was removed were yearlings. Most floaters left the study area within 10 days indicating that floaters seldom remain within a restricted area. In marshes in the woodland area, 14 of 463 floaters (3.0%) claimed a territory and 5 (1.1%) were captured as a floater in the following year. Forty-nine floaters returned to the roadside marshes; 8 (16.3%) successfully claimed territories and 1 (2.0%) remained a floater. Only 56 of 490 floaters (11.4%) were recaptured or seen holding a territory, with most apparently dispersing. Most territory claimants the next year were newcomers that were probably floaters from outside the study area. Thirteen floaters obtained territories when they were 2 years old, 6 when they were 3 years old, and 1 at age 4 years. Of the original territory owners and their subsequent replacements that were removed, only original territory holders were successful in reclaiming their territory after

they were released; only 50% were successful (Orians 1980; Shutler and Weatherhead 1991, 1992, 1994; Yasukawa 2013).

The mating system is polygynous. The Red-winged Blackbird is the most polygynous species in North America. Although some males mate monogamously, most have 2-5 or 6 females; as many as 33 females have nested in a single territory. The mean number of nesting females within a territory ranges from 1.6 to 5.8. Harem sizes are significantly higher in marshes than upland habitats. In upland areas of Luther Marsh, all males appeared to be monogamous. In Wisconsin, 20% of males were monogamous, 64% had 2 mates, and 16% had 3 mates. Overall, approximately 90% of males are polygynous and 99% of females are in polygynous relationships. Polygyny occurs because of the highly skewed sex ratio dominated by females. This is because all females nest but yearling males mostly do not. Harem size and territory size are not correlated. Higher-quality territories support larger harem sizes. Territories in marshes with open water dispersed among cattails support larger harems than areas of monotypic stands of emergents. High-quality territories habitually support larger harems even if the attending male changes. New males acquiring high-quality territories tend to inherit a large harem (Beletsky and Orians 1990; Besser et al. 1987; Blakley 1976; Dickinson and Lein 1987; Dolbeer 1976; Ewald and Rohwer 1982; Joyner 1978; Nero 1956c; Orians 1961a, 1980; Picman 1980a, 1981; Short 1985; Weatherhead and Robertson 1977b; Yasukawa and Searcy 1981, 2020; Yasukawa et al. 2009). Near Kingston, Weatherhead and Robertson (1977b) found no correlation between harem size and territory quality. Near Ottawa, Pribl and Picman (1996) studied whether females preferred to settle on similar territories defended by bachelors or males already in a monogamous relationship. There were 2 classes of females: older birds that settled early in the season that preferred to mate monogamously, with all selecting bachelor males, and young females that settled later with males that were already mated. Some females may choose mates that are already mated over bachelors if the mated male has a superior territory. New females tended to avoid territories where they would nest synchronously with the resident female and selected territories where they would be nesting asynchronously. The cost of polygyny declines with the season. Resource competition declines due to asynchronous nesting, aggression of resident females declines, and clumping of nests may be beneficial in deterring predation and parasitism. Others have reported that nesting of females within a given male's territory is asynchronous. In Iowa, males rarely acquired more than a single female at the beginning of the breeding season. In most cases, 4-20 days passed before another female settled. In Washington and Indiana, there was no evidence that nest asynchrony declined with the season or that harem size influenced the degree of synchrony (Blakley 1976; Nero 1956c, 1980; Orians 1961a; Yasukawa and Searcy 1981, 2020). Weatherhead and Robertson (1977b) hypothesized that females could either chose a high-quality territory with low female density and a higher chance of nest success or a low-quality, high-density territory where the chances of success were reduced but that any male offspring produced would be expected to have a superior ability to recruit mates. This was termed the sexy-son hypothesis, but there has been limited support for it. In most cases, nesting polygynously does not come at a cost for females. Females in eastern populations that nest polygynously may be at a disadvantage because eastern males tend to assist in feeding of the nestlings. In these cases, only primary females tend to benefit from the care of the male. Western males rarely assist in feeding the nestlings, so polygyny is not a disadvantage for females paired with them (Yasukawa and Searcy 1981, 2020). In

Iowa, most primary females were older birds. Some older females were secondary but in these cases the primary bird was also old. Only 4 yearling females were primary: 2 were in monogamous relationships and in the other 2 cases the secondary females were also yearlings. In no case was a yearling the primary female with a secondary older female in the territory. There was no difference in the clutch size of primary and secondary adult females but primary yearlings laid significantly more eggs than secondary yearlings. Both yearling and older primary females fledged significantly more young than secondary females (Crawford 1977). Polygynous mating is highly beneficial for males. The larger the harem is, the greater the reproductive success of the male. Near Kingston, larger males had significantly larger harems and greater reproductive output. Females appeared to prefer larger and older males (Weatherhead and Boag 1995).

The pair bond dissolves as soon as the female leaves the territory with the fledglings, often as early as June. Many pair bonds do not last throughout the season. Females frequently shift territories and mates between nesting attempts. In Washington, almost half of females bred on territories other than their first mate's. The duration of a pair bond may be no longer than the length of a failed nest attempt. When both members of a pair return in the following year, they may or may not reunite. In Washington, 57% of females bred with another male even when their previous mate was still alive and territorial. Females whose last nest was successful in the previous year were most likely to pair with their old mate, but 50% of these selected a different male suggesting that mate fidelity was unimportant to females. Similar patterns have been observed elsewhere (Beletsky and Orians 1991; Dolbeer 1976; Nero 1956a, 1956c, 1984; Yasukawa and Searcy 2020).

The male commonly attempts to guard his mate by keeping himself between her and neighbouring males (Nero 1956c, 1984; Yasukawa and Searcy 2020). This strategy is ineffective because both sexes actively seek extra-pair copulations and they are an important component of the Red-winged Blackbird's mating strategy. About 50% of nests contain extra-pair young. The rate of extra-pair young varies among populations: 26% in Ontario, 24% in New York, 31% in Wisconsin, 31% in Washington, and 40% in Kentucky (Yasukawa and Searcy 2020). Roberts and Kennelly (1980) tested the promiscuity of females by vasectomising their mates so they could not fertilize eggs. Phase 1 birds were vasectomised before the females arrived and phase 2 males were vasectomised after breeding began. Over 2 years, 100% and 86% of clutches in territories of phase 1 males were fertile and 36% and 100% of phase 2 birds were fertile. Overall 70% of clutches in territories of vasectomised males were fertile. Promiscuity declined as the season advanced. North of Kingston, females fledged fewer young as the proportion of extra-pair young in their nests increased, probably because males defended their nest less vigorously when they contained illegitimate young. Weatherhead and Boag (1995) assessed the parentage of 617 nestlings from 203 nests in 103 territories. A total of 25.6% of nestlings were extra-pair: 20.1% of young that fledged and 39.2% of those that did not fledge. Approximately 19% of illegitimate nestlings were sired by nonterritorial floaters: 4.9% of all nestlings and 4.3% of those that fledged. Larger males sired more young on their own territories and had higher success at siring extra-pair young. Older males sired significantly more young on other males' territories. Males were consistent in their breeding success on their own territories annually but their success in obtaining extra-pair copulations was not. Male body size was the only secondary sexual trait that affected reproductive success. Large males were more successful because more females nested on their territories and they tended to sire more extra-pair

young. Age was only weakly linked to reproductive success. Large males were more successful on their own territories, but older males were more successful at extra-pair fertilizations. Gray (1977a, 1977b) studied extra-pair copulations in Washington. Females actively sought extra-pair copulations; 17-21% of observed copulations were extra-pair. An average of 30% of females engaged in extra-pair copulations. Thirty-five percent of nestlings were extra-pair and 50% of broods contained extra-pair young. Neighbours sired 111 of 117 extra-pair young (94.9%) and the remainder were sired by nonadjacent territorial males nesting in the same marsh. Females that copulated with neighbours benefitted because the neighbouring male allowed them to forage on his territory. Females that engaged in extra-pair copulations were significantly less likely (32%) to have their nests depredated than faithful females (54%). Males that copulated with a neighbouring female aggressively defended her nest against predators. Age and breeding experience did not influence whether a female engaged in extra-pair copulations. Females appeared to select extra-pair partners based upon their harem size. They benefitted by hatching and fledging a significantly higher proportion of their eggs. They may also copulate with multiple males to ensure fertility of all their eggs because male sperm supplies become depleted as the season advances. Some males are effectively sterile later in the season. There was no evidence that extra-pair copulations were costly to females.

Intraspecific nest parasitism is a rare mating strategy. In some populations, 0.5% of nests contain parasitic Red-winged Blackbird eggs. In other areas, no intraspecific parasitism has been reported (Yasukawa and Searcy 2020). Eggs in an Ontario 7-egg clutch were apparently laid by 2 different females (Peck and James 1987).

The Red-winged Blackbird forages in both aquatic and terrestrial habitats. Those that nest in marshes may forage exclusively in their territories, in both their territories and adjacent uplands, or only in upland areas. Birds are most likely to forage within their territories if they are larger or highly productive, with areas of open water and abundant emerging aquatic insects. Best wetland foraging areas are the outer edges of emergents and shores of marshes where there are no emergents. Shorelines with emergents and interior patches of emergents are inferior foraging areas. Females foraging within marshes are usually confined to their mate's territory, but those who engage in extra-pair copulations with neighbouring males are allowed to forage on their territories. Birds that nest in upland areas have much larger territories that encompass the feeding areas. In addition to marshes with emergent vegetation, birds may feed in meadow marshes bordering cattail marshes, in hayfields, open areas with scattered trees, grain fields, at edges of deciduous woods, in old field and meadow habitats, pastures, prairies, lakeshores with exposed mud, on bare ground, on tree trunks, on floating mats of vegetation, on floating logs and snags, and even on the back of a turtle (Bird and Smith 1964; Gray 1977a; Hurly and Robertson 1984; Nero 1956c, 1984; Orians 1961a, 1980; Orians and Collier 1963; Sinclair et al. 2003; Wiens 1965; Yasukawa and Searcy 2020). In eastern Ontario, females nesting in beaver ponds foraged in forest edges. Those nesting in sewage lagoons foraged mostly in their territories in cattails around the margins of the lagoons, but also on the shorelines (Zimmerling and Ankney 2005). It is a highly versatile forager that can exploit a wide range of food resources. It is adept at feeding in trees and shrubs, can cling to vertical stalks of emergent vegetation, and also forages on the ground. In aquatic habitat, it turns over stones weighing as much as 45 g to reveal stoneflies and fly larvae. It frequently moves floating debris among stones and

aquatic vegetation by a sideways movement of the head and bill. This motion is also used in grasslands to move dead vegetation from the ground and extract spittle bugs from their froth. In cattails and grasslands, it inserts its bill into the vegetation to expose insects and seeds. In trees and shrubs, it gleans among the leaves. It may split open ragweed stalks to expose pupae of the ragweed borer moth. It captures insects on the wing and emerging odonates when they ascend stalks of emergents. It has been observed feeding on insects on Canadian waterweed 2-3 cm below the surface of water. It landed on the waterweed and fluttered with its wings or walked with the legs and tail partially submerged while capturing insects. Foraging may occur in the flowers of water-lilies where it captures flower flies. In New York, females broke tern eggs open and ate the contents. It feeds on white ash seeds by seizing and dropping them and squeezing the fruits to obtain the seeds. It may follow tractors discing or plowing fields to feed on exposed invertebrates, including orthopterans, beetles, caterpillars, and earthworms. It also preyed upon young leopard frogs, and nestling and juvenile voles. As the tractor moved forward, birds at the rear of the flock flew to the front and resumed feeding. While feeding on spittle bugs in a field of sweet clover, it took leaves or small stems into its beak and moved them forward slowly over and past the froth, exposing the bugs. It occasionally flips over cow dung to obtain insects. It obtains seeds by picking them off the ground and may use a double-scratching motion with its feed to uncover food under the litter layer. It occasionally hovers at trees while gleaning caterpillars and may fly as far as 800 m to obtain cankerworms to feed its nestlings. It feeds on white pine seeds and pulls pine seedlings from the ground to eat the seeds. In Wisconsin, birds learned to fly 800 m to visit a zoo where they fed on bread (Beasley and Crothers 1974; Bent 1958; Macklin 1958; Nero 1950, 1984; Orians 1961a; Orians and Horn 1969; Pessino 1968; Richardson 1947; Snelling 1968; Yasukawa and Searcy 2020). Birds quickly learn to avoid unpalatable foods and other flock members learn to avoid these foods more quickly when experienced birds are present (Avery 1994).

The foraging techniques of the Red-winged Blackbird were compared with those of the Western Meadowlark, Yellow-headed Blackbird, and Brewer's Blackbird. There was very little overlap with the Western Meadowlark because it obtains most of its food by digging in the ground. The Red-winged Blackbird forages on the ground, but not by digging. Both the Red-winged Blackbird and Yellow-headed Blackbird are adept at feeding from vertical surfaces of emergents, but the Red-winged Blackbird also forages in shrubs and trees, habitat that is avoided by the Yellow-headed Blackbird. The Yellow-headed Blackbird forages on aquatic prey all day whereas the Red-winged Blackbird forages in upland habitat in the afternoon. Due to their interspecific territoriality and their different foraging habitat preferences in afternoons, these 2 blackbirds are almost always spatially segregated. In addition, they use different foraging techniques in marshes. The Red-winged Blackbird forages swiftly through the vegetation 0.3-0.9 m above the water. The Yellow-headed Blackbird forages near the water line by slowly moving around clumps of cattails and by searching on floating dead vegetation. The Brewer's Blackbird forages mostly by walking on bare ground or over short sedges bordering lakes and streams. It is not adapted to foraging from vertical stalks of emergents. The Red-winged Blackbird has shorter legs and has trouble walking through the short sedges that the Brewer's Blackbird prefers to feed in. In sagebrush, the Red-winged Blackbird readily climbs through the shrubs to forage. The Brewer's Blackbird forages on them by leaping up from the ground or walking on top of them. The Brewer's Blackbird is subordinate to the Red-winged

Blackbird and is not permitted to feed in their territories (Orians 1980; Orians and Horn 1969; Voigts 1973).

In western populations, most male Red-winged Blackbirds do not feed their nestlings and spend their time attempting to attract additional females. In Washington, 1.2-9.3% of males fed nestlings over a 6-year period. Other reported rates of males feeding nestlings in western populations include 0% in upland habitat in Iowa, 6% in Washington, and rare in Michigan, California, New York, and British Columbia. A higher proportion of males feed their nestlings in the east: 46.7-87.5% near Kingston, Ontario, 59% in Indiana, 45.5% and 88% in New York, and 87% in Wisconsin. In both New York and Wisconsin, males rarely fed nestlings in some populations; most males provisioned their young in other populations (Allen 1914; Beletsky and Orians 1990; Blakley 1976; Muldal et al. 1986; Nero 1956c, 1984; Orians and Collier 1963; Patterson 1991; Yasukawa and Searcy 2020). In most populations, males preferentially feed their primary brood and tend to feed secondary broods only if the nest of the primary female fails. Near Kingston, males were equally likely to assist primary and secondary females, but rarely assisted tertiary females. In other areas, nests of primary and secondary females may be asynchronous enough so that the male can provision both sequentially. One male fed at 2 nests simultaneously, alternating trips between nests. Near Kingston, no male assisted more than 2 females on his territory. Nests that were assisted by the male fledged more and a significantly higher proportion of nestlings than unassisted nests. Starvation of the youngest nestling may be common, particularly in larger harems. Starvation seldom occurs in nests where the male feeds the young. Males assist older females with larger broods, selecting females that have the greatest reproductive potential. In Indiana, territories of feeding males were larger and contained more edge interface between open water and marsh vegetation. These areas were much more productive in producing aquatic insects. If the female dies, the male is capable of rearing the brood on his own (Beletsky and Orians 1990; Francis 1975; Muldal et al. 1986; Orians 1980; Patterson 1991; Yasukawa and Searcy 2020). In Michigan, males that were not feeding young began to do so when the brood size was artificially increased. Males that fed young spent less time singing and intruding into other territories, reducing their efforts to acquire additional females and extra-pair copulations (Whittingham 1993). Nesting in many locations is timed so that the period of peak emergence of odonates or grasshoppers coincides with the nestling period. When feeding nestlings, females tended to feed those that were larger, in the best condition, and that begged the loudest. At fledging, male nestlings are 30% heavier and need nearly 30% more energy than females, so this strategy helps sustain male nestlings (Krauss and Yasukawa 2013; Miller 1968; Orians 1961b; Patterson 1991). Males that had fertile mates did not respond to nestling hunger and may withhold parental care at 1 nest to protect paternity at another (Whittingham and Robertson 1993).

In Manitoba, adults foraged for nestlings' food in both marsh and upland habitats. Arthropods in the marsh were significantly larger than those in the upland and the representation of orders of insects differed significantly in the 2 habitats. Nestlings were fed significantly larger prey than were available in both habitats. There was a significantly higher proportion of nymphs and larvae in nestlings' diets than was available in the marsh. The apparent selection for these might be attributed to their soft bodies and their ease of capture (Wilson 1978). The food provided to nestlings in Connecticut consisted of 100% animal matter, predominantly insects with some spiders, molluscs, and miscellaneous items. In marshes, young were fed 55% terrestrial food items (42% caterpillars);

upland young were fed 98% terrestrial food items (26% caterpillars). Aquatic prey comprised 33% of the food items for nestlings in marshes (21% odonates) and 1% in uplands, which were all odonates. Some marsh nestlings had both aquatic and terrestrial prey in their esophagus (Robertson 1973). In New York, nestlings were fed insects almost exclusively, with mayflies, caddisflies, and caterpillars most important in the diet (Allen 1914). Bent (1958) reported that nestlings were fed wireworms, crickets, beetles, grasshoppers, five-spotted hawk caterpillars, and geometer moth caterpillars. In Quebec, Bendell and Weatherhead (1982) studied the diet of nestlings in 2 upland areas. One was in grain, hay, and pasture and the other was along a railway near a river. Nestlings were fed insects from 27 families in 9 orders as well as spiders, isopods, snails, and grain. In every collection of samples, 1 insect order comprised more than 50% of the diet. June samples at both sites were dominated by caterpillars, especially owlet moths, and samples from the area near the river also contained a high proportion of mayflies. Samples collected at the first site 23 July to 2 August differed markedly from the June samples. Caterpillars, mayflies, and beetles were absent in the diet and were replaced by orthopterans and orb-weaver spiders. Females were selective in the prey that they fed their nestlings, preferring passive slow-moving species with no escape reactions. These required a high degree of searching but little active pursuit. The slow-moving long-horned grasshoppers were taken preferentially over the more abundant agile short-horned grasshoppers. The most important prey were herbivorous insects taken from grasses, alfalfa, and clover. Insects that inhabited soil and surface litter were strikingly absent in the diet. It preferentially preyed upon owlet moth caterpillars, the clover leaf weevil, and the European skipper. In Washington, prey delivered to nestlings in a marsh was 76% aquatic invertebrates even though they were not abundant in the environment; the marsh was surrounded by coniferous forest. If spiders were considered aquatic, most of which were taken from emergents, then the diet consisted of 90% aquatic items. The most important prey were beetles (leaf, whirligig, rove, ground, and marsh beetles) followed in order of decreasing abundance by flies (midges, biting midges, crane flies, and flower flies), spiders, lepidopterans (owlet moths, leafroller moths, twirler moths, and snout moths), snails, odonates, soft-winged bugs (froghoppers, aphids, and fulgorid planthoppers), hymenopterans (braconid wasps and sawflies), springtails, green lacewings, stoneflies, millipedes, and annelids. At 1 lake in 1 year, there was limited emergence of damselflies and an unusually high number of nestlings starved (Orians 1980). In an Alabama hayfield, 93.2% of prey brought to nestlings was terrestrial. Soft-winged bugs, mostly froghoppers and leafhoppers, were most prevalent in the diet. Caterpillars were also important, especially owlet moths with some geometer moths. Other prey consumed in small amounts included springtails, adult skimmer dragonflies, short-horned and long-horned grasshoppers, spiders, and snails (Orians 1980).

Voigts (1973) compared the diets of nestling Red-winged and Yellow-headed blackbirds in Iowa. Narrow-winged damselflies were the most important food item for both species all day. For both species, there was increased use of marsh foods and decreased use of upland foods during midday. Narrow-winged and spread-winged damselflies and larval shore flies were selected more between 0900 and 1659 h with fewer treehoppers, aphids, and owlet moths consumed at midday. In addition, they ate leaf beetles, crickets, ground and scarab beetles, snout moths, crane flies, midges, flower flies, anthomyiid flies, and spiders. As the season progressed, the Red-winged Blackbird tended to forage more in marshes and the Yellow-headed Blackbird more in uplands. Before 20 June, owlet

moths gathered in shrubs and trees were the most important prey for the Red-winged Blackbird. Important food items for the Yellow-headed Blackbird at this time included narrow-winged damselflies, larval soldier flies, and adult midges. After 20 June, the Red-winged Blackbird fed less on terrestrial prey and the importance of damselflies and soldier flies increased in the diet. The total overlap in food by volume of the 2 species was 46-49%. The least overlap in diet occurred 0900-1259 when most teneral damselflies were available. The 2 species selected many of the same foods, but at different times during the nesting season. In Washington, Orians and Horn (1969) compared the diets of nestling Red-winged, Yellow-headed, and Brewer's blackbirds. The Red-winged Blackbird ate approximately equal amounts of odonates, flies, and lepidopterans early in the morning. By 1000 h, its diet consisted of 75% odonates with equal numbers of the other groups. At noon, the diet consisted of 40% odonates, 2-3% flies, 30% lepidopterans, and almost 30% other items. At 1600 h, the diet consisted of 20% odonates, 5% flies, 35% lepidopterans, and 35% other items. At 1800 h, the diet consisted of 20% odonates, 30% flies, 20% lepidopterans, and 10% other items. Other items included small snails, spiders, and insects that exhibited no diurnal variations in abundance. The percentages of food items fed to nestlings by Red-winged, Yellow-headed, and Brewer's blackbirds, respectively, were: odonates, 56%, 37%, and 34%; orthopterans, 1%, 2%, and 7%; leafhoppers, 1%, 3%, and 1%; lepidopterans, 4%, 30%, and 24%; flies, 24%, 13%, and 21%; other insects, 7%, 5%, and 7%; spiders, 4%, 7%, and 5%; and other items, 3%, 3%, and 1%. Orthopterans and cicadas were numerically insignificant but contributed a major proportion of the total energy delivered to nestlings. Most of the lepidopterans were very small plume moths and the flies were small so they contributed little energy even though they were eaten in large numbers. Odonates were important in both numbers and calories delivered. The overall diet overlap for all blackbird species was high for all periods of the day, especially during midmorning when all species were feeding almost exclusively on emerging damselflies. The overlap was also high for Red-winged and Brewer's blackbirds in the afternoon when both fed mostly on caterpillars and orthopterans from sagebrush and grasses. Despite the large overlap in prey, competition among the 3 blackbird species was reduced because of partial spatial segregation and differing foraging techniques, and, in the case of the Yellow-headed Blackbird, interspecific territoriality. In 1 spring, there was an invasion of cicadas and they comprised 25% of the energy provided to Red-winged Blackbird nestlings and 10% of the energy for Brewer's Blackbird nestlings. The Yellow-headed Blackbird did not attempt to capture them.

In a Wisconsin marsh, Snelling (1968) compared the diets of nestling Red-winged Blackbirds and Common Grackles. The diet of Red-winged Blackbirds consisted of 92.1% animal matter and 7.9% vegetable matter. Nestling grackles consumed 33.4% animal matter and 66.6% vegetable matter, which was mostly white bread. There were no differences in the mean size of prey items for the 2 species: 10.09 mm for the Red-winged Blackbird and 9.79 mm for the grackle. By volume, the diet of nestling Red-winged Blackbirds consisted of 31.99% owlet moths, 28% geometer moths, 5.76% skimmer dragonflies, 4.95% narrow-winged damselflies, 3.65% soldier flies, 3.17% darners (dragonflies), 2.64% spiketails (dragonflies), and 1.59% fishflies. Small amounts of nematodes, leeches, spiders, isopods, ground and marsh beetles, other lepidopterans (snout, leafroller, and ermine moths), flies (midges and crane, flower, fruit, and bristle flies), and soft-winged bugs were consumed. The vegetation that was eaten consisted of green leaves, bread, and peanut chips. From

11 June to 30 July, locusts (43.21% by volume) and 8.53% brush-footed butterflies, including the red admiral, were important in the diet. By this time, the grackle had completed its nesting. During the period of overlap in the nesting of the 2 species, lepidopterans were most important in the Red-winged Blackbird's diet, with geometer and owlet moths comprising 63.73% of the total volume. Fall webworms comprised 11.32% of the total volume. After the grackle finished feeding its young, locusts, owlet moths and narrow-winged damselflies constituted 62.08% of the Red-winged Blackbird's diet. The change in diet was due to differences in prey abundance and not competition with the grackle. Prey was not limiting for either species and they foraged in different areas so competition was minimal.

The Red-winged Blackbird has a highly diverse diet, yet shows some distinct preferences with these differing in aquatic and terrestrial areas. During the breeding season, it is predominantly insectivorous. In eastern Ontario, birds nesting at sewage lagoons fed predominantly on midges and those at beaver ponds fed mostly on owlet moth caterpillars (Zimmerling and Ankney 2005). McNicol et al. (1982) studied its diet in Frontenac and Leeds counties and collected samples from wetlands in mixed forest and agricultural landscapes. The overall diet was nonspecialized and consisted of 31% corn, 18% weed seeds, 6% oats, 40% insects, 2% other animal matter, and 3% unidentified material. When habitats, sexes, and seasons were considered separately, some specializations were apparent. When males returned in spring, few insects were available and their diet consisted almost exclusively of waste grain and weed seeds. Despite limited amounts of crops in the forested landscape, males were still able to obtain a significant proportion of their diet from waste grain. During the breeding season, both sexes in both habitats dramatically increased their consumption of insects, but waste grain remained an important component of the diet throughout the breeding season. The breeding season diet of males in the agricultural landscape consisted of 51% insects, 42% waste grain, 4% weed seeds, and small amounts of other animal material and oats. Insects were most important during the nestling period, least important during incubation, and of intermediate importance during the fledgling stage. In the forested landscape, males consumed 84% insects, 7% weed seeds, and 3% waste grain with insects most important during the nestling and fledgling stages. Females in the agricultural landscape consumed 67% insects, 21% waste grain, 4% weed seeds, and 4% non-insect animals. Females in the forested landscape ate 79% insects, 9% non-insects, and 8% weed seeds. In Algonquin Park, it feeds on spruce budworms during outbreaks (Tozer 2012). In Manitoba, the June and July diet consisted of 70% animal material in agricultural landscapes and 100% animal material in a large marsh; young were fed animal food exclusively. Differences in food items in different areas were due to local differences in food abundance. Diet in a marsh consisted of 3% vegetation (sunflowers), 96% animal food, and 0.5% grit. The animal food included 37% orthopterans, 14% lepidopterans, 14% beetles, 9% flies, 2% damselflies, 1% harvestmen, a few snails, and 4% unidentified matter (Bird and Smith 1964). Potvin et al. (1976) determined that its overall diet consisted of 23.3% corn, 17.4% barley, and 21.0% beetles in Quebec. From 10 to 19 May, the diet consisted of 46.8% vegetation, 29.1% insects, and 24.2% unidentified: 42.0% grain, 4.8% smartweeds, less than 0.1% sheep sorrel, 2.1% grasshoppers, and 20.7% beetles (weevils and scarab, leaf, click, cedar, and sap beetles). From 14 to 29 July, the diet consisted of 25.6% vegetation, 43.4% insects, and 31.0% unidentified: 24.8% grain, less than 0.1% sheep sorrel, 0.8% dock, 7.9% grasshoppers, 3.9% flies, 8.0% weevils, and 23.6% other beetles (ground, rove, sap, and

click beetles). From 12 August to 16 September, the diet consisted of 61.3% vegetation, 17.3% insects, and 21.4% unidentified: 55.3% grain, 3.6% smartweed, 0.6% sheep sorrel, 1.8% perennial sow thistle, 4.3% snout moths, 4.3% stink bugs, 4.3% aphids, and 4.4% stag beetles. Although it is not the case in all marshes, in Washington and British Columbia, Orians (1980) reported that emerging aquatic insects were the most important prey, and that their abundance was a function of water chemistry, marsh depth and permanence, the types of predators present, and the distribution of emergent and submergent vegetation. The most important prey was damselflies, mostly taken as tenerals as they emerged on stalks of emergent vegetation. These also swim to shore where blackbirds prey upon them and they are easy to capture in upland habitats early in the morning before they become active. Predatory arthropods such as spiders were sometimes major components of the diet, but midges were second in importance to odonates. Mayflies were irregularly abundant and formed a trivial portion of the diet. At 1 lake where there was almost no emergence of odonates or flies, aquatic leaf beetles were a major food item for nestlings. In a New York marsh, the breeding season diet was initially dominated by caterpillars but later by green lacewing larvae, weevils, and other beetles, and finally by aquatic leaf beetles when they constituted 100% of the diet. It ate some fly larvae, spiders, and ground beetles (Allen 1914). In some areas, odonates are the staple of the diet but they are consumed in negligible numbers in other areas. This is probably because most odonate nymphs take at least a year to metamorphose into adults. Permanent wetlands may produce large numbers of odonates; wetlands that dry up may not produce any. Beal (1897a, 1900) examined 1,063 stomachs. Upon arrival in spring, the diet consisted of grubs, caterpillars and other larvae, beetles, cutworms, earthworms, crickets, aphids, and weevils. The nonbreeding season diet consists of 90% vegetation in spring and again in autumn through the winter, with the breeding season diet consisting mostly of animal matter. Later on in the summer, it eats fruits of blackberries, raspberries, gooseberries, snowberry, hackberry, blueberries, wild strawberries, and wild cherries. The annual diet consisted of 73.4% vegetation and 26.6% animal matter, with animal matter comprising 1.4% of the January diet, increasing gradually to 88.2% in June, and dropping to less than 1% in November. Oats were the preferred grain, which constituted 6.3% of the diet, but it also ate corn, wheat, and barley. Grain formed 13.9% of the annual diet; peak consumption was in July and August. Forage crop species such as timothy, sorghum, and clover were unimportant in the diet. Weed seeds were the favourite food item, comprising 54.6% of the annual diet, especially in spring and autumn. Weed seeds comprised only 3% of the June diet. The most abundant weed seeds eaten were those of barnyard grass followed by smartweeds, ragweed, panic grasses, docks, wild rice, paspalum, sunflowers, chickweeds, amaranths, goosefoots, gromwells, and plantains. Some birds were collected while they were picking pine seeds from the tops of trees. One bird each had eaten beechnuts and sedge seeds. Beetles were the most important animal prey, comprising 10% of the diet, with a maximum of 22.4% in June. These were mostly weevils but also included ground, click, leaf, and June beetles. Caterpillars constituted 5.9% of the annual diet, with a maximum of 20% in May, almost 0% in August when grasshoppers were abundant, and increasing again in September. Caterpillars it commonly consumed included armyworms and tent caterpillars. Grasshoppers were important animal foods, constituting 4.7% of the annual diet with a peak of 17% in August. Other animal foods of minor importance included ants, wasps, bugs, flies, dragonflies, spiders, and centipedes. In terrestrial habitat in Manitoba, the diet consisted of 57% vegetation, 35% animal food, and 8% grit in an agricultural landscape.

Vegetation included 23% sunflowers, 6% wheat, 6% oats, 0.5% barley, 2% corn, 1.5% wild oats, 13.5% green foxtail, 1.5% black bindweed, 1% sedges, 1% smartweeds, and 2% unidentified. The animal food included 8.5% grasshoppers, 7% beetles, 3.5% lepidopterans, 3% crickets, 3% ground beetles, 2% flies, 2% spiders, 1% damselflies, traces of snails, and 2% unidentified. Birds from another agricultural landscape with a different mix of crops consumed 58.5% vegetation, 20.5% animal material, and 11% grit. Vegetable matter consisted of 37% wheat, 13% oats, 9% barley, 7% green foxtail, 2% wild oats, and 0.5% sedges. Animal food consisted of 6% beetles, 5.5% orthopterans, 2% ground beetles, 1.0% lepidopterans, 3% unidentified, 1.0% flies, and 0.5% each of harvestmen, damselflies, crickets, and hymenopterans. Wheat and oats were taken mostly as waste grain but were also removed from the ripening heads in the milk and dough stages. Sunflowers were very attractive to it and it concentrated on them from when the kernels formed until the seed coat became too tough to break. Green foxtail seeds were eaten in great quantities, with 984 found in a single stomach (Bird and Smith 1964). The Red-winged Blackbird may eat newts (Bent 1958).

Two studies (Ewald and Rohwer 1982; Wimberger 1988) provided supplemental food in territories to determine the effects of unlimited food. In both cases, supplemental feeding significantly advanced the breeding season suggesting that food availability limits when breeding can commence. At 1 site, harem sizes were significantly larger in territories with supplemental food. In the other area, the supplemental food attracted predators and resulted in higher predation rates and reduced harem sizes because males had to spend more time defending the territory and less time trying to attract additional females.

The Red-winged Blackbird is a common host of the Brown-headed Cowbird. It readily accepts cowbird eggs and incubates clutches comprised solely of cowbird eggs. It also accepts artificial cowbird eggs, strangely coloured artificial eggs, and miniature and over-sized eggs (Ortega and Cruz 1988; Ortega et al. 1993; Ward et al. 1996). In Illinois, Red-winged Blackbirds removed cowbird eggs in 43.5% of nests (Paruk 1992). The Red-winged Blackbird's primary defence against parasitism is to exhibit high levels of aggression toward cowbirds, and it is more aggressive toward female than male cowbirds. Clustering of nests reduced parasitism rates, with nests close to each other less likely to be parasitized than those distant from other nests. Nests where nesting density is high are less likely to be parasitized than those in low-density areas. Nests at the periphery of a colony are more likely to be parasitized and those in upland habitats are usually parasitized at a significantly higher rate than nests in adjacent marshes (Clotfelter and Yasukawa 1999b; Henger and Hauber 2014; Nickell 1955; Ortega and Cruz 1988; Robertson and Norman 1976, 1977; Strausberger 2001; Yasukawa et al. 2016). Nest abandonment is another antiparasitic behaviour. Females typically abandon the nest if a cowbird lays an egg in the nest before it contains any blackbird eggs. In Wisconsin, nest abandonment rates were significantly higher for parasitized than unparasitized nests. No nests were abandoned if they were parasitized after the blackbird clutch was complete (Clotfelter and Yasukawa 1999c; Yasukawa and Searcy 2020). One Ontario nest had a cowbird egg buried in it (Peck and James 1987). Parasitism reduces the reproductive success of the Red-winged Blackbird, with parasitized nests having significantly smaller clutch sizes and fledging significantly fewer young. The smaller clutch size is due to direct removal of eggs by the cowbird and cracking of blackbird eggs. Eggs may be cracked by the thicker-walled cowbird eggs rolling around in the nest or by the female blackbird inadvertently damaging her eggs while trying to strike a cowbird

egg. Females that abandon their nests due to parasitism and renest raise fewer fledglings than they would have if they had incubated their original clutches. This is due to lower nesting success later in the season. Later nests are less likely to be parasitized because the cowbird laying season ends earlier than that of the Red-winged Blackbird. In some cases, the female cowbird does not remove an egg, resulting in a higher than normal clutch size. Larger clutches may be inefficient to incubate, resulting in lower fledging rates. The cowbird may also destroy eggs and nestlings in unparasitized nests, presumably to prompt the bird to renest and offer an opportunity for parasitism (Blankespoor et al. 1982; Clotfelter and Yasukawa 1999c; Granfors et al. 2001; Orians et al. 1989; Ortega and Cruz 1988; Rivers et al. 2010: Yasukawa and Searcy 2020). Parasitism rates of 0-74% have been reported. Parasitism rates may vary considerably at a given site annually. There are many factors that affect parasitism. Low parasitism rates in marshes along an interstate highway in Illinois were attributed to a lack of nearby suitable foraging habitat for the cowbird. In South Dakota grasslands, the odds that a nest would be parasitized decreased by 6% for every 1% increase in tree cover within 1 km. Bird densities were higher in wooded areas and provided a higher density of potential hosts. In the same state, marshes with a high edge to area ratio had higher parasitism rates. Cowbird density also affects parasitism rates with higher rates where the cowbird is more abundant (Besser et al. 1987; Blankespoor et al. 1982; Galligan et al. 2006; Linz and Bolin 1982; Paruk 1992; Pietz et al. 2009; Yasukawa and Searcy 2020). Peck and James (1998b) reported that 170 of 6,554 Ontario nests (2.6%) were parasitized. Near Kingston, 49 of 2,039 nests (2.4%) were parasitized (Robertson and Norman 1976). In Wisconsin, 222 of 1,320 nests (16.8%) were parasitized including 24.8% at a wet-mesic prairie and 14.3% in an old field (Clotfelter and Yasukawa 1999c) and 18% of nests at another Wisconsin site were parasitized (Yasukawa et al. 2016). In Illinois, 46 of 356 nests (12.9%) in marshes along an interstate highway were parasitized (Paruk 1992); Strausberger (2001) reported that 52 of 139 nests (37.4%) in upland habitats were parasitized compared with 2 of 101 nests (2.0%) in marshes. In Michigan, 7 of 1,300 nests (0.5%) were parasitized (Nickell 1955), 0 of 35 New York nests were parasitized (Hahn and Hatfield 1995), 4 of 263 Indiana nests (1.5%) were parasitized (Galligan et al. 2006), 40 of 309 nests (12.9%) at natural wetlands and 0 of 34 nests at restored wetlands in Iowa were parasitized (Delphey and Dinsmore 1993), 2 of 239 Maryland nests (0.6%) were parasitized (Burhans et al. 2010), 2 of 73 nests (1.6%) in South Carolina and Georgia were parasitized (Kilgo and Moorman 2003), and 12 of 755 nests (1.6%) in Louisiana were parasitized (Brown and Goertz 1978). Parasitism rates tend to be higher in the west where the cowbird is more abundant: 109 of 258 nests (42.2%) in North Dakota (Linz and Bolin 1982), 186 of 873 nests (21.3%) in Kansas (Rivers et al. 2010), 14 of 19 nests (73.7%) and 14 of 34 nests (41.2%) in South Dakota (Blankespoor et al. 1982), 0-40.9% in Colorado (Ortega and Cruz 1991), and 18 of 1,416 nests (2.0%) and 29 of 258 nests (11.2%) in British Columbia (Campbell et al. 2001).

There are 2 cases of the Yellow-billed Cuckoo parasitizing the Red-winged Blackbird. The blackbirds accepted cuckoo eggs and fed the cuckoo nestlings. In 1 case, the cuckoo nestling appeared to have fledged. The other nest was depredated (Nickell 1954; Yasukawa 2010).

The Red-winged Blackbird has experienced loss and degradation of both its aquatic and upland nesting habitats. Wetlands may be drained and filled to improve agricultural production and fragmented by roads and other infrastructure. It has been estimated that 70-80% of the original wetlands in southern Ontario have been lost. Loss of wetlands is a universal problem in its range. In

some areas most of the population breeds in upland habitats due to the scarcity of wetlands. Marshes are dynamic ecosystems and their balance is easily upset. Water levels define the extent and configuration of emergent vegetation and they fluctuate naturally seasonally. When this process is altered, water levels may become too deep or shallow to support productive populations of emergents. When water levels are too high, emergents may be drowned out. When they are too low, the emergents become dense monotypic stands without the openings that this blackbird prefers. If there is no standing water beneath the emergents, fewer birds nest in them and those that do have reduced reproductive success due to better access for predators. Introduction of carp into wetlands greatly reduces their quality. Carp uproot aquatic vegetation and result in reduced populations of aquatic invertebrates. Turbidity from stormwater and runoff from fields and roads reduces light penetration into wetlands, killing submergent vegetation and decreasing the abundance and diversity of aquatic insects (Graber and Graber 1963; Jobin and Gauthier in Gauthier and Aubry 1996; McCracken 2003b; Orians 1980; Weller and Fredrickson 1973; Weller and Spatcher 1965; Yasukawa and Searcy 2020).

European settlers created upland habitats that provided suitable nesting habitat for the Red-winged Blackbird. Initially, these were predominantly hay and pasture fields with some fields planted to cereal grains. The composition of the agricultural landscape has changed considerably, with most lands that were in forage crops being converted to small grain and corn fields. Corn and soybeans are now the dominant crops in southern Ontario, with lesser amounts of small grain crops and limited areas in pasture and hay. Most hayfields are now alfalfa rather than the original hay crops of grasses and clovers. Alfalfa fields are not particularly suitable for nesting for this blackbird. CRP and DNC fields provide nesting habitat, but they are typically sinks, and early mowing of hayfields greatly reduces productivity (Jobin and Gauthier in Gauthier and Aubry 1996; Walk et al. 2011; Yasukawa and Searcy 2020). Clark and Weatherhead (1986) and Clark et al. (1986, 1988) chronicled the population changes of the Red-winged Blackbird in the St. Lawrence River valley in eastern Ontario and western Quebec and related them to the crops that were grown. The greatest increase in this species in North America for 1966-76 occurred within this area. During this period, there were significant changes in Quebec including a decline in the area planted to hay and oats and an increase in corn, wheat, and barley. The only significant change in Ontario was a decrease in oats. There was a clear association between the abundance of the Red-winged Blackbird and cereal grains, particularly corn, which provides energy in the form of waste grain through spring and summer. The sole function of cornfields is to provide food; they are not used for nesting. Where hayfields are common but corn production is limited, the population is limited by food. Where cornfields are common, food is abundant but breeding sites are scarce. At some intermediate mix of hay and corn, production should be at its maximum. Further corn production may lead to declines in Red-winged Blackbirds and these declines have already started.

Mowing of hayfields is detrimental to the Red-winged Blackbird. In Michigan, breeders remained in their territories more than 48 hours after mowing but did not establish territories or attempt to nest in cut fields after the vegetation grew back (Albers 1978). In Iowa, birds did not recolonize alfalfa fields after they were cut. By the time the vegetation had re-established itself, its nesting season was over (Frawley and Best 1991). In Arkansas, cutting hay early (26-31 May) had a strong negative effect on nest survival with no nests surviving. The effects of late haying (17-26 June)

were trivial (Luscier and Thompson 2009). In Maryland, mowing destroyed most nests (Fankhauser 1964). In Nebraska, grazing had no apparent effects on it (Kim et al. 2008).

Agricultural chemicals may have adverse effects on the Red-winged Blackbird. Several were found dead adjacent to a North Carolina cornfield where carbofuran had been applied (Augspurger et al. 1996). Myers et al. (1990) administered a single dose of methyl parathion, an organophosphorus insecticide, to free-living females attending their nests. It caused ataxia, lacrimation, and lethargy, and significantly depressed cholinesterase activity, but there were no apparent effects on reproduction. There were no significant differences in weights of nestlings of treatment and control females. There were no significant differences in return rates of females by treatment in the next year: 5 of 11 controls (45.5%), 6 of 6 birds (100%) given a low dosage, and 6 of 12 (50.0%) given a high dosage returned.

Where the 2 species are sympatric, the Marsh Wren is a significant predator of Red-winged Blackbird nests. Wrens peck eggs and nestlings and may cause complete brood failures. Blackbird nest success is significantly lower for nests closer to a wren nest and significantly higher for nests closer to an active blackbird nest. Proximity to a wren nest may be a factor that females consider when selecting a mate. In Washington, all Red-winged Blackbird nests in Marsh Wren territories failed. Blackbirds nesting with wrens may reduce their impacts by both sexes aggressively attacking them, nesting in sparse vegetation where it is easier to defend against the wrens, females nesting in a clumped pattern to better protect nests, and females selecting older, more experienced males thereby increasing their potential nest success. Protection against the Marsh Wren may be another reason for females to nest polygynously (Milks and Picman 1994; Orians and Willson 1964; Picman 1980a, 1980b, 1981; Picman et al. 1988).

Red-winged Blackbirds may be affected by the amount of rainfall received and temperatures. Rainfall determines how many wetlands there are in the landscape, water depths in wetlands and consequently the distribution of aquatic plants, and the permanence of ponds and the resulting aquatic invertebrate populations they support. In North Dakota, its abundance was positively correlated with the number of ponds present in the current and previous years (Niemuth et al. 2008). In the Prairie Pothole Region of Canada, its abundance was strongly affected by the previous year's precipitation and spring temperature. Below-average temperatures affected nesting success because of exposure and a reduction in food supplies (Forcey et al. 2007). In California, clutch size was significantly lower in dry seasons and declined throughout the season (Fletcher and Koford 2004). In Nebraska, its abundance varied significantly with drought indices, but there were no clear trends. It appeared to decrease with increasing wetness, but only slightly (Kim et al. 2008). Heavy rains early in the season may result in nests being flooded (Campbell et al. 2001).

In Minnesota, Hanowski et al. (1977b) applied methoprene and Bti to cattail marshes to control mosquito larvae. There were no apparent effects on the Red-winged Blackbird. In North Dakota, Linz et al. (1996) treated 50%, 70%, and 90% of wetland areas with glyphosate to control cattail growth and reduce numbers of breeding Red-winged Blackbirds. Two years post-treatment, density was higher in control wetlands than in 90% treatment wetlands, but not significantly. Its abundance was positively correlated with the percent coverage by live vegetation during the 2 post-treatment years

and negatively correlated with the percent coverage by dead vegetation in the year following treatment.

Status

The Red-winged Blackbird has always been common to abundant in Ontario. McIlwraith (1894) stated that it bred throughout the province. Baillie and Harrington (1937) considered it common in suitable marshy areas from the southern portion of the province north to at least the transcontinental railway and west to western Kenora District. A specimen from Moose Factory suggested that its breeding range extended northward to James Bay. The first atlas revealed that its range extended from the south northward to include the entire Boreal Forest Region and it also occurred in the Hudson Bay Lowland along the west shore of James Bay north of Akimiski Island. It was observed in every square south of the Canadian Shield and in most squares in the Shield portion of the Great Lakes–St. Lawrence Forest Region. It was abundant in agricultural landscapes, becoming uncommon to rare north in the Boreal Forest Region (Weatherhead in Cadman et al. 1987). James (1991) considered it an abundant summer resident in the south, locally common in the north to Sandy Lake and Moosonee, and rare north to Hudson Bay.

The second atlas indicated that there had been no substantive changes in the range of the Red-winged Blackbird since the first atlas. It was documented in a few more blocks in the Hudson Bay Lowland but not in some blocks in the northern Boreal Forest Region where it was present during the first atlas. Its probability of observation declined significantly since the first atlas province-wide and in the Great Lakes–St. Lawrence and Boreal Forest regions. It experienced a nonsignificant decline in the Carolinian Forest Region and a nonsignificant increase in the Hudson Bay Lowland. It was most abundant from southwestern Ontario north and east through Cornwall and the Ottawa Valley. Lower densities occurred in urban Toronto where there are few wetlands and along the heavily forested Niagara Escarpment. Some of the highest densities occurred at sewage lagoons where there is an abundance of insects. Densities dropped off sharply in the Canadian Shield and areas further north (Zimmerling in Cadman et al. 2007).

During European settlement, the population of the Red-winged Blackbird probably declined initially due to wetland drainage and market hunting. The population increased significantly when it adapted to nesting in upland habitats. Populations are now declining due to habitat loss, changes in land use and management practices, climate change, and efforts to control its depredation on crops. It is still the most abundant bird species in North America, with the population estimated at 100-400 million. According to the Breeding Bird Survey (BBS), the Ontario population peaked in 1976 and has been declining significantly since. During 1966-2015, the North American population declined at a significant rate of 0.93% annually with the negative trend more pronounced in the east (McCracken 2003b; Yasukawa and Searcy 2020; Zimmerling in Cadman et al. 2007). BBS data indicate that it decreased at annual rates of 0.11% in Canada and 0.845% in Ontario 1970-2021. Trends for 2011-21 were an annual increase of 1.83% in Canada and an annual decrease of 1.11% in Ontario. All results were highly reliable (A.C. Smith et al. 2023). In Great Lakes coastal wetlands, it increased at an annual rate of 3.8% 2011-21 (Tozer et al. 2024).

POSTFLEDGING PERIOD

Fledglings remain in the marsh for approximately 2 weeks during which time they may be fed by both adults. In Washington, only 1.1-11.7% of males fed their fledglings in each year; 24.1% of males that fed their nestlings also fed the fledglings. After 2 weeks, fledglings are led to uplands by the female where she feeds them for another 2 weeks. In 1 case, the youngest fledgling was too small and weak to leave the territory. It remained in the territory and was fed by the male (Beletsky and Orians 1990; Nero 1956c, 1984; Nero and Emlen 1951; Orians 1961a; Yasukawa and Searcy 2020). After independence, juveniles join flocks with older females; males remain in discrete flocks. At this time, juveniles forage in uplands during the day and roost in marshes at night. During the moult, juveniles may remain in marshes all day. Later in the season, juveniles form roosts with adults of both sexes (Yasukawa and Searcy 2020).

The sexes segregate as soon as the female leaves the territory with the young and they remain in separate flocks during the postfledging period into autumn migration. Juveniles initially occur in flocks of females, but later may join male flocks, and male flocks may include scattered females. Most birds move into agricultural landscapes at this time. Marshes surrounded by forests may be completely abandoned but those in agricultural landscapes may be used as night roosts by flocks. In Matchedash Bay and the Kingston area, large flocks form in mid-July and are present in the St. Lawrence River valley by late July. In Presqu'ile, flocks occur as early as late June. Flock sizes are initially small but quickly swell and remain large until they gradually diminish during autumn migration. Most birds disperse in late October or early November. At Presqu'ile, flocks abandon the park by mid- to late August and move to surrounding cornfields. Most leave Algonquin Park in August to seek more favourable foraging areas (Clark et al. 1986; LaForest 1993; McNicol et al. 1982; Nero 1984; Somers et al. 1981; Tozer 2012). During the moult in August, birds may remain in marshes all day and hide in dense emergents until they replace their tail and flight feathers (Bent 1958; Bird and Smith 1964; Nero 1984; Orians 1961a; Yasukawa and Searcy 2020).

Postbreeding flocks congregate in large roosts overnight. To be suitable, roosts must be within a few kilometres of abundant food sources. At Matchedash Bay, birds fed in areas as far as 13 km from the roost. In California, birds flew as far as 32 km from the roost to forage. Marshes with emergent vegetation are preferred roost sites. In Ontario, they are typically dominated by cattails or common reed. Marshes are preferred elsewhere as well, with cattails and common reed preferred but wild and cultivated rice and bulrushes are also used. A major requirement of roosts is that they must offer dense cover. Roosting habitat may also include deciduous thickets and coniferous stands. Roosts may contain other species of birds, particularly European Starlings, Brown-headed Cowbirds, and Common Grackles. At a roost in Niagara Region, all these species roosted with the Red-winged Blackbird along with swallows and a few Rusty Blackbirds. Large roosts in the Matchedash Bay and Kingston areas routinely support as many as 100,000 birds. Individual roosts in the southeastern United States frequently support several millions of birds, particularly in autumn and winter (Besser et al. 1987; Bird and Smith 1964; Black and Roy 2010; Brugger 1988; Brugger and Dolbeer 1990; Joyner et al. 1980; Orians 1961a; Short 1985; Somers et al. 1981; Weir 2008; Yasukawa and Searcy 2020).

Each day birds fly from the roost to foraging areas that are predominantly agricultural fields. At the Matchedash Bay roost, there was a progression in the use of habitats from 16 July until the fourth week of September with the use of cornfields becoming increasingly important throughout the summer. Sightings in pastures, wheat stubble, and other fields were infrequent after the first week of August. Oat fields were important foraging areas from mid-July to mid-August. The Red-winged Blackbird visited wheat stubble fields but not those in which winter wheat was growing. Adult and juvenile males were frequently seen together. Males were active at mean distances of 3.2-4.4 km from the roost. Two males moved 3.9 and 7.6 km to new foraging areas. Some birds were sighted as far as 13 km from the roost. In morning, birds moved directly from the roost to foraging areas. Movements of the sexes were similar. There may be a large turnover of individuals foraging in a given field (Somers et al. 1981). At a California roost, birds left the roost early in the morning but returned to the marsh after the morning feeding and made another major feeding flight in mid-afternoon before returning to roost overnight. There was steady movement in and out of the roost, with individuals probably feeding at least once a day in addition to the 2 major feeding flights (Orians 1961a). Birds store food in the gullet on foraging trips, presumably for consumption during the night (Bird and Smith 1964).

Dolbeer (1978, 1982) summarized banding recoveries of the Red-winged Blackbird during the postfledging period. It was fairly sedentary in the Great Lakes area and the Midwest, but in New England, it often moved 200-350 km from the nesting area by August.

During the postfledging period, the Red-winged Blackbird switches from a predominantly insectivorous diet to one dominated by vegetable matter, particularly agricultural crops. In Frontenac and Leeds counties, oats were briefly exploited in late July, then replaced in the diet by corn and weed seeds, with males concentrating on corn and females on weed seeds. By the time they migrated in October and November, the diet was similar to that observed immediately following spring arrival. During early postbreeding and autumn flocking, the male diet consisted of 56% corn, 24% seeds, 11% insects, 5% oats, and some waste grain and other vegetable matter. The female diet consisted of 44% weed seeds, 28% corn, 15% insects, and 10% oats. Eighty to 90% of the insects that were consumed were injurious to agricultural crops. Few insects contributed more than 5% of the diet and only forest tent caterpillars and tawny-edged skippers constituted more than 20% of the diet. Insects that contributed 5-20% of the diet included weevils, leafhoppers, and froghoppers. Insects comprising less than 5% of the diet included click beetles, scarab beetles, leaf beetles, long-horned beetles, flat bark beetles, geometer moth caterpillars, owlet moth caterpillars, corn borers, aphids, flies, chinch bugs, and short-horned grasshoppers. The percentage of the total number of seeds consumed by males and females, respectively, was: foxtails, 19% and 59%; barnyard grass, 4% and 19%; smartweeds, 6% and 3%; gromwell, 4% and 0%; chicory, 0% and 1%; American three-square bulrush, 34% and 9%; water-lily, 6% and 0%; and traces of quack grass, chickweed, common dandelion, panic grass, redroot amaranth, and lamb's-quarters. At no time during their 8-9 month residency in eastern Ontario did grain comprise less than 25% of the diet. Males appeared to be responsible for most of the crop damage. Females are much more likely to be beneficial because they eat less grain and more weed seeds, are more abundant, and also prey on insects to feed nestlings and fledglings (McNicol et al. 1982). In Oxford County, the Red-winged Blackbird commonly fed on the seeds of giant ragweed during the postfledging, autumn migration, and

winter periods. Flocks as large as 600 were seen suggesting that it may be a valuable source of food (Dance et al. 2012).

Considerable research has been undertaken on Red-winged Blackbirds foraging in cornfields and the damage it inflicts on both sweet and field corn. It feeds extensively on the northern corn rootworm, a serious pest that may be abundant in silky tassels and leaves. It also preferentially feeds on the European corn borer by slitting open the husks and removing them from infected ears. It is attracted mostly to fields that support these pests and feeds heavily on them in the period before the corn is ripe. Fields infested with these insects are more likely to sustain crop damage from blackbirds because birds continue to visit these fields once the corn crop ripens. Field experiments demonstrated that corn in plots treated to kill these insects is less likely to suffer blackbird depredation than untreated plots in the same field. The apparent benefit from blackbirds feeding on these insects is outweighed by the damage they do later to the crop. In Quebec, the reduced density of corn borers due to predation by blackbirds only compensated for about 20% of the damage that they inflicted. Approximately 1% of the entire North American corn crop is destroyed by the Red-winged Blackbird, predominantly in localized areas, mostly within 8 km of a roost. Fields close to a roost may sustain 5% or more damage. Fifteen days after silking, corn kernels enter the milk stage and this is when they are first vulnerable to blackbirds. Field corn is allowed to mature and dry, so it is vulnerable for several weeks. Sweet corn is usually harvested 16-20 days after silking, so it is vulnerable for only a few days. Red-winged Blackbirds feeding in cornfields during the silking period should be considered beneficial but management may be required during the milk stage. In North Dakota cornfields, males ate more corn and less foxtail seeds than females. Aphids were the most prevalent animal prey in cornfields, followed by spittle bugs, green lacewings, and spiders. Most damage to corn crops is by males (Bendell et al. 1981; Bernhardt et al. 1987; Bollinger and Caslick 1985; Dolbeer 1990; Linz et al. 1984; Straub 1989).

The Red-winged Blackbird may inflict serious damage to sunflower crops. Odds of a field receiving damage were 2.1-3.9 times higher in 2 years for fields adjacent to marshes than for fields distant from marshes. Birds avoided fields with plowed fields adjacent to them if no wetlands were present. If wetlands were present, this cancelled out the negative effects of plowed fields (Otis and Kilburn 1988). In North Dakota sunflower fields, more than 75% of bird damage occurred in the first 18 days after antithesis and then gradually decreased until harvest. Forty percent of damage occurred 3-4 days after antithesis. Soft seeds received 86% of the damage indicating that this stage was preferred (Cummings et al. 1989). In North Dakota sunflower fields, there was no difference in the diets of adults and juveniles. Males ate significantly more sunflower seeds and fewer foxtail seeds than females. From 12-25 August, males in sunflower fields ate 25% animal matter compared with 28% for females. In the following 10 weeks, animal matter comprised only 4% of the male diet and 5% of the female diet. The animal food included 20% beetles, 16% aphids, 13% leafhoppers and spittlebugs, and 6% green lacewing larvae. Weevil larvae were commonly consumed from 23 September to 20 October. Males were largely responsible for damage to sunflowers (Linz et al. 1984).

In Oklahoma, Goddard (1969) studied the diet of the Red-winged Blackbird in sorghum crops. The percent occurrence of food items was 93% sorghum, 75% ragweed, 36% insects, 36% sunflower seeds, 24% Johnson grass, 10% foxtails, 10% lamb's-quarters, 10% amaranths, 7% croton, 5% panic

grass, 2% sand dropseed, 2% grama grass, and 1% each smartweed, bush-clover, and bluestems; 11% of material was miscellaneous or unidentified. Sorghum crops harvested by mid-October sustained little damage but considerable damage occurred when the harvest was delayed due to poor weather. In California, it concentrated its foraging in late summer on seeds of barnyard grass. It also feeds on rice seeds that are coming into the milk stage at this time. Considerable damage to rice crops is sustained then. They continue to feed on it until it is harvested and on waste grain after harvest. The Red-winged Blackbird also forages in newly sprouting alfalfa fields where it captures insects (Orians 1961a). In New York before agriculture consisted of extensive monocultures of row crops, the diet consisted of 82% vegetable matter, with aquatic leaf beetles and weevils dominating the animal prey. The vegetable matter was dominated by seeds of yellow foxtail with lesser amounts of ragweed, bindweed, and other grass seeds. Later in autumn, the food consumed in upland areas was almost 100% vegetation, mostly foxtail and ragweed seeds with a little grain (corn, wheat, and oats; Allen 1914)).

Because of its crop depredation, the Red-winged Blackbird is considered a serious agricultural pest. The most significant limiting factor to it during the postfledging, autumn migration, and winter periods is mortality due to humans. In the days of the early settlers, many states offered a bounty for killing it. Other jurisdictions ascribed a quota to landowners who were fined if they did not kill enough Red-winged Blackbirds (Allen 1914; Beal 1897a). An amendment to the 1918 *Migratory Birds Convention Act* allowed both lethal and nonlethal control of blackbirds to protect resources such as ornamental or shade trees, crops, livestock, or wildlife and human health. Lethal control methods included dynamiting, shooting, trapping, poisoning with pesticides and avicides, and spraying with surfactants. Surfactants are detergents that cause the birds' feathers to lose their waterproofing ability. Following aerial spraying of surfactants, bird roosts were sprayed with cold water resulting in them dying of exposure. From 1974 to 1992, 38.3 million birds were killed using surfactants, 13% of which (5 million) were Red-winged Blackbirds. DRC-1339 was a nonpersistent organochlorine pesticide that shuts down liver and kidney functions. It was applied as bait on the ground or seeds were coated with it. Millions of Red-winged Blackbirds were killed with this chemical. Largest kills occurred at winter roosts. Because birds from a wide geographic area were represented at winter roosts, these massive kills had no apparent effects on any breeding populations. The use of surfactants and DRC-1339 has since been discontinued, but millions are still killed each year (Bent 1958; McCracken 2003b; Yasukawa and Searcy 2020).

Several nonlethal control methods have been attempted. These include habitat management, integrated pest management, bird-resistant sunflowers, decoy crops, chemical frightening agents and repellents, mechanical scaring devices, propane exploders, chemosterilants to lower reproduction, and Avitrol, a chemical that causes birds to behave abnormally and emit distress calls when they ingest it. Most of these methods are time consuming and ineffective and often cost more to implement than the value of the crop that is damaged. Cost-benefit analyses suggest that local control may be effective only for the most damaged fields (Dolbeer 1990; Yasukawa and Searcy 2020). In Simcoe County, Joyner et al. (1980) tested the effectiveness of methiocarb as a repellent in field corn. It was ineffective, with approximately 75% of ears damaged in both treated and untreated areas. The overall mean damage per ear was 29% for treated corn and 30% for untreated corn. The costs of applying methiocarb exceeded the benefits.

MIGRATION

Most populations of the Red-winged Blackbird are migratory but some in the western United States and along the Gulf Coast are resident. Those breeding in the Great Lakes region travel approximately 1,200 km to their wintering grounds. Adult females migrated 187-300 km further south than adult males (mean 247 km). Juveniles migrated 200-350 km further than adult males, about the same distance as adult females. Southern Ontario birds overwinter in Alabama, Georgia, South Carolina, and Florida. Ontario birds also winter in coastal and adjacent states from Maryland south to Florida (Brewer et al. 2018; Dolbeer 1978, 1982; Yasukawa and Searcy 2020). Burtt and Giltz (1974) analyzed 10,664 banding recoveries. Birds in the Atlantic Flyway flew southwest, those in the Mississippi Flyway flew south, and those in the Central and Pacific flyways flew south and southwest. Those in the first 3 flyways wintered mostly along the north coast of the Gulf of Mexico. Knittle et al. (1987, 1996) analyzed spring migration from winter roosts in Missouri, South Dakota, and Minnesota. Birds from Missouri travelled through a broad corridor from eastern Montana to eastern Wisconsin, a distance of about 3,000 km. Breeders from this roost were also found in east-central Alberta, southern Manitoba, and southwestern Ontario. These birds dispersed over an area of about 18,000,000 km^2. Many South Dakota birds nested locally and dispersed over a smaller area of 405,000 km^2, to east-central Alberta, central Saskatchewan, and Manitoba. Most birds from Minnesota concentrated in southern Saskatchewan, northeast North Dakota, and northwest Minnesota. Distances travelled from the South Dakota and Minnesota roosts were 856-1,093 km. It is a diurnal migrant that tends to move in flocks smaller than 100 birds (Yasukawa and Searcy 2020).

In the western United States, spring migration was correlated with the 1.7°C isotherm (Dolbeer 1978, 1982; Miller 1968; Yasukawa and Searcy 2020). In Wisconsin, males arrived over a period of 9-43 days per season (mean 29.2 days). Arrival dates of individual males varied as much as 20 days over the years (average 13.6 days). Certain males were consistently early arrivals; others were consistently late. Males that previously held territories at the site were usually the first to arrive (Nero 1956a, 1984). Males usually arrive 1-3 weeks before females. Yearling males usually do not arrive until adult birds have initiated nesting and yearling females may not arrive until a week after yearling males (Bent 1958; Bird and Smith 1964; Devine 1975b; Nero 1984). In Michigan, the time lag between male territory establishment and arrival of females on territories varied by habitat: at least 4 weeks for pastures; 1-3 weeks for old hayfields, old fields, and wetlands; and females arrived as soon as males established territories on new hayfields (Albers 1978). At a spring roost at Beauharnois, Quebec, the population was almost exclusively males in late March but there was equal representation of the sexes by the end of April. In late March, the male population consisted almost entirely of adults but yearling males predominated in late April. Territorial males became established in marshes at the same time that representation by adults in the roost declined (Greenwood and Weatherhead 1982). Allen (1914) broke spring migration into 7 periods in New York: arrival of vagrants, migrant adult males, resident adult males, migrant females and yearling males, resident adult females, resident yearling males, and resident yearling females. Vagrants arrived in February when marshes were still frozen and there was snow on the ground. The first true migrants were adult males that arrived an average of 13 days after the vagrants. They stopped briefly then continued migrating. Migrant males continued to arrive for about 2 weeks and then the resident breeding males arrived. The first migrant females and yearling males arrived a few days before the resident females; the first females travelled

with adult and yearling males. As numbers of females increased, flocks comprised solely of females occurred. Resident adult females arrived in the early part of the first week of April, yearling males arrived around the first week of May after most adult males had begun nesting, and yearling females began to arrive around mid-May.

In southern Ontario, the Red-winged Blackbird arrives in mid- to late February. Larger numbers arrive after the first week of March and waves of migrants continue to arrive through May. Females usually do not arrive until early April (Curry 2006; Hurly and Robertson 1984; LaForest 1993; Lancaster et al. 2004; Weir 2008). Birds arrive in the St. Lawrence River valley in eastern Ontario in late February or early March but do not disperse to territories until early May (Clark et al. 1986). Arrival in the southern Shield is in mid- to late March (Mills 1981; Tozer 2012).

At Delta Marsh in Manitoba over a 63-year period, the Red-winged Blackbird arrived significantly earlier in later years in response to warmer temperatures (Murphy-Klassen et al. 2005).

Autumn migration to wintering roost areas does not begin until October, and most birds arrive on the wintering grounds in November. Males migrate later than females in autumn (Dolbeer 1978; Yasukawa and Searcy 2020). Most leave the southern Shield by mid-November. Birds may remain at feeders into late November or the first week of December (Mills 1981; Tozer 2012). Migration out of the St. Lawrence River valley is nearly complete by early November (Clark et al. 1986). Most leave the Kingston area in early November (Weir 2008). In the Hamilton area, large numbers are recorded in early November and late migrants may occur until early December (Curry 2006). In Elgin County, autumn migration is evident from late October to mid-November when mixed flocks of thousands of blackbirds migrate westward along the Lake Erie shoreline (Lancaster et al. 2004).

During spring migration, the Red-winged Blackbird mostly inhabits marshes and other habitats typical of breeding habitat. It may visit parks and gardens, stubble fields, beaches, small islands, wet fields, airfields, and pipeline rights-of-way to forage (Campbell et al. 2001; Sinclair et al. 2003). During spring migration in Pennsylvania, it was significantly more abundant in shrubby habitat than in forests (Smith and Hatch 2008). In Wisconsin and Minnesota, it was significantly more abundant in mature floodplain forests than mature upland forests during spring migration (Kirsch et al. 2013). During autumn migration, the habitat that is used is the same as during the postfledging period, with birds concentrating in agricultural fields to feed.

Roosts are important during spring migration. In some areas, the Red-winged Blackbird simply roosts in the marshes that are subsequently used for breeding. During the day, they spend most of their time away from the marsh foraging in upland habitats. The sexes may roost together but tend to segregate early in the season (Orians 1961a; Orians and Collier 1963; Yasukawa and Searcy 2020). In some areas, large numbers of Red-winged Blackbirds, often in the company of starlings, cowbirds, and Common Grackles, form large spring roosts before nesting commences. At Beauharnois, the roost area was devoid of birds in mid-March, built up to a peak population of about 100,000 birds on 9 April, and continued to be used until at least late May when observations were terminated. The population gradually declines as birds move to their territories (Greenwood and Weatherhead 1982). Roosting habitat usually consists of marshes with emergent vegetation, particularly cattails and common reed (Greenwood and Weatherhead 1982; Orians 1961a). In Kansas, spring migrant flocks roosted in tall grass (Fitch 1958). Roosts used during autumn migration are similar to those used

during the postfledging period. Many postfledging roosts continue to be used through migration with migrating birds joining postfledging flocks in roosts.

During spring migration, the Red-winged Blackbird commonly visits bird feeders to obtain seeds. Before insects are abundant, waste grain may form a large proportion of the diet. Once insects are plentiful, it quickly switches to an insectivorous diet, with most prey captured in upland habitats. In New York during spring migration, the diet of birds feeding in uplands consisted of 66% vegetable matter and 34% animal matter. Seeds of yellow foxtail and common ragweed were the most important vegetable foods, with traces of corn and rye. The animal food was dominated by caterpillars followed by ground beetles, centipedes, grasshoppers, and other insects. Food obtained in marshes consisted of 19% vegetation (all cutgrass seeds) and 81% animal food. Weevils were the most important animal prey followed in order by caterpillars, ground beetles, spiders, centipedes, and fly larvae (Allen 1914). During spring at Presqu'ile, it feeds on flooded lawns and in the marsh (LaForest 1993). In September and October in Algonquin Park, it commonly forages with other blackbird species in areas such as campgrounds, clearings, and marshes (Tozer 2012).

James (1991) considered the Red-winged Blackbird an abundant migrant in Ontario. Flocks of 10,000 are fairly common in the south, and flocks as large as 50,000 have been observed.

WINTER

In Ontario, most Red-winged Blackbirds occur singly or in small flocks in winter, usually near a food source such as a feeder or corn crib. They may also occur in cattail marshes (Curry 2006; LaForest 1993; Lancaster et al. 2004). In the core of its winter range, it prefers cornfields, shrubbery of all types, pastures, feedlots, garbage dumps, sewage lagoons, stubble fields, unharvested grain fields, and feeders (Campbell et al. 2001; Graber and Graber 1963).

Due to its scarcity in winter in Ontario, no large roosts of Red-winged Blackbirds occur. Major roosts, often in common reed, occur in the southeastern United States from Texas to southwest Indiana east to the Atlantic Coast and north to Maine, with some roosts in California. Most birds wintering in Kentucky, Tennessee, and Alabama come from the Great Lakes region. Some roosts support 20-30 million birds and 1 in Arkansas supported 40 million birds in 1965. There are approximately 150 roosts in the United States that support at least a million birds (Nero 1984; Root 1988; Yasukawa and Searcy 2020).

Banding recoveries suggest that the Red-winged Blackbird is fairly sedentary within winter, with most recoveries in the same year within 25 km of the banding site. Only 6% of recoveries within the same year were more than 100 km from the roost where the bird was banded. Birds may travel as far as 80 km from the roost to forage, but distances travelled are usually much less. The distance between banding and recovery locations was further between years, with a mean of 88 km in 1 study and 154-231 km in another. It is much less faithful to wintering than breeding areas (Dolbeer 1978, 1982; Yasukawa and Searcy 2020). It spends an average of only 4 nights at a particular roost before moving on to a different roost, typically 4.8-13.6 km from the previous roost, although some may move 5 times that distance (Dunn and Tessaglia-Hymes 1999).

The Red-winged Blackbird may use some different foraging strategies in winter. In North Carolina, a flock of 2,000 fed in a dense stand of pines. Some extracted seeds from cones. Others

searched for insects on terminal buds or beneath bark. While searching for prey under bark, it pecked in a manner similar to a woodpecker or nuthatch. Most searching under bark was done on limbs and not on trunks (Meanley 1966). In New York, it often fed on the seed capsules of sweetgum. After a heavy snowstorm, it fed on standing giant ragweeds, splitting the stalks open with the bill to obtain small leafroller caterpillars (Fischer 1953). In Wisconsin, it preyed upon larvae of the cattail borer moth. It also commonly ate cocklebur seeds (Nero 1984). The diet of birds in a Tennessee winter roost consisted of 38% corn, 36% weed seeds, and smaller amounts of sorghum, wheat seeds, tree seeds, and insects. The weed seeds were from 15 genera of plants, with those of ragweeds and rough cocklebur most important. Weed seeds comprised 62% of the diet from November to March (Yasukawa and Searcy 2020).

Highest numbers of Red-winged Blackbirds at feeders occur during spring migration. Smaller numbers use them throughout the winter, mostly where agricultural crops and weedy fields are scarce, or when snow covers food resources. Its favourite feeder foods include mixed seeds, millet, sunflowers, and cracked corn, and probably milo. It infrequently consumes safflower, whole corn, hulled peanuts or hearts, suet, bird puddings, fresh fruit, baked goods, wheat, and oats (Dunn and Tessaglia-Hymes 1999).

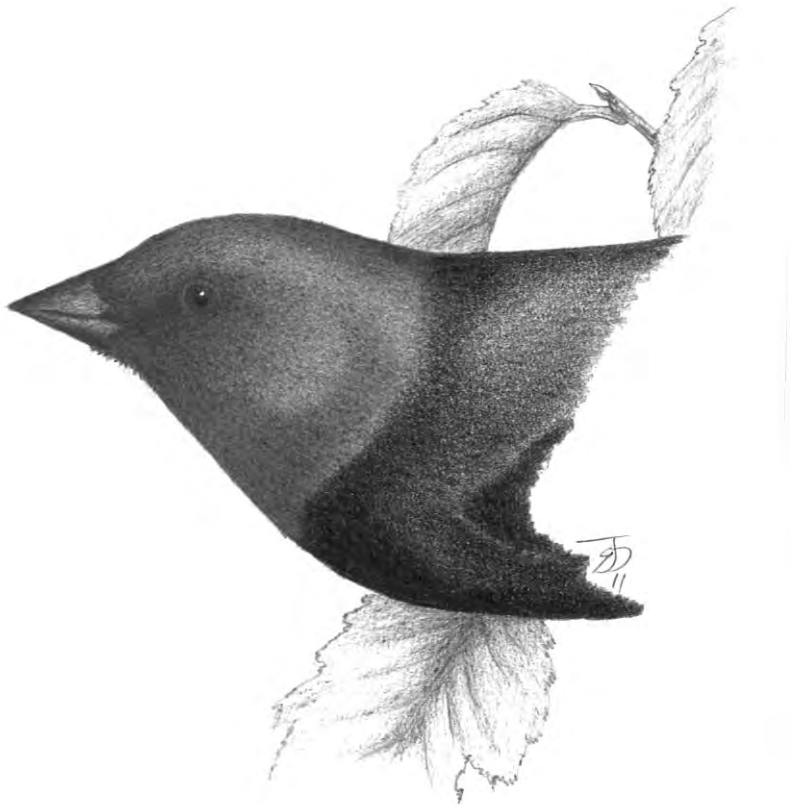
Severe winter weather may cause significant mortality. In Kentucky, 25 cm of snow fell over a week, making it difficult for birds to find food, and the overnight temperatures dropped to −24.4°C. The Red-winged Blackbird represented 0.9% of the birds at a roost but 6.3% of the dead birds found. Its mortality rate was 7 times higher than other species in the roost (Stewart 1978). In Illinois, heavy snow and extreme cold occurred during a January storm. Its density in bottomland forests declined by 10.9% after the storm and some carcasses were found (Graber and Graber 1979). North of Kingston, Weatherhead (2005) documented a steep decline in the breeding population from 1974 to 1995. Harem sizes were negatively correlated with variation in the North Atlantic Oscillation Index in the previous 6 months. Harem size and male return rates were significantly correlated. He concluded that more frequent or severe winter storms could be causing the decline.

James (1991) considered the Red-winged Blackbird an uncommon winter resident in the south north to Toronto, and occasional and rare north to Thunder Bay and Moosonee.

There are some indications that the Red-winged Blackbird has increased as a wintering species over historical conditions, and that the core of its wintering range may have shifted northward. This may be due to the current abundance of cereal crops which were formerly much less common, and the proliferation of bird feeders. McIlwraith (1894) was aware of no winter records for the province. Freedman and Riley (1980) analyzed Christmas Bird Counts (CBC) for southern Ontario for 1929-77. It demonstrated an irregular increase in abundance and frequency of occurrence beginning in 1958, but total annual numbers continued to be low. CBC data indicate that it decreased in Ontario at annual rates of 0.86% 1970-2021 and 0.14% 2009-21 (National Audubon Society 2022).

Brown-headed Cowbird

Molothrus ater

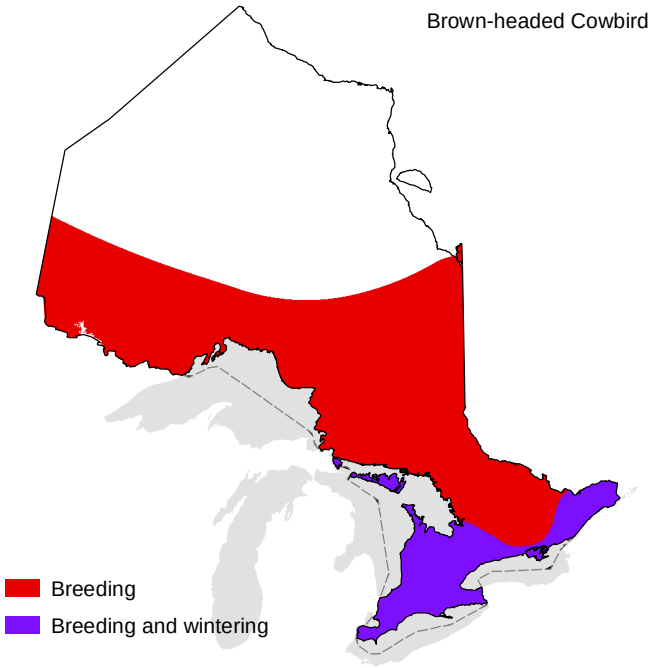


BREEDING SEASON

Habitat Requirements

The Brown-headed Cowbird is Ontario's only obligate brood parasite. It lays its eggs in nests of other species and leaves the rearing of their young to the host species. Because of its parasitic behaviour, the cowbird has been much maligned. Some birders and even ornithologists illogically think that it should have human morals (Bent 1958; Ortega et al. 2005). Many people remove cowbird eggs from nests and cowbird control programs (which consist of killing them) have been implemented in many areas. Instead of being cast as a villain, the cowbird should be viewed as a native species that is in significant decline and that has some very interesting physiological and behavioural adaptations to support its parasitism.

Cowbird parasitism always has an adverse effect on the reproductive success of the host. Hosts that accept eggs typically raise fewer of their own eggs to fledging. Many smaller hosts typically raise only cowbird young when they are parasitized. Hosts that are smaller than the cowbird and those with long incubation periods are affected the most. Parasitism may also affect species that



reject cowbird eggs. The female cowbird may remove one of their eggs, thus reducing the clutch size of hosts. Ejectors may also damage their own eggs while attempting to eject a cowbird egg. If eggs are pierced in the nest, the leaked contents may glue the host's eggs together and to the nest, resulting in poor hatching success. For species that abandon parasitized nests, there is a loss of energy and time as a result of this activity. Replacement nests tend to have smaller clutch sizes than first nests, so there is often a loss of reproductive success as a result of nest abandonment. Nest desertion does not guarantee that the replacement nest will not be parasitized. Time and energy costs may be slightly less for species that that build a new layer in the lining of the nest and bury the cowbird egg. These species also often bury some of their own eggs with a resultant loss in reproductive effort. The mere presence of cowbirds may result in nest losses because the distress responses of the potential host often attracts predators, and the noisy vocalizations of cowbird nestlings may also attract predators (Grzybowski and Pease 1989; Peer et al. 2005; Rothstein 1975; Rothstein and Peer 2005; Smith 1999; Zanette et al. 2007).

A good parasite should not harm its host population; if the host population declines so will the parasite. Parasites tend to be rare in relation to their host so that the host population is not adversely affected by parasitism. The Brown-headed Cowbird meets both these criteria. It has not been confirmed causing the decline of any host species, and its population is approximately 3% of the population of suitable host species. Brittingham and Temple (1983) did a major disservice to the cowbird by suggesting that it might be responsible for recent declines in songbirds. This paper is still widely cited but contains a major flow. They used Christmas Bird Count (CBC) data for the southeastern United States where most cowbirds overwinter to determine its population trend. Instead of calculating the actual number of cowbirds counted, they simply tallied the number of counts it was detected on 1900-80. The number of counts it was observed on increased over this period and they interpreted this as an indication that its populations was increasing. Actual CBC data and results of the Breeding Bird Survey (BBS) indicated that it was declining in their study period. Their conclusion that increasing cowbird populations were adversely affecting songbird populations was incorrect. There is no evidence that the cowbird has caused the decline of any of its host species, but it has been accused of causing the decline of Kirtland's Warbler, Least Bell's Vireo, Southwestern Willow Flycatcher, Black-capped Vireo, and Golden-cheeked Warbler. Populations of these species are or were previously low and parasitized heavily by the cowbird. This lead to cowbird control programs which included killing cowbirds and removing cowbird eggs from nests. The Kirtland's Warbler is the best studied example, with the population declining to an estimated 201

singing males. After 18 years of cowbird control, the male population was still 200 indicating that the population was at carrying capacity. A further study of the Kirtland's Warbler population revealed that most nest mortality was due to predation and that mortality related to parasitism was only 16.8% of the total. The Kirtland's Warbler population did not recover until an out-of-control prescribed burn created about 100 km^2 of new habitat. The Least Bell's Vireo population is the only one that increased during cowbird control. The population began to rebound before the control program was initiated due to increased habitat availability following extensive wildfires. Despite the lack of evidence that cowbird control programs are effective in endangered species recovery, no major control program has been terminated. In all cases, the species of concern are endangered due to limited availability of suitable habitat. The cowbird gets blamed for habitat loss and fragmentation caused by humans. Although parasitism exerts costs on individuals that are parasitized, there are no effects on the host population as a whole. Failure to recognize this fact explains much of the lack of understanding between advocates and opponents of killing cowbirds in control programs (Chace et al. 2005; Lowther 2020c; Martin 1992; Mayfield 1977a; Ortega et al. 2005; Peer et al. 2005; Rothstein and Peer 2005; Schweitzer et al. 1998; Smith 1999).

The Brown-headed Cowbird is a generalist parasite, laying its eggs in a variety of bird species' nests. As of 2005, it had been documented parasitizing 228 species; 87 host species were confirmed in Ontario (Peck and James 1998b). Many hosts are parasitized rarely or only accidentally; only 132 of the 228 hosts (57.9%) have successfully raised a cowbird (Chace et al. 2005). To be a suitable host, the species should be altricial and not precocial; its manner of feeding should not depart greatly from the normal passerine method; and it should feed its young insects, worms, soft seeds, and other typical passerine foods. Most suitable hosts are within 4 families: tyrant flycatchers, vireos, sparrows, and warblers; thrushes are also frequently parasitized. Almost all nonpasserine species are unsuitable hosts as are many passerines. The Mourning Dove is unsuitable because their young thrust their bill into the adult's throat instead of vice versa. Swallows may raise a cowbird while it is in the nest but it probably dies after fledging because fledglings are trained to catch prey in the air. Most finches feed their young a granivorous diet and cowbird nestlings rarely survive without the protein in insects that they require. Birds nesting in cavities (woodpeckers, certain wrens, nuthatches, chickadees, and bluebirds) are seldom parasitized because the cowbird prefers open-cup nests and may not be able to access nests with small cavity entrances. Species that regularly eject eggs are unsuitable hosts. Poor hosts are a major source of reproductive loss for the cowbird. The breeding success of the cowbird is much lower than that of its most important hosts (Friedmann 1929, 1963).

Parasitism by the Brown-headed Cowbird has resulted in the evolution of antiparasitic behaviours by hosts and, in some cases, further adaptations by the cowbird to offset these strategies. Avoiding parasitism is the best defence, but this is seldom achievable. Eastern Kingbirds aggressively defend their nests and Red-winged Blackbirds mob cowbirds. These strategies may reduce the incidence of parasitism but do not completely eliminate it. In response to this, the cowbird lays its eggs very early in the morning before dawn when the host is usually not at the nest. The most common defence against parasitism is rejection of the parasitic egg by ejecting it, burying it in the nest, or deserting the nest. The cowbird's response to this is mimicry of the most common hosts'

eggs, particularly those in the central portion of the continent where the species have been in contact the longest (Rothstein 1975).

Habitats in which parasitized nests have been reported in Ontario provide an indication of the cowbird's habitat preferences. Most nests were in dry open or semiopen areas with growths of deciduous (49.2% of nests), mixed (41.2%), or coniferous (8.8%) shrubs or small trees a predominant feature. Breeding areas included farmlands (54.5% of nests) dominated by overgrown fields and fencerows (26.9%), young conifer plantations and orchards (20.7%), and open fields (6.9%); woodland areas (14.3% of nests) including wooded edges (12.6%), second-growth woods (1.2%), mature woods (0.4%), and swamps (0.1%); residential areas (14.1% of nests), including gardens, parks, and streets; shrubby edge areas (13.2% of nests), including shorelines and floodplains (8.8%) and roadsides (4.4%); and wet areas (3.9% of nests), including cattail marshes, sedge meadows, fens, bogs, and muskegs (Peck and James 1987).

The cowbird avoids extensive tracts of forest. In Algonquin Park, it avoided forests and inhabited shrubbery and more open country (MacLulich 1938). It has been essentially absent as a breeder in the park since the 1980s. The habitat is almost completely unsuitable for it due to the lack of agricultural lands for foraging and the nearly contiguous forests now present due to natural succession (Tozer 2012). In the Boreal Forest Region of Ontario, it avoided most coniferous forests, occurring regularly only in stands dominated by white pine or red pine. It was characteristic of artificial grass and shrub habitats within agricultural areas. It occurred in low densities in stands dominated by balsam fir, poplar and/or white birch, and maple-beech, and in urban suburbs (Erskine 1977). In the agricultural and urban landscapes of southern Ontario, it is almost ubiquitous because of the variety of habitats that its hosts prefer. Near Kingston, 6 habitats supported cowbirds: sugar maple–beech-elm–white pine–red pine mixed forest; shoreline areas of alder, staghorn sumac, cattails, and ferns; open grassy areas with shrubs and saplings; grassy areas with scattered tall trees; mixed open areas with both shrubs and scattered trees; and short-grass areas such as lawns or cattle pastures (Teather and Robertson 1985). In Durham Region, it occurred in very young and mature pine plantations, a black spruce bog surrounded by red maple–poplar swamp, a variety of open deciduous and mixed forests in both upland and lowland areas, and mature deciduous woods. Speirs and Orenstein (1975) considered it a mid-successional species but it occurred in all stages of succession. On the University of Western Ontario campus in London, its habitat consisted of lawns interspersed with trees and shrubs and a narrow strip of second-growth shrubby woodland growing between the campus and the Thames River (Darley 1983; Scott 1977). These are just a few examples of the habitats it occupies in southern Ontario. It has a high preference for agricultural lands, particularly where livestock is common.

In Ontario forests south of the Canadian Shield, the cowbird was positively correlated with the amount of forest more than 100 m from edge and negatively correlated with woodlot size, the amount of forest within 2 km, and the amount of regional forest cover. The negative relationship with the amount of regional forest cover was highly significant. The other relationships were nonsignificant (Austen et al. 2001).

The Brown-headed Cowbird has 3 main habitat requirements during the breeding season: nesting, feeding, and roosting areas. These areas may be considerable distances from each other

rather than confined within a small territory. What is unique about the cowbird is that it completely abandons the nesting area in late morning and does not return until dusk or the next morning. It is able to do this because it does not have to attend to a nest. The habitat of the breeding and feeding areas is quite different. The breeding area consists of shrubby or forested lands where it spends most of its time in elevated perches. Feeding areas have very short vegetation and cowbirds spend most of their time on the ground foraging. In highly fragmented landscapes, all 3 habitat components may be found in a small area. In contiguous landscapes, cowbirds may commute long distances between forested areas that provide breeding habitats and openings that provide a source of food. Good breeding habitat that is too far from a suitable feeding area is not occupied. Even excellent feeding areas will not be used if they are not within commuting distance of a breeding area. Distance from feeding areas appears to be one of the most important determinants of its breeding abundance, having greater influence than forest type or host density (Chace et al. 2005; Curson et al. 2000; Friedmann 1929; Gates and Evans 1998; Goguen et al. 2005; Rothstein et al. 1980, 1984; Thompson 1994). Distances travelled between breeding and feeding areas vary depending upon the distribution of habitat within the landscape. In many areas, daily commuting distances tend to be 1-3 km: 1.2 km in Missouri and Illinois, 2.27 km in Maryland, 4.1 km in California, and 1.47 km at a forest-prairie ecotone in New Mexico. At another New Mexico site in a bison-grazed landscape, female commuting distances averaged 7.24 km (range 0.16-11.81 km). In Michigan, no cowbirds were found in potential breeding habitat further than 3 km from agricultural land that provided feeding habitat. Another New Mexico study reported mean commuting distances of 11.8 km (range 9.3-13.2 km) for females. For 3 females, the mean distance between roosts and breeding areas was 19.0 km (range 17.8-20.6 km). It was previously thought that the maximum commute distance was about 7 km. This study demonstrated that the cowbird can penetrate forest tracts to breed considerably further. Only a small proportion of the population consisted of long-distance commuters. In California, the mean distances between daily activity centres were 2.27 km (range 0.30-6.14 km) between breeding and feeding areas, 2.96 km (0.29-9.84 km) between feeding and roosting areas, and 1.35 km (0.08-4.91 km) from roosting to breeding areas. Females usually had 2 feeding, 1 breeding, and 1 roosting home range. Occasionally feeding and roosting areas, breeding and roosting areas, and breeding and feeding areas overlapped. In New Mexico, 70% of hosts were parasitized in areas close to grazed pastures, but only 33% were parasitized at distances of 8-12 km from pastures (Chace et al. 2005; Curson et al. 2000; Gates and Evans 1998; Goguen and Mathews 2000; Goguen et al. 2005; Rothstein et al. 1984; Stribley and Haufler 1999; Thompson 1994).

Numerous studies examined the habitat preferences of the Brown-headed Cowbird at the landscape scale. Most dealt with the amount of forest cover in the landscape. It is generally believed that the cowbird avoids heavily forested landscapes, but this is not always the case. Chace et al. (2005) examined factors affecting its distribution and abundance at continental (greater than 50 km), regional (10-50 km), and landscape (1-10 km) levels. Because it may travel 15 km between breeding and feeding sites, forests would have to be larger than 700 km^2 to entirely exclude cowbirds. Results at the 50-km and 10-50-km scales were ambiguous suggesting that it did not make habitat selection decisions at these scales. At the 10-km scale, its abundance and parasitism rates on host species showed a consistent negative relationship with the amount of forest cover surrounding the study area. Parasitism declined linearly as forest cover at this scale increased from

6% to 95%. When the amount of forest cover was considered at the 1-10-km scale, the most significant relationships were at the 10-km scale for both sexes combined and only at 3-5 km for females. Abundance and parasitism rates increased with the proportion of grassland and agriculture in the landscape at the 3-km scale. In Michigan, the most important habitat variable determining cowbird abundance was the presence or absence of agriculture within 3 km. It was 3-3.5 times more likely to occur in a forest stand where agriculture occurred within 3 km. The probability of finding it dropped considerably when the nearest agricultural lands were no closer than 2 km (Stribley and Haufler 1999). Hochachka et al. (1999b) examined 23,448 nest records for the cowbird across the United States. Sites with higher forest cover tended to have a lower probability of parasitism, although the pattern only approached significance. The probability of parasitism was not significantly affected by the amount of forest cover at the 50-km or 10-km scales. There was a 95.3% probability that increased forest cover within 10 km resulted in a decreased incidence of parasitism. Hosts were parasitized at a lower rate where there was greater forest coverage. A 10% increase in forest cover was predicted to result in a 1% decrease in the proportion of nests that were parasitized. In Montana and Idaho, 73% of points where it was detected were within 10 km of agricultural areas and almost 90% were within 20 km. It was found closer to developed areas and in landscapes with more open and xeric forests and less coverage by subalpine and mesic forests. Proximity of upland shrub areas, such as clear-cuts, was not related to its occurrence (Young and Hutto 1999). In Saskatchewan, it was more common than expected in fragmented landscapes but was not influenced by the amount of forest cover within 5 km (Hobson and Bayne 2000). In North Dakota, Pietz et al. (2009) studied the influence that woody vegetation had on parasitism rates of grassland birds. A previous study determined that 14% of grassland passerine nests were parasitized in treeless landscapes compared with almost 0% in grasslands within aspen-parkland landscapes. In their study, the relationship between the percent tree cover within 2 km of nests and the probability of parasitism was negative for all grassland species. For every 1% increase in tree cover within 2 km, the probability that a nest would be parasitized decreased by 12%. The cowbird is less likely to target grassland species in landscapes with sufficient tree cover to provide alternative hosts in woodlands. In Vermont where 77% of the area was forested, higher probability of cowbird occurrence was associated with the number of food sources within 7 km and the distance to the nearest disturbance (maintained wildlife openings, residences, hayfields, pastures, and ski areas). Large disturbance areas and clustered patches of them had a higher probability of occurrence. It preferred landscape elements that produced edge, so the larger the area of disturbance, the higher the probability that it would be used. It tended to occur in disturbance patches close to other disturbance patches. Distance to the nearest livestock area was not an indicator of cowbird abundance, but the number of them within 7 km was. Areas isolated from livestock areas (the preferred feeding areas) and chronic disturbance areas had a low probability of being occupied. It was largely absent from heavily forested regions, so it may prefer to travel within these landscapes along corridors of chronic disturbances. Large continuously forested areas may act as a barrier to its movement (Coker and Capen 1995). Males preferred landscapes that were 42-75% forested in North Dakota; no areas supported more than 75% forest cover. Females preferred landscapes that were 8-40% forested. In New York, males preferred landscapes with 39-60% forest cover (Cunningham and Johnson 2019). In Quebec, its distribution corresponds with open habitats, especially those created by agriculture. It nests in almost all settled landscapes. Its relative abundance is highest in the St. Lawrence

Lowlands where agriculture, urban, and suburban habitats predominate. It becomes less common where forest cover increases (Houle and Choiniere in Gauthier and Aubry 1996; Michaud in Robert et al. 2019).

The Brown-headed Cowbird lays its eggs in nests in a variety of habitats. It breeds in nearly every major habitat type in North America. It has bred in deciduous, mixed, and coniferous forests, urban and suburban areas, riparian vegetation, tallgrass and short-grass prairies, shrublands, shrubsteppe communities, agricultural fields, savannahs, bottomlands, clear-cuts and other logged areas, meadows and old fields, fencerows, utility and road rights-of-way, pastures, hayfields, Dense Nesting Cover and Conservation Reserve Program (CRP) grasslands, pine and oak barrens, coniferous plantations, small stream corridors through forests, marshes, prairie potholes, willow and alder thickets, forest burns, windthrows in forests, urban parks and green spaces, fens with scattered trees, orchards, farmyards, and tundra (Bielefeldt and Rosenfield 1994; Campbell et al. 2001; Chace et al. 2005; Delphey and Dinsmore 1993; Faanes and Andrew 1983; Falardeau et al. 1999; Grundel and Pavlovic 2007b; Hartley 1994; Hoffman 1989a, 1989b; Morris and Thompson 1996; Mossman 1988; Mossman and Hoffman 1989; Mossman et al. 1991; Niemi and Hanowski 1984a; Noon et al. 1979; Norris 1947; Robinson et al. 1999; Samson 1979; Sinclair et al. 2003; Temple et al. 1979; Walk et al. 2011; Whitmore 1977; Wood et al. 2013; Yahner 2003).

Although the Brown-headed Cowbird breeds in almost every habitat type, it prefers habitats with more complex structure, such as forests, savannahs, shrublands, and old fields. These habitats support a higher diversity and abundance of hosts than grasslands and marshes. They also provide elevated perches from which they can search for host nests (Chace et al. 2005). Forests are highly preferred over grasslands. In Oklahoma, nests in open habitats were usually not parasitized, with most parasitized nests on edges of adjacent low shrubby thickets (Wiens 1963). In Pennsylvania prior to 15 May, the cowbird was never seen in forested areas and it parasitized birds nesting in open habitats. Later, when forest songbirds returned, most cowbird eggs were laid in nests of woodland species, although it continued to parasitize some open-country birds (Norris 1947). In New York, Hahn and Hatfield (1995) studied parasitism rates in a 1,300-ha forest and old-field habitats adjacent to the forest within commuting distance. The parasitism rate in the forest (32.3%) was significantly higher than in the old fields (6.7%). The Eastern Phoebe occurred in both forested and open habitats. In forest, 42.1% of its nests were parasitized compared with 0% in the open. Habitat was the only significant variable predicting parasitism rate. Both the species that are traditional hosts and the field-edge community, which is often considered its preferred habitat, were conspicuously underused compared with species nesting in forest interior further than 50 m from edge. There was no relationship between parasitism and proximity to edge, consistent with their observations of cowbirds throughout the forest. In North Dakota, parasitism rates of grassland birds declined as the amount of forest cover increased, indicating that it preferred hosts inhabiting forests (Pietz et al. 2009). In heavily forested landscapes of Vermont, it significantly preferred permanent forest openings to temporary regenerating openings such as clear-cuts, shelterwood cuts, or group-selection cuts. Its preference for permanent openings was probably due to the presence of short grass. Lawns and other areas that are maintained as short grass may provide feeding areas as well as breeding habitat at forest edges (Coker and Capen 1995). In Illinois, highest densities occurred in shrubs at edges of forests and in shrublands and hedgerows (Graber and Graber 1963). Illinois

parasitism rates were higher in forests than in shrublands, edges, and grasslands. Grasslands consistently had the lowest abundance of cowbirds and savannahs had the highest abundance. Parasitism rates were significantly higher in shrublands and savannahs than in forests; parasitism rates in grasslands were significantly lower than in any other habitat type. Grasslands may be difficult for it to search for nests because of the scarcity of perches, dense grass cover, and the cryptic behaviour of these host species near their nests. Grasslands that have some woody vegetation that provide perches have elevated parasitism rates, but these are still lower than for other habitats. The preference for savannahs may have been because of the numerous perches and lack of dense ground cover (Robinson et al. 1999). It was more abundant in forests than in shrublands in southern Illinois but equally abundant in these habitats in the remainder of the state (Walk et al. 2011). In British Columbia, it preferred open habitats with low or scattered trees. It preferred forest-field ecotones over extensive forests or fields. Thirty-four percent of parasitized nests were associated with rural habitats, including cultivated farmland (12%), farmyards (11%), orchards (7%), and pastures (4%); 30% were in forests including deciduous (13%), coniferous (9%), and mixed (8%) stands; 16% of nests were in riparian areas; 11% were in suburban and urban areas; and 6% were in shrublands. Specific habitats included 33% backyard and farmyard gardens and residential areas; 29% mature and second-growth forests and regenerating clear-cuts, forest edges, and road edges through forests; and 25% riparian habitats including forested shores of lakes and watercourses, cottonwood bottomlands, and willow thickets. Orchards, urban parks, sagebrush shrublands, and transportation corridors were used to a lesser extent (Campbell et al. 2001).

The Brown-headed Cowbird exhibits habitat preferences within the major breeding habitat categories. Forest age may be a factor in its habitat selection in certain areas. In Pennsylvania, it occurred in 36.5% of old-growth forests, 87.7% of forests statewide, and 83.4% of forests in the Appalachian Plateau. Haney (1999) considered it to have a negative affinity with old-growth forests. In Alberta, it was significantly more abundant in young and old-growth than mature trembling aspen stands (Schieck et al. 1995); results were similar in British Columbia (Campbell et al. 2001). In the Prairie Provinces, it was associated with young mixed or deciduous forests. These tended to be on moist nutrient-rich soils (Kirk et al. 1996). In South Dakota green ash stands, it was significantly more abundant in late than early seral stages. Bird abundance was greater in late seral stands, so its habitat preference may have been related more to the abundance of potential hosts rather than stand age (Rumble and Gobeille 1998). In Saskatchewan, it was significantly more abundant in trembling aspen stands than in white spruce stands and mixed woods (Hobson and Bayne 2000). In Montana and Idaho, it occurred at 1.3% of points in old growth, 5.1% in mature forests, 5.6% in young forests, and 10.0% in selectively cut forests. It was common in extensively logged areas but more abundant in partially logged stands than clear-cuts. It occurred in all major habitats except hemlock-cedar, but did not use all cover types equally. It was largely absent from dense old growth and high-elevation forests. It was abundant in open coniferous forests, grasslands, agricultural areas, and riparian cover. Grasslands and agricultural areas were used much more than clear-cuts. The distribution of potential hosts was similar to that of cowbirds (Young and Hutto 1999). Evans and Gates (1997) sampled 6 habitat types in a 15,699-ha forest in Maryland: forest–power line edges, forest–open-canopy road edges where there was less than 10% canopy cover at the centre of the dirt road, forest–closed-canopy road edges with more than 90% canopy cover at the centre of the

road, forest-brush edges, forest-stream edges, and forest interior 250 m or more from edge. The cowbird was detected in all habitats except forest interior. Its frequency of occurrence was 50% at forest-brush edges, 46.4% at streams, 33% at power lines, 14.3% at open roads, and 10.3% at closed roads. Host species richness was lowest at closed roads and highest at brush and power line edges. Host abundance was significantly higher at power lines and open roads than at streams, closed roads, and forest interior. Habitat where it was most frequently detected had both high mean snag basal area and total vegetation volume. It was found near visible openings, ranging from narrow road and stream corridors to larger clearings. Both high numbers of snags and high vegetation volume were required to attract high densities of cowbirds. If one of these factors was low, the frequency of use was also low. It was attracted to distinct edges formed by canopy openings and secondarily by the occurrence of high snag basal area and total vegetation volume. These may be cues that direct the cowbird to habitats with the potential for supporting high host nest densities. In Iowa, it parasitized a significantly higher proportion of Red-winged Blackbird nests at natural than restored prairie pothole wetlands. Delphey and Dinsmore (1993) attributed this to the presence of trees around the perimeter of natural wetlands, providing observation perches for cowbirds.

Several studies examined microhabitat preferences of the Brown-headed Cowbird. Microhabitat preferences can be subdivided into those selected in forests and grasslands. Its distribution is influenced by plant species diversity, tree density, canopy closure, and vegetation cover or volume at various height classes. Some studies determined that host nest concealment affects parasitism rates; other studies found that nest concealment is not a factor. Many studies concluded that abundance of potential hosts is more important than habitat. Others found that habitat is selected rather than potential hosts. Individual host species may be parasitized at different rates in adjacent old fields and forests, and this may be related to the degree of nest concealment. Parasitism rates on individual species vary geographically, with suitable abundant hosts such as the Red-winged Blackbird not being parasitized in some areas and heavily parasitized in others. As a result of all these factors, it is difficult to definitively define its microhabitat requirements (Chace et al. 2005; Hauber and Russo 2000).

Most information on the cowbird's microhabitat preferences is for forested habitat. In Michigan, its abundance could be predicted based on 5 habitat variables: presence of agricultural land within 3 km, total percent non-agricultural openings within 0.5 km, percent vertical cover 0-1 and 1-7 m from the ground, and mean canopy height. Areas with mean basal area less than 16 m^2 per ha were significantly more likely to support it than denser forests. Where agriculture was present in the landscape, lower occurrence occurred in stands with more than 70% canopy cover. The percent cover 0-1 m from the ground was the most significant predictor of occurrence after agricultural lands (Stribley and Haufler 1999). In Montana and Idaho, ground cover was the most important predictor of its occurrence. Ground cover was high where it occurred, both in forests and grasslands (Young and Hutto 1999). In Wisconsin, parasitized nests were characterized by a more open subcanopy (3-10% coverage) and canopy, and more cover 0-0.5 m from the ground than unparasitized nests. Associated with these differences were a significantly higher density of low shrubs and saplings and a lower density of shrubs taller than 5 m and small trees (7-14.5 cm diameter at breast height [DBH]) around parasitized nests. The number of shrubs and saplings was higher around parasitized nests, but not significantly. The number of dead trees did not vary between

parasitized and unparasitized nests and the percentage of nests parasitized was similar for nests closer or further than 11.3 m from a snag. An open canopy and subcanopy would enable the cowbird to attain an elevated perch with an unobstructed view of nest-building activities. Snags below the canopy do not provide better observation sites than exposed branches of living trees, which may explain why nest distance from a snag did not affect parasitism rates (Brittingham and Temple 1996). In Indiana, it was significantly associated with the density of dead trees (Grundel and Pavlovic 2007a). In Illinois, it was positively correlated with shrubs and negatively correlated with sugar maple and basal area (Blake and Karr 1987). In New York, parasitism rates were higher on forest-host nests 1 m or less from the ground than on higher nests. There was a high rate of parasitism on species that nested on the ground and short heights above it, consistent with observations that it frequently moved about in the lowest vegetation strata, both by walking on the forest floor and perching at heights of 1 m or less. Ground nests that were particularly well concealed, such as those of the Ovenbird, Black-and-white Warbler, Louisiana Waterthrush, and Carolina Wren, experienced a high rate of parasitism. The bulky and conspicuous nests of the Wood Thrush experienced much lower rates of parasitism, but its nests were higher. In adjacent old fields and edges in New York, nest height had no effect on the rate of parasitism (Hahn and Hatfield 1995). In the mid-Atlantic states, it was positively correlated with foliage density 0.3-1 m from the ground and the number of trees around the point count station (Robbins et al. 1989). In Illinois, the rate of parasitism on ground nests (41.2%) was less than on nests in shrubs, saplings, and the canopy (75.0%; Robinson 1992). In Wisconsin, its density in forests was inversely related to the distance to openings in the canopy 0.2 ha or larger. It occurred at 40% of points at an opening, 30% 200 m from an opening, 20% 300 m from an opening, and 15% of points 400 m from an opening. Parasitism rates decreased with distance to the nearest opening: 65% at 0-99 m, 46% at 100-199 m, 36% at 200-299 m, and 18% for 300 m and further. Parasitism rates were greater near openings 0.2 ha or larger than near openings smaller than 0.1-0.2 ha. The type of forest opening (agricultural field, recently logged area, or brushy second growth) did not influence parasitism rates. The frequency of parasitism increased significantly as the amount of open habitat within 200 m of a nest increased: 38% at 0-20% open habitat, 50% at 21-40%, and 92% at more than 40% open habitat. It preferred open habitat near areas where it searched for nests (Brittingham and Temple 1983). In New Jersey, Rich et al. (1994) examined its abundance at forest interior 300 m from edge and at 3 types of corridors cutting through the forest: power lines, 16-m-wide paved roads, and 8-m-wide unpaved roads. It was significantly more abundant at paved roads than in forest interior adjacent to these corridors. For power lines and unpaved roads, there was no difference in its abundance at the corridor and in adjacent forest interior. It was significantly more abundant at points with mowed grass (along paved roads) than at sites with shrubs or saplings. It preferentially selected corridors with mowed grass where both sexes often foraged, and males often displayed from power line poles. With an abundance of hosts near the forest edge, grassy corridors through the forest appeared to provide optimum habitat. In Wyoming, it was absent in subalpine areas, most abundant in lowland woods, and common in mid-elevational shrublands. Its abundance was negatively correlated with shrub density. It showed an affinity for areas with a more open understorey (Finch 1991a).

Less information is available on the cowbird's microhabitat preferences in grasslands. In North Dakota, litter depth was greater, the percent coverage by aspen was much greater, and the percent

cover by native herbaceous vegetation was less where it was present than absent. It was positively correlated with the amount of aspen within 100 m but negatively correlated with the amount of aspen within 500 m. Several other parameters had no influence on its presence or absence. These included maximum vegetation height, percent live vegetation, shrubs taller or shorter than 1 m, and amount of Kentucky bluegrass, brome grass, and sweet clover within 100 m (Grant et al. 2004). In Saskatchewan, its occurrence was affected by the amount of residual vegetation. It was positively correlated with the density of standing dead vegetation within 10 cm of the ground and negatively correlated with the amount of dead standing vegetation at greater heights (Davis 2004). Chapman et al. (2004) studied native grasslands that were being invaded by red cedar in Oklahoma. It was associated with shrubs and its density increased as coverage by cedar increased.

The Brown-headed Cowbird is considered an edge species in both grasslands and forests. This tends to be true only where there are large tracts of habitats that are not fragmented by roads, houses, or other disturbances. In fragmented habitats, it tends to parasitize hosts throughout habitat patches. Although it may occur in the interior, parasitism rates and its abundance tend to be higher near edges due to the greater abundance and diversity of hosts and host species. In Midwestern forests, parasitism rates were lower in patches 200-3,000 ha. Only at very large scales (greater than 30,000 ha) are forest-interior habitats likely to be entirely free of parasitism. As the cowbird population density increases, so does the distance that it penetrates into forest interior (Chace et al. 2005). In New York, parasitism occurred in all areas of a 1,300-ha forest. Parasitism rates were not higher closer to edge (Hahn and Hatfield 1995). In large riparian treed wetlands in Michigan, it was equally abundant in interior and edge (Inman et al. 2002). In Illinois, cowbird abundance and parasitism rates were high throughout forests 19-65 ha in size (Robinson 1992). It was abundant and widespread throughout the Great Cypress Swamp in Delaware, Maryland, and Virginia. Heckscher (2000) concluded that even the largest forest patch (5,000 ha) was too small to reduce parasitism effects. In New Jersey, it was common 300 m from forest edge (Rich et al. 1994). In Michigan, it was significantly less likely to occur at distances more than 300 m from edge, but it still occurred in the interior (Stribley and Haufler 1999). In Maryland, Gates and Giffin (1991) studied its distribution relative to a 3.4-m wide stream through a 270-ha forest. It was recorded most frequently near the stream and was absent further than 240 m from it. In riparian forests in Maryland and Delaware, the cowbird was equally abundant in all widths of forests, which ranged from 50 to 800 m (Keller et al. 1993). In Maryland, 94.4% of fixes of radiotracked females were 220 m or closer to forest edge. Females often moved hundreds of metres into the interior, but were often less than 50 m from an edge. Based on point counts, forest interior more than 250 m from edge was not used. Forest interior had a significantly more closed canopy, higher numbers of small trees and snags less than 30 cm DBH, and fewer seedlings and saplings than core breeding areas. Gates and Evans (1998) concluded that it would likely penetrate more than 600 m into the interior in highly fragmented landscapes. When feeding in grazed pastures, females were most often 50-100 m from edge where livestock grazed most frequently.

The Brown-headed Cowbird is not an area-sensitive species. It is mostly uninfluenced by forest and grassland size and tends to occur at higher densities in smaller patches. Johns (1993) considered it area sensitive in trembling aspen groves in Saskatchewan, although it occurred in woodlots as small as 0.1 ha. In Illinois, Blake and Karr (1987) concluded that its abundance was related to woodlot

size. They studied woodlots 1.8-600 ha in size. Their results were more an indication that it did not avoid forest interior than it was area sensitive. In Saskatchewan forests, Hobson and Bayne (2000) did not consider it area sensitive and Hayden et al. (1985) reached the same conclusion in Missouri. In CRP grasslands in Montana, North and South Dakota, and Minnesota, it favoured smaller patches. The interior of these grasslands lacked perches and the grasses were too tall to provide foraging habitat (Johnson and Igl 2001). In Saskatchewan pastures, Davis (2004) considered it area insensitive. It was more abundant in irregularly shaped patches with a greater density of shrubs, but patch size had no influence on its occurrence.

Feeding areas are the second important component of the habitat of the Brown-headed Cowbird. Birds move to feeding areas in late morning (1000-1100 hours) and remain until near dark. It has a high propensity to feed in association with large grazing ungulates. It was originally known as the buffalo-bird but became the cowbird after bison numbers were greatly reduced and they were replaced by cattle. It forages to a lesser extent with other wild and domestic ungulates such as elk, pronghorns, horses, pigs, and domestic sheep. Corrals with horses are often favoured feeding areas because the feed provided also provides food for cowbirds; manure may also be an important source of insects. The large grazing species provide foraging opportunities by creating feeding microhabitats, decreasing vegetation height thus facilitating foraging, increasing insect abundance, and flushing insects while they are grazing. The backs of large ungulates may provide sites for social interactions and displays and possibly perches for females searching for nests (Chace et al. 2005; Gates and Evans 1998; Goguen and Mathews 1999; Goguen et al. 2005; Payne 1973; Rothstein et al. 1980, 1987; Sinclair et al. 2003; Thompson 1994). In New Mexico, females fed with bison 77.0% of the time and with elk 9.9% of the time. Most of the times when they did not feed with bison occurred when there were few within 10 km of the breeding area. In cattle-grazed landscapes, the cowbird fed almost exclusively (98.7% of the time) with cattle or horses at active livestock corrals (Goguen et al. 2005). In Illinois and Missouri, 57% of 1,351 feeding observations were associated with livestock (Thompson 1994). In Maryland, 82.9% of fixes of radiotracked feeding females were in grazed pasture and 97.5% were in agricultural land (Gates and Evans 1998).

Although feeding areas associated with grazing or penned ungulates are highly preferred, the cowbird forages in a variety of habitats. These may include row crops, agricultural fields, ungrazed grassy fields, lawns, golf courses, cemeteries, urban yards, bird feeders, campgrounds, dry lake beds, open short-grass prairie, and mowed verges of roads. Where cattle are present, row crops are unimportant as feeding areas, but may be important where cattle are scarce. The cowbird makes extensive use of late-planted soybean fields in Illinois. These continue to provide bare ground habitats favourable for foraging long after corn has grown to a height so that it is no longer suitable for foraging. Urban and suburban habitats provide important feeding habitats in many areas (Chace et al. 2005; Gates and Evans 1998; Goguen et al. 2005; Rothstein et al. 1984; Thompson 1994). The distribution, abundance, and quality of feeding areas are important in determining the cowbird's distribution and abundance.

Morris and Thompson (1998) examined cowbird usage of 5 habitats for foraging in Missouri. These included short (2-20 cm) grazed grass, short (2-10 cm) ungrazed grass such as lawns and mowed hayfields, tall (5-30 cm) grazed grass, tall (more than 30 cm) ungrazed grass such as uncut

hayfields, and feedlots lacking grass where cattle were fed processed feed or grain. They also measured invertebrate biomass and density to determine if habitat preferences and foraging success were related to food availability. Flock sizes were greatest in short grazed grass and smallest in tall ungrazed grass. Density was significantly higher in feedlots than all other habitats, but density was artificially high due to their small size. Density in short grazed grass was higher than in tall grazed grass, and density in tall grazed grass was higher than in the other 2 habitats. Flock size and the number of females were positively related to invertebrate density but male numbers were unrelated to invertebrate density. There were no relationships between invertebrate biomass and either sex. Short grazed grasslands were the primary habitat used for foraging. Intermediate use was made of feedlots because of the readily available food, but females had to also seek invertebrates in short and tall grazed grass to meet their nutritional requirements. Cowbirds appeared to select short grazed grass because of the high density of invertebrates. Cattle were an important component of foraging habitat. Grass height was less important than cattle, but within grazed habitats short grass was preferred.

Roosts are the third important habitat component. These may be either in the breeding or feeding areas or at a disjunct site. In Illinois and Missouri, roosts were often in single trees or fencerows in agricultural areas or in developed areas. A communal roost consisted of a stand of flooded dense sapling-sized silver maples along a drainage ditch. It supported at least 200 cowbirds and 1,000 Common Grackles. The other roosts supported solitary birds (Thompson 1994). In New Mexico, females roosted individually in coniferous forests or riparian woodlands, or colonially in a cattail marsh. The colonial marsh supported 600-1,000 cowbirds and lesser numbers of Yellow-headed Blackbirds, Red-winged Blackbirds, and Common Grackles (Curson et al. 2000). Cowbirds roosted in marshes in California and females roosted communally in trees at edges of woods (Payne 1965, 1973). Friedmann (1929) reported that roosts may be in urban areas and on university campuses. Bent (1958) stated that grasses and reeds in large meadows were favourite roosting sites. It also roosted in dense coniferous trees and other thickets. In California, 1 male roosted alone in a patch of brush all 3 nights he was detected. Three nonbreeding males roosted in a blackbird roost on a shrubby hillside. The roost was used mostly by Brewer's Blackbirds. No females or breeding males were found at this roost (Rothstein et al. 1984). In Maryland, roosts occurred in a range of habitat types but particularly in deciduous forests. Some roosting occurred on developed land near houses. Nearly all roosts were in trees with 60% in deciduous woods, 6-10% each in mixed and coniferous woods and developed areas, and less than 1% in grazed pasture. Most roosts supported a single or only a few individuals (Gates and Evans 1998). In New York, all females roosted solitarily on their breeding home range (Hahn et al. 1999).

Near Kingston, the cowbird used 3 techniques to find nests. The most frequent method was to perch at the tops of trees or shrubs for 9-21 minutes and watch hosts' activities. In every case where Norman and Robertson (1975) observed this behaviour, a nest 4.6-7.6 m from the perch was parasitized the following morning. The second technique was to walk silently over the forest floor, looking about and sometimes stopping to watch birds in the canopy. The third technique was to make a series of short flights just above the shrubbery, landing abruptly in the leaves with considerable wing flapping. One female worked her way along the shrubby edge of a woodlot until she flushed a Chipping Sparrow. The sparrow's nest was parasitized the next morning. In Ohio, no

artificial nests with quail eggs in them were parasitized, but natural nests experienced a high rate of parasitism. This indicated that host activity was important in finding a nest (Thompson and Gottfried 1976). Strausberger (1998) observed a female flying in a hovering fashion less than 1 m above 15-cm tall grass. It flew in a circular pattern looking down, or occasionally dropping to the ground without feeding, then flew up and repeated the process about 20 cm away. The next morning a Song Sparrow nest within 0.5 m of where the female had been walking and hovering was parasitized. In the case of Ovenbirds, cowbirds found nests by watching the host build it (Hann 1941). Watching hosts is the most common form of nest searching but actively flushing hosts from nests also occurs (Chace et al. 2005; Mayfield 1961). Presence of the host in the vicinity of the nest appears essential to nest finding. Hackemack et al. (2016) determined that nest shape and size were not factors determining whether a nest was parasitized.

The cowbird is confined to parasitizing hosts that nest within its home range, so this may limit the possibility of preferentially selecting hosts (Hahn et al. 1999). Some individuals or populations are selective. In Georgia and South Carolina, all host species nested in shrubby habitat or in the understorey of deciduous forests. No species that nested on the ground or in tree canopies were parasitized. Parasitism rates were low, which may have allowed cowbirds to select preferred hosts (Kilgo and Moorman 2003). In Kentucky, it preferentially parasitized Dickcissel nests, parasitized vireo nests according to their availability, and parasitized Red-winged Blackbirds and other host nests less than their availability, indicating avoidance of them. The Dickcissel may have been preferred because it nests later into the season than other birds, readily accepts eggs, and can fledge as many as 5 cowbirds. Vireos are capable of fledging only a single cowbird and often desert heavily parasitized nests. The Red-winged Blackbird can fledge 2 cowbirds but may effectively defend its nest against parasitism (Rivers et al. 2010). Elliott (1977) studied a population in Kansas where most parasitized nests contained more than 1 cowbird egg. The first eggs of individuals were not randomly distributed among host nests, suggesting that some degree of selection or avoidance was being exercised. Subsequent eggs were randomly distributed. In most areas, the cowbird parasitizes a variety of host species, exhibiting no particular preferences, but some individuals may exhibit preferences. A female in Michigan laid all her 18 eggs in Yellow Warbler nests but other females used a variety of species (Friedmann 1929). The cowbird has been confirmed selectively parasitizing older and more experienced Willow Flycatcher and Song Sparrow nests. The female cowbird may inspect nests that she parasitized later in the season to determine the nest fate. Birds that successfully fledged cowbirds the previous year may be preferentially parasitized (Arcese et al. 1996; Smith 1981; Smith and Arcese 1994).

In Ontario, the 10 host species with the largest numbers of parasitized nests, in decreasing order, were Chipping Sparrow, Song Sparrow, Yellow Warbler, Red-winged Blackbird, Eastern Phoebe, Red-eyed Vireo, American Goldfinch, Veery, Cedar Waxwing, and Northern Cardinal. These hosts accounted for 67.6% of all cowbird nest records (Peck and James 1987). Four of these abundantly parasitized hosts are of interest. The Yellow Warbler is a poor host. It raises few cowbirds because of its high propensity to reject eggs. In Michigan, the success rate of cowbird eggs laid in Yellow Warbler nests was only 18% (McGeen 1972). The American Goldfinch is also a poor host that rarely raises a cowbird due to the diet it provides the young (Middleton 1991). The cardinal is another poor host that rarely raises cowbirds in Ontario (Graham 1988). The Cedar Waxwing is a known rejecter

species (Rothstein 1975) so the incidence of parasitism on it may have been higher. The 26 Ontario hosts with more than 20 parasitized nests comprised 87.9% of all cowbird nest records; 30 species with more than 15 parasitized nests comprised 90.2% of records; and 38 species with more than 10 parasitized nests comprised 93.3% of records. Species with the highest percentages of parasitized nests in descending order were House Finch, Purple Finch, Red-eyed Vireo, Chipping Sparrow, Yellow-rumped Warbler, and Yellow Warbler. Those with the lowest percentages included Tree Swallow, Barn Swallow, Eastern Bluebird, Common Grackle, Spotted Sandpiper, and American Robin (Peck and James 1987). Of the 6 most frequently parasitized species, 3 are poor hosts for the cowbird: the Yellow Warbler and the 2 finch species. Cowbirds that hatch in finch nests almost always die because of the granivorous diet they are fed (Kozlovic 1998; Peck and James 1987; Wootton 2020).

In Ontario, 80.4% of hosts' nests were elevated and the remainder were on the ground. Of 1,690 elevated nests, 57.0% were in living deciduous trees and shrubs, 33.2% were in living coniferous trees and shrubs, 0.7% were in dead trees and stumps, 5.4% were inside or outside buildings, 1.7% were on bridges, and 1.7% were in cavities in trees, bird houses, fence posts, and light fixtures. Nests in deciduous trees, shrubs, and vines (47 species, 63.2% of nests) were selected more frequently than those in coniferous trees and shrubs (8 species, 36.8%). The most frequent nest substrates were hawthorns (253 nests), pines (232 nests), spruces (131 nests), maples (116 nests), white cedar (114 nests), raspberries (84 nests), willows (63 nests), and apple (51 nests). Ground nests were in clumps of grasses, weeds, cattails, and ferns (59.6% of nests); at bases of trees and shrubs and among roots (22.9%); in or under brush, dead branches, and leaves (5.5%); under overhanging rocks (4.0%); in sphagnum moss hummocks (2.5%); in rock crevices (2.5%); under rocks, logs, and boards (1.5%); beside logs (0.8%); and in upturned roots (0.8%). Elevated nests were 0.2-19.8 m from the ground, with most 0.9-1.2 m up. Of 1,925 nests, 29.4% were 0.2-1.1 m from the ground, 42.8% were 1.2-3.0 m from the ground, and 8.2% were at heights of 3.4-19.8 m (Peck and James 1987). In British Columbia, Campbell et al. (2001) reported nests 0-15.0 m from the ground, with most 0.9-2.1 m up. The cowbird prefers to nest in the shrub and sapling layer, although it may nest from the ground to the top of the canopy. It has nested as high as 24 m from the ground (Friedmann 1929).

Both the male and female maintain a distinct home range which may or may not be defended. What is unusual about the cowbird is that the female defends the territory and not the male. The female parasitizes nests within her home range. Whether the female defends the home range is dependent upon the density of host nests and also the cowbird density. Territoriality may be unnecessary at low densities of hosts or cowbirds and would be energy inefficient with limited rewards. At high densities of cowbirds, it is too difficult and energetically expensive to defend the entire home range. It is only at moderate densities of cowbirds in areas of moderate to high densities of hosts that defence of an area is viable. Territoriality is most prevalent in the east where cowbird densities are moderate. Where home ranges are defended, there is limited overlap in them but home ranges overlap considerably where they are not defended due to high cowbird densities. Most cases of parasitism by multiple females in a single nest occur where territories overlap or home ranges are undefended and overlap widely. Home ranges appeared to be defended in London but not in the Kingston area (Darley 1983; Dufty 1982; Friedmann 1929; Gates and Evans 1998; Hahn et al. 1999; Laskey 1950b; Rothstein et al. 1984; Teather and Robertson 1985; Yokel 1989). In London and New York where home ranges were defended, most aggressive encounters occurred at mutual

boundaries, with less aggression within the boundaries and outside the home range. At Kingston where home ranges were not defended, most aggressive behaviours by females occurred in the centre of their activity centres. Home ranges are maintained throughout the egg-laying season and aggression may continue until the home range is abandoned (Darley 1983; Dufty 1982; Hahn et al. 1999; Laskey 1950b; Teather and Robertson 1985). Males also have distinct home ranges but do not defend them. Instead, they establish dominance hierarchies with the dominant male mating with the resident female. Occasionally the sexes have the same home range boundaries. In the case of polygynous males, their home ranges overlap those of all females they are mated with. The overlap in the home ranges of the sexes is largely because males closely guard their females from other males. Males accompany their females most of the day, including in the afternoon feeding ranges. Movements of mated males may be restricted by their attendance to females but they occasionally move as far as 900 m outside their home range. Both sexes are within the breeding home range from just before sunrise until 1000-1100 hours, although some birds roost overnight within the breeding home range (Darley 1978, 1982, 1983; Dufty 1982; Elliott 1980; Gates and Evans 1998; Rothstein et al. 1984; Teather and Robertson 1986).

At London, the mean size of home ranges for mated males was 7.9 ha (range 0.4-25.0 ha). Ranges of unmated males were significantly larger and averaged 8.7 ha. Females had mean home ranges of 4.5 ha (range 0.9-13.4 ha). These was no significant difference in the home range sizes of yearling (4.4 ha) and adult (4.8 ha) females (Darley 1982, 1983). Near Kingston, the 90% core ranges of females averaged 8.58 ha or 9.89 ha using convex polygons. The range of members of a monogamous pair was similar, although the male's home range was larger (5.45 compared with 3.48 ha). The range of a bigamous male was 4.69 ha and encompassed most of his mates' home ranges which were 2.52 and 3.18 ha. The range of a trigamous male was 4.94 ha and overlapped the ranges of all 3 females, who had ranges of 1.95, 2.55, and 3.06 ha (Teather and Robertson 1985, 1986). In Illinois, female breeding home ranges averaged 9.10 ha, not significantly different from those of males (12.38 ha). Home ranges of the sexes overlapped by a minimum of 68% (Strausberger and Ashley 2003). In New Mexico, breeding home ranges averaged 38.5 ha in bison-grazed landscapes and 53.8 ha in cattle-grazed landscapes (Goguen et al. 2005). In New York, the average home range size of females was 9.38 ha (range 2.6-32.3 ha, median 7.6 ha). Six females that returned in the subsequent year used almost the same home ranges; they averaged 8.0 ha (Hahn et al. 1999). Another New York study reported breeding home ranges of 3-14 ha (Hahn and Fleischer 1995). In Ohio, home ranges were typically 7.3-8.1 ha, but occasionally as large as 12.1 ha (Nice 1937). In New York, 12 home ranges averaged 20.4 ha (range 11.0-29.7 ha). Ranges of the male and female of 1 pair were identical (Dufty 1982). In California, breeding home ranges averaged 68 ha. The smallest home range was in dense riparian habitat which appeared to be preferred habitat. The larger home ranges were probably related to the low density of both cowbirds and hosts (Rothstein et al. 1984). In Maryland, home ranges averaged 1,592 ha (range 105-6,958 ha). Although home ranges were large, most of the area was little used by females. Core home ranges were much smaller, covering a mean of only 3.5% (range 0.7-11.3%) of the home range. Average core home range was 31.6 ha (range 11.8-56.7 ha; Gates and Evans 1998).

Feeding home ranges are usually not occupied before 1100 hours except by nonbreeders. Birds remain at feeding areas until dusk when they move to the nocturnal roosts. Neither sex defends the

feeding home range although males may continue to display to each other and monogamous males may guard their mates (Darley 1983; Dufty 1982; Laskey 1950b; Rothstein et al. 1984). In some cases, home ranges were combined, with roosting home ranges occurring in both breeding and feeding home ranges and occasionally breeding and feeding home ranges were combined. Single-use core ranges were often oval or elongated in shape with a higher edge-to-area ratio than multiple-use core ranges. The long axis of core ranges often paralleled a habitat edge formed by an opening in a forest such as a stream or road. Roosting core ranges were longer and narrower than other types of core ranges and had significantly higher edge-to-area ratios. Core ranges used for more than 1 activity tended to be circular in shape. Mean core range sizes were 9.5 ha for breeding, 21.8 ha for breeding and feeding, 16.5 ha for feeding, 11.2 ha for feeding and roosting, 1.8 ha for roosting, 9.8 ha for roosting and breeding, and 31.6 ha overall. Breeding and feeding core ranges were significantly larger than roosting home ranges (Gates and Evans 1998). In New Mexico, the overall home range of cowbirds averaged 3,238.3 ha in bison-grazed landscapes and 740.3 ha in cattle-grazed landscapes (Goguen et al. 2005). California males were highly mobile both in the morning and afternoon. One male's movements covered 510 and 550 ha in 2 days. Males used more feeding home ranges (mean of 3.0) than females (1.6) and occasionally visited 3 feeding areas in a single afternoon. Males had larger total home ranges (195-385 ha for yearlings and 350-1,025 ha for adults) than females, with a range of 70-435 ha (Rothstein et al. 1984).

Limited information is available on natal philopatry rates. In Kansas, 2 of 13 nestlings (15.4%) returned (Elliott 1978). In Michigan, 12 of 15 young were recovered the next year in the same 10-minute block and the other 3 were recovered within 40 km of the natal area (Payne 1972). In California, 110 of 1,393 juveniles (7.9%) returned. These were banded as independent fledglings in feeding areas that were as far apart as 50 km and supported birds from a wide geographic area (Anderson et al. 2005). These results may not give an accurate representation of the proportion of birds that return to their natal area.

Adults tend to have high site fidelity. At London, 75.0% of mated males returned, 77.8% of unmated males returned, and 31.0% of nonresident males returned. The 2 nonresidents that returned and mated the following year settled 300 and 600 m away from their previous ranges (Darley 1982). Darley (1971) estimated the mortality rates from autumn to spring at 38% for males and 55% for females. The higher mortality rate of females may be due to egg laying, with the energy in a single egg representing 9% of the female's weight. At Delta Marsh, 65.5% of resident males and 46.6% of resident females returned in a subsequent year. Hahn et al. (1999) noted that site fidelity makes it likely that the female will encounter many of the host birds that bred there in the previous year. This allows it to monitor the progress of its young in host nests and preferentially select superior birds in subsequent years. In New York, females returned to the general area of their previous home range. Six returning females used nearly the same 8.0-ha home range. Another female was present in 3 years. In the second year, her home range overlapped with 53% of the year-1 home range. In the third year, her home range overlapped 89% with the areas used in years 1 and 2. Dufty (1982) also reported birds returning to the same home ranges in New York. In grassland habitat in Kansas, only 4.5% of males and 9.4% of females returned (Verheijen et al. 2017). Anderson et al. (2005, 2012) reported return rates of 10.2% and 12.1% in feeding areas in California. Because these were feeding areas that attracted birds over a large regional area, they do not represent breeding site fidelity rates.

In California, Elliott (1978) reported that only 3 of 14 adults (21.4%) returned to grassland habitat. This was a breeding area where a high proportion of nestlings returned. It is possible that adult fidelity rates to grasslands are lower than in other habitats. Rothstein et al. (1984) only attempted to find a single bird in a subsequent year and found the female in the same feeding area as the previous year. Breeding birds have strong homing instincts when displaced from their breeding ranges, with males more likely to return. Birds transported as far as 550 km have returned to their breeding home ranges within the same season. No transplanted juveniles returned (Manwell 1962; Wood 1952).

Limiting Factors

The Brown-headed Cowbird has evolved several adaptations for its parasitic behaviour. The parasitic cowbirds are the only North American species that are indeterminate egg layers. It can lay an egg a day for extended periods, similar to the domestic chicken. This allows it to lay eggs throughout the entire breeding season of their primary hosts (Jackson and Roby 1992; Payne 1965; Scott and Ankney 1980, 1983). Timing of egg laying is another adaptation. The cowbird lays its eggs very early in the morning, usually before it is light. At London, egg laying occurred an average of 9.14 minutes before sunrise. In Manitoba, females laid their eggs an average of 35.6 minutes before sunrise. By laying its eggs very early in the morning, it is considerably less likely to encounter the host at the nest. During the early egg-laying period, most hosts are absent from the nest. In order to parasitize a nest in the dark, the cowbird may check a nest for several days in advance before parasitizing it. In this manner, it knows where to deposit its egg a day in advance. Another adaptation is that the cowbird lays its eggs very quickly, spending only 5-10 seconds to slightly over a minute in the host's nest. This lessens the odds that the host and cowbird will encounter each other. A final adaptation is that eggs are typically laid during the host's egg-laying period, usually after there is at least 1 egg in the nest and before the host's clutch is complete. This ensures that the cowbird's egg is in the same timing sequence as those of the hosts. If the cowbird egg is the first egg in the nest, this increases the probability that the host will abandon it. Eggs laid once the host has started incubation may not have time to hatch. Cowbirds are often forced to lay in hosts' nests out of the preferred timing. This may occur if there is a shortage of host nests or if the nest that was selected for parasitism the previous day is unavailable due to predation or other factors. Cowbirds are completely silent in the morning, another adaptation to reduce the probability of detection by hosts. They do not vocalize until egg laying is complete in the morning (Ellison et al. 2019; Friedmann 1929; Hann 1941; Neudorf and Sealy 1994; Norris 1947; Scott 1991; Sealy 2015). The egg itself is highly adapted for parasitism. It closely mimics those of its traditional grassland hosts in the Midwest. There was no difference in the mean ground cover, colour, and density of maculation in cowbird eggs and those of Sprague's Pipit, Vesper Sparrow, Savannah Sparrow, Baird's Sparrow, Chestnut-collared Longspur, and Western Meadowlark in Saskatchewan. The cowbird has evolved a generalized egg appearance that mimics the eggs of multiple species in grassland communities (Klippenstein and Sealy 2010). Mimicry reduces the likelihood that cowbird eggs will be rejected by the host because hosts may have trouble distinguishing their eggs from those of the parasite (Peer et al. 2005). The cowbird's egg is 40% thicker than expected based upon its volume and can withstand approximately 2 times the amount of pressure than comparably sized eggs. The cowbird egg is also more rounded in shape than most eggs. This makes it more difficult for hosts to pierce cowbird eggs. Hosts often damage their own eggs while trying to pierce a cowbird egg through deflection of the blow. The cowbird

also drops its eggs into the nest from a height of 4-8 cm. The stronger eggshells prevent damage when laying and may damage hosts' eggs when dropped into the nest, thereby reducing competition for the cowbird nestling (Ellison et al. 2019; Picman 1989, 1997; Rohwer and Spaw 1988; Spaw and Rohwer 1987; Weatherhead 1991). The thickened eggshell has the potential to impeded gas flow to the developing embryo. Cowbird eggs have 1.9 times more pore area than those of the Red-winged Blackbird and significantly greater gas flux than those of comparable species. This adaptation allows cowbird eggs to hatch significantly earlier than expected (Jaeckle et al. 2012). Cowbird eggs typically hatch 1 or more days before those of the host, thereby conferring a significant competitive advantage to the cowbird nestling over the hosts' nestlings (Peer et al. 2005). For smaller hosts, the presence of the larger cowbird egg may reduce the amount of heat hosts' eggs receive. The cowbird egg may receive a disproportionate amount of the heat, thereby hastening its hatching. Cowbird eggs hatch faster even than the much smaller eggs of the Yellow Warbler. In Manitoba, the incubation period per ml of egg was 4.22 days for the cowbird and 8.92 days for the Yellow Warbler (Briskie and Sealy 1990; Friedmann 1929; McMaster and Sealy 1998). In order to provide additional competitive advantage to the cowbird egg, the female cowbird often removes host eggs or punctures them. It tends to remove eggs when there are 2 or more host eggs present. The last host egg is not usually removed because this may stimulate nest desertion. Eggs are typically removed from hosts' nest 1 or more days after it is parasitized. Removal of hosts' eggs fulfils 2 functions. The first is that the addition of the cowbird egg may increase the clutch size to the point where the host cannot adequately incubate the clutch. The second is that this results in 1 less host nestling that the cowbird nestling has to compete with. Removed eggs may be eaten, but many are just dropped or placed on the ground, indicating that eggs are not removed to obtain food (Carey 1986; Granfors et al. 2001; Hann 1941; Mayfield 1961; Peer et al. 2005; Scott et al. 1992). Female cowbirds may remove eggs and kill nestlings in unparasitized nests. The purpose of this appears to be to induce the host to renest, thereby providing another opportunity for parasitism (Elliott 1999; Granfors et al. 2001; Norris 1947; Peer et al. 2005). Cowbird nestlings usually grow faster than hosts' nestlings because they hatch earlier. Because they are larger, they also receive a disproportionate amount of the food that the adults provide. Host nestlings tend to beg for food only when an adult approaches the nest. Cowbird nestlings are much louder than host nestlings and beg continuously, ensuring that they get most of the food.

Females establish home ranges immediately upon arrival and pair formation occurs shortly thereafter (Darley 1983; Lowther 2020c; Teather and Robertson 1985). Eggs have been reported in Ontario nests from mid-April until the first week of August, with most present from the middle of the last week of May until slightly after mid-June (Peck and James 1987). At London, egg laying extended from the beginning of May until mid-July (Darley 1982). Also at London, the onset of laying was 3 or 4 May but was not until 13 May in the coldest year. The average laying rate was 0.73 egg per day. Fifty percent of birds were still laying in the last week of June. Scott and Ankney (1980) concluded that the average laying period was 4 May until 28 June, a total of 56 days. In Algonquin Park, eggs were present from early June to mid-July, nestlings were present mid-June to late July, and dependent fledglings were recorded from late June to late August (Tozer 2012). Other studies found that the egg-laying period lasts for 11-12 weeks. The initiation date may vary depending upon weather conditions but the end of the laying season is fairly constant. Egg-laying rates of 0.77-0.79

egg per day have been reported elsewhere (Fleischer et al. 1987; Igl and Johnson 2007; Norris 1947; Rivers et al. 2010). Incubation periods of 9-14 days have been reported in Ontario, and these varied by host species: 9-12 days in Eastern Phoebe nests, 9-10 days in Red-winged Blackbird nests, 14 days in a Northern Cardinal nest, 12 days in an Indigo Bunting nest, at least 10 days in a Purple Finch nest, and 9 days in an American Goldfinch nest. The incubation period was considered to be the time between the laying of the last host egg until the cowbird egg hatched. Incubation periods of less than 10 days probably indicated that the host began incubation before the clutch was complete (Peck and James 1987). In British Columbia, the incubation period was 10-13 days (Campbell et al. 2001). In Ohio, Nice (1939b) reported incubation periods of 11-14 days. In Pennsylvania, the average nestling period was 8.7 days (range 8-10 days). Friedmann (1929) stated that the incubation period was usually 10 days but that it could be as long as 12 days. Young may leave the nest at age 9 days if disturbed. Woodward (1983) reported nestling periods of 8-13 days (mean 10.9 days); 10-11 days was typical.

The cowbird is capable of laying approximately 40 eggs during a breeding season. In London, females laid an average of 40 eggs per season. An average of 4.0-4.6 eggs was laid on consecutive days, usually separated by 2 days without laying or occasionally only a single day. Twenty-eight percent of birds laid only 1 or 2 eggs before a day of not laying. The number of consecutive eggs has been termed a clutch by many authors. In late May and early June, the London clutch size averaged 4.5 eggs but declined to 3.5 eggs in late June and early July (Scott and Ankney 1980, 1983). In Illinois, laying patterns varied. One female laid an egg every day for 32 days and a total of 40 eggs in 48 days. Laying patterns were not significantly different from random and gave no indication that eggs were laid in clutches or sets. One female never laid on consecutive days and 18 had laying runs of 5 consecutive eggs with a mean of 9.0 days of uninterrupted laying. Many nonlaying runs lasted only a single day but some were as long as 17 days. These females were all yearlings that were capable of producing 30 eggs per year. These studies were done on wild birds confined in aviaries. Birds in pens may potentially lay more eggs than wild birds because they are fed ad libitum and do not expend energy by flying long distances (Jackson and Roby 1992). Chace et al. (2005) reported that females commuting 12 km between breeding and feeding areas laid 50% fewer eggs in a 5-day period than those commuting 2 km. In California, Fleischer et al. (1987) estimated that females laid an average of 30.5 eggs per season. Yearlings laid only 70.7% of the number of eggs as adults did, probably because they begin laying later in the season. Yearling laying rates were significantly lower than those of adults in May but similar later. In California, Oklahoma, and Michigan, Payne (1965, 1973, 1976) reported the same patterns as in London, with females laying a series of eggs on consecutive days with intervals of a few days to a few weeks between laying periods. The number of consecutive eggs averaged 3.1-3.8 (range 1-6 eggs), and the number of consecutive eggs laid was significantly higher at the start of the breeding season. Each female laid about 30 eggs, 200% of her body weight. The breaks between days of consecutive laying may be a result of the female not have enough stored protein or fat to produce an egg. In Michigan, a female laid 25 eggs in host nests over a period of 66 days (Walkinshaw 1949). Norris (1947) concluded that females laid at least 14 eggs per season in Pennsylvania. These 2 studies may have underestimated the actual number of eggs laid. The researchers may not have found all nests that the female parasitized. Eggs lost due to being dumped outside a nest, ejection by the host, or predation may not have been accounted

for. In New York, Hahn et al. (1999) calculated the effective fecundity of the cowbird to be 8.16 eggs per female per season. The effective fecundity included only those eggs that were laid in appropriate host nests and were not subsequently rejected by hosts. When a female does not find an appropriate host nest, she may dump an egg in an inappropriate host's nest or elsewhere, reabsorb the egg in the oviduct, or eat it after laying it to regain the nutrients. Although the cowbird lays a large number of eggs within a breeding season, only about 20% of them have an opportunity to develop into nestlings.

The cowbird greatly prefers to lay a single egg in each host nest and avoids laying more unless host nests are limited and it has no alternative. If more than 1 egg is laid in a host's nest, the cowbird nestlings have to compete with each other for food. Many smaller hosts are incapable of raising more than a single cowbird (Darley 1983; Goguen et al. 2011). In New York, only 1 of 92 nests (1.1%) was multiply parasitized by the same female. Approximately a third of nests were multiply parasitized and 73.3% were where home ranges overlapped. Home ranges, especially where they are defended, are important in reducing the incidence of multiple parasitism. Much multiple parasitism may be due to opportunistic laying by yearling females who may not be mature enough to hold a home range (Hahn et al. 1999). In Pennsylvania, 61.6% of parasitized nests contained a single cowbird egg and most (but not all) multiply parasitized nests were parasitized by more than 1 female. In Kansas, all nests were multiply parasitized, probably due to the high densities of cowbirds and broadly overlapping home ranges. About 40% of nestlings were full siblings, indicating that a single cowbird had laid multiple eggs in the nest; 19.6% of nests were parasitized by 3 or more females (Rivers et al. 2010, 2012). Friedmann (1929) reviewed approximately 9,000 records of parasitized nests of 195 host species and found that 66% contained a single cowbird egg. Ontario parasitized nests (n = 2,504) contained 1-7 cowbird eggs, with single records of 10 and 12 eggs. Of these, 65.3% contained a single cowbird egg and an additional 24.6% contained 2 eggs (Peck and James 1987). In British Columbia, parasitized nests contained 1-8 cowbird eggs, with 69% containing a single egg (Campbell et al. 2001).

Both sexes are capable of breeding when they are 1 year old. Payne (1973) concluded that it was unlikely that yearling males bred, or at least not in proportion to their numbers in the population. Yearling males have significantly smaller testes than adults but some are large enough to allow breeding. At London, there was no significant difference in the ability of yearlings and adults to procure mates and a similar proportion of each age class became paired. To acquire a mate, a male has to defend only the female and not an entire territory. The sex ratio of this population was 1.5 males to 1 female, so competition for mates was intense. Since yearlings succeed despite this extra competition suggests that male experience is not a critical factor in attracting a mate (Darley 1978). The Brown-headed Cowbird appears to be the only species in which adult males dominate yearlings at food resources but not at mate acquisition (Weatherhead and Teather 1987). In New York, 41.6% of paired males were yearlings, similar to their proportion in the population (Dufty 1982). Near London, yearling males were more likely to be paired or in groups of males; adult males were much more likely to be single. Because of the highly skewed sex ratio, many males were unsuccessful in acquiring a mate (Ankney and Scott 1982). At London, 113 of 154 males (73.4%) were unmated. Previous experience and age were not factors in whether a male became mated. Of 10 returning males that were mated the previous year, only 5 (50%) acquired a mate in the current year

(Darley 1982). It is typically assumed that all females breed, but this was not the case at London. Of 102 females, 44 (43.1%) were breeding residents, 2 (2.0%) were nonbreeding residents, and 56 (54.9%) were nonresidents. The 2 nonbreeding residents were yearlings (Darley 1983). In California, some males did not breed. Their behaviour differed from those of mated males. They did not have a consistent morning range, were equally likely to occur in feeding as breeding areas in the morning, were silent and sedentary on the breeding range, and used a communal roost rather than roosting individually similar to mated birds (Rothstein et al. 1984).

The mating system of the Brown-headed Cowbird has been described as monogamous, polygynous, polyandrous, and promiscuous. Most early studies concluded that the differing conclusions were because some researchers studied only associations of males and females; others based their conclusions on observed copulations. It is now recognized that the cowbird uses all these mating strategies. Although mating strategies often vary geographically, they are mostly determined by the density of cowbirds. Even within a given area, individuals may use differing mating strategies. In London, monogamy prevailed. Most females copulated with a single male and the pair remained mated for the entire season. Darley (1982) temporarily removed some females. Some replacement males were mated neighbours, resulting in them becoming bigamists. Bigamy occurred despite the presence of unmated males indicating that females preferred to mate with dominant males. Near Kingston, Teather and Robertson (1986) reported 4 cases of monogamy and 3 of polygynous matings, including 1 male that was trigynous. There were also 2 possible cases of polyandry, but data were insufficient to confirm this. Some males exhibited simultaneous polygyny, being associated with more than 1 female at the same time. They usually alternated days with their mates, spending 1 day with one and the next day with the other. When a male was removed, the number of times his female was courted by other males increased significantly, suggesting that mate guarding was effective. Forty-five percent of males were unmated. Observed copulations suggested that there were opportunities for them to obtain extra-pair copulations. Both the spatial distribution of host nests and the sex ratio of the cowbird population may influence the mating system. If host nest density is high, females may defend their home ranges. Mate guarding would result in monogamy in this scenario. If the distribution of host nests is such that it is not advantageous for the female to defend the home range, the effectiveness of mate guarding declines and promiscuity results. Pair bonds may also break down as the sex ratio approaches unity, thus reducing the advantage to males of mate guarding. In Tennessee, Laskey (1950b) concluded that the cowbirds around her house were monogamously mated. Females displayed against males other than their mates who attempted to court them. In the London area, the mating system was a combination of monogamy and promiscuity. Males use 2 tactics to obtain copulations. The first is to obtain a mate and vigorously defend her from other males, resulting in a monogamous relationship. The second tactic is to not attempt to mate but to steal copulations from mated females (Ankney and Scott 1982). Friedmann (1929) concluded that most birds near Ithaca, New York, were monogamous. Dufty (1982) also concluded that the population he studied in New York was predominantly monogamous. In Kansas, the mating system was promiscuous. Males regularly courted and chased several females daily and females were observed copulating with different males. In this area, cowbirds were abundant but hosts were less abundant, so females did not defend their home ranges. Long-term pair bonds appeared to be nonexistent (Elliott 1980). In

California, the mating system was monogamous. Males attempted to be bigamous but few (5%) were successful. Mated females refused advances from males other than their mate; 0 of 73 observed copulations were extra-pair. Monogamy appears to be the dominant mating system where cowbird densities are low and where females establish well-defined home ranges (Yokel 1986, 1989; Yokel and Rothstein 1991). At another California site, there was little monogamy in the population (Rothstein et al. 1984). In Illinois, Strausberger and Ashley (2003) used DNA analysis of eggs and nestlings to determine mating strategies. Results indicated frequent repeat matings among pairs (monogamy) and frequent polygyny. Both sexes sometimes reproduced with multiple partners (promiscuity) and 5 females mated polyandrously with 2-3 males. Polygynous males typically mated with females that parasitized nests in the zone of overlap of home ranges. The mating system did not fall neatly into any of the 4 mating system categories and exhibited varying degrees of each category. The cowbird reproduced most frequently with a primary partner and less often with additional individuals. The incidence of monogamy may decline as cowbird density increases and extensive overlap of home ranges may contribute to the frequency of promiscuous behaviour. Most pair bonds persisted throughout the breeding season in Iowa and New York (Dufty 1982; Lowther 1987). In New York, both members of some pairs returned the following year. Some reunited and occupied much the same home ranges as in the previous year. One female settled with a new mate in an area adjacent to her former mate, who also had a new mate (Dufty 1982).

Feeding home ranges differ from breeding areas by having areas of short grass or other low vegetation. Breeding areas are rarely used for foraging, but the cowbird may feed opportunistically on cicadas or on oak flowers (Curson et al. 2000; Schweitzer et al. 1998). Nonbreeding birds may forage within breeding areas (Rothstein et al. 1984). Feeding rarely occurs during the first 5 hours after sunrise. This may cause stress to birds, particularly females due to the energetic costs of reproduction. Females spend more time at feeding areas and less time travelling between feeding and breeding areas than males. Only females exhibit a peak in feeding just before dark (Rothstein et al. 1984). Almost all feeding occurs on the ground, usually by hopping, pecking, or scratching, and it preferentially forages with cattle, horses, or other large ungulates. When foraging with cattle, it groups around foraging and moving cattle rather than those that are stationary. They remain within 1 m of the cow, behind its feet and mouth, and dart after insects flushed by the cow's feet. It eats seeds exposed in grazed vegetation, in bare soil, and in dried lakebeds. At horse corrals, it commonly hawks slow-flying insects and pecks insects from livestock manure. It eats dandelion seeds from seed heads by pinning the stem to the ground with 1 foot. It follows tractors working up the land in flocks mixed with Red-winged and Brewer's blackbirds. These flocks feed in a rolling-block formation, with birds at the back of the flock continuously flying to the front just behind the tractor. Early in spring, it may feed on leaf buds (Beasley and Carothers 1974; Bent 1958; Fitch 1958; Friedmann 1929; Gates and Evans 1998; Goguen and Mathews 1999; Goguen et al. 2005; Laskey 1950b; Lowther 2020c; Morris and Thompson 1998; Rothstein et al. 1980; Schweitzer et al. 1998). Weatherhead and Teather (1987) provided food for cowbirds and determined that adult males were dominant to yearling males in 81.8% of cases. Bent (1958) reported a female cowbird feeding young in a Rose-breasted Grosbeak nest. It fed only the cowbird nestling and pecked the young grosbeaks on their heads when they begged. There is a record of a female cowbird feeding a cowbird nestling in a Yellow Warbler nest. In both cases, it was unknown if the female cowbird was the parent.

Nestlings are fed the same food that hosts provide to their own nestlings. This entails little adaptation by cowbird nestlings. Although adults of the host species may eat a wide variety of food items, most feed their young an insectivorous diet. Those that feed their young seeds, such as the finches, are poor hosts because the diet they provide is deficient in the protein that young cowbirds require. The diet of 14 nestlings included march flies, caterpillars, spiders and their eggs and cocoons, foxtail seeds, short-horned grasshoppers, weevils, burrowing mayflies, dock seeds, snail shells, stink bugs, click beetles, leaf beetles, ground beetles, hymenopterans, smartweed seeds, wolf spiders, grubs, buds, cicadas, dragonflies, moths, treehoppers, ants, dodder seeds, and sedge seeds. Most stomachs contained 99-100% animal matter but one was half full of vegetation fibres. Cowbird nestlings have been observed being fed cutworms, small insects, caterpillars, and small moths by Red-eyed Vireos and Chipping Sparrows; neuropterans, cutworms, caterpillars, mayflies, wasps, and moths by Chestnut-sided Warblers; and earthworms by American Robins. One Common Yellowthroat fed a small garter snake to a young cowbird. Many species feed it eggshells (Friedmann 1929).

Early in spring, the adult diet is predominantly vegetarian through the prelaying period, becomes insectivorous during laying, and switches back to mostly plant foods postlaying. Animal food comprises 10-15% of the spring diet, mostly weevils and caterpillars. The plant food is mostly foxtail seeds but the cowbird also eats seeds of barnyard grass and ragweed. During laying, the consumption of insects is much more pronounced in females. Both sexes eat snail shells at this time, especially females during the laying period. By mid-July or earlier, the diet once again becomes mostly vegetarian (Friedmann 1929; Payne 1965; Scott and Ankney 1980). Overall, the diet consists mostly of weed seeds: 94% by volume in winter and 48% in summer. Foxtail seeds are favoured in most areas and ragweed seeds are important in some regions. Other seeds it commonly consumes include those of oats, corn, crabgrass, wheat, smartweeds, panic grasses, croton, timothy, and barnyard grass. Less frequently, it consumes smooth sumac, blackberries, blueberries, mulberries, thistle seeds, amaranths, chickweeds, mustard seeds, blackberries, huckleberries, wild cherries, and wild grapes. Grasshoppers and locusts are favoured insect foods and these are the species most frequently flushed by foraging ungulates. It commonly eats beetles and lesser numbers of caterpillars, spiders, and millipedes are eaten. Other animal foods include house fly pupae, ants, plant bugs, scarab beetles, harvestmen, thread-waisted wasps, true bugs, weevils, long-horned grasshoppers, and leafhoppers. In Ohio, the diet consisted of 28.0% wheat, 26.7% corn, 10.6% flatsedges, 6.6% bulrushes, 6.3% smartweeds, and 3.4% animal matter, including dragonflies, beetles, and flies (Bent 1958; Friedmann 1929; Lowther 2020c). In Quebec by volume, the diet 10-19 May consisted of 40.7% vegetable matter, 31.8% animal matter, and 27.5% unidentified material. The vegetation consisted of 34.4% barley, 3.4% corn, 2.2% prostrate knotweed, 0.7% timothy, and less than 0.1% curly dock. The animal food consisted entirely of beetles: 15.8% scarab beetles, 6.4% weevils, and 3.2% each for bark, ground, and click beetles. The diet 14-29 July was comprised of 44.5% vegetable matter, 38.0% animal matter, and 17.5% unidentified material. The vegetation consisted of 23.4% barley, 5.8% prostrate knotweed, 5.5% curly dock, 3.9% corn, and 3.9% foxtails. The animal matter consisted of 9.5% spiders, 4.8% ants, 4.8% millipedes, and 18.9% beetles (9.5% scarab beetles, 4.7% click beetles, and 4.7% weevils). The diet 12 August to 16 September was comprised of 64.1% vegetable matter, 7.5% animal matter, and 28.4% unidentified material. The

plant food consisted of 27.0% barley, 10.9% prostrate knotweed, 9.7% corn, 5.3% panic grass, 4.5% foxtails, 3.7% timothy, and 3.0% curly dock. The animal food consisted of 1.9% crickets, 1.9% scarab beetles, 1.9% rove beetles, and 1.8% true bugs (Potvin et al. 1976). Beal (1900) examined the contents of 544 stomachs. The birds had consumed 22.3% animal matter and 77.7% vegetable matter. The animal food was almost entirely insects and spiders with a few snails. Insects included wasps and ants, bugs, a few flies, beetles, grasshoppers, caterpillars, and bugs. The bugs were mostly stink bugs and leafhoppers but it consumed a few cicadas. It ate many leafhoppers, especially in June and July when they constituted 60% of the contents of some stomachs, but they represented only 1.5% of the annual diet. Wasps and ants constituted 3% of the annual diet and beetles represented 5.3% of the diet. These were mostly weevils that were consumed April through June. Grasshoppers were the favourite animal food, comprising about half the animal food and 11% of the annual diet; in August, they represented 45.1% of the diet. Caterpillars were eaten every month but constituted only 2% of the entire diet, peaking at 10% in May. Grain constituted 16.5% of the diet (8.6% oats, 1.4% wheat, and 6.5% corn) with about half being waste grain. Fruit was insignificant in the diet with only a few raspberry and blueberry seeds in stomachs; they may have been eaten as seeds rather than fruits. Weed seeds were the most important component of the diet and were consumed year-round. It ate weed seeds almost exclusively in winter and they comprised 60% of the total annual diet. The most abundantly eaten seeds in decreasing order were barnyard grass, ragweed, panic grass (with these 3 dominating the diet), smartweeds, sorrel, paspalum, and amaranths, with small amounts of thistles, black mustard, chickweed, plantains, sunflowers, gromwells, and blue-eyed grass.

Habitat loss is a significant limiting factor for the Brown-headed Cowbird, although limited mention has been made of this in the literature. The eastern population has declined in the United States due to an increase in forest cover and planting grasslands to trees. Natural forest regeneration reduces habitat and has made more areas unsuitable for it in the Canadian Shield of Ontario (Chace et al. 2005; Houle and Choiniere in Gauthier and Aubry 1996; Tozer 2012). Loss of grasslands and pastures are more significant than an increase in forest cover, particularly south of the Shield in Ontario and Quebec. A high proportion of these have been converted to row crops which provide no breeding habitat and foraging habitat that is inferior to grasslands. Pastures that support livestock are optimum for foraging, but the number of cattle in the province has declined significantly and continues to decline (Statistics Canada 2018). In addition, cattle are now often confined to barns or other enclosures where their feeding activities do not stir up insects for cowbirds to prey upon. Its decline in Quebec between their 2 atlases was attributed in part to new farming practices and habitat loss. In the St. Lawrence Lowlands approximately 75% of perennial crops were replaced by annual crops from 1993 to 2004, accompanied by livestock confinement (Houle and Choiniere in Gauthier and Aubry 1996; McCracken 2003b; Michaud in Robert et al. 2019). In Illinois, the decline in area of pastures in the first half of the 20th century was considered an important loss of both breeding and feeding habitat (Graber and Graber 1963). Another form of habitat loss is the decline in populations of several host species. As the number of potential hosts declines, there are fewer nests to parasitize and fewer cowbirds will be raised. A scarcity of host nests can lead to multiply parasitized nests, further lessening the likelihood of cowbirds fledging (Friedmann 1929). Grassland birds are generally in decline and these are the cowbird's traditional hosts.

Another significant limiting factor for the Brown-headed Cowbird is its low nesting success. It rarely lays eggs in nests of completely inappropriate hosts in which the egg has no chance of survival (Sealy 2015), but egg dumping outside a nest may be common. It frequently lays eggs in nests of species that eject eggs and these eggs have limited potential for success. These include the kingbirds, meadowlarks, orioles, American Robin, Gray Catbird, Brown Thrasher, and Cedar Waxwing. At London, 43.8% of catbird nests were parasitized but these produced few cowbirds. There is evidence that some of the larger species that were formerly acceptor species are beginning to eject eggs at a higher rate and are evolving into rejecter species, particularly the meadowlarks and Baltimore Oriole. Laying eggs in nests of rejecters is a significant source of mortality for the cowbird (Chace et al. 2005; Friedmann et al. 1977; Grzybowski and Pease 1999; Lowther 2020c; Peer et al. 2000, 2005; Rivers et al. 2010; Scott 1977). Hosts that feed their nestlings a granivorous diet may be frequently parasitized, but cowbird eggs laid in their nests have little chance of survival. These include the House Finch, Purple Finch, Pine Siskin, and American Goldfinch. Aerial insectivores such as swallows and wood-pewees may cease feeding their nestlings for extended periods during inclement weather. These species typically raise few or no cowbirds (Campbell et al. 2001; Grzybowski and Pease 1999; Kilpatrick 2002). The nest success rate of the cowbird is much lower than that of its host species. This is because many hosts abandon parasitized nests, bury cowbird eggs, or have other defences. It has been estimated that the average survival of a cowbird egg to adulthood is only 3%. When a host deserts a parasitized nest, the cowbird egg dies but the host has an opportunity to raise a replacement brood. In Pennsylvania, 26.8% of cowbird eggs laid in a variety of host nests produced fledglings compared with 37.7% for hosts. In Michigan, 1 female laid 25 eggs and 0 produced a fledgling. Most parasitized nests were deserted and a few were depredated. Yellow Warblers tend to either bury the cowbird egg or abandon parasitized nests. Cowbird success rate has been determined to be very low in Yellow Warbler nests in Manitoba, Michigan, and Ontario, with only 5.4% of Ontario eggs producing a fledgling. Nonetheless, parasitism rates on the Yellow Warbler tend to be high. In Kansas, only 13 of 157 cowbird eggs (8.3%) were successful. This was attributed in part to the high density of cowbirds and a high rate of multiple parasitism. In Prairie Warbler nests, only 9 of 102 cowbird eggs (8.8%) hatched and only 5 produced fledglings. At London, 80% of Northern Cardinal nests were parasitized. Cowbird egg mortality was 85% in cardinal nests as a result of egg removal or nest desertion. Only 5.4% of cowbird eggs produced fledglings and this occurred only in broods with a single or no cardinal nest mates. The cardinal is another commonly parasitized species that produces few cowbirds. South of the Shield in Ontario, parasitized nests of the Red-eyed Vireo, Yellow Warbler, cardinal, Chipping Sparrow, and Song Sparrow were all abandoned significantly more than unparasitized nests (Campbell et al. 2001; Elliott 1977; Friedmann 1963; Graham 1988; McGeen 1972; Nolan 1978; Norris 1947; Peer et al. 2005; Scott and Lemon 1996; Walkinshaw 1949; Weatherhead 1989). Species that have been in long contact with the Brown-headed Cowbird have learned to recognize it as a threat and are extremely aggressive toward it. These include some of the superior hosts such as Red-winged Blackbird and Song Sparrow as well as the Eastern Kingbird, Willow Flycatcher, Eastern Phoebe, and Red-eyed Vireo. Aggression appears to be effective only where the host occurs at high densities relative to the cowbird. The Red-winged Blackbird's mobbing behaviour is the most effective at preventing or reducing the incidence of parasitism. It is one of the best hosts for the cowbird, along with the Song Sparrow, but is parasitized significantly less than its availability because of its aggressive nature

(Chace et al. 2005; Friedmann 1963; McGeen 1972; McLaren et al. 2006; Nice 1937; Peer et al. 2005; Robertson and Norman 1976, 1977). Most hosts continue to evolve behaviours to avoid or reduce parasitism and these are likely to lead to further declines in cowbird productivity unless it can evolve new strategies such as laying highly mimetic eggs. In this event, egg patterns may have to be distinct in different areas to reflect local host populations (Peer et al. 2005). Another factor that may lower cowbird productivity is the constant begging of its nestlings. This has the potential to attract predators.

Humans often directly affect cowbird nesting success by removing eggs from hosts' nests and killing adults to reduce parasitism rates. Many individuals believe that they are doing a good deed by removing a cowbird egg from a nest, but the cowbird is a native species whose population is declining significantly. No targeted cowbird control programs have been implemented in Ontario, but several occur in the United States in efforts to conserve species-at-risk songbird populations. The most common method is to trap and kill cowbirds in the local area and remove parasitic eggs from nests. This may be effective in reducing parasitism rates and improving nest success rates of the target species, but in no case has this resulted in an increase in the host population. Other techniques have been used to attempt to reduce parasitism rates. These include moving grazing cattle to extend the distance between breeding and feeding areas, controlling cowbirds on feeding ranges that serve as a network of breeding areas, and massive kills of birds at winter roosts. These other techniques have generally failed because of the prevalence of feeding areas other than grazed pastures; many birds, especially females, do not exhibit a consistent commuting pattern between breeding and feeding ranges; and birds from winter roosts disperse to disparate geographical areas so a large kill at 1 site has minimal effect on breeding populations at a given area. The only effective control method is local removal within the area of a population of an endangered species. Control methods should be considered temporary stopgap measures until the real limiting factors affecting the endangered host can be rectified. Long-term control programs have the potential to have 2 adverse effects. The first is the perception that appropriate management is being undertaken. Control programs may divert funds that would be better invested in creating habitat for the species at risk. The second is that host communities that experience long-term periods of parasitism control may not evolve their own antiparasitic behaviours that could protect them in future from parasitism (Bent 1958; Chace et al. 2005; Hahn et al. 1999; Laymon 1987; Lowther 2020c; Ortega et al. 2005; Rothstein et al. 1987).

The cowbird responds favourably to forest management. In the Boreal Forest Region, it increased by 60% when 80% of trees were removed. It was almost 100% more abundant when 0% of trees were retained compared with where 100% of trees were retained (Vanderwel et al. 2007). In Ontario south of the Shield, it was significantly more abundant in heavy diameter-limit cuts than in selective cuts and uncut forests. It was not significantly more abundant in woodlots selectively cut than in those that were not cut. It was negatively correlated with basal area (Holmes et al. 2004). In Minnesota, it increased in abundance in response to tree removal (Hanowski et al. 2003, 2005). In Pennsylvania, it was more than 2 times as abundant in forest stand improvement plots where snags were retained than where snags were removed. Areas with snag retention had a more patchy and open growth and greater abundance of low plant growth (Stribling et al. 1990). In New York, the

cowbird occurred regularly in clear-cuts in low numbers. Its density was low 2-5 years after cutting, moderate 6-10 years after cutting, and low 14-120 years after cutting (Keller et al. 2003).

The cowbird responds favourably to all types of forest fragmentation (Lowther 2020c). In West Virginia, it increased significantly closer to well pads, access roads, and pipelines and was attracted to them. Its probability of occurrence increased to 40% from almost 0% (Farwell et al. 2019). In Alberta, it was more abundant near seismic lines than in adjacent forest interior, but not significantly. It was significantly more abundant at well pads than in adjacent forest interior (Bayne et al. 2016). In New Jersey and Pennsylvania over a 15-year period, hemlock declined from 56% of the total basal area to 46% due to the hemlock woolly adelgid; the amount of deciduous understorey increased. The cowbird increased and exhibited one of the strongest positive associations with hemlock decline (Toenies et al. 2018).

Two studies concluded that fires in grasslands elicit no significant responses by the cowbird (Madden et al. 1999; Roberts et al. 2012). Rose and Simons (2016) studied its response to fire in a pine-oak forest. It occurred more frequently in burned than unburned areas, but only after high severity burns that caused almost complete removal of the understorey and more than 60% mortality of the canopy. Peak occupancy occurred 0-5 years after fire and declined thereafter.

Status

It is unlikely that the cowbird occurred in Ontario prior to European settlement. At that time, it was endemic to the short- and mixed-grass prairies of the Midwest where it was associated with bison. Widespread destruction and fragmentation of forests by Europeans created much more habitat and allowed it to expand its range eastward and, to a lesser extent, westward. It was widespread in the eastern United States by the early 1800s and reached the far west by the 1920s. It moved into Ohio and Michigan just before 1840. Other factors that contributed to its range expansion included widespread draining of swamps and marshes to create croplands, irrigation of arid lands in the southeast, and the proliferation of cattle (Chace et al. 2005; de Vos 1964; Friedmann 1929; Lowther 2020c; Rothstein and Peer 2005; Schweitzer et al. 1998).

The cowbird was first recorded in Ontario in the 1870s according to McLaren et al. (2006), but Weir (2008) reported that it was common in the Kingston area in the 1850s. It appeared to decline starting in the 1970s. In Elgin County, it was extremely common in 1891 (Lancaster et al. 2004). It occurred in the southern counties of Ontario by 1886 and first appeared in Muskoka and Parry Sound districts in 1889 (de Vos 1964; Mills 1981). de Vos (1964) reported that it was frequent at North Bay in the late 1930s and that there had been significant increases west of Lake Superior. In the 20th century prior to his publication, its range expanded northward approximately 320 km. Fleming (1907) considered it an abundant summer resident in Toronto. Friedmann (1929) considered the Ontario range of the cowbird to extend from the southern Great Lakes to the north shore of Lake Superior and Lake Huron. It was absent in the Boreal Forest Region. Baillie and Harrington (1936) reported that it occurred north to Moose Factory and west to Lake of the Woods. It had been found breeding throughout this range, but was not common in the northern parts of its range except in the extreme west. The first atlas determined that its range included all of Ontario south of the Boreal Forest Region, with occasional records within this area in the northwest, east of Lake Nipigon, and in the Clay Belt. Breeding was confirmed in the Moosonee area. It was most abundant in the

agricultural south. It associated mostly with agriculture in the north, but also occurred along highways through densely forested landscapes (Graham in Cadman et al. 1987). James (1991) considered the cowbird a common summer resident north to Kenora, Lake Nipissing, and Cochrane and rare to Pickle Lake and Moosonee.

The second atlas revealed only minor changes in the distribution of the cowbird since the first atlas. It was not recorded in many of the blocks in the Boreal Forest Region where it was previously documented. It continued to breed in the Moosonee area. Its probability of observation declined significantly province-wide and in all regions except the Carolinian Forest Region. The declines were attributed to agricultural intensification, loss of pastureland, disappearance of small dairy farms in the south, and increased forest cover in the north. Highest densities occurred in the intensively farmed areas of southwestern Ontario. The entire area south and east of the Canadian Shield supported moderate to high densities. Low densities were reported in the Shield portion of the Great Lakes–St. Lawrence Forest Region and around the northern shore of Lake Superior (Falk in Cadman et al. 2007).

BBS data indicate that the Brown-headed Cowbird has been decreasing at a significant rate continent-wide and in Canada since the survey was initiated in 1966. Declines are most pronounced in eastern Canada and the eastern United States, but it is still increasing in the far west where it is a more recent arrival (Chace et al. 2005). McCracken (2003b) stated that it had been declining at a rate of 2.3% per year since the BBS started. This resulted in a continent-wide cumulative loss of 33% of its population. Losses were higher in Canada at 57%. Cadman et al. (2016) reported that it declined in Ontario at a rate of 3.7% per year from 1983 to 2013. It was tied for 15th for the greatest decline rate of all Ontario breeding birds. BBS data indicate that it decreased at annual rates of 0.958% in Canada and 4.16% in Ontario 1970-2021. Trends 2011-21 were annual decreases of 0.58% in Canada and 4.17% in Ontario. All results were highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

There are 5 stages of fledgling development: leaving the nest, inactive, active, superactive, and independence. At fledging, young are capable of very weak flight and tend to move 3 m or less from the nest. Height above the ground after fledging was 0-5 m in Virginia and Maryland (average 2 m). Nine fledglings perched in a tree or shrub and one remained on the ground. Shortly after fledging, they tend to move higher in the vegetation, usually by short flights or climbing through trees. The inactive period lasts for the first 2-3 days out of the nest. They perch quietly during this stage except when the foster parents arrive with food or they have not been fed in a while. They occasionally fly short distances, usually less than twice an hour. Most mortality of fledglings occurs in the inactive stage. The active stage occurs 3-13 days out of the nest and is characterized by 2-9 flights an hour, increasing with age. Flights are usually independent of the hosts' activities but they occasionally fly toward an adult to be fed. Fledglings start pecking 1-6 days out of the nest and first feed themselves at age 20-22 days. As they mature, they spend more time on the ground, 5-13 days after fledging at age 14-23 days. The superactive stage begins 12-23 days out of the nest at age 21-32 days and 3-11 days before independence. This stage is characterized by constantly flying after their hosts and actively begging. They forage for themselves when the hosts are absent, but stop feeding and beg when they return. They become independent 16-28 days after leaving the nest at age 25-39 days

(mean 31.5 days). The final step in achieving independence occurs when the host stops feeding. Fledglings do not become imprinted on their hosts. They appear to recognize them as a species but not as individuals. They are occasionally fed by host-conspecific birds that had not raised them. Birds of other species are usually ignored but they regularly beg from their host. Occasionally they beg from other species and may even be fed by them. Fledglings raised by different host species behaved in the same manners except for their perch heights. They typically perched near the heights where hosts obtained their food and this varied by species: 0-3 m for Carolina Wren, Song Sparrow, and Eastern Bluebird; 6.1-9 m for White-eyed Vireo, 9.1-12 m for Eastern Phoebe, and 12.1-15 m for Acadian Flycatcher and Blue-gray Gnatcatcher. The difference in height preferences often occurred in the same habitat patches, so the variability was due to host preferences. Home ranges of fledglings were 0.3-5.6 ha and highly correlated with the hosts' home range size. Only perch height and home range size were modified in a host-specific manner. Their primary adaptation was their loud and persistent begging resulting in them being fed more than the hosts' fledglings (Friedmann 1929, 1963; Woodward 1983; Woodward and Woodward 1979b).

Fledglings develop the typical cowbird foraging behaviour regardless of which host species raise them. This increases their chances of survival during the period that they depend upon the host. By the time they are 20-25 days old, they have developed all behaviours required to maintain them. The feeding rate for fledglings varied from host to host but was always significantly greater than for the hosts' young. They are fed different foods depending upon the host. Phoebes fed larger items such as dragonflies, adult and larval lepidopterans, flies, crickets, plant bugs, and mulberries. Carolina Wrens fed smaller items that were mainly isopods and harvestmen with some adult lepidopterans and caterpillars. The Eastern Bluebird provided caterpillars, moths, grasshoppers, flies, and blueberries. Common Yellowthroats provided grasshoppers and caterpillars. The Acadian Flycatcher, Blue-gray Gnatcatcher, and Song Sparrow provided food items that were too small to identify. When 2 fledglings leave the same nest, they separate until late in the fledging period but are aware of the other being fed (Woodward 1983).

There is some evidence that adults may associate with their own young and possibly feed them on occasion. In New York, Hahn and Fleischer (1995) used DNA analysis to determine that 4 of 11 pairs of adult females and juveniles trapped together were related; 0 of 18 randomly paired trapped birds were related. This suggested that the female may follow the progress of her eggs and associate with her offspring once they become independent, or nestlings could become visually and vocally familiar with the female if she is frequently in the area. Lorenzana and Sealy (1998) reported 5 cases of both adult males and females feeding cowbird nestlings and fledglings. In Saskatchewan, 2 independent fledglings were observed soliciting food from a pair of adults. Bent (1958) reported a cowbird feeding an individual cowbird fledgling but ignoring others. In Hamilton, 2 males used vocalizations to wean a fledgling away from its Northern Cardinal host (Curry 2006).

Once they become independent, juveniles form large flocks that do not contain any adults. These flocks wander widely in open habitats. Flocks may form as early as the end of July and are most prevalent toward the end of August (Campbell et al. 2001; Friedmann 1929). Once the egg-laying period is over, adults vacate the breeding areas. They may completely disappear from a site around mid-July and not be observed again until autumn migration in September or October. In

some areas, adults disappear by the end of June, with females leaving later than males. The reason for the disappearance of the adults is uncertain, but may be related to the moult which starts in late July or early August and extends to mid-September. It has been stated that adults spend the moult in marshes but no study has been done on this (Campbell et al. 2001; Friedmann 1929; Norris 1947; Payne 1973; Rothstein et al. 1980).

During the postfledging period, cowbirds leave the treed and shrubby habitats where most breeding occurs and concentrate in feeding areas. These often are in different locations than the breeding season feeding areas. Birds wander considerably at this time and their habitat preferences may change. In the Hamilton area, flocks initially concentrate around grazing cattle and move to harvested cornfields later in the season. The early part of the postfledging period may be when it concentrates most around livestock, but the switch to agricultural lands prior to migration is typical throughout its range. Historically, it inhabited patches of wild rice at edges of marshes in Ontario. It may occur in a variety of habitats in both urban and rural areas. In British Columbia, it heavily uses farmlands, especially pastures and feedlots with horses and cattle as well as agricultural crops. It also occurs in nurseries, urban parks, backyard feeders and gardens, utility rights-of-way, clear-cuts, garbage dumps, marshes, reservoirs, ponds, and estuaries. Similar habitats are used in Ontario and other locations. It usually occurs in flocks, with flocks as large as 10,000 reported elsewhere. Once it moves to agricultural croplands, it may occur in mixed flocks with other blackbird species (Campbell et al. 2001; Curry 2006; Friedmann 1929; McIlwraith 1894; Porneluzi et al. 2014).

Roosts are an important habitat component during the postfledging period. Cowbirds roost communally and often with other species such as the Purple Martin, American Robin, European Starling, House Sparrow, Red-winged Blackbird, and Common Grackle. In mixed roosts, the dominant species are usually starlings, Red-winged Blackbirds, and grackles, with cowbirds representing a small proportion of roost mates (Friedmann 1929; Joyner et al. 1980; Lyon and Caccamise 1981; Weatherhead et al. 1980). In New York, 20 roosts were in hardwood stands and 2 were in common reed. The cowbird avoided contiguous forests avoided as roost sites and selected smaller wooded patches. Roost sites were 0.13-10.4 ha, with larger areas supporting more birds. Tree density was typically high at roosts (average 1,741 trees per ha). No sites with fewer than 720 trees per ha were used. The most consistent characteristics of roost sites were related to canopy structure. The canopy at roosts was closed with a compact vertical arrangement of twigs of uniform size. These features were typical of young stands in early successional stages. The mean age of stands supporting roosts was 25 years (range 18-34 years); 68% of roosts were in stands 21-26 years old. The mean age of stands supporting roosts was significantly less than stands without roosts (41 years). These roosts were dominated by starlings and grackles, so their habitat preferences may have affected roost-site selection by the cowbird (Lyon and Caccamise 1981). In late August and September, it often selects marshes for roosting along with other blackbird species (Friedmann 1929; Joyner et al. 1980; Sheppard et al. 1936).

The diet of the cowbird changes during the postfledging period. Early in the period, it continues to feed on animal foods, particularly beetles, caterpillars, grasshoppers, and leafhoppers and later switches to vegetable matter. In Oklahoma, the percent occurrence of food items in 35 stomachs was 71% sorghum, 63% ragweeds, 63% insects, 49% sunflowers, 49% Johnson grass, 46% foxtails,

26% lamb's-quarters, 20% croton, 14% amaranths, 14% sand dropseed, 14% paspalum, 6% panic grasses, 3% bush-clovers, 3% bluestems, 3% wheat, and 3% miscellaneous and unidentified matter (Goddard 1969).

Unlike some blackbird species, the cowbird inflicts minimal damage on agricultural crops. Bernhardt et al. (1987) determined that it was least likely to attack ripening corn compared with the Red-winged Blackbird, Common Grackle, and European Starling. It was ineffective at opening husks, could open only a small area in the ear, and ate only the kernels within this area. It often fell off corn ears attempting to open the husk. It damaged 19% of ears with a mean of 1.8% damage to each ear, the least of all species. It may do some damage to ripening corn, but probably only after the ears have been opened by another species. In Oklahoma, it did not do significant damage to sorghum crops unless the harvest was delayed by late autumn rains (Goddard 1969). In Louisiana, it did not cause measurable damage to rice crops (Brugger 1988).

MIGRATION

The Brown-headed Cowbird is a diurnal migrant that travels early in the morning and late in the afternoon. During the remainder of the day, it wanders considerably, often in large mixed flocks with the Red-winged Blackbird and Common Grackle, and also Brewer's and Rusty blackbirds where their ranges overlap. Cowbirds typically comprise only 1-3% of the birds in these flocks (Friedmann 1929; Lowther 2020c). Birds banded in Ontario were recovered December through February in Ontario (17%), states just south of the Great Lakes (31%), the Gulf Coast states (32%), and states in between. Only a few were found in New England coastal states. One Ontario bird was recovered at sea south of Nova Scotia 1,461 km away. Others wintered in Texas, Florida, and Arizona as far as 2,169 km from the banding location. There was no differential migration between sex and age classes (Brewer et al. 2018). Movements from Ontario were southwestward to the northern tip of Lake Michigan and the southern portion of that lake, through Essex County, and through the Kingston area at the eastern end of Lake Ontario (Burtt and Glitz 1977). Birds from the Great Lakes area averaged 1,225 km away in January and 1,137 km in February. There were no significant differences in migration distances for the sexes (Dolbeer 1982).

During spring migration, adult males arrive first followed by adult females then yearlings. In New York, Friedmann (1929) broke migration into 6 phases: arrivals of vagrants, migrant males, resident males, migrant females, resident females, and yearling males and females. Vagrants arrived before true migration began. These were likely birds that wintered not far away and their movements may have been wandering rather than migration. They were mostly single males but some females occurred. No vagrants arrived in some years. Migrant males arrived about 1 week after vagrants and continued to move northward. They occurred as scattered individuals within flocks of Red-winged Blackbirds. The interval between the arrival of migrant and resident males was about 3 days. Residents immediately established themselves at their singing posts in their home ranges. Female migrants simply passed through and arrived simultaneously with the resident males. They initially arrived as individuals within flocks of other blackbirds but later formed their own flocks; males paid little attention to these females. Resident females arrived within another week and these were courted by the males. Yearlings may not arrive until a month later. By this time, some adults that initiated nesting early had already completed breeding. In Pennsylvania, males arrived about 9 days

before females (Norris 1947). The interval between arrival of the sexes was 10 days in Tennessee (Laskey 1950b).

Cowbirds returned to London at the end of March or in the first week of April. Adults of both sexes arrived first, followed 2 weeks later by yearling males. Yearling females arrived another week later. Sixty percent of adults were present by the time the first yearlings arrived (Darley 1982, 1983). In Elgin County, the first arrivals are males who appear in late February or early March. Numbers increase through March and it is common and widespread by April (Lancaster et al. 2004). At Long Point, the mean capture date was 25.1 April for adult males, 28.5 April for yearling males, and 2.6 May for males of undetermined age (Stewart et al. 2002). In southern Ontario, it regularly arrives in mid-March with earliest arrivals in late February and peak numbers occurring in late April and early May (Curry 2006; LaForest 1993; Weir 2008). In the St. Lawrence River valley in southeastern Ontario and southwestern Quebec, some birds are present by 31 March, but most arrive in the first half of April (Weatherhead et al. 1980). In the southern Shield, it arrives in late March or early April (Mills 1981; Tozer 2012).

At Delta Marsh in Manitoba over a 63-year period, it exhibited no significant change in arrival times in response to warmer temperatures (Murphy-Klassen et al. 2005).

In Algonquin Park, most leave by late August with a few recorded in September and October and single birds occur at feeders in early November and December (Tozer 2012). In early autumn in the St. Lawrence River valley, most birds present are those that have bred locally. More than 20% leave by the end of September (Weatherhead et al. 1980). In the Kingston area, autumn migration is obvious during late September and October; birds may tarry until late November (LaForest 1993; Weir 2008).

Different habitat is used by the Brown-headed Cowbird during spring and autumn migration. Migrants occur in typical breeding habitat in spring mornings and in feeding areas in the afternoon. At night, migrants roost communally in marshes with other blackbird species. Resident birds that intend to breed in the area roost solitarily in their home ranges (Friedmann 1929). Early migrants often visit bird feeders. During spring migration in Minnesota and Wisconsin, it was equally abundant in mature upland and floodplain forests (Kirsch et al. 2013). During spring migration in Pennsylvania, it was significantly more abundant in shrublands than in forests (Smith and Hatch 2008). During autumn, it occurs in the same habitats as in the late postfledging period. These are predominantly agricultural lands where it continues to occur within flocks of mixed species of blackbirds. Communal roosts with other blackbirds continue to be an important habitat feature during autumn migration (Friedmann 1929; Lowther 2020c).

Spring migrants that continue to move northward feed predominantly on weed seeds and also visit bird feeders. In early spring, resident males tend to eat caterpillars and other animal foods (Friedmann 1929). Many birds landed on a ship off the coast of Massachusetts during an autumn storm. Two cowbirds had killed a wren which was reduced to a partially eaten mass of feathers and entrails. This appears to be the only documentation of it killing and eating vertebrate prey, but it may have been an act of desperation (Backus 1954). Fitch (1958) observed cowbirds eating fruits of rough-leaved dogwoods during autumn migration in Kansas. In autumn, the diet consists of weed seeds and grain. In Elgin County, flocks consisting only of cowbirds or flocks with mixed blackbird

species frequently feed on waste grain in fields along the Lake Ontario shoreline (Lancaster et al. 2004).

Blackbirds cause significant damage to corn and small grain crops in the St. Lawrence River valley. The possibility of killing blackbirds at their spring and autumn roosts was considered, with roosts supporting Red-winged Blackbirds, Common Grackles, and starlings in addition to cowbirds. Based on the migration timing of the roosting species, Weatherhead et al. (1980) concluded that the cowbird would be affected by control procedures implemented in early spring and early autumn, but not in late autumn. Control when the cowbird was present would affect mostly the local breeding population.

James (1991) considered the Brown-headed Cowbird a common to locally abundant migrant. Flocks as large as 5,000-6,000 have occurred (Curry 2006).

WINTER

The Brown-headed Cowbird continues to be gregarious in winter and to associate with other blackbird species. Migrants from many disparate breeding populations merge together in unstructured flocks where the composition changes day to day. In winter, it occurs mostly in the southeast with a range extension northward along the Mississippi and Ohio rivers. The densest population is in Georgia, but there are disjunct wintering populations in California, Arizona, and New Mexico (Dunn and Tessaglia-Hymes 1999; Root 1988). Friedmann (1929) reported that the winter range extended northward to Massachusetts, New York, and Michigan. By the 1950s, its range included southern Ontario and southern Illinois, where it was absent 1907-09 (Graber and Graber 1963; Lowther 2020c). The northward range extension may have been due to the increase in cereal crops and bird feeders.

In winter, the cowbird usually inhabits bird feeders and feedlots with concentrations of cattle. In snow-free areas, it continues to visit grain stubble fields to forage on waste grain. In Ontario, most wintering birds occur near feeders, but some are found at feedlots (Bent 1958; Fitch 1958; LaForest 1993; Lancaster et al. 2004; McIlwraith 1894; Tozer 2012; Weir 2008).

Roosts continue to be important in winter. In Niagara Region, it associated and roosted with House Sparrows (Sheppard et al. 1936). Bent (1958) stated that solitary birds often roosted with House Sparrows. In Hamilton, McIlwraith (1894) reported birds roosting on beams of barns above cattle. In 1976, there was a large roost in a cedar swamp in Guelph (Curry 2006). Elsewhere, communal roosts that usually supported other species were in oak trees on university campuses, in deciduous trees at margins of pine plantations, in shrubby marshes, in cattail marshes, in a woodlot of second-growth maples, and in ornamental elms around an urban courthouse. In this roost, starlings roosted in the uppermost branches and the cowbirds roosted beneath them. Some roosts that support multiple species of blackbirds and starlings are quite large. In the southeastern states, there are at least 125 known roosts that support more than 1,000,000 birds. Cowbirds represent a small proportion of birds in these flocks. It was estimated that 2-5% of birds in 1 roost of 5,000,000 birds were cowbirds. As many as 300,000 cowbirds have been reported at a single roost (Arnold and Johnson 1983; Bent 1958; Dolbeer 1982; Dolbeer and Smith 1985; Dunn and Tessaglia-Hymes 1999; Johnson et al. 1980; Lowther 2020c).

Based upon continent-wide banding returns, there was extensive replacement of cowbirds from 1 wintering area to another in subsequent years. Birds at a given wintering area represent populations from a wide breeding area (Dolbeer 1982). Brewer et al. (2018) concluded that it exhibited little site fidelity to wintering areas. At a roost in Texas, there was limited turnover in the cowbirds present within a given year; recaptures suggested reasonable site fidelity (Arnold and Johnson 1983; Johnson et al. 1980).

In winter, the cowbird feeds mostly on seeds and other plant material but also eats small quantities of insects when they are available. The diet of 57 birds collected at an Ohio roost was dominated by corn, comprising 65.5% of the total stomach contents by weight. Grass seeds constituted 20.6% of the diet and 67% of these were foxtails. Ragweed seeds were next in abundance at 2.6%. Insect parts, amaranths, pokeweed, and miscellaneous seeds (common St. John's-wort, stitchwort, nightshade, rushes, and smartweeds) all contributed less than 1% to the diet. Significantly more corn was eaten by males than females. Females ate significantly more weed seeds. The sexes exploited slightly different food niches in winter, thereby reducing competition for food (Dolbeer and Smith 1985). Birds at a Kentucky roost consumed 74% weed seeds, including those of sorghum, smartweeds, and goosegrass, plus corn (Lowther 2020c).

The cowbird frequently visits bird feeders. It is more abundant at eastern than western feeders and at rural than suburban or urban feeders. It is most common at feeders during migration, particularly in spring in Ontario. Males are dominant to females and are frequently found at the best food resources. It prefers mixed seeds, millet, cracked corn, and probably pet food. It infrequently selects sunflowers, safflower, hulled peanuts, suet, bird puddings, water, canary seed, milo, dried fruit, and oats (Dunn and Tessaglia-Hymes 1999). A total of 40,108 cowbird feeding observations demonstrated that it preferred white proso millet and platform feeders over tube and hopper feeders (Horn et al. 2014).

Blackbirds cause significant damage to rice and other crops in the southeastern United States. Extensive efforts are undertaken to control their populations, and this is typically done at winter roosts. All birds in roosts are indiscriminately targeted, including the cowbird. From 1974 to 1992, a detergent that eliminates the waterproofing ability of feathers was sprayed on roosts followed by spraying of cold water. This resulted in the birds dying of exposure. Hundreds of millions of blackbirds were killed in this manner. In Kentucky and Tennessee, an estimated 28,000,000 were killed 1974-82. This method of control is no longer allowed. Subsequently, DRC-1339 was applied as bait on the ground or spread on rice grains. This chemical kills birds by shutting down liver and kidney functions. Millions of birds were killed by this organochlorine pesticide. The proportion of birds that are killed that are cowbirds is unknown, but may be in the order of 2-5% of the total kill. Nonetheless, the number of cowbirds killed by these control methods is substantial (Dolbeer 1982; McCracken 2003b).

Mortality may occur at winter roosts due to natural causes. Some mortality occurred annually at a Texas roost and the cowbird was the species affected most. Over a 2-year period, 9,500 cowbirds died. One mortality event was caused by a violent rainstorm. Males experienced higher rates of mortality than females, and adult males were more likely to succumb than juvenile males. The mortality appeared to be related to depletion of winter food supplies (Arnold and Johnson 1983;

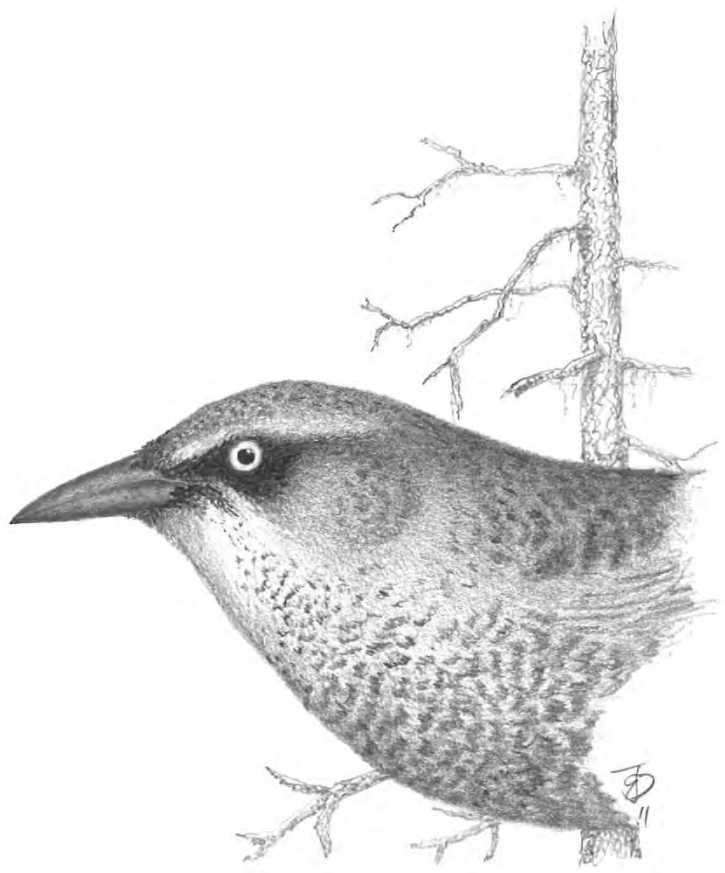
Johnson et al. 1980). At a Kentucky winter roost supporting 45,000 starlings, Red-winged Blackbirds, cowbirds, and grackles, a snowstorm resulted in 0.8% of birds dying. No dead cowbirds were found (Stewart 1978).

James (1991) considered the cowbird a rare to uncommon winter resident in the south north to Ottawa, and occasional and rare at Thunder Bay. At Hamilton, McIlwraith (1894) had only 2 records of cowbirds overwintering, both flocks of 10-12 birds. Curry (2006) reported that a few usually overwintered each year in the Hamilton area. He reported a roost of 85,000 in Guelph in January 1978, 1,500 near Cayuga on 15 January, and 120 on 20 February in Brantford. Winter flocks consisted primarily of males. Lancaster et al. (2004) considered it uncommon in Elgin County in winter and Mills (1981) considered it rare in Muskoka and Parry Sound districts.

Freedman and Riley (1980) summarized CBC results for southern Ontario for 1929-77. The cowbird increased both in abundance and frequency, especially since 1960, but it still occurred in low numbers. CBC results indicate that it decreased in Ontario at annual rates of 2.8% 1970-2021 and 0.79% 2009-21 (National Audubon Society 2022).

Rusty Blackbird

Euphagus carolinus



BREEDING SEASON

Habitat Requirements

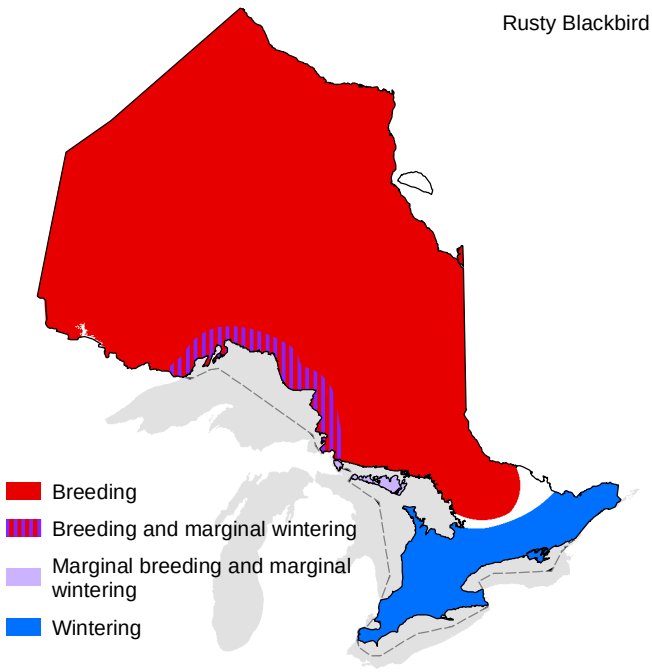
In Ontario, Rusty Blackbird nests were near forest edges or openings (52.8% of nests) and in open areas (30.6% of nests). They were almost always near water, including lakes, rivers and streams, swamps, bogs, fens, and beaver ponds. Occupied wooded areas were mostly coniferous (57.9%), with 36.8% of nests in deciduous woods and 5.3% in unspecified woods. Open areas included bogs and fens (50% of nests in open areas), lake and stream shorelines (25%), old beaver meadows (12.5%), and fields near highways (12.5%; Peck and James 1987).

Through the Hudson Bay Lowland of Ontario and Manitoba, the Rusty Blackbird was most abundant in coniferous scrub followed by mixed scrub, heath, deciduous scrub, coniferous forest with an understorey, and mixed forest. It was absent in deciduous forest, coniferous forest without an understorey, and tundra (McLaren and McLaren 1981). Along the northern Ontario coasts, it nests mostly in willow shrub thickets at edges of rivers and in wetlands (Manning 1952; Manning and

MacPherson 1952). It probably breeds at most forested areas, if there is water nearby (Wilson and McRae 1993).

In the Clay Belt, Welsh and Lougheed (1996) found it in 3 forest stands: 2 dominated by black spruce and 1 by balsam poplar–white cedar. All stands were on wet sites. The spruce stands were nutrient-poor; the other was nutrient-rich. In the Ontario portion of the Boreal Forest Region, Erskine (1977) reported it nesting in peat with low conifers.

In Algonquin Park, the Rusty Blackbird nested along swampy and marshy creeks (MacLulich 1938).



Throughout its range, the Rusty Blackbird is closely associated with water, especially wetlands. Occasionally it nests in drier habitats such as recent clear-cuts. On Cape Breton Island, it nests in drier pasture edges and plantations. In Nova Scotia it breeds in young clear-cuts in northern hardwood stands (Campbell in Stewart et al. 2015; Erskine 1992; Freedman et al. 1981; Morgan and Freedman 1986). The most common nesting habitat includes margins of wetlands, watercourses, and lakes imbedded in boreal forest and taiga. It nests mostly in dense stands of young conifers, particularly spruce and balsam fir, and in shrub thicket swamps dominated by willow and alder. It may use stands of dead conifers and deciduous shrubs for nesting. Black spruce and balsam fir near emergent vegetation, ponds, and particularly lakes, may be favoured habitat. Where conifers are scarce or form contiguous stands, it selects deciduous shrubs along watercourses, water bodies, and wetlands. Breeding occurs in swamps, bogs and fens with coniferous tree growth, alder and willow swales, beaver ponds and meadows, wetlands adjacent to mature coniferous forests and young clear-cuts, wetlands associated with recent burns, open moss- and lichen-spruce woodlands, sedge marshes, islands and floating bogs, and areas of windthrow within coniferous forests. In addition to willow and alder, it may nest in shrub thicket swamps dominated by sweet gale and buttonbush (Avery 2020; Bent 1958; Buidin in Robert et al. 2019; Campbell et al. 2001; Erskine 1977; Gillespie and Kendeigh 1982; Greenberg and Droege 1999; Imbeau et al. 1999; Jehl and Smith 1970; Kennard 1920; LaRue et al. 1994; Machtans et al. 2007; Matsuoka et al. 2010b; Nadeau in Gauthier and Aubry 1996; Powell et al. 2010a, 2010c, 2014; Savignac 2006; Sinclair et al. 2003; Whitaker and Montevecchi 1997, 1999).

Some studies examined the habitat of the Rusty Blackbird at the landscape scale. Savignac (2006) reported that its breeding range was closely associated with the Boreal Forest Region and the taiga ecozone, where it was associated with coniferous forest wetlands. The 2 Quebec atlases found that it was most common in black spruce and spruce-moss ecoregions and slightly less common in areas dominated by balsam fir and white birch. Within these ecoregions, it preferred

wetlands interspersed with small patches of forest (Buidin in Robert et al. 2019; Nadeau in Gauthier and Aubry 1996). In Alaska, it was positively correlated with the area of lakes, ponds, and emergent vegetation. Areas with nesting pairs had 10 times the mean surface area of lakes and ponds and 1.5 times the mean area of emergent vegetation than areas without nesting pairs. The number of nesting pairs increased with the area of lakes and ponds and decreased with the area of upland habitat. At another site, it decreased as the area of low shrub wetland increased. Areas with nesting pairs had 41% of the mean area of low shrub wetlands found in areas without Rusty Blackbirds. It was associated with open water, but where water was rare it nested in riparian woody wetlands. At Anchorage, it selected shrub-scrub wetlands, with lesser numbers of nests in emergent wetlands, forested swamps, and uplands. It was 7.4 times more likely to nest in forested wetlands than in uplands, which it tended to avoid. On the Tanana Flats of Alaska, it nested mostly in sedge meadows and forested wetlands, with intermediate use of tall shrub wetlands. It avoided low shrub wetlands and areas with tall canopies and selected areas with dense growths of balsam fir 1-3 m tall (Matsuoka et al. 2010a). In Maine, Powell et al. (2010a, 2010c) concluded that optimum landscapes contained combinations of wetlands with patches of shallow water rich in aquatic prey, and undisturbed wetlands with small confers for nesting. In Maine and Vermont, wetlands surrounded by more than 70% conifers were 2 times more likely to be occupied, those with shallow (less than 6 cm) water that was not connected to flowing or other open water were more than 4 times likely to be occupied, wetlands with beaver activity were 2 times more likely to be occupied, and wetlands that were previously occupied were more than 2 times likely to be occupied than wetlands without these features. It selected wetlands surrounded by conifers regardless of their age. It appeared to select habitat at multiple scales, targeting wetlands surrounded by at least some short coniferous growth and also good foraging habitat such as shallow water supporting high invertebrate biomass. These areas of shallow water were an important component of habitat selection. Beavers probably create both nesting and foraging habitat. They selectively remove hardwoods and promote growth of conifers, and their ponds result in increased biomass of important aquatic prey such as dragonflies, damselflies, caddisflies, and snails (Powell et al. 2014). In Maine and New Hampshire, habitat selection was affected by the basal area (BA) of small conifers with a diameter at breast height (DBH) of 4 cm or less, and canopy closure. For each 5 m^2 per ha increase in BA of small conifers, the odds of occupancy for nesting increased by 65%. With each 10% increase in canopy closure, occupancy decreased by 39%. The home-range scale consisted of a 500-m radius around the nest. Nests in Maine had 20% wetland cover at this scale compared with only 6% in New Hampshire. The conifers in Maine were young and pole-sized. Occupied areas in New Hampshire contained significantly more mature conifers and hardwoods. Luepold et al. (2015) found evidence for an effect of young conifers on habitat selection at the home-range scale and of an interaction between site and wetlands. With each 10% increase in wetland cover, the odds of occupancy increased by a factor of 5.47 in Maine and 2.46 in New Hampshire. For both areas, each 10% increase in young conifer cover resulted in a 46% increase in the probability of occupation. There was a preference for young conifers even when they were the result of timber harvesting. Overall, high BA of small conifers and a lack of overhead canopy closure were important predictors of site occupation, but the amount of wetland area was more important.

Other studies examined microhabitat preferences of the Rusty Blackbird and the effects they have on nest success. At Anchorage, it nested in black spruce and white spruce in proportion to their availability and avoided nesting in alders and white birch. In interior Alaska, it selectively nested in black spruce and white spruce, used willow and alder in proportion to their availability, and avoided white birch and balsam poplar. In Anchorage, it nested in areas with a higher density of black spruce than random sites. In the interior, there were no differences between nest sites and random areas. At Anchorage, nest sites were characterized by a preponderance of black spruce and a scarcity of willow but the opposite was true in the interior. In both areas, canopy closure was sparse at 20.5% and 25.2%. Nesting in wetlands may be advantageous because densities of red squirrels and other predators were low (Matsuoka et al. 2010b). In Maine and New Hampshire, 88% of nests were in harvested stands. Total BA within a 5-m radius of nests was significantly higher in New Hampshire (57.5 m^2 per ha) than in Maine (36.9 m^2 per ha). BA of conifers was also significantly different: 41.6 m^2 per ha in New Hampshire and 24.7 m^2 per ha in Maine. Alder density was significantly higher in Maine (9.5 stems) than in New Hampshire (2.8 stems). Mean nest-tree DBH was 4.4 cm in Maine and 4.1 cm in New Hampshire. BA was the most important variable influencing nest success with nest success higher in denser conifers. Mean BA was 57.6 m^2 per ha around successful nests and 35.3 m^2 per ha around unsuccessful nests. This was because young dense stands of spruce or balsam fir do not produce cones and therefore support few red squirrels, thereby enhancing nest success (Luepold et al. 2015). In British Columbia, fallen trees and flooded snags around wetland shorelines provided important foraging habitat (Campbell et al. 2001). In Nova Scotia, its presence was positively correlated with canopy height heterogeneity and negatively correlated with depth to water table, canopy height, and distance to a coniferous stand. Presence of a high water table was the most important factor (Bale et al. 2020).

The Rusty Blackbird is predominantly an edge species, frequently nesting at the transition between wetland and forest habitats. In balsam fir and balsam fir–white cedar forests in Newfoundland and Quebec, it occurred only in deciduous wetlands along streams and was absent in adjacent coniferous forests (LaRue et al. 1995; Whitaker and Montevecchi 1997, 1999). Kennard (1920) reported a nest that was 90 m from a stream within a swamp.

This blackbird does not appear to be area sensitive. In Maine and Vermont, Powell et al. (2014) detected it in 1 of 78 wetlands (1.3%) smaller than 0.1 ha. Wetlands less than 0.5 ha were less likely to be occupied than larger wetlands.

Ontario nests were near or over water, with 72.7% in living and 18.2% in dead trees and shrubs. One nest was on the ground, one was in a fallen dead spruce over water, and one was in a hollow trunk standing in water. Coniferous trees (22 nests in 3 species) were preferred to deciduous trees and shrubs (6 nests in 4 species). Preferred species included spruces (19 nests), willows (3 nests), and balsam fir (2 nests). Nests were most often against the trunk on horizontal branches and in forks. Two nests were near the base of a tree and another was on branches between the trunks of 2 small spruces. Elevated nests were 0.3-2.7 m from the ground, with most 0.8-1.8 m up (Peck and James 1987).

Most nests are in small trees or shrubs. Powell et al. (2010c) found 43 nests in Maine and Vermont: 23 in black or red spruce, 16 in balsam fir, 2 in white spruce, 1 in white cedar, and 1 in a

viburnum shrub. The mean age of nest trees was 17.9 years (median 14 years, range 8-50 years). All nests were within 75 m of water (range 0-71 m); 29 were in wetlands and the 14 nests in uplands averaged 7.3 m from the wetland-upland interface (range 0.3-95 m). Matsuoka et al. (2014) found 184 nests in Alaska and summarized results across Canada for an additional 230 nests. Nest substrates included 59.8% conifers, 34.2% deciduous shrubs, and 6.0% deciduous trees or other substrates. It was most likely to nest in conifers in all areas except the interior of Alaska where 15% of nests were in conifers and 78% were in shrubs, including living and dead willows and alders. Of nests in conifers, 75% in Alaska and 80% in Canada were in spruce with small numbers of Canadian nests in balsam fir and white cedar. Most nests in spruce were in black spruce with small numbers in white spruce. In Alaska, 39% of spruces used for nesting were dead. Eleven nests were in deciduous trees: white birch, balsam poplar, red maple, and pin cherry. Two nests were in grasses, 6 were in emergent sedges or cattails, and 1 was on the ground on a beaver dam. The average height of 321 nests was 1.6 m but it varied by nesting substrate: 0.23 m for ground, grass, sedge, and cattail nests (range 0-0.5 m); 1.0 m for shrubs (range 0-4.1 m); 1.3 m for deciduous trees (range 0.3-5.0 m); and 2.0 m for conifers (range 0-16.2 m). Kennard (1920) found several nests in Vermont and Maine, almost all in dense growths of young conifers but also in other sites. Nests were in spruce (both dead and living), balsam fir, dead branches of a broken-off spruce top, a dead spruce top in a stream, sweet gale, buttonbush, and at the top of a large stump standing in water. Some nests were in intermingling branches of 2 conifers but most were near the trunk of a tree. Nests in dead trees were well concealed by dense growths of beard lichen. Fifteen nests were 0.3-6.1 m from the ground or water (average 1.83 m). In Maine, nests averaged 1.8 m from the ground in trees 3.4 m tall. In New Hampshire, nests averaged 1.7 m from the ground in trees 2.5 m tall (Luepold et al. 2015). At Churchill, Manitoba, nests were 0.3-1.5 m from the ground in willows (Jehl 2004). In British Columbia, 59% of nests were in small or medium-sized conifers, usually black spruce, followed by deciduous shrubs (31%) and small deciduous trees. Fifty-six percent of nests were over standing water, usually among flooded woody vegetation, or in trees or shrubs overhanging water; 34% were in dead or dying trees and shrubs; 6% were on islands in lakes; and one was in a natural cavity in a pine tree. Nests were in thick clumps of woody vegetation or among horizontal branches, usually near the trunk but occasionally as far as 60 cm from it. Nests were 0.2-6.1 m from the ground, with most 0.6-1.5 m up. The lowest nests were usually in dead flooded trees or shrubs. Higher nests were on drier ground, well concealed in live conifers (Campbell et al. 2001). Bent (1958) reported a nest 3 m up in the top of a broken-off spruce in a damp pasture thickly overgrown with spruce. New nests are built for replacement clutches and in subsequent years. They may be placed close to the previous year's nest (Avery 2020; Bent 1958; Campbell et al. 2001; Kennard 1920; Matsuoka et al. 2010b).

It is unknown whether the Rusty Blackbird defends a territory. In most cases, only a single pair nests at a wetland, but occasionally groups of 2-6 pairs nest at a wetland. Grouped pairs are reported mostly in Newfoundland, Labrador, and Alaska, with 1 report in Maine. In Alaska, only 4 pairs of nests have been found within 50 m of each other (Bent 1958; Campbell et al. 2001; Kennard 1920; Matsuoka et al. 2010b; Powell et al. 2010a, 2010b). Avery (2020) reported that it nested both solitarily and colonially in Nova Scotia. Colonial groups occurred where water levels fluctuated and isolated pairs occupied areas where water levels were stable. Powell et al. (2010b) reported a colony of 6 nests within 6.9 ha in Maine; 2 other nests were 869 and 1,481 m from the colony. It is uncertain if

this was a true colony, with nests averaging 283 m apart (range 67-531 m). On 3 occasions, they observed males aggressively chasing each other and males cooperatively mobbed field crews. Birds that nested in groups had larger home ranges than those that nested singly. Group nesting was rare. The authors surveyed 561 wetlands in Maine and Vermont and found 43 nests but only 1 colony. No birds returned to nest in the colony in the following year. The Rusty Blackbird is known to fly long distances during the breeding season (Matsuoka et al. 2010a). In Maine, the mean size of 13 home ranges was 37.5 ha (range 3.8-172.8 ha). The mean core area was 11.1 ha (range 1.5-34.8 ha). Birds included an average of 2.8 wetlands within their home range and 1.4 in their core areas. They often visited wetlands and wet patches that were not connected to the wetland that was used for nesting. There was no significant difference in the mean home range sizes of males (48.0 ha) and females (28.4 ha) or home range sizes of males (23.1 ha) and females (22.0 ha) paired to each other. Core area sizes did not differ by sex: 12.0 ha for males and 10.3 ha for females for all birds and 7.4 ha for males and 8.2 ha for females within pairs. Home ranges of birds nesting in the colony were significantly larger (51.8 ha) than for those nesting solitarily (14.6 ha). Eleven of 13 birds had home ranges larger than 10 ha. Two birds that were presumably nonbreeders had home ranges of 72 ha and 173 ha. Wetlands encompassed only 12% of home ranges and 19% of core areas, but their significance may have been underestimated due to the scale of their mapping. It was often observed foraging in very small wetlands such as seeps, depressions resulting from logging and road construction, skidder ruts, roadside ditches with alders, and borrow pits. Many were less than 16 m^2 and too small to be delineated as wetlands (Powell et al. 2010a).

No information is available on natal philopatry. Limited information is available on adult site fidelity rates. In Vermont and Maine, Kennard (1920) found several nests close to where he had observed nests in previous years. He assumed that the same birds had returned but they were not banded. In Alaska, 60% of Rusty Blackbirds banded in 2008 returned the following year, but only 18% of those fitted with geolocators returned. The body mass of these birds was lower than in the previous year, suggesting that geolocators may affect survival rates (Johnson et al. 2012). Zero of 6 nesting pairs returned to a nesting colony in Maine (Powell et al. 2010c).

Limiting Factors

Eggs have been reported in Ontario nests from the beginning of May until the last week of June, with most present from the last week of May until mid-June (Peck and James 1987). In Algonquin Park, eggs are present from early May to early June, nestlings are present from late May to early July, and dependent fledglings have been observed from early June to late July (Tozer 2012).

No information is available on how long it takes to build the nest. Eggs were laid in 1 nest before the lining was complete suggesting that intervals between nest completion and initiation of egg laying are brief. Incubation appears to begin with the laying of the first egg, particularly during cold weather. Later in the season, incubation may be initiated with the laying of the penultimate or last egg. The incubation period in Alaska averaged 11.8 days (range 10-13 days). The eggs hatch over a 1-2 day period. The nestling period in Alaska averaged 11.5 days (range 10-13 days; Avery 2020; Bent 1958; Kennard 1920; Matsuoka et al. 2010b).

The Rusty Blackbird raises a single brood in a season but may renest if the first nest is lost. In Nova Scotia, 2 nests were collected and the females began building new nests the next day. Two

Alaska females renested 57 m and 196 m from their first nests after they failed. In Vermont and Maine, most females vacated the home range when their nest was collected. One female built 4 nests and laid 4 clutches after the researcher collected the first 3 nests (Bent 1958; Kennard 1920; Johnson et al. 2012; Matsuoka et al. 2010b). Clutches of 3-5 eggs were reported in Ontario, with 4-egg clutches most common (mean 4.00 eggs; Peck and James 1987). Clutches of 3-6 eggs have been reported, with most containing 5 eggs, but 4-egg clutches are also common. Only a single complete 3-egg clutch has been reported; 1 nest contained 7 nestlings. Mean clutch sizes include 5.3 eggs in Alaska (mode 5 eggs), 4.6 eggs in Canada (mode 4 eggs), 4.4 eggs in unharvested and 4.5 eggs in recently harvested forests in Maine and Vermont, and 4.47 eggs for clutches reported to the Western Foundation of Vertebrate Zoology. Clutch size declines as the season advances (Avery 2020; Bent 1958; Campbell et al. 2001; Matsuoka et al. 2010b; Powell et al. 2010c).

The age at first breeding is presumed to be 1 year, but this has yet to be confirmed. It is unknown if all adult and yearling birds breed. In Maine, 2 adult birds appeared to be unmated (Powell et al. 2010a). The mating system appears to be monogamous particularly since most pairs nest solitarily. Those nesting in groups may have opportunities to engage in extra-pair copulations, but this has never been documented (Avery 2020).

The diet of the Rusty Blackbird may be the main reason for its preference for wetlands. During the breeding season, it feeds predominantly on aquatic insects and other invertebrates and small vertebrates associated with water. It often feeds on moist soils and in shallow water where it wades, often ducking its bill or entire head underwater to obtain prey. It feeds on floating logs and mats of vegetation, among emergent wetland plants, and in seasonally flooded meadows. It may flip dead leaves at the edge of a wetland or lake in the manner of a waterthrush. In addition to margins of larger water bodies, it forages in puddles and very small wetlands and may visit landfills and forage with gulls. It picks caddisfly cases from the substrate of water bodies and opens them to obtain the larvae or pupae inside. It inspects rotten wood at ends of logs and excavates it to obtain insects and gleans prey from moss and litter and from under twigs and other debris. It exposes prey in soft mud and loose soil by inserting its bill and opening it to loosen the substrate. It may make nearly vertical flights to about 4.6 m above the ground to hawk mosquitoes and caddisflies, then glide to the ground and repeat the process. During severe cold or snowy weather in late winter or early spring on the breeding grounds, it may attack and kill other birds. It has killed Wilson's Snipes, American Robins, American Goldfinches, Lapland Longspurs, Snow Buntings, White-throated Sparrows, White-crowned Sparrows, American Tree Sparrows, Dark-eyed Juncos, and Brown-headed Cowbirds. It does not always eat its victims but when it does, it eats mostly the brain and tissue from the head. This appears to occur only when there is a food shortage during adverse weather (Avery 2020; Beal 1900; Bent 1958; Cade 1953; Campbell 1974; Greenberg and Droege 1999; Matsuoka et al. 2010a; McRae 1992; Powell et al. 2010a, 2014).

Nestlings are fed aquatic insects, particularly dragonfly nymphs. Limited information is available on the breeding season diet of adults. It feeds mostly on aquatic invertebrates and small vertebrates such as dragonfly nymphs, beetles, mayfly nymphs, caddisfly larvae and pupae, snails, crayfish, tadpoles, salamanders, and small fish (Avery 2020; Beal 1900; Kennard 1920; Matsuoka et al. 2010a, 2010b; Powell et al. 2010a).

The ranges of the Brown-headed Cowbird and Rusty Blackbird barely overlap, so parasitism is rare. There are 2 old reports of parasitism from Alberta (Avery 2020), and Campbell et al. (2001) reported that 1 of 27 British Columbia nests (3.7%) was parasitized.

The most significant limiting factors for the Rusty Blackbird occur within its wintering range, but habitat loss on the breeding grounds is also occurring. The most extensive habitat losses occur outside Ontario but some losses are occurring within the province. The largest habitat losses have been in the southern Boreal Forest Region in the Prairie Provinces, where forest has been converted to agricultural uses. In northern Quebec and Labrador, more than 10,000 km^2 of boreal forest were flooded by hydroelectric dams. Habitat loss is also occurring due to mining, oil and gas exploration and development, and a number of other industrial activities. It has been estimated that about 5% of Canada's boreal forest is no longer suitable habitat and another 4% loss is projected to occur within the next 50 years. Indirect habitat loss is occurring due to rising temperatures caused by climate change. Satellite imagery indicates that the total area of shallow ponds and boreal lakes decreased by 6,700 km^2 during 2000-09. Climate modelling predicts a 64-90% reduction in core habitat for the Rusty Blackbird by 2100. In Alaska, the area of lakes and ponds has been declining since 1950. There has been a decrease in the amount of surface area of ponds of 4-31% and in the number of water bodies by 5-54%. Large volumes of groundwater and surface water may be displaced during oil and gas extraction, and this may lead to habitat loss or alteration (Greenberg and Droege 1999; Greenberg and Matsuoka 2010; Greenberg et al. 2011; Matsuoka et al. 2010a; Savignac 2006, 2017).

Some authors stated that timber harvesting is the greatest threat to its breeding habitat. Others have reported effects to be negligible. A massive spruce budworm outbreak from 1968 to 1985 defoliated balsam fir and spruce across 550,000 km^2 of forest from Lake Superior to the Atlantic coast. This and related salvage logging may have caused widespread changes to its habitat. More than 60% of the commercially viable southern boreal forest has already been allocated to timber companies for harvesting. Tree harvest rates in Canada are highest in British Columbia, Ontario, and Quebec. From 2000 to 2012, 110,412 km^2 of forest were harvested in Canada. Clear-cutting opens areas to colonization by the Red-winged Blackbird and Common Grackle, species that are dominant to the Rusty Blackbird. Clear-cutting has the potential to create habitat for the Brown-headed Cowbird, although this is not preferred habitat for it (Avery 2020; Baker and Thomas 2015; Greenberg et al. 2011). In Maine and Vermont, Powell et al. (2010a) concluded that clear-cuts constituted an ecological trap for the Rusty Blackbird. Clear-cuts provided dense growth of young conifers which attracted the blackbirds but nest survival rates were significantly lower in clear-cuts (33%) than in areas with no history of recent logging (76%). They suggested that buffers at least 75 m wide around occupied wetlands would improve success rates. A large-scale reduction in nest survival in logged forests may have contributed to its population decline and range contraction. In Maine and New Hampshire, Luepold et al. (2015) found no evidence that harvested stands acted as ecological traps. Nest survival rates were similar to those reported elsewhere in undisturbed stands. They recommended that the practice of precommercial thinning not be done in regenerating stands, particularly in those near wetlands. This reduces stocking densities and enhances growth of select crop trees and is an increasingly common practice. Precommercial thinning may eliminate the dense patches of conifers that it prefers for nesting, make nests more vulnerable to predators and

decrease nest survival rates, and accelerate the development of mature forest that is unsuitable nesting habitat.

Acid precipitation is an issue for the Rusty Blackbird, particularly in the eastern portion of its range in New England and the Maritime Provinces. It does not appear to have had much effect in Quebec. Acid precipitation affects it in 2 manners. The resulting lower pH in wetlands and water bodies may reduce food availability and abundance. Snails and other molluscs are among the first to disappear when water becomes acidified, and these are important components of its diet. Many other aquatic invertebrates are intolerant of acidic waters. The second effect of acid precipitation is that it results in the release of natural mercury from sediments. Acidification promotes the formation of methylmercury, which is the most toxicologically significant form of mercury in birds because of its high bioavailability. The Rusty Blackbird is vulnerable because its diet focuses on prey higher up in the food chain such as predatory aquatic invertebrates (dragonflies) and small fish. Mercury has negative effects on reproduction through decreased egg volume and embryo weight, eggshell thinning, abnormalities and deformities, and deleterious changes in adults' behaviour. Birds were sampled for mercury in New England, the Maritimes, and Alaska during the breeding season, and in the wintering range. Concentrations were significantly higher on the breeding range than the wintering range, with highest concentrations in Vermont and Nova Scotia. Mercury concentrations in Rusty Blackbirds were 13-17 times greater than for Red-winged Blackbirds from the same areas. In addition, mercury may be released by flooding areas or through direct discharges (Edmonds et al. 2010; Greenberg and Droege 1999; Greenberg and Matsuoka 2010; Greenberg et al. 2011; Nadeau in Gauthier and Aubry 1996).

The Rusty Blackbird may have been adversely affected by DDT and carbofurans before the usage of these chemicals was banned (Savignac 2017).

Rusty Blackbird populations appear to fluctuate in complex cycles associated with climate and weather conditions and population cycles of other wildlife species. Savard et al. (2011) monitored the number of Rusty Blackbirds during autumn migration at Tadoussac, Quebec over a 15-year period. Numbers fluctuated greatly between years, with peak movements occurring at 5-year intervals. Numbers ranged from 54 to 2,156 per year with daily averages per year on days observed of 3-80. In peak years, 84% of birds were juveniles. Only 25% were juveniles in low years, indicating high reproductive success in years of abundance. They correlated blackbird abundance with Boreal Owl numbers and climate. The 3 largest movements occurred in years when few Boreal Owls were captured and 1-3 years after peaks in owl abundance. This owl feeds predominantly on the red-backed vole, which has a 4-5 year cycle of abundance. When voles are abundant, the Boreal Owl remains on the breeding grounds in winter but migrates in years of vole scarcity. Rusty Blackbird numbers were highest in peak years of vole abundance, suggesting that the Boreal Owl may seek alternative prey, such as blackbirds, in years when voles are scarce. Autumn abundance of the Rusty Blackbird was positively correlated with the North Atlantic Oscillation (NAO), a large-scale climatic phenomenon that influences winter temperatures and moisture budgets for much of eastern North America. A positive correlation means that it was cooler in the Boreal Forest Region during the breeding season and wet in the southeastern United States during winter. It was negatively correlated with precipitation amounts in June, July, and August. Summers with low amounts of

precipitation may increase the amount of suitable foraging habitat and reduce nestling mortality due to heavy rain. Its current decline may be exacerbated by patterns in the NAO. More frequent negative indices may result in lower reproductive success and possibly reduced winter survival. Reproductive success of the Rusty Blackbird is also tied to the conifer cone abundance cycle and populations of red squirrels. The red squirrel is the primary predator of blackbird nests. Luepold et al. (2015) determined that the red squirrel population increased significantly the year after abundant cone production. All recorded nest predation events by red squirrels occurred in the year that they were most abundant. The abundance of the Rusty Blackbird may be affected by beaver abundance. By creating ponds, beaver activity provides good foraging habitat. Beavers preferentially down deciduous trees, thus favouring growth of conifers that may provide nesting habitat. The beaver was brought to the brink of extinction by excessive trapping by 1930. It is probable that low numbers of beavers had an adverse effect on the Rusty Blackbird population. As a result of trapping restrictions, the beaver population has rebounded and this was beneficial for the blackbird. It is probable that beaver populations will remain high due to anti-fur trade sentiments and low prices of pelts (Avery 2020; Powell et al. 2010c, 2014; Savignac 2017).

Baker and Thomas (2015) cited 1 study that stated nest survival of the Rusty Blackbird was lower nearer roads in New England. The effects of roads may be site specific or may vary annually. Powell et al. (2014) concluded that there was no evidence that major roads had a negative impact on occupancy of sites. Luepold et al. (2015) found that nest survival was highest distant from roads in 1 year and close to roads in the following year.

The Rusty Blackbird does not appear to be adversely affected by fire or be suffering from chronically low nesting success that might explain its drastic population decline (Matsuoka et al. 2010b).

Status

Baillie and Harrington (1936) considered the Rusty Blackbird a fairly common breeder from Grey County and Algonquin Park north through the remainder of the province. MacLulich (1938) reported that it was an uncommon but regular breeder in Algonquin Park. Baillie and Hope (1943) found that it was rare along the north shore of Lake Superior. The first atlas demonstrated that the range of the Rusty Blackbird included northern Ontario to slightly south of Algonquin Park, with scattered records south of the Canadian Shield in eastern Ontario, on the southeastern shore of Georgian Bay, and on the Bruce Peninsula and Manitoulin Island. None of the southern records were of confirmed breeding. It was not reported in a large area of northwestern Ontario. Flood (in Cadman et al. 1987) concluded that the distribution map in the north was conservative and that it probably bred in all blocks. James (1991) considered it an uncommon breeder in the north and in the Algonquin Highlands and rare south to the Bruce Peninsula, Haliburton County, and Ottawa.

The second atlas revealed that there had been little change in the distribution of the Rusty Blackbird. It was essentially absent south of the Shield, but was confirmed to breed in northwestern Ontario where it was overlooked during the first atlas. There was no change in its overall probability of observation, but it declined significantly in the Boreal Forest Region and the Shield portion of the Great Lakes-St. Lawrence Forest Region. It increased significantly in the Hudson Bay Lowland. It was possible that it had not declined province-wide but shifted its range northward. Highest densities

occurred in the Hudson Bay Lowland. In this area, it was detected on 45% of point counts; 39% of squares where it was reported were within this region despite relatively low effort. It was 24 times more abundant in the Hudson Bay Lowland than in the Boreal Forest Region and 120 times more abundant than in the Shield portion of the Great Lakes-St. Lawrence Forest Region. The high densities in the taiga portion of northern Ontario were not previously documented. It is uncertain whether this high density has always been present or whether the dramatic decline in this blackbird's population has affected it differently in different areas of the province. There has not been a significant decline or change in habitat in the Canadian Shield of Ontario, suggesting that declines in the Rusty Blackbird may be related to issues on the wintering range (Francis in Cadman et al. 2007). Mills (1981) stated that the Rusty Blackbird was extremely local in Muskoka and Parry Sound districts. In Algonquin Park, it was formerly a common breeder, but sightings of nests and fledglings became very infrequent after the early 1980s (Tozer 2012).

The Breeding Bird Survey (BBS) indicates that the Rusty Blackbird has declined at a significant rate throughout its range and in Canada and Ontario. The BBS is not well suited for estimating its abundance because of its patchy distribution, solitary breeding habits, and use of boreal wetlands that are frequently remote and inaccessible (Matsuoka et al. 2010b). Coverage by the BBS is limited to less than 30% of its range and is concentrated in the southern portion of the Boreal Forest Region. It may not be representative of trends in more northern areas where its density may be higher and there are fewer threats to its habitat. It is also detected on few routes, many of which have been surveyed sporadically and have frequent observer turnover, resulting in poor precision with wide confidence limits (Greenberg et al. 2011). In the Mackenzie Valley of the Northwest Territories, Machtans et al. (2007) compared its occurrence and relative abundance in 1970 and 2006 and found no significant differences. Although there are deficiencies in the BBS, results from most other studies corroborate that the Rusty Blackbird has experienced a significant decline, and that this decline probably began long before the BBS was initiated in 1966. Greenberg and Droege (1999) reviewed historical accounts that referred mainly to its abundance during migration and winter. It was described as very common to abundant in 56% of accounts published prior to 1920, in 19% of those published 1920-50, and in 6.7% of those published after 1950. It was described as uncommon in 0% of pre-1950 publications, 18% of those published 1951-80, and 53% of those published after 1980. This historical information suggests a decline over the last century with the rate of decline accelerating. The Rusty Blackbird winters in the southeastern United States where it is well surveyed by the Christmas Bird Count (CBC). CBC results indicate that it is declining at a significant rate. Trends at some migration monitoring stations also indicate declines. In Quebec, its probability of observation declined by 60% between the 2 atlases; the Quebec checklist program also indicates a significant decline (Buidin in Robert et al. 2019).

Since 1966 when the BBS was initiated, results of that survey suggest that the Rusty Blackbird population declined by approximately 95%. This is one of the steepest declines recorded by the BBS for any species. The trend in Ontario was −14.9% per year, greater than for the population as a whole (Greenberg and Droege 1999; Greenberg and Matsuoka 2010; Greenberg et al. 2011). Savignac (2006) reported a significant decline on the BBS of 9.97% per year rangewide 1966-2003 and 10.3% in Canada 1968-2003. Machtans et al. (2007) reported a decline in Canada of 12.8% 1966-2005. Baker and Thomas (2015) reported a decline of 6.3% per year 1970-2012 in Canada, with declines most

severe in southern and eastern regions. These were the areas where estimated trends are most reliable but are also on the periphery of the core range where habitat disturbances and changes due to climate are likely to be more prevalent. The rate of decline appears to be levelling off. Savignac (2017) reported a decline rate for Canada of 3.5% per year 1970-2014 and 2.6% per year 2004-14. In Ontario, there was a significant decline of 4.61% per year 1970-2014 and a nonsignificant decline of 2.68% 2004-14. The Canadian results translate into an approximately 80% decline in population 1970-2014. Cadman et al. (2016) reported that the Rusty Blackbird declined at a rate of 5.9% per year 1983-2013, the seventh greatest decline of all Ontario birds. BBS data for 1970-2021 indicate that it decreased at annual rates of 3.31% in Canada and 3.73% in Ontario. The trends 2011-21 were annual decreases of 0.0632% in Canada and 0.0842% in Ontario. The long-term trends were of medium reliability; the short-term trends were of low reliability (A.C. Smith 2023).

As a result of its significant decline and the ongoing threats to the Rusty Blackbird, it has been designated special concern in Canada and Ontario. Baker and Thomas (2015) prepared a management plan with a 2-fold objective: to stop the decline and maintain the population at its 2014 level, and to increase the population, resulting in a 10-year sustained increase in its Canadian population. The current significance of many potential threats is poorly understood, so the short-term objective is to stop the decline and maintain the population. Once threats are better understood and potential mitigation measures are identified, the objective is to create a sustained 10-year increase in population.

POSTFLEDGING PERIOD

Fledglings remain in the immediate vicinity of the nest for the first 2 days after leaving the nest, climbing and hopping among shrubs and low trees. By about the third day out of the nest, they are capable of flight. Later on, they tend to be closer to the adults' foraging areas than the nest. In Vermont, vegetation used by fledglings differed from that at the nest site by having more alder and spruce, although total vegetation density remained high. A pair with fledglings was observed in spruce and willow scrub on a dry ridge on the west James Bay coast. Fledglings have been observed with the adults 4 weeks after leaving the nest. Both adults feed the fledglings (Avery 2020; Kennard 1920; Manning 1952).

Beginning in about mid-July and continuing into August, groups of adults accompany fledglings from multiple nests and form small flocks. Later, flocks merge with other blackbird species such as Red-winged Blackbirds and Common Grackles. It also associates with European Starlings prior to initiation of autumn migration. The Rusty Blackbird may move considerable distances during the postfledging period in preparation for migration. In Alaska, birds were last seen in the breeding areas in mid-July. Distances travelled from the breeding areas during the postfledging period averaged 145 km (range 128-175 km; Avery 2020; Campbell et al. 2001; Johnson et al. 2012; Kennard 1920; MacLulich 1938; Powell et al. 2010a; Tozer 2012).

Once conspecific and multispecies flocks form, the Rusty Blackbird occurs in a variety of habitats. These are often anthropogenic areas such as stubble fields, pastures, and plowed fields. It occasionally visits cornfields where it eats ripening corn (Avery 2020; Campbell et al. 2001).

MIGRATION

Avery (2020) stated that the Rusty Blackbird was a diurnal migrant, but it appears as though most migration occurs at night. In northern Ohio near Lake Erie, 82% of spring departures and 95% of autumn departures occurred at night (Wright et al. 2018a). In late autumn, it may rest in stopover areas for approximately 1 month before proceeding to the wintering areas. Although it is considered a short-distance migrant, those breeding in the northwest may travel in excess of 5,000 km to reach the wintering area (Wright et al. 2018b).

Wright et al. (2018a) radiotracked migrating Rusty Blackbirds captured in Ohio on the southeastern shore of Lake Erie. Wright et al. (2018b) determined that 97.6% of spring migrants were undergoing a prealternate moult of body and/or head feathers. For both sexes, moult peaked during the middle of the migration period. This moult occurs commonly in waterfowl and shorebirds but has not previously been described for other passerines. Four Motus towers within the study area, a 28-km^2 wetland complex, were classified as the local array and the remainder (mostly in Ontario) were called regional arrays. Mean stopover duration for all birds was 25.3 days in spring and 25.7 days in autumn, with ranges of 3-62 days in spring and 2-58 days in autumn. Stopover periods were shorter for birds that arrived or were captured later. Males had longer stopover periods than females in 1 year, but shorter stopovers in the next year. Higher moult scores resulted in longer stopover periods when birds were in poor condition, but had no effect for birds in good condition. Of 39 spring migrants, 28 (71.8%) crossed Lake Erie and the remainder went around the lake. Spring departures were associated with later capture dates, increasing tailwind, and lower body condition. Autumn departures were associated with tailwinds. Nineteen of 58 (32.8%) spring and 35 of 49 (71.4%) autumn migrants made confirmed or probable stopover relocations. Stopover relocations ranged from 10 to 35 km from the local array, often in directions opposite to the predominant migratory direction. The mean capture day of birds that relocated was significantly earlier than for birds that did not relocate. In spring, males were much more likely to relocate than females (58% compared with 15%). Unlike most passerines, the Rusty Blackbird does not undertake rapid migrations punctuated with short refuelling stops. It spent 5 times longer on stopovers than warblers at the same location. Its migration pattern is more analogous to that of shorebirds, with longer stopovers required in spring to moult.

During migration, the Rusty Blackbird travels in flocks. In autumn, these are mostly mixed flocks that contain Red-winged Blackbirds and Common Grackles and possibly Brown-headed Cowbirds and European Starlings. Spring flocks may consist solely of Rusty Blackbirds but may contain these other species (Avery 2020; Lancaster et al. 2004).

At a stopover site in Ohio, there was no difference in the arrival times of the age classes, but males arrived significantly earlier than females by 13.1 days (Wright et al. 2018a). It is probable that males arrive on the breeding grounds before females, but the interval between their arrival may not be as great as at staging areas. In southern and central Ontario, it passes through in late March and early April. Most leave by mid-May, but some remain until late May (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008). Manning (1981) observed flocks and single birds 20-25 May on the Twin Islands in James Bay.

Wright et al. (2018a) reported that there were no differences in autumn arrival dates in Ohio among age and sex classes. Manning (1952) reported 35 at Moose Factory on 27 September and singles on the Twin Islands on 2 and 30 September (Manning 1981). In the southern Shield, migration extends from late August until late November or even until late December, with peak movements in October (Mills 1981; Tozer 2012). In the south, it usually arrives in late September and leaves in mid-November; it may arrive as early as late August (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008).

During migration in Ontario, the Rusty Blackbird has been documented in wet woods, recently plowed and harvested fields, and at cattle feedlots. In Algonquin Park in autumn, it feeds on exposed mud along edges of rivers and inhabits riparian alder thickets, road margins, and campgrounds (Lancaster et al. 2004; McIlwraith 1894; Tozer 2012; Weir 2008).

Two studies characterized Rusty Blackbird migration habitat at the landscape level. In northern Ohio, a major stopover location was comprised of a 28-km^2 complex of wetlands near the Lake Erie shoreline (Wright et al. 2018a). The mean composition of core stopover areas of birds migrating between Alaska and the wintering grounds consisted of 60% croplands, 36% grasslands, 2% water, 1% wetlands, and 1% other habitats (Johnson et al. 2012).

The Rusty Blackbird has been documented in herbaceous-dominated wetlands, small water bodies, grasslands, agricultural crops, pastures, edges of swamps, bogs, swampy lake shorelines, beaver ponds, shrubby or treed margins of rivers and streams, landfills, sewage lagoons, and grassy edges and shrub areas of large wetlands. It is most frequently seen in wet areas or areas with damp soils (Avery 2020; Bent 1958; Campbell et al. 2001; Nadeau in Gauthier and Aubry 1996; Savignac 2017; Sinclair et al. 2003). During spring migration in Ohio, dogwood-willow swamp was the most strongly selected habitat, followed by forest and prairie. These were the least available habitats within the landscape. As spring progressed, dogwood and marsh patches were used less and forests and prairies were used more. Compared with random points, spring foraging areas were closer to habitat edges and in areas with less grass cover, more wet leaf litter, and more shallow water. In autumn, it selected dogwood-willow swamps, followed by forests, open water, and emergent marshes. Marshes were more likely to be used later in the season and forests earlier in the season. Compared with random sites, autumn foraging areas were in areas with more shallow water and dry leaf litter, and less grass, forbs, and herbaceous shrub cover (Wright et al. 2020).

Roosts are important for the Rusty Blackbird during migration. In spring, it often roosts in conspecific flocks but tends to join large multispecies roosts during autumn migration. During spring migration, flocks may roost on the ground in dense ground cover. Most frequently, it roosts in wooded areas, particularly swamps. It also roosts in cattail marshes and buttonbush and willow swamp thickets. In Niagara Region, autumn migrants and overwintering birds roost in a common reed marsh (Avery 2020; Bent 1958; Black and Roy 2010; Fitch 1958). In Ohio, roosting habitat in both seasons occurred in monotypic common reed or cattail marshes with emergents a mean of 2.3 m tall (Wright et al. 2020).

At a stopover site in Ohio, between-season site fidelity was 29% spring 2015 to autumn 2016 and 36% autumn 2016 to spring 2017. Migratory route fidelity was 43% for spring 2017 and 71% for autumn 2016. Site fidelity was high during migration, but several birds migrated past the site

without stopping. This suggests that migratory site fidelity is better measured at larger scales. The Rusty Blackbirds spends about 25% of its life cycle at staging areas, often repeatedly using the same sites and flyways (Wright et al. 2018a).

In early autumn in Ohio, the Rusty Blackbird consumed dogwood berries, with 68% of autumn foraging observations occurring in dogwood thickets (Wright et al. 2018a). Beal (1900) analyzed the contents of 132 stomachs, predominantly from migrating and wintering birds. The diet included 53% animal material, more than any other blackbird except the Bobolink. Beetles represented 13.8% of the annual diet, including 1.7% ground beetles, 2% scarab beetles (11.7% of the April diet), and 10.1% other beetles, which were mostly aquatic beetles and their larvae plus leaf beetles. Grasshoppers constituted 12% of the annual diet, peaking at 44.3% in August and almost as high in October. Caterpillars constituted 2.5% of the diet, peaking at 11.7% in May. A variety of insects, including ants, bugs, flies, dragonflies, caddisflies, and mayflies, constituted 13.7% of the diet. The diet included 4% spiders and millipedes, peaking at 23% in August. Crustaceans, snails, salamanders, and small fish constituted 7% of the diet. The 47% vegetable food consisted of grain, weed seeds, and small amounts of fruit and mast. Corn was the favourite grain and comprised 17.6% of the annual diet. Wheat and oats collectively comprised 6.8% of the diet, with oats preferred and representing 15.4% of the March diet. Most grain was waste grain or taken from corn cribs. Weed seeds did not appear to be preferred, representing 6% of the annual diet with a maximum of 23.3% in May. Fruit was unimportant in the diet but included buffalo-berry, hackberries, and raspberries. Mast was found in a few stomachs. Animal food was preferred, and the proportion that it represents in the diet would have been higher if samples were available from the breeding season. It was not considered a threat to agricultural crops. Other studies reported that it eats grasshoppers, earthworms, rye, foxtails, panic grasses, ragweeds, grapes, elderberries, acorns, beechnuts, pine seeds, white ash seeds, and fruits of American holly, Hercules' club, flowering dogwood, and black gum (Avery 2020; Bent 1958).

The Rusty Blackbird may use traditional stopover sites during migration where it remains for extended periods. These sites may be as critical to it as similar areas are to certain shorebirds during their migration. Few critical stopover areas have been identified for the Rusty Blackbird. Most stopover areas are within agricultural landscapes where they are threatened by fragmentation and isolation due to agricultural intensification (Johnson et al. 2012; Wright et al. 2018a).

The Rusty Blackbird is not protected in Canada. This means that it can legally be killed at any time and its nests destroyed (Savignac 2006). Although it is not protected, it is unlikely that many are killed in Canada. In the United States, it is protected under the *Migratory Bird Treaty Act* but there is a clause in this act that allows it to be killed if it causes property damage. It is legally subjected to blackbird control programs in the United States.

Although the Rusty Blackbird is a nocturnal migrant, it rarely strikes communication towers. At a Florida tower, only 8 were killed out of more than 35,000 birds (Avery 2020).

James (1991) considered the Rusty Blackbird a common migrant in Ontario.

All indications are that the Rusty Blackbird has declined significantly as a migrant throughout its range. In Elgin County, it was a common migrant in 1891 but it was uncommon by 2000 (Lancaster

et al. 2004). It was formerly fairly common as a migrant but is now uncommon in the Hamilton area (Curry 2006). Fleming (1907) considered it an abundant migrant at Toronto. Results from Ontario banding stations are inconclusive, probably because few are captured and the time period is recent (2004-14) and short: +11.4% at Prince Edward Point in autumn (nonsignificant), +6.5% at Innis Point in spring (nonsignificant), −17.5% at Pelee Island in autumn (significant), and −7.7% in autumn at Thunder Cape (nonsignificant). These figures represent the rate of annual decline (Savignac 2017). Autumn banding results in Tadoussac indicated an ongoing decline (Savard et al. 2011). It is probable that a large decline in the numbers of the Rusty Blackbird occurred before any modern surveys were implemented. Beal (1900) stated that it was one of the most familiar sights in spring in New England, with flocks around every farmhouse. It was seen in immense numbers, particularly in the Mississippi Valley. Bent (1958) reported that flocks of 10,000 were seen in Manitoba in 1882 and 100,000 were reported in New York on 1 May in 1880. In October 1937 in Massachusetts, a flock was reported to be 1.6 km long. The spring migration was spectacular, with Rusty Blackbirds ubiquitous. Birds could be seen in enormous numbers almost everywhere in cultivated fields, stubble fields, and treed swamps.

WINTER

The Rusty Blackbird is associated with snow. It is least likely to occur where there are frequent changes between snow cover and bare ground (Keyser et al. 2023).

In northern areas outside the normal wintering range, such as Ontario and British Columbia, the Rusty Blackbird inhabits agricultural fields and livestock feedlots, and visits bird feeders. It avoids very open areas in winter and during cold spells early in spring. It is associated with anthropogenic habitats (Campbell et al. 2001; LaForest 1993; Lancaster et al. 2004; Weir 2008).

Johnson et al. (2012) characterized the winter habitat of 3 individuals at the landscape scale. Core wintering areas of a male and female consisted of 99% cropland and grassland. The winter range of another female consisted of 51% coniferous forest, 17% deciduous woodland, 18% wetlands, 10% croplands and grasslands, and 4% other habitats.

The most important wintering habitat in the southeastern United States is bottomland hardwoods, but the Rusty Blackbird uses other forested habitats that produce mast, such as pecan orchards. Flooded woodlands, wooded vegetation along streams, and forested river floodplains are its main habitats. It is commonly associated with livestock feedlots and manured fields. It prefers contiguous semi-flooded forests but in drier areas is associated with smaller wetlands such as beaver ponds. It prefers forests with mature oaks, small creeks, and patchy inundated areas of shallow water and exposed substrate. It may use red cedar thickets bordering on open marsh. It frequents cornfields and rice patches and may occur on race courses, golf courses, and lawns. Two resources appear to be important for suitable winter habitat. Semi-flooded wetlands where the water is unfrozen is required for foraging, and it also requires small-seeded oaks and pecans (Avery 2020; Baker and Thomas 2015; Bent 1958; Greenberg and Droege 1999; Greenberg and Matsuoka 2010; Greenberg et al. 2011; Hobson et al. 2010; Savignac 2017).

Luscier et al. (2010) surveyed 219 sites in Arkansas, Louisiana, and Mississippi over 3 winters to determine the habitat preferences of the Rusty Blackbird. Habitats they examined included swamp forests with water deeper than 50 cm, wet bottomland forests with water 5-20 cm deep, moist

bottomlands with water 2-10 cm deep, and dry bottomlands with water 0-2 cm deep. Water in dry bottomlands was predominantly due to precipitation. Water in the other habitat types was due to flooding from agricultural lands and watercourses. Swamp forest was the only habitat where they did not detect flocks of 100 or more birds in any year. All habitats except dry bottomlands had detections of 20 or more blackbirds in every year. Habitat type was not a consistent predictor of its occupancy rates: canopy cover, tree density, and water cover were not consistently good predictors. It was not as specialized in its winter habitat use as previously reported. It appeared to have flexibility in its choice of winter habitat and possibly diet that allowed it to respond to variable conditions. It was equally likely to occupy agricultural fields adjacent to wetlands and bottomland forests but avoided large open fields distant from these features. It may move to different areas depending upon water levels. Water depth is important because it requires shallow water for foraging.

During winter, the Rusty Blackbird may segregate by age and sex classes, with females and juveniles wintering further south than adult males. Male foraging areas may be of higher quality and have greater food availability than areas used by females and juveniles (Baker and Thomas 2015).

Roosts are an important component of winter habitat. In Niagara Region, the Rusty Blackbird roosts in a wetland dominated by common reed (Black and Roy 2010). In British Columbia, it prefers to roost in wooded areas (Campbell et al. 2001). In the core of its winter range, roosts occur in fields, scrub, and forests. Preferred roosts were often in afforestation areas with dense vegetation near the ground, but were also in fields with short vegetation or in trees and shrubs in residential yards. These often supported 20-400 Rusty Blackbirds, with urban roosts also containing large numbers of other blackbird species. As winter progresses, it occurs more frequently in large mixed-species blackbird roosts. These may support millions of birds, with Rusty Blackbirds typically representing less than 1% of the total number of birds. In South Carolina, most roosts are in cattail marshes adjacent to salt marshes (Avery 2020; Greenberg et al. 2011; Savignac 2017).

The most significant limiting factors for the Rusty Blackbird appear to occur in the wintering range, and are related to habitat loss and blackbird control programs. Habitat loss is the most significant factor. Since European settlement, there has been a continuous decline in its winter habitat, with 75-80% of bottomland forests converted to agricultural uses. Conversion of forest to agriculture has progressed from drier to wetter areas over time. Habitat conversion in the last half of the 20th century may have been more deleterious because it winters in wetter areas. Some low-lying areas remained uncultivated until the 1970s when high soybean prices resulted in their being cleared and farmed, and this may have been some of the best habitat. Subsequent declines in soybean prices led to afforestation, but shifting markets could result in these lands being converted back to agricultural uses. The direct loss of habitat has been significant and has caused indirect effects. Much of the remaining wooded wetlands and bottomland forests are small patches. Fragmentation may degrade habitat by exposing the Rusty Blackbird to increased predation and increased competition from Common Grackles and other blackbirds. Draining and diversion of water may change soil moisture regimes and affect the quality of foraging habitat. The effects of the numerous water control projects on the Mississippi River and its major tributaries on the Rusty Blackbird are potentially quite large but have not been evaluated (Greenberg and Droege 1999; Greenberg and Matsuoka 2010; Greenberg et al. 2011).

The Rusty Blackbird is not an agricultural pest, but many are killed on the wintering grounds because it associates with other blackbird species that are significant depredators of crops. From 1974 to 1992, 83 roosts were sprayed with a surfactant that killed 38 million birds. These were mostly grackles, starlings, Red-winged Blackbirds, and cowbirds. It was estimated that 120,000 Rusty Blackbirds were killed, but this was a crude estimate based on the fact that less than 1% of the birds at mixed-species roosts are typically Rusty Blackbirds. The use of this surfactant was banned in 1992. The toxicant DCR-1339 was used in the rice production areas of Texas and Louisiana. These poison baits were placed in staging areas and at feedlots and dairy farms. No estimates on the number of Rusty Blackbirds that were killed by this compound are available. Some researchers have trivialized the effects of blackbird control programs on the Rusty Blackbird because the number of birds killed is low relative to other species and none of the other species have declined significantly as a result. The latter point is not true because significant declines in the eastern populations of the Common Grackle have been attributed to blackbird control programs. Other studies acknowledge that the number killed and the effect on the Rusty Blackbird population is unknown (Greenberg and Droege 1999; Greenberg and Matsuoka 2010; Greenberg et al. 2011). Winter populations fluctuate considerably year to year (Greenberg and Matsuoka 2010) and this may be consistent with the cyclic pattern observed during autumn migration in Quebec. Savignac et al. (2011) concluded that a cyclic pattern in its abundance and reproductive success could make it more vulnerable to blackbird control programs than other blackbird species.

In Illinois, Graber and Graber (1979) observed a 75% decline in the abundance of the Rusty Blackbird after a severe winter storm. It was unknown whether the birds suffered mortality or emigrated.

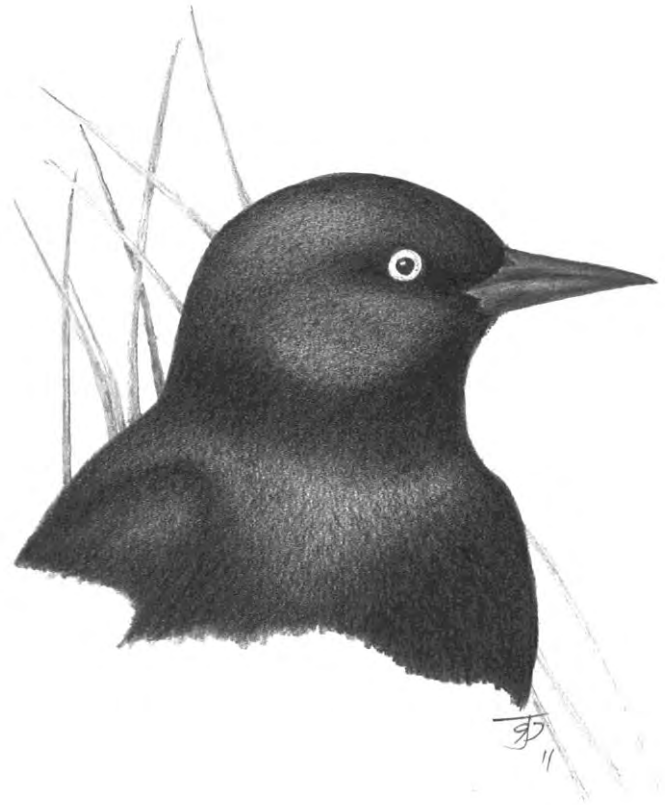
James (1991) considered the Rusty Blackbird rare to common in winter in the south north to Manitoulin Island and Ottawa, and occasional and rare north to Thunder Bay, Wawa, and Moosonee.

The number of wintering Rusty Blackbirds in Ontario appeared to increase in the first half of the 20th century before declining. McIlwraith (1894) had no winter records for it. Freedman and Riley (1980) analyzed CBC data for southern Ontario for 1929-77. They found a recent trend to greater abundance and frequency of occurrence, but at low total numbers. In the Hamilton area, it overwintered regularly singly or in small numbers in the last half of the 20th century, but it is now rare (Curry 2006). In the Kingston area, it appears to have become more common since 1991 (Weir 2008).

CBC data indicate a significant long-term decline in the Rusty Blackbird. Data for 1966-2005 indicate a decline of 4.5% per year, which equates to an 85% population decline. High numbers were detected in the 1950s and early 1960s, although it had probably declined previously, and there was a marked decline around 1965 continuing into the 1970s. During 1994-2003, the rate of decline levelled off at 2.1% per year (Greenberg et al. 2011; Savignac 2017).

Brewer's Blackbird

Euphagus cyanocephalus

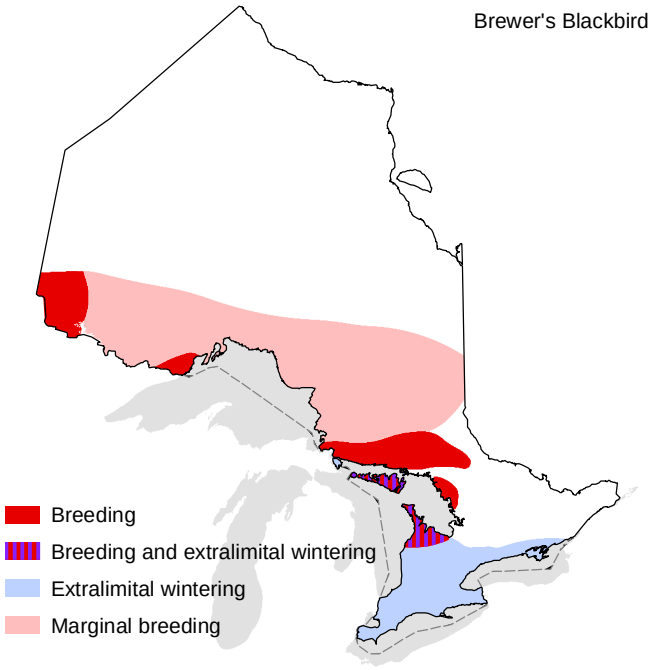


BREEDING SEASON

Habitat Requirements

Ontario Brewer's Blackbird nests were along road and railway rights-of-way on edges, ditches, and embankments (71.3% of nests); in fields and pastures (17.1%); in open bogs (6.7%); in open clear-cuts or burns (3.0%); on dry ridges and dunes (1.2%); and in a black ash swamp (0.6%). Nesting areas were usually open and occurred in both wet and dry sites (Peck and James 1987).

Most nesting habitat described for Ontario was in the Canadian Shield portion of the Great Lakes-St. Lawrence Forest Region, although the Brewer's Blackbird occasionally nests in the southern Boreal Forest Region and south of the Shield. At Fort Francis, it nested in peatlands with willow shrubs, but vacated the area after it burned. The first colony reported for Ontario was at Thunder Bay in a 3.2-ha clearing between 2 roads. The site supported a few dead trembling aspens that it used as perches. In the highway corridor between Sault Ste. Marie and Sudbury, most nesting



occurred along the highway, often between the road and railway in planted conifers or on the ground. A small colony occurred in a 4-ha marsh dominated by woolgrass with a few narrow-leaved cattails, red-osier dogwoods, and meadowsweet. There was a dense growth of alders and willows around 2 sides of the marsh. Another colony was in wet grassy fields at the junction of 2 highways. In Parry Sound District, colonies were found at Magnetewan, Powassan, South River, Trout Creek, Sundridge, and Verner. At the first 3 sites, the colonies were in peatlands, one of which had been logged a few years previously. These supported typical bog and fen species such as leatherleaf, cottongrass, bog laurel, sedges, sphagnum moss, and scattered black spruce and tamarack. Where it nested in peatlands, open fields, roadsides, golf courses, and other open habitats were usually present in the immediate vicinity. The Trout Creek colony was in a clear-cut with windrows, the Sundridge colony was in hayfields, and the Verner colony was in rows of conifers. A nest in Muskoka District was in open farmland near a road (Allin and Dear 1947; Baillie 1961; Crins and O'Donnell 1993; Devitt 1964; Walton 2000; Wood 1955).

Throughout its range, the Brewer's Blackbird nests in many open habitats. These include patches of shrubs, particularly sagebrush in the west; highway, railway, and utility rights-of-way; villages and suburban areas; bogs and fens; marshes with emergent vegetation; dry marshes that have been burned; damp meadows and fields; riparian habitats along wetlands, streams, and lakes; grazed pastures; on banks of streams and ditches; in stubble agricultural fields; in fields planted to vegetables; urban parks and yards; shrubby prairies; clear-cuts and burns; conifer plantations; pine and oak barrens; windbreaks; hayfields; and university campuses. Although most nesting habitat is anthropogenic, it nests at higher altitudes in mountain meadows and along shrub-lined watercourses. In heavily forested landscapes, it is restricted to nesting in wetlands and along human-created rights-of-way. Highest numbers tend to occur in rural and agricultural settings (Campbell et al. 2001; Finch 1991a; Furrer 1975; Horn 1968; Leighton et al. 2002; Martin 2020; Mossman et al. 1991; Niemi and Hanowski 1984a; Orians and Horn 1969; Pitelka 1942; Stepney 1979; Walkinshaw and Zimmerman 1961; Williams in Bent 1958). In British Columbia, 59% of nests were associated with human-modified habitats, 14% with forested lands, 10% with shrublands, 7% with wetlands, and 6% with grasslands. Modified habitats included 41% farmland, 28% rural land, 23% suburban areas, 4% urban areas, 3% orchards and vineyards, and 1% clear-cuts. Natural nesting habitats were comprised of 45% shrublands, 28% wetlands including marshes, and 20% forest edges. Nesting areas were often close to wetlands or low-lying areas that it used for foraging. In farmlands and rural areas,

nesting habitats usually included hedgerows, tangles of vegetation, or ditches with sloped banks. In grasslands and shrubby areas, nests were in copses of shrubs, dense ground cover, or at edges of clumps of trees. In wetlands, it nested in willow thickets, emergents such as cattails, or on hummocky ground. In suburban areas, it nested in large gardens with ornamental trees, especially conifers. It also nested in riparian thickets and open pine woodlands. In boreal areas, it often nests in open burns (Campbell et al. 2001).

In Washington, nesting colonies typically had 3 habitat features: the nesting habitat, a nearby foraging area, and high perches from which the nest sites were visible. All sites with all 3 features had either active colonies or a number of nests remaining from previous years. Single nests were occasionally found where there were no extensive areas of densely foliated sagebrush, the predominant nesting substrate. No colonies were found in the absence of water bordered by short grasses or sedges, the primary foraging habitat, and no nesting occurred where elevated perches were absent. Males spend much of their time on perches when females are laying and incubating where they guard against predators. Perches tend to be 3-7 m high and may consist of trees, cliffs, and telephone and hydro poles and wires. These latter features are greatly preferred as roosts by birds nesting near roads (Horn 1968, 1970; Williams 1952).

On an elevational gradient in Wyoming, the Brewer's Blackbird nested mostly in mid-elevational areas in dense shrubs. It was associated with drier areas with increased ground cover and occupied a variety of upland habitats far from streams. It occurred in areas with more than 65% coverage by herbaceous species and grasses that were densely foliated by shrubs in the mid-canopy layer; many sites were moist. It used an intermediate range of habitats and its habitat preferences most closely approximated those of the Song Sparrow (Finch 1989b, 1991a).

Most Ontario nests were well concealed; 88.0% were on the ground and the others were elevated. Ground nests were often in depressions, sometimes excavated by the females, or were in vegetation such as moss. They were in or under clumps of grasses and forbs (40.4% of nests); in or under shrubs (39.4%); at the base of saplings, stumps, and trees (8.5%); under dead branches (3.2%); in moss (3.2%); fairly exposed on bare ground (2.1%); under an overhanging bank (1.1%); in the open end of a fallen stump (1.1%); and in a pail lying on its side (1.1%). Most elevated nests were over dry land, but 18.2% were over water. Of 22 elevated nests, 18 were in living trees or shrubs, one was in a cavity in a dead tree, one was on top of a sawed-off stump, one was in an open Tree Swallow nest, and one was in rushes. Both coniferous (2 species, 10 nests) and deciduous (4 species, 8 nests) trees and shrubs were used, with the most frequently used species being pines (8 nests), spruces (3 nests), blueberries (3 nests), Labrador tea (2 nests), and Manitoba maple (2 nests). Elevated nests were 0.2-2.7 m from the ground, mostly 1.2-1.8 m up (Peck and James 1987). At Sault Ste. Marie, 2 nests were on the ground in sparse woody cover and 3 were in tops of solitary spruce 3 m tall (Wood 1955). Near Sudbury, 8 nests were 1.2-1.8 m (average 1.5 m) from the ground in conifers. All were in extremely dense vegetation that had developed around the flattened tops where the crowns had been cut off (Stepney 1975a). Nests at Sault Ste. Marie were also in dense foliage resulting from pruning. Conifers without human disturbance apparently were not dense enough to be attractive to nesting birds. Four colonies that had been under observation for a few years all contained conifers that were not used for nesting, although nests were often placed under them. A nest at Luther Marsh

and several at a colony at Sault Ste. Marie were less than 30 cm above water. Nests in the Sudbury area were on dry knolls in low vegetation, sunken into the ground so that their tops were flush with it. One was partially hidden beneath dead bracken fern and a small spirea. In addition to these species, vegetation around the nests consisted of strawberries, raspberries, blueberries, asters, goldenrods, fringed false milkwort, Canada mayflower, willow, yarrow, sweet fern, and flat-branched tree-clubmoss. Another nest was in the centre of a clump of dried rushes in a marsh, 15 cm above water (Devitt 1964). A nest at Thunder Bay was on the ground and covered with 15-cm tall grasses, mostly redtop. Sedges, violets, and early leaves of other herbaceous species occurred in the immediate vicinity of the nest (Allin and Dear 1947, 1955).

Furrer (1975) described 4 nest types in Washington: those in shrubs, nests in emergent vegetation, ground nests, and nests in crevices and on ledges of cliffs. No nests were found in trees and those on cliffs were rare. Overall, 66.7% of nests were in shrubs, 16.2% were on the ground, and 17.1% were over water. There were seasonal differences in the frequency of nest types. During the peak of nest building in early spring, almost all nests were in shrubs, with other nest types becoming more frequent later in the breeding season. Ground nests occurred in both dry and wet areas. Upland ground nests disappeared before the end of the season and wet ground nests did not appear until later. It took longer for vegetation to become sufficiently established in wet areas to provide cover. Most nests on dry ground relied on shrubs for cover. There was no optimal nest type that was suitable for all conditions. There was no correlation between the type of a bird's natal nest and the type of nest that it built, and individuals did not always build the same type of nest. Nests are commonly placed in trees and dead stubs standing in water. Several nests were in anthropogenic or unusual features. These included a bird box in Manitoba, in a Tree Swallow nest box, on building support beams, on ledges, in fence posts, on telephone poles, in haystacks, on a road grader, under a walkway, in an abandoned car, among the roots of a fallen tree, in a burned-out woodpecker cavity, and in an abandoned mine shaft in a tunnel under a rock (Baily 1950; Bancroft 1986b; Butler 1981; Campbell et al. 2001; Wiggins 1990). In British Columbia, 38% of nests were in deciduous and coniferous shrubs, 29% were in trees, 17% were on the ground, 2.2% were on beams or sides of buildings, 1.9% were on posts or poles, 1.7% were in snags or stumps, 1.6% were in vines, and 1.3% were in reeds or cattails. Sixty-five percent of nests in live trees were in conifers. The Brewer's Blackbird appeared to have regional preferences for nest types. There were equal numbers of nests in trees and shrubs in 1 area. In other areas, nests were mostly in shrubs, in trees, or on the ground (Campbell et al. 2001). A variety of trees, shrubs, and emergents have been used for elevated nests. These include sagebrush (which is highly preferred in the western United States), pines, oaks, firs, cypress, junipers, willows, apple, wild roses, juneberries, gooseberries, poplars, cattails, eucalyptus, and snowberry. Nests in trees are usually saddled on a horizontal branch or often near the top of the tree in dense foliage. They are rarely at the end of a limb in dense tufts of needles. Nests in shrubs are in those with the densest foliage, and the nest is in the densest portion of the shrub. There is 1 report of a colony nesting in cavities at tops of tall fir trees with none lower than 45.7 m above ground. This is exceptional and most elevated nests are much lower than this. At the same colony the previous year, all nests were 1.2 m or less above ground in shrubs. Tree nests in California were 2.1-13.1 m from the ground with most 6.1-9.1 m up. In British Columbia, nests were 0-10.0 m from the ground, with most 0.5-2.2 m up. In Nevada, elevated nests were 0.15-

6 m from the ground (average 1.55 m). Average height above ground in Colorado was 17.7 cm (Campbell et al. 2001; Furrer 1975; Horn 1968, 1970; Leighton et al. 2002; Martin 2020; Pitelka 1942; Walkinshaw and Zimmerman 1961; Williams 1952; Williams in Bent 1958). Nests on the ground are often associated with an abrupt change in relief such as the slope of a railway grade, a ditch bank, the base of a perpendicular bank bordering a stream, or at the top of a small bank or rise. They may also be placed at distinctive changes in vegetation or at the base of a plant that differs in height or colour from the rest of the habitat, including beneath features that are taller than the general cover. Ground nests are under or next to a clump of vegetation, among thick ground cover, or at the base of a sapling (Campbell et al. 2001; Martin 2020). In Nevada, all 75 nests were in shaded areas protected from the sun but across its range and between years, nest placement varies from bright sun to deep shade. Nests are placed in all directional orientations. There are 2 records from British Columbia of nests being reused (Campbell et al. 2001; Martin 2020; Walkinshaw and Zimmerman 1961).

The Brewer's Blackbird is colonial and defends only a small area around the nest. Solitary nesting occurs, but most birds nest in loose colonies. In Ontario, 14 isolated nestings were reported compared with 56 colonies with an average of 4-5 nests (Peck and James 1998b). In California, Williams (1952) reported 10 colonies in about 300 km^2 and found no singly nesting pairs. The female begins to aggressively defend the nest site against other females as soon as she selects it. The area around the nest may or may not be defended by the male. Males may be aggressive at the nest site and adjacent guard perches, but only after pair formation has taken place, with the peak of aggression during nest building and egg laying. Nests tend to be more widely spaced than those of many other blackbird species. At a Sudbury colony, nests were 4.6-109.7 m apart. At a California colony, nests were 2.7-11.3 m apart. Most colonies are small, supporting 10-30 nests, with a maximum of 12 nests in Ontario. Maximum colony size in British Columbia is 22 nests (average 8 nests). Colonies larger than 100 pairs have been reported in Nevada (Campbell et al. 2001; Horn 1968; Martin 2020; Stepney 1975a; Walkinshaw and Zimmerman 1961; Williams 1952; Williams in Bent 1955).

In Washington, Horn (1968, 1970) examined whether aggregations of nests were true colonies and if nesting in groups was beneficial. Nests were always near water and therefore the clumped distribution of nests might be due in part to the patchy distribution of water. Other factors pointed toward coloniality. Males give alarm calls from their perches in response to predators and fly out to harass those that approach the colony too closely. Predators were attacked 100 m from the nest, approximately 4 times the mean distance between nests. This resulted in mobbing that was effective in deterring flying birds but did not drive away snakes, mammals, or perched birds. The mobbing effectively prevented Ring-billed Gulls from flying over colonies and eliminated predation due to this species. Birds that lost their own nest due to predation left the colony and did not stay to help defend other nests. In colonies in nonlinear patches, nests that were further apart than the median distance were depredated more frequently than those closer together. In linear-shaped colonies, nests that were closer together were depredated more frequently. The predation pattern conferred a slight advantage to nest clumping in nonlinear colonies. Dispersed nests were more advantageous in linear colonies. In both types of colonies, predation by Ring-billed Gulls was prevented by nest grouping. Displays of nesting birds resulted in high nest synchrony in colonies.

Those nesting on the periphery of the colony or distant from it may not be synchronized. Nest synchrony may be advantageous in predator mobbing if all birds are on the same schedule. If extra-pair copulations are an important mating strategy, synchronized nesting could be beneficial. Feeding may be the main reason for coloniality. Suitable feeding areas are often patchily distributed and the suitability of each site changes frequently. Whenever there was a steady wind of 8 km or greater, Brewer's Blackbirds foraged on the lee shores of lakes because emerging damselflies were more abundant there. All birds tend to forage in the same location and follow those that were successful at foraging. In this manner, the colony usually exploits the best food source at all times. Occasionally, colonies shift because of human disturbance or habitat degradation. When this occurs, all birds move together to a new site, including individuals who could have still used portions of the old site.

The only information on natal philopatry rates is from Washington where Furrer (1975) banded 555 nestlings in 1 year and 679 in the next year. Of the 555, 46 (8.3%) were resighted and 45 of the 679 (6.6%) were resighted, for an overall return rate of 7.4%. Results were higher for those banded in the first year because of the extra year for recovery. Four (0.7%) nestlings banded in the second year were not seen as adults until 3 years later. A nestling banded in Michigan was recovered in Ontario the next breeding season (Martin 2020).

Colony sites tend to be stable and used year after year. Brewer's Blackbirds are flexible enough to move entire colonies if the habitat becomes unsuitable or the colony is disturbed. One colony was apparently deserted because a Loggerhead Shrike nested near it. When colonies shifted in Washington, the birds continued to use the same foraging areas (Campbell et al. 2001; Horn 1970; Martin 2020). No information is available on the rate of adult site fidelity, but it may be high. In California, some birds were mated together in as many as 5 consecutive years (Williams 1952). In Washington, some birds shifted among colonies. Each bird made only a single change. After moving from another colony, they remained at their new colony until they disappeared (Williams 1952). An adult female that nested in Washington nested in British Columbia 3 years later (Martin 2020). One banded in June in Michigan was recovered the next June in Ontario 340 km from the banding location (Brewer et al. 2018).

Limiting Factors

Eggs have been found in Ontario nests from early May to early July, with most present in the last week of May and first week of June (Peck and James 1998b). Resident birds form pairs while they are still in winter and early spring flocks. New pairs are established shortly after arrival at the colony. In resident populations, pair formation may last 12 weeks but it is likely much less in migratory populations and may be very brief in polygynous matings. Females took 9-10 days to build nests in Ontario but only 5-9 days in California. Egg laying usually starts 1 day after the nest is complete and 1 egg is laid per day. Incubation typically begins with the laying of the penultimate egg. In some cases, hatching may take place over a 3-day period suggesting that incubation may begin earlier. In Ontario, the incubation period is 12 to 13 days. Elsewhere, incubation periods of 11-17 days have been reported with 12-13 days typical. The nestling period is 12-16 days but mostly 13-13.5 days. If nests are disturbed, young may leave the nest when they are as young as 9 days (Campbell et al. 2001; Furrer 1975; Horn 1970; Martin 2020; Peck and James 1987; Williams 1952).

The nesting season is very short in Ontario and only a single brood is raised. In most areas, the Brewer's Blackbird raises a single brood but double broods are fairly common in coastal California, Washington, and Oregon and in much of British Columbia. Only 1 brood is raised in northern British Columbia. Replacement clutches are common if the first nest is lost, with the new nest built close to the original one. As many as 3 attempts may be made to raise a brood (Campbell et al. 2001; Martin 2020; Peck and James 1998b; Williams 1952). Peck and James (1987) reported clutches of 2-6 eggs in Ontario (average 4.93 eggs, mode 5 eggs). Mean clutch size in the Sudbury area was 4.72 eggs. Elsewhere, clutches of 3-7 eggs have been reported with rare records of 8 eggs or nestlings. In British Columbia, clutches of 1-7 eggs were reported and 1 nest contained 8 nestlings. Most nests contained 4 or 5 eggs with May clutches tending to have 5 eggs and June clutches having 4 eggs. Overall mean clutch size has been estimated at 4.98 eggs (mode 5 eggs). Mean clutch sizes in other areas include 5.00 in Colorado, 4.87 in Nevada, and 4.9 and 5.6 in Washington (Campbell et al. 2001; Martin 2020; Stepney 1975a; Williams in Bent 1958).

Both sexes are capable of breeding when they are 1 year old and they breed annually thereafter. In California, an older male evicted a yearling mate and took his mate as his secondary female. This suggests that yearlings may not be able to compete successfully with older males. Unmated birds have been observed in some populations but their age and sex were not determined (Martin 2020; Pitelka 1942; Williams 1952).

The Brewer's Blackbird is monogamous in Ontario, Colorado, Nevada, and Washington, but polygyny has been reported in California (Martin 2020; Orians 1980). At a California site, there were 80 cases (69.6% of matings) of monogamy and 35 (30.4%) of polygyny. Polygyny was most frequent in the year that there were 2 times as many females present as males. Polygyny also occurred when mated males mated with a neighbouring female after her mate died or her nest was destroyed. Most polygynous males (82.9%) were bigamous but 14.3% were trigynous and 1 (2.9%) had 4 mates. Of 29 males that were present for 2 or more years, 6 (20.7%) were constantly monogamous, 1 (3.4%) was constantly polygynous, and 22 (75.9%) switched status. Nests of females mated to a polygynous male were occasionally in the same tree, but also in different trees, sometimes with the nest of another pair in between. Of 69 females, 34 (49.3%) were always primary, 20 (29.0%) were always secondary, and 15 (21.7%) changed status. Some changed from primary to secondary status for their second nest. Only 2 females became primary to females that they had been secondary to previously. Males guarded secondary females as assiduously as primary females. Usually the eggs of the primary female are hatching when the secondary female begins to incubate. Of 29 males with 2 mates, 20 (69.0%) fed nestlings at both nests, 2 of 4 (50.0%) with 3 mates fed nestlings at all nests, and the male with 4 mates did not feed at all nests. Males may feed fledglings from the primary nest and nestlings in the secondary nest on the same day. Polygyny is advantageous to males because they produce more offspring. Feeding rates by polygynous males were lower than for monogamous males with a resulting higher death rate of nestlings. Mating with a polygynous male may be disadvantageous for females (Williams 1952). The pair bond lasts for a single season but birds frequently remate if both return in a subsequent year. Some California pairs bred together in as many as 5 consecutive years. In 45 cases, both members of a primary pair returned; 42 (93.3%) remated and 3 (6.6%) divorced. Of 45 secondary pairs, both members returned in only 6 cases and they all divorced (Williams 1952).

It is probable that extra-pair copulations are an important component of the mating system, but this has not been tested genetically. During the nest-building phase, females frequently display for copulation. All males in the vicinity respond even if they are already mated. Males are usually successful in guarding their females from the advances of rivals but promiscuous copulations have been observed. Males do not guard the female constantly during the incubation period and this may provide him opportunities to seek extra-pair copulations or another mate (Howell and Bartholomew 1952; Martin 2020; Williams 1952). Intraspecific parasitism is a rare mating strategy. Five of 162 nests (3.1%) in Washington were parasitized by another Brewer's Blackbird (Martin 2020).

The Brewer's Blackbird regularly forages in both aquatic and terrestrial habitats. In wetlands and water bodies, it prefers to forage in short grasses and sedges along margins of lakes and wetlands. It has longer legs than Yellow-headed and Red-winged blackbirds and is much better adapted to exploiting resources in this zone. The other blackbirds are adept at clinging to vertical stems of emergent wetland plants but the Brewer's Blackbird is very clumsy when attempting this. When it forages in marshes, it prefers areas of blown-down cattails and bulrushes where it can walk over a more or less flat surface. The other 2 blackbird species expel the Brewer's Blackbird from their territories. Within marshes, the foraging areas of these 3 blackbirds are spatially distinct. They all forage in short grasses and sedges, but the Brewer's Blackbird is much more efficient in this habitat. Where newly emerged damselflies are the primary aquatic prey, both the Brewer's and Red-winged blackbirds shift their foraging areas during the day. They feed in aquatic habitat during peak periods of damselfly emergence in mid- to late morning and in terrestrial habitat in the afternoon. Most foraging by Brewer's Blackbirds occurs near the colony but birds may make foraging flights as far as 1.6 km. It responds quickly to changes in food availability and feeds on the lee shore of lakes whenever the wind exceeds 8 km per hour because emerging damselflies are more abundant in calm areas (Horn 1968, 1970; Orians 1980; Orians and Horn 1969). It commonly wades in water as deep as its belly to obtain aquatic prey, occasionally in the company of shorebirds. It also forages on exposed sandbars covered in flotsam (Campbell et al. 2001; Williams in Bent 1958). In Nevada, it foraged on extensive growths of Canada waterweed in a lake. It landed on the plants with the water coming up to the middle or upper parts of its tarsometatarsi. It also walked and fed on water-lily pads. It was once seen on a river hovering near open water and snapping food from the surface. It has been observed dipping bread and popped corn into water before eating it (Richardson 1947; Williams in Bent 1958). In terrestrial habitat, the Brewer's Blackbird forages mostly on the ground. A foraging sequence consists of a period of walking in a zigzag fashion followed by a brief pause. In Ontario, foraging-site suitability was determined by vegetation height and ease of walking. Areas of short (2.5 cm) grass were preferred to taller grass or shrubs by adults foraging for themselves. Grasses taller than 15 cm were preferred by adults capturing food for nestlings. When foraging in taller grasses, it preferred areas lacking litter and other features that impeded movement, with areas supporting fresh growth after burning particularly favoured. Areas of taller grass that were used usually abutted borders of low vegetation or road margins with birds penetrating only short distances into the tall vegetation. While foraging, it mostly gleans from the ground or low vegetation. It flips over cattle dung, stones, and small branches and rarely probes in the soil with its bill. It forages in shrubs by walking underneath them and capturing insects on the branches above, or in tops of denser shrubs. It does not forage among the branches of shrubs as does the Red-

winged Blackbird. The Brewer's Blackbird rarely feeds while perched on fairly rigid vegetation such as sunflowers. It has been observed gleaning insects from sheep. It may sally from the ground or an elevated perch to capture insects, with males hawking more than females and closer to the ground. In early spring, it may feed in manure piles. It occasionally feeds in trees, taking spittle bugs from among pine needles and cherries from trees in orchards. It may glean bread, popped corn, and other human foods while foraging in parking lots. It frequently feeds in flocks in fields by following tractors plowing or disking the soil where it captures insects and other invertebrates and young leopard frogs and voles. It has fed on other birds, including Barn Swallows, young Ring-necked Pheasants, and fledgling Lesser Goldfinches and Brewer's Sparrows. The Barn Swallow was carrion. It was uncertain if the other species were carrion or killed by the blackbirds. The Brewer's Blackbird uses a variety of terrestrial habitats for foraging including shrubby prairies, pastures, barnyards, roads, streets in villages and towns, lawns, agricultural fields, parking lots, golf courses, cemeteries, mowed urban parks, university campuses, overgrown fields, schoolyards, and railways. It is a highly opportunistic forager that readily abandons a traditional foraging area to exploit an insect outbreak or an abundant source of food elsewhere (Beal 1900; Beasley and Carothers 1974; Campbell et al. 2001; Martin 2020; Orians 1980; Orians and Horn 1967; Powers and Wheeler 1987; Verbeek 1964; Walkinshaw and Zimmerman 1961; Williams 1952; Williams in Bent 1958).

In most areas, the Brewer's Blackbird does not defend a foraging area. Feeding areas may be used by all or most birds in a colony, and the foraging site may change daily or even within a day. It is not profitable for a bird to attempt to defend a feeding area when the best foraging areas are transient and constantly changing. An exception was near Sudbury where suitable foraging sites were limited. Pairs vigorously defended feeding territories with high-intensity pursuits and threat displays. The size of 7 foraging territories ranged from 0.05 to 0.2 ha with no overlap in areas where adjacent pairs foraged for their young. Where feeding territories were defended, most food was collected within 50 m of the nest (Horn 1968; Martin 2020; Orians 1980).

Females are capable of fledging young without male assistance. Some birds may fly several kilometres to obtain food for nestlings. Birds foraging within 50 m tend to bring a maximum of 7 food items per trip but those returning from longer distances bring very large loads of food (Martin 2020; Orians 1980; Walkinshaw and Zimmerman 1961; Williams 1952). In Washington, the nestling diet consisted of 34% odonates (predominantly damselflies), 21% flies, 7% orthopterans, 7% other insects, 5% spiders, 1% cicadas, and 1% miscellaneous items. Orthopterans and cicadas were numerically unimportant yet provided 24% and 11% of the calories delivered to nestlings respectively. Odonates were important at 34% of the diet both numerically and from a caloric perspective. The prey items delivered to nestlings varied during the day because adults foraged in upland areas in early morning and mid- to late afternoon and in wetland areas from mid-morning to early afternoon. In the morning, the diet consisted predominantly of small amounts of flies (mostly midges and mosquitoes), lepidopterans (small caterpillars and adults of a plume moth), plus other items that have no diurnal variations in abundance such as small snails, spiders, and other insects. At 1000 hours, the use of odonates peaked at about 98% of the diet. In the afternoon, few odonates were taken, with flies, lepidopterans, and other items constituting much of the diet. In 1 year there was an irruption of cicadas that was not exploited by the Yellow-headed Blackbird but they constituted 10% of the energy delivered to Brewer's Blackbird nestlings and 25% of the energy

for Red-winged Blackbird nestlings. Although the diet of the 3 blackbirds overlapped considerably, competition for food was minimized by their different foraging techniques and microhabitats. The average size of prey delivered to nestlings by Brewer's Blackbirds from near the water (mostly damselflies) was much greater than the average size delivered from upland areas (midges, mosquitoes, and caterpillars). The importance of food taken near water was much greater (Horn 1968; Orians 1980; Orians and Horn 1969). These studies demonstrated the importance of damselflies in the diet of nestlings. In many areas, the Brewer's Blackbird may nest in drier locations where damselflies are scarce or absent in the diet. Martin (2020) reported that 634 food items collected from the gizzards of 78 Ontario nestlings consisted of 4% odonates, 11% orthopterans, 2% true bugs, 14% beetles, 61% lepidopterans, 1% flies, 1% hymenopterans, 3% spiders, 1% snails, and 1% miscellaneous. Of 500 items in Ontario, the diet consisted of 1% odonates, 6.5% orthopterans, 3% true bugs, 6.5% beetles, 1.5% caddisflies, 35% lepidopterans, 14% flies, 1% hymenopterans, 22% spiders, 3% snails, and 6.5% miscellaneous.

In Washington, adults foraging for nestlings usually ate the same foods (Orians 1980). In British Columbia, summer flocks often fed in fields on waste grain, weed seeds, and grasshoppers (Campbell et al. 2001). Beal (1900) analyzed the contents of 146 stomachs collected in every month except April. The diet consisted of 31.8% animal matter and 68.2% vegetable matter. The animal food was almost entirely insects except for a few spiders and snails. The insects were mostly beetles, ants, wasps, and grasshoppers. Beetles constituted 7.8% of the diet. These were mostly weevils which constituted 29% of the May diet but only 3.4% of the annual diet; ground beetles represented 1.7% of the annual diet. Hymenopterans comprised 2.5% of the annual diet but represented 14.8% of the August diet. These were mostly ants and wasps, with a few smaller parasitic species. Grasshoppers were the favourite animal food, constituting 16.1% of the annual diet and 47.5% of the August diet. Miscellaneous insects included flies, bugs, and caterpillars; these were not important in the overall diet. The vegetation consumed included 60.3% grain with all other vegetation representing only 7.9% of the diet. Grains consumed included oats, corn, wheat, and a little barley. The Brewer's Blackbird highly preferred oats which comprised about 75% of the grain consumed and was eaten in every month. It ate both waste and ripening grain and subsisted almost entirely on grain in winter. It has eaten newly sown wheat. The other vegetation consisted of weed seeds. The major prey item of birds foraging on Canada waterweed was recently emerged damselflies (Richardson 1947). Martin (2020) reported that 125 stomachs collected from all months in California contained 38% animal matter and 62% vegetable matter. Animal matter peaked at 100% of the diet in June and was lowest at 3% in December. Of 1,135 animal food items, all were insects except for 1 spider. Beetles, especially weevils, were the dominant insects in the diet. Vegetable matter peaked at 97% in December but was 0% of the June diet. It most frequently consumed grains, followed by weed seeds such as those of red-root amaranth, pale smartweed, duckweed, and barnyard grass. During insect outbreaks, the Brewer's Blackbird gorges on crickets, butterflies, treehoppers, alfalfa weevils, cutworms, termites during their dispersal flights, grasshoppers, corn earworm moths, and forest tent caterpillars. Six birds collected in June in Utah had eaten treehoppers, alfalfa weevils, clover leaf weevils, clown beetles, click beetles, grasshoppers, stink bugs, milkweed bugs, leaf bugs, aphids, leafhoppers, metallic wood-boring beetles, caddisflies,

caterpillars, fly larvae, ants, and spiders. It may feed on shore flies in the company of sandpipers (Williams in Bent 1958).

The Brewer's Blackbird is a host of the Brown-headed Cowbird that readily accepts the parasitic eggs and typically raises fledglings of both species. Despite egg removal by the cowbird, parasitism appears to have no significant effect on the Brewer's Blackbird (Martin 2020). One of 206 Ontario nests (0.5%) was parasitized (Peck and James 1998b). In British Columbia, 24 of 797 nests (3.0%) were parasitized and there were 5 reports of it feeding cowbird fledglings (Campbell et al. 2001). Parasitism rates reported elsewhere include 268 of 837 nests (32.0%) in Washington; 85 of 371 nests (22.9%) in Alberta, Saskatchewan, and Manitoba; 10 of 27 nests (37.0%) in Manitoba; 42 of 217 nests (19.4%) in Colorado and Wyoming; and 0 of 28 nests, 3 of 83 nests (3.6%), and 4 of 13 nests (30.8%) in California (Martin 2020).

Habitat loss and degradation do not appear to be limiting factors for the Brewer's Blackbird in Ontario or throughout its range. It has increased due to habitat modifications by humans. Fragmentation of forests by roads, railways, and utility corridors has allowed it to expand its range into formerly unsuitable or inaccessible habitats. It also benefitted from establishment of cattle feedlots and irrigation in arid areas (Martin 2020).

The Brewer's Blackbird and Common Grackle appear to be interspecifically competitive. In Ontario, the eastward expansion of the Brewer's Blackbird resulted in competitive exclusion of the grackle from long-occupied sites in rural settings dominated by grassy habitats. Grackles formerly nesting in grasslands were forced to move into marshes, but the Brewer's Blackbird was unable to encroach into suburban and urban habitats where the grackle remained dominant (Martin 2020). In the west, the Brewer's Blackbird declined in cities and towns and around farmsteads in apparent response to an increase in grackle populations. The Brewer's Blackbird appears to be dominant to the grackle in grassland habitats but subordinate near rural dwellings and human communities (Jones and Bock 2002; Martin 2020).

Human disturbance early in the breeding season may result in colonies being abandoned. In Washington, a colony was disturbed by large numbers of fishermen. This colony moved but still nested that year and used the same foraging areas (Horn 1970). Other colonies may not be able to successfully relocate if there is no nearby suitable nesting habitat or if foraging areas are too distant.

Some nests are destroyed by flooding in boggy areas and in emergent vegetation in reservoirs (Martin 2020).

In Saskatchewan, Pylypec (1991) examined the effects of fire in native fescue grassland on the Brewer's Blackbird. There were no significant differences in its abundance in burned and unburned plots. In Ontario, burning of grasslands improved conditions for foraging (Martin 2020).

The Brewer's Blackbird may be affected by climate change, particularly by increasing temperatures. Iron (1998) observed Brewer's Blackbirds near Coldwater when the temperature was 27°C. They were all panting but Red-winged Blackbirds and Common Grackles in the same area exhibited no evidence of heat stress. She surmised that the Brewer's Blackbird may not be able to tolerate heat and humidity and that these factors may have inhibited it from spreading throughout

southern Ontario. Price (2004) predicted that it could disappear as a breeding species in southern Ontario if the average summer temperature increased by 2°C.

Status

The Brewer's Blackbird experienced a significant eastward range expansion. Prior to the 1900s, its eastern distributional limit was in the Red River valley in Minnesota. Its occurrence further east was probably restricted by the broad band of forest that paralleled this valley. By 1800, the forest had already been removed from areas that it colonized later in Minnesota and Wisconsin, but range expansion was delayed until the intervening band of forest was removed around 1900. With its removal, range expansion was rapid and appeared to be accomplished by single birds or small groups pioneering to the nearest suitable habitat. Local populations became established at Fort Francis, Thunder Bay, Sault Ste. Marie, and Sudbury, presumably due to the increase in grassland habitat around these population centres. One route of expansion was north from Minnesota, which divided into northern and eastern routes. The northern route further subdivided into western and eastern routes, establishing populations in Fort Francis and Thunder Bay respectively. The eastern route resulted in colonies in the Sault Ste. Marie and Sudbury areas. The routes of expansion followed the main railways and highways linking human activity centres, with the Great Lakes and changes in vegetative cover acting as the main barriers to movement (Stepney and Power 1973). Power (1971) collected birds from Ontario and Manitoba and found no differences in skin and skeletal characteristics. Ontario birds do not represent a closed population and this supports the hypothesis that range expansion was a gradual movement into the nearest suitable habitat rather than long-distance pioneering. Once an area became densely populated, birds started to spread. Baillie (1967) concluded that it was possible that the birds that nested at Luther Marsh entered the province via southern Michigan. It started breeding 80 km west of the Detroit River as early as 1955.

The first record of the Brewer's Blackbird in Ontario was in June 1939 when a male was collected at Lake Attawapiskat, but there was no evidence of breeding. A male was seen at Thunder Bay in 1943 and the first nesting for the province was confirmed there in 1945. By 1955, it was established in 5 areas around the Lakehead and was fairly common in the Thunder Bay area by 1958. It nested near Fort Francis 1951-57 until fire altered the habitat. Nesting was confirmed at Sault Ste. Marie in 1953 and in the Sudbury area in 1962. In 1963, 13 groups as large as 8 birds were observed in a single day in 1963 along Highway 17 between Sault Ste. Marie and Sudbury. The Sudbury records represented an eastern range expansion in excess of 1,100 km. Nesting occurred at Luther Marsh in 1967, in Oshawa in 1968, and at Holland Marsh and near Coldwater in 1969 (Allin and Dean 1947; Baillie 1961, 1967; Devitt 1964; Power 1971; Stepney 1975a; Wood 1955). The first atlas indicated that the Brewer's Blackbird population declined sharply after 1975, but its distribution was still greater than in the late 1960s. In addition to the Sault Ste. Marie–Sudbury corridor, it bred in the south on Manitoulin Island and the Bruce Peninsula, at single locations on Lake St. Clair and near Point Pelee, and 2 sites south of Lake Simcoe. In the north, it continued to nest around the Lakehead and from Thunder Bay to Lake of the Woods and in the southern Boreal Forest Region north to Red Lake, east of Lake Nipigon, and Lake Abitibi. Highest densities occurred in the Sault Ste. Marie–Manitoulin Island area. It was locally common from the Manitoba border to Thunder Bay and from Sault Ste. Marie to the north shore of Lake Nipissing (Gordon in Cadman et al. 1987). James (1991) considered the Brewer's Blackbird locally uncommon Kenora to Thunder Bay, Sault Ste. Marie to North Bay, on

Manitoulin Island, and on the Bruce Peninsula; and rare north to Red Lake, Geraldton, and Timiskaming District, south to Point Pelee, and east to Prince Edward County. New colonies were found in Bruce County and Parry Sound District in 1991 and more than 100 pairs were observed in the southern half of Bruce County in 1993 (Crins and O'Donnell 1993; Peck and James 1998b).

The second atlas revealed that the breeding range of the Brewer's Blackbird had shrunk and become more discontinuous since the first atlas. It was not documented between the city of Thunder Bay and Rainy River District, in most areas of the southern Boreal Forest Region, and around the Lakehead. It was not found in many of the areas near Sudbury and on Manitoulin Island where it previously occurred and was absent in the extreme southwest. Its probability of observation decreased province-wide and in all regions where it occurred, but only the decline in the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region was significant. This was primarily due to a decrease in its occurrence between Sault Ste. Marie and Sudbury. There was an increase in detections on the Bruce Peninsula and in scattered areas east of Georgian Bay (Dunn and Gordon in Cadman et al. 2007).

The Brewer's Blackbird has experienced a rangewide decline in population, with a decrease of 35% since the Breeding Bird Survey (BBS) began in 1966 (McCracken 2003b). The rate of decline has levelled off in the United States. During 1966-98, it declined overall 4.0% per year, including declines of 0.7% per year in Canada and 5.3% per year in the United States. During 1980-98, the overall rate of decline was 1.9% per year, including declines of 1.0% per year in Canada and 2.1% per year in the United States (Martin 2020). BBS data indicate that it decreased at annual rates of 2.41% in Canada and 1.51% in Ontario 1970-2021. For 2011-21, it experienced annual decreases of 2.3% in Canada and 3.93% in Ontario. All results were highly reliable except that Ontario short-term trend was of low reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

When young leave the nest, they can fly distances of 0.9-2.1 m, and crouch low in the vegetation. In Ontario, fledglings have been observed on a wet hummock of small black spruce, leatherleaf, bog laurel, and sphagnum. In the Northwest Territories, they were seen among willow shrubs in a cleared area adjacent to a gravel airstrip (Crins and O'Donnell 1993; Martin 2020; Stepney 1979; Williams 1979).

Both sexes feed the fledglings and may continue to do so for as long as 26 days after they leave the nest. Fledglings join their parents in family groups. One to 2 weeks after fledging, several family groups coalesce into a flock that remains in the vicinity of the breeding area as the young develop independence at age 34-39 days. The fledglings are adept at flying by the time they are 23 days old. At this time, the flock of multiple families becomes more mobile and may either move a moderate distance from the breeding area or completely leave. Larger flocks form in August and congregate in good foraging sites, which are predominantly agricultural areas. Foraging flocks may mix with other blackbird species, including grackles, cowbirds, and Red-winged, Yellow-headed, and Rusty blackbirds (Campbell et al. 2001; Martin 2020; Williams 1952).

The Brewer's Blackbird begins to roost communally during the postfledging period. It roosts both solely with other Brewer's Blackbirds and with the other blackbirds that it forages with. In multispecies roosts, it tends to segregate from the other species and roost at margins of the roost.

Roosts may be in a variety of habitats including urban and suburban areas, marshes, woodlands, savannahs, broom-sedge fields, and on the ground in grain stubble. They are often along edges of open habitat such as on ridges, field edges, along edges of water, or along railway tracks or dykes. Most roosts are in dense upland cover including coniferous hedges, large coniferous trees, and riparian thickets. In wetlands, it roosts in cattails, bulrushes, or willows. One roost was on floating duck blinds. Large flocks assemble late in the day and then move en masse to the roost. Prior to roosting or after leaving the roost, birds often assemble on roadside utility wires (Campbell et al. 2001; Martin 2020; Williams in Bent 1958).

During the postfledging period, the Brewer's Blackbird eats grain and insects in open habitats such as lawns, pastures, feedlots, grain stubble, fallow land, burned fields, freshly plowed or disked fields, beaches, and mudflats (Martin 2020).

MIGRATION

The Brewer's Blackbird is a partial medium-distance migrant. It is a year-round resident in California, coastal Oregon, and southern British Columbia. Populations east of there are migratory. It migrates during the day in conspecific and mixed-species flocks containing cowbirds, grackles, European Starlings, and Red-winged, Yellow-headed, and Rusty blackbirds. When it travels with other species, the Brewer's Blackbird tends to move independently or at the edge of a larger flock, maintaining some segregation. Flocks in the northern part of the winter range are composed mostly of males, indicating that females migrate further south (Martin 2020). A bird banded east of Sault Ste. Marie in June was recovered in winter in Mississippi, a distance of 1,490 km (Brewer et al. 2018).

The winter range of the Brewer's Blackbird has expanded, probably due to the eastward expansion of its breeding range. In 1900, it occurred only sporadically east of the Mississippi River, but it is now established as a regular winter resident in the Gulf Coast states. Banding results suggest a general tendency for birds occupying the eastern portion of the breeding range to winter more to the southeast (Stepney 1975b).

Spring migration is rapid and birds arrive at the breeding grounds on predictable dates. Males tend to arrive several days in advance of females (Martin 2020). In southern Ontario, spring migrants have been observed from mid-March to late May, but mostly from mid-April to mid-May (Black and Roy 2010; Curry 2006; Lancaster et al. 2004; Weir 2008).

Autumn migration is much more protracted. Birds may start wintering in the more northern portion of their range and gradually withdraw southward as winter progresses and conditions deteriorate. The timing of the onset of winter greatly affects the location of the population. In the south, numbers may peak after Christmas Bird Counts (CBC) have been completed (Stepney 1975b). It is probable that some of Ontario's winter records are of late autumn migrants. A flock of 12 was seen at Longlac on 1 September (Devitt 1964). In southern Ontario, most migrants arrive around mid-October, but birds may be present from late August until January (Black and Roy 2010; Curry 2006; Lancaster et al. 2004; Weir 2008).

During autumn migration, habitat of the Brewer's Blackbird is similar to that used during the postfledging period. At this time, it forages with other blackbirds and has a predominantly vegetarian diet consisting of waste grain, weed and grass seeds, and stockyard spillage and waste

(Martin 2020). Habitats described for migrants in British Columbia are typical: pastures, plowed and stubble fields, berry patches, nurseries, barnyards, sewage lagoons, feedlots, garbage dumps, vacant lots, grassy roadsides, dykes, golf courses, railway lines, campgrounds, lawns, backyards with feeders, marshes, beaches, mudflats, lake shorelines, sedge meadows, riparian thickets, and bottomland forests (Campbell et al. 2001).

Communal roosts continue to be an important habitat component during autumn migration, and these are in similar areas as those used during the postfledging period. No migratory roosts have been reported in Ontario.

James (1991) considered the Brewer's Blackbird a rare to locally uncommon migrant. In Elgin County, it had not been observed by 1891; by 1954, there was a single record. By 2000, it was a very rare spring and autumn migrant with a total of 9 records (Lancaster et al. 2004). There are only 6 records of migrants for Niagara Region (Black and Roy 2010). Curry (2006) considered it a vagrant in the Hamilton area with a total of 20 records; it was first observed in 1958. The first record for Kingston was in 1972, where it is a very rare irregular migrant (Weir 2008). For Algonquin Park, there is 1 record for both spring and autumn (Tozer 2012).

WINTER

The winter distribution of the Brewer's Blackbird and its abundance appear to be dictated by snow cover. Most birds winter in areas that receive less than 2.5 cm of snow or that have 10 or fewer days of snow cover. It occurs in lower numbers in areas that receive as much as 63.5 cm of snow and snow cover persisting as long as 40 days (Stepney 1975b). Due in part to the effects of snow cover and snowfall, it has low fidelity to wintering sites. Birds commonly vacate areas used in previous years and move to more favourable locations as they become available (Martin 2020).

In winter, the Brewer's Blackbird uses habitat similar to the postfledging and autumn migration periods, with increased use of feedlots, fields of waste grain and stubble, and bird feeders. Communal roosts continue to be important habitat, with the Brewer's Blackbird representing about 2% of the blackbirds and starlings that roost in the United States in winter (Martin 2020). In California, abundance of the Brewer's Blackbird was positively correlated with grasses and feeders (Kalinowski and Johnson 2010).

In winter, the Brewer's Blackbird forages in flocks that may contain other blackbird species. There is a negative relationship between temperature and the amount of time spent foraging. In British Columbia, it spent 16 and 25% of its time foraging on 2 days when the temperature was +7.8°C, but 53% of its time at –0.6°C, 54% of its time at –1.1°C , and 56% of its time at –2.2°C. Food was unlimited, so temperature was the only variable that affected the amount of time spent foraging (Verbeek 1964). The winter diet is predominantly vegetarian. Although it frequently congregates and forages with the Red-winged Blackbird, there is little overlap in their diets (Martin 2020). The Brewer's Blackbird is a sporadic visitor to feeders and is most likely to visit them during spring migration. Nonetheless, a high proportion of late autumn and winter sightings in Ontario are at feeders. Favourite feeder foods include mixed seeds and cracked corn. Infrequent choices include water, striped and black oil sunflowers, and hulled peanuts (Dunn and Tessaglia-Hymes 1999).

The Brewer's Blackbird plays little role in crop depredation. Because it occurs in mixed winter flocks and roosts, it is subject to the blackbird control programs that are implemented in the southern United States. No information is available on how many Brewer's Blackbirds are killed by these programs (Martin 2020).

James (1991) considered the Brewer's Blackbird occasional and rare in winter in the south, north to Manitoulin Island, and also in the north at Thunder Bay, Schreiber, and Matachewan. It is uncertain how many birds persist throughout the winter, with many occurring early in the winter only. In Elgin County, there are 3 records at feeders spanning the period December through February (Lancaster et al. 2004). CBC data indicate that it decreased in Ontario at annual rates of 3.75% 1970-2021 and 4.53% 2009-21 (National Audubon Society 2022).

Common Grackle

Quiscalus quiscala

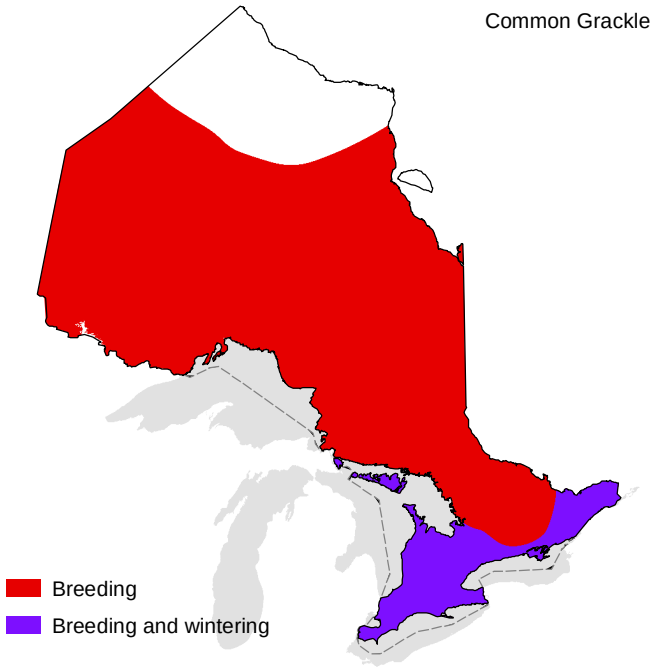
BREEDING SEASON

Habitat Requirements

Ontario Common Grackle nests were in woodlands (29.0% of nests); in urban and rural residential and recreational areas, including gardens, parks, farmyards, and golf courses (27.7%); wetlands, including marshes, beaver ponds, swamps, and bogs (25.4%); lake and river shorelines, islands, ditches, and dykes (9.7%); farmland, including pastures and abandoned fields (6.2%); sand dunes (1.2%); and rock cliffs (0.8%). Coniferous and mixed forests were selected slightly more often than deciduous stands. No noticeable preference was apparent for wet or dry areas. Nest-site availability was probably more important than the moisture regime (Peck and James 1987).

In the Boreal Forest Region, the Common Grackle was scarce near the town of Pickle Lake. It also nested on abandoned mine derricks (James 1980). Erskine (1977) reported that it preferred wetter

areas such as bogs and fens dominated by sedges and low shrubs such as sweet gale and willow. It also nested in farmland and old fields and the inner suburbs of Ottawa.



In the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region in Muskoka and Parry Sound districts, the Common Grackle shunned contiguous forests and bred in rural and residential areas, on small islands, in broken forests, and in bogs and beaver ponds (Mills 1981). In Algonquin Park, it nested along creeks and lakeshores, and in marshes, bogs, swamps, beaver ponds, forest clearings and open areas, and around human structures (MacLulich 1938; Tozer 2012). Martin (1960) reported it in both wet and dry bogs in Algonquin Park where it occurred predominantly from the top of the shrub layer to the tops of dead stubs. It occurred in low density in white birch–poplar–balsam fir–spruce stands.

In the Great Lakes–St. Lawrence Forest Region south of the Shield, Speirs and Orenstein (1975) reported the grackle in a young open forest with standing water, a black spruce bog surrounded by a red maple–poplar swamp, an open-canopy forest, a mature white cedar–elm swamp, a mature sugar maple–oak forest sloping down to a river floodplain, a mature beech–sugar maple forest, a sugar maple forest sloping down to an open white cedar–balsam fir–spruce swamp, and an old beech woodlot with a pond and creek. In Toronto, it nested in residential areas including recent subdivisions with no vegetation, areas with trees taller than 9 m lining the streets, and areas where most vegetation was lower than 9 m and formed an open canopy. Subdivisions had either 1-storey or 2-storey homes in differing densities (Savard and Falls 1981). At Luther Marsh, it originally nested in dead stubs over water, in cavities in flooded timber, in willow shrubs, and rarely in Wood Duck nests (Boyer and Devitt 1961). Once the coniferous plantations around the marsh matured, they became the preferred nesting habitat, although the other habitats were still used sparingly (Sandilands 1984).

In the Carolinian Forest Region, McIlwraith (1894) concluded that the grackle preferred to nest near water. It was very common at that time, breeding close to the banks of the Grand River in Cambridge. He also reported a colony nesting in a Norway spruce at a Hamilton residence.

In Great Lakes coastal wetlands, the Common Grackle was positively correlated with wetland cover and the amount of urban and agricultural land in the watershed. It was not affected by water levels (Tozer et al. 2024).

South of the Shield in southern Ontario, abundance of the grackle was negatively correlated with the amount of forest cover more than 100 m from edge, woodlot size, and the amount of

regional forest cover. It was positively correlated with the amount of forest cover within 2 km. All relationships were nonsignificant (Austen et al. 2001). There was no significant difference in its abundance on organic and conventional farms. It was positively correlated with farmsteads, hayfields, pastures, woods, row crops, and spring grain. It was negatively correlated with the biomass of crops and herbicides (Kirk et al. 2011).

The Common Grackle nests in a variety of habitats. These include urban parks, ornamental trees and shrubs near buildings, red cedar groves and savannahs, dense stands of conifers including plantations, buttonbush and willow thicket swamps, riparian forests along watercourses and lakeshores, roadside trees and shrubs, cattail and common reed marshes, botanical gardens and university campuses, shelterbelts, white cedar groves and plantings, Christmas tree plantations, field borders and hedgerows, open woodlands and forest edges, treed and shrub swamps, pine and oak barrens, brush prairies, oak savannahs, sewage lagoons, shrub carrs, alder thickets, flooded woods, old fields and meadows with some tree or shrub cover, bogs and fens, drainage ditches, orchards, cemeteries, pastures, hayfields, young strip-cuts and clear-cuts, along railway and utility corridors, and in or on buildings and bridges. It most commonly nests near water, agricultural fields, and buildings. In Illinois, it preferred edge shrubs, hedgerows, marshes, and agricultural areas but was found in all habitat types that were surveyed (Bent 1958; Campbell et al. 2001; Conover et al. 2009; Erskine 1977; Falardeau et al. 1999; Graber and Graber 1963; Gross in Bent 1958; Hoffman 1989b; Homan et al. 1996; Howe 1976, 1978; Karr 1968; Lenington and Scola 1982; Maddox and Weatherhead 2012; Maxwell 1970; Mossman 1988; Mossman and Hoffman 1989; Mossman et al. 1991; Peer and Bollinger 2020; Petersen and Young 1950; Snelling 1968; Suthers 1988; Wiens 1965; Yahner 1982).

Several studies described the habitat of the Common Grackle at the landscape level. Peer and Bollinger (2020) reported that it avoided extensive mature woodlands. Taylor and Taylor (1979) concluded that it was restricted to large and small woodland openings and edges. In North Dakota, it nested in areas with 2-22% forest cover. In the mid-Atlantic states, it was significantly negatively correlated with the amount of forest cover within 2 km (Robbins et al. 1989). Its distribution in the Maritime Provinces corresponded well with the distribution of agriculture. It was less abundant in the main agricultural areas of Nova Scotia where the fields were larger, there were fewer hedgerows, and there were fewer abandoned buildings for nesting (Erskine 1971). The Quebec atlases determined that it was most abundant in urban and agricultural landscapes, particularly in the St. Lawrence Lowland. It was associated with areas populated by humans. It was much less abundant in the Boreal Forest Region where it was associated with swamps, beaver ponds, edges of other water bodies, clearings, roads, clear-cuts, resorts, and other human structures (Alvo in Gauthier and Aubry 1996; Denault in Robert et al. 2019). In Ontario, the grackle is most abundant south of the Canadian Shield where the landscape is dominated by agricultural and developed landscapes (Zimmerling in Cadman et al. 2007).

Several studies examined microhabitat preferences of the grackle. In Mississippi, it was equally abundant in fields with no vegetated borders and those with borders 10 m and 30 m or more wide (Conover et al. 2009). In Illinois on reclaimed strip mines, it was common in early shrub habitat where the oldest trees were 10 years old and absent in late shrub habitat where the trees were 37 years

old (Karr 1968). In New Jersey successional fields, it occurred in those that were 10, 20, and 40 years old. It was most abundant in the 20-year-old field which had the greatest diversity of shrubs, saplings, and herbaceous vegetation (Suthers 1988). In South Dakota green ash woodlots, it was 6.5 times more abundant in early than late forest seral stages. Younger stands had less chokecherry coverage in the understorey, more patchy distribution of woody vegetation from less than 1 to 2 m tall, and a more open and patchy canopy (Rumble and Gobeille 1998). In British Columbia, most nests were in wetlands near pastures or farmland (Campbell et al. 2001). In the Prairie Pothole Region of Iowa, its abundance was positively correlated with the percentage of a wetland that was marsh or wet meadow vegetation (Fairbairn and Dinsmore 2001a, 2001b). In Wisconsin, Wiens (1965) compared the nest sites of the Common Grackle and Red-winged Blackbird in a cattail marsh. Nests of both species were usually on edges of cattail clumps bordering on open water. Grackle nests were in denser cattail clumps and slightly lower than Red-winged Blackbird nests. Grackle nests were somewhat hidden and usually shaded. Red-winged Blackbird nests were usually exposed and well lighted. Homan et al. (1996) and Yahner (1982) studied usage of shelterbelts by the Common Grackle in North Dakota and Minnesota. More than 50% of birds nesting in multi-row shelterbelts in these 2 states were grackles. It used single-row windbreaks, but only in proportion to their availability. It highly selected shelterbelts. In North Dakota, shelterbelts of inhabited farmsteads were used more frequently than expected; pothole wetlands, woods, ravines, railway corridors, and lakesides were used less than expected; and abandoned farmstead shelterbelts, pastures, towns, and windbreaks were used in proportion to their availability. Nest sites 100 m or less from a farmstead were used more than expected. Those further away from a farmstead were used less than expected. Colonies were significantly larger in inhabited than abandoned farmsteads. Stands 0-300 m from a residence were used significantly more than those further away. Nest sites 301-500 m from water were used more frequently than expected; those further away were used less than expected. Shelterbelts containing Siberian elm, green ash, Manitoba maple, caragana, hawthorn, blue spruce, lilac, and white elm were more likely to be colonized than those consisting of willow, cottonwood, and trembling aspen. Within colonies, tree species were not used according to their availability. Blue spruce, Siberian elm, and black poplar were used more than expected. Green ash, willow, white elm, trembling aspen, Russian olive, and cottonwood were used less than expected. The preferred trees are profusely branched which aids in nest attachment and concealment and possibly a warmer microclimate. The avoided species had a scarcity of secure nest attachment sites. The grackle also displayed a preference for taller vegetation. Higher nests may be safer from predators and tall vegetation offers good perch sites. In Minnesota, the preferred conifers for nesting were blue spruce and white spruce with white cedar, red pine, and Douglas-fir seldom used. The preferred deciduous species were eastern cottonwood, silver maple, and Manitoba maple. In order of preference, it selected Manitoba maple, blue spruce, white spruce, cottonwood, silver maple, and ponderosa pine. Species that it avoided included green ash, tartarian honeysuckle, white cedar, jack pine, caragana, Amur maple, Norway spruce, white elm, willow, buffalo-berry, flowering crabapple, common lilac, red elderberry, highbush cranberry, river birch, honey locust, and chokecherry. The grackle used 16 of 25 available plant species for nesting and was a generalist. Shelterbelts may provide important habitat where trees are otherwise scarce. In Minnesota, grackle nests represented 54.3% of all nests within shelterbelts. The Mourning Dove, Gray Catbird, American Robin, and Chipping Sparrow were also common. Nests of these 5 species comprised 95.5% of all nests. Yahner (1982) compared the

nest sites of these species. Mean height of grackle nests was 6.27 m, significantly higher than the other species; tree canopy diameter was 2.43 m, significantly lower; height of ground cover was 0.30 m, significantly less; 39.3% closure by vegetation within 1 m of the nest, significantly lower; height of nest tree or shrub 10.07 m, significantly higher; and 0.08 cm diameter of the largest woody stem touching the nest, significantly larger. Grackle nests were 0.23 m from the trunk, significantly less than for the Mourning Dove and Chipping Sparrow; had 44.8% herbaceous vegetation within 1 m, significantly less than for the catbird, robin, and Chipping Sparrow; had 0.36 woody stems less than 2.5 cm within 1 m, significantly less than for the catbird and Chipping Sparrow; and had 0.14 woody stems larger than 2.5 cm within 1 m, significantly lower than for the catbird. Grackle nests were typically high above the ground and exposed, catbird and Chipping Sparrow nests were close to the ground and concealed by herbaceous vegetation, and Mourning Dove and robin nests were intermediate in height and percent herbaceous cover. The shelterbelts were sufficiently heterogeneous to allow these 5 common bird species to select distinct nest sites, resulting in high densities of nests.

In forested habitat, the Common Grackle is an edge species but may penetrate further into the forest if there are gaps in the canopy or flooded areas. In North Dakota shelterbelts, nests were placed randomly with respect to distance from edge (Homan et al. 1996) and the same was true in Wisconsin white cedar stands (Petersen and Young 1950). In Maryland and Delaware riparian forests, there were no significant differences in its probability of detection in forests 50-800 m wide (Keller et al. 1993).

The Common Grackle is not an area-sensitive species, frequently nesting in isolated trees. In Iowa marshes, Brown and Dinsmore (1986) observed it in 67% of wetlands smaller than 1 ha and in 92% of those larger than 20 ha. They considered it area independent. In red maple swamps in Rhode Island, it was more abundant in stands smaller than 1 ha than those 1-5, 6-10, or 11-20 ha (Golet et al. 2001).

Communal roosts are used by the Common Grackle most of the year except during the early stages of the breeding season. It leaves the large multispecies roosts prior to settling on the breeding site. Even during the breeding season, small numbers of grackles may roost together. From late March through May in New Jersey, most birds roosted solitarily but some roosted in scattered groups of less than 12 birds. In mid- to late April, 8-10 roosted in a clump of switch cane in a backyard. Another roost in a backyard white pine supported 2 grackles, 2 robins, 3 starlings, and 2 cowbirds. The grackle appeared at roost sites earlier in the year than the other species (Stewart 1975a). Larger postfledging roosts start to form in early June in New Jersey (Caccamise and Fischl 1985). Roosts may not become well established in southern Ontario and Quebec until mid-July (Alvo in Gauthier and Aubry 1996).

One Ontario nest (0.2% of nests) was on the ground at the base of a stump in a bog and the remainder were elevated. Most (53.5%) were in trees, shrubs, and vines; 21.4% were in or on human-made structures including houses and other buildings, bridges, towers, dams, bird houses, posts, trellises, duck blinds, boards, and a bucket; 13.9% were in cattails, sedges, bulrushes, or grasses; 8.3% were on stumps and logs; 2.2% were in upturned and exposed roots; and 0.5% were in crevices and on ledges of cliffs. Nest trees and shrubs were usually living but sometimes dead. Coniferous species

(7 species, 60.4% of nests) were preferred to deciduous species (23 species, 39.6% of nests). Tree and shrub species most frequently selected included cedars (117 nests), spruces (104 nests), pines (68 nests), willows (65 nests), junipers (36 nests), and hawthorns (33 nests). Many nests in trees and shrubs were in crotches. Fewer were on horizontal branches and some were supported between 2 or 3 adjacent trunks. Most were centrally located at or near the trunk. Others were 0.3-6 m from the trunk, mostly 1.2-3.7 m. Forty-nine tree nests were in old woodpecker and natural cavities. New nests were usually built each year, but old nests were occasionally repaired and reused, one for 4 consecutive years. Three nests were on top of old grackle nests, and old American Robin nests were used on 3 occasions. Two nests were in the base of an Osprey nest and one was in the base of a Great Blue Heron nest. Elevated nests were 0.2-18 m from the ground, with most 1.2-4 m up (Peck and James 1987). Axtell (1955) reported a grackle nest on an occupied beaver lodge in Algonquin Park, among the sticks slightly below the top of the more steeply sloping side. The pond was a flooded black spruce–leatherleaf bog that supported several pairs of grackles. Most had their nests within a few cm of the water and the bottom of one nest was in water. Another nest was 2.1 m up in a hollow stub standing in the water. Nests have been found in Muskoka and Parry Sound districts on buildings and bridges and in bird houses at heights of 0.3-14.3 m (Mills 1981). In residential areas in Toronto, all grackle nests were in conifers although deciduous species were common. They were at heights of 3.66-12.19 m above ground (average 6.55 m). It nested much higher in urban areas than nonurban areas. At 1 site where more than 45% of trees were taller than 9 m, average nest height was significantly higher (8.53 m) than at other sites (6.20 m). Nest height was independent of house density. It appeared to select the most suitable cover available, nesting over a wide range of heights. The exclusive use of conifers probably occurred because deciduous species had not leafed out when nest-site selection occurred. It nested at greater heights in urban areas because suitable low vegetation was less abundant in this habitat (Savard and Falls 1981). Peck and James (1998b) reported 2 nests in a marsh that contained buried Red-winged Blackbird eggs, suggesting that grackles had built their nests on occupied Red-winged Blackbird nests.

Almost all Common Grackle nests reported elsewhere were elevated in trees, shrubs, vines, and aquatic emergent vegetation, or were on or in human-made structures. It is a generalist, nesting in a wide variety of species. Maxwell et al. (1976) summarized 2,601 nests reported to the Cornell Lab of Ornithology. Conifers were highly preferred as a nesting substrate, supporting 62.5% of nests, probably because these provide better cover early in the spring. The remaining nest substrates included 27.4% deciduous trees, 7.8% shrubs, and 6.3% other locations. Red cedar was selected most frequently of the coniferous species, followed by Scotch pine, yew, red pine, juniper, blue spruce, white pine, white cedar, and Norway spruce. Osage orange was the preferred deciduous tree, followed by willow, crabapple, apple, mulberry, oak, and poplar. Honeysuckle was the most frequently used shrub, followed by buttonbush, lilac, bayberry, and dogwood. Other locations included bridges, cattails, nest boxes, buildings, towers, tree cavities, snags, stumps, vines, on a channel marker, under a pail, on a power pole, on a cliff, on a farm implement, and on a railroad bed. In Cape Breton Island, 55.6% of nests were in trees and shrubs less than 4.6 m tall (28.2% in alder, 11.1% in hawthorn, 7.7% in willow, and 8.5% in other), 6.0% were in trees or tree stubs, 11.1% were in abandoned buildings (mostly barns), and 27.4% were on road or railway bridges. Results were biased because fieldwork was conducted only along rivers (Erskine 1971). Other species and

locations where nests have been reported include Siberian elm, Manitoba maple, white elm, cottonwood, sycamore, gooseberry, on top of an active House Sparrow nest, in a roll of fence wire in a marsh, in flooded dead timber or shrubs, in active Osprey nests, in vines on the sides of buildings, and on barn beams with Barn Swallows (Alvo in Gauthier and Aubry 1996; Bent 1958; Campbell et al. 2001; Gross in Bent 1958; Gutzwiller and Anderson 1986b; Hamilton 1951; Homan et al. 1996; Peer and Bollinger 2020; Petersen and Young 1950; Rand and Rand 1952; Yahner 1982). Nests in trees and shrubs may be suspended between 2 or more upright trunks, on lateral branches, in deep crotches, or less frequently, in natural and Pileated Woodpecker cavities. In red cedars in Ohio, most nests were at ends of branches in dense foliage or in a main fork of a horizontal branch. Nests have been reported 0-22 m from the ground or water. Nest height is determined by the available substrate, with the grackle being adaptable enough to adjust its nest height to the vegetation height. In New York, mean nest height was 2.3 m in conifers, 3.3 m in deciduous trees, and 1.8 m in shrubs. Nests were 1.5-8 m (average 3.3 m) from the ground in planted spruce in Michigan and at heights of 1-2 m in a buttonbush swamp. Average nest height was 50.8 cm (range 22.9-68.6 cm) in a Wisconsin cattail marsh. Most British Columbia nests were 0.5-1.2 m up (range 0-16 m). Nests in red cedar averaged 6.1 m from the ground (range 2.1-10.7 m; Bent 1958; Campbell et al. 2001; Gross in Bent 1958; Howe 1976, 1978, 1979; Maxwell 1970; Maxwell et al. 1976; Petersen and Young 1950; Wiens 1965).

The grackle defends only a small area around the nest and may nest singly or in loose colonies. In Ontario, the average size of 310 colonies was 8 nests with most nests at least 4.6 m apart. An exception was a larger leafy structure that resembled a squirrel drey that was used by 2 nesting grackles simultaneously (Peck and James 1987, 1998b). A colony in a coniferous plantation at Luther Marsh supported 40-50 nests (Sandilands 1984). In Michigan, nests were either more than 15 m apart or clumped 1-3 m apart. In North Dakota, 202 colonies contained an average of 18 nests. British Columbia colonies contained 2-13 nests. As many as 10 grackle nests have been reported in a single Osprey nest; 12 nests were in a large Manitoba maple, some within 60 cm of each other; and 28 pairs nested in a Norway spruce (Bent 1958; Campbell et al. 2001; Gross in Bent 1958; Homan et al. 1996; Howe 1978, 1979). As soon as the nest site is selected, the pair defends it against other pairs. Defence is initially intermittent because birds do not remain close to the nest site until nest building begins. Strongest territorialism occurs by the male during nest construction. Later in the nesting season, grackles may visit other nests without encountering aggression even when the other adults are present. There is little to no agonistic behaviour away from the nest site. The entire colony mobs potential predators. Males defend their females from other males and females, even away from the colony. The male keeps in close contact with the female by perching near her, following her, and engaging in mutual displays (R.W. Ficken 1963; Howe 1976, 1979; Lenington and Scola 1982; Maxwell 1970; Wiens 1965). Wiens (1965) studied territorial interactions of Common Grackles and Red-winged Blackbirds nesting together in a Wisconsin cattail marsh. Interactions between the species occurred most frequently during the early part of courtship prior to initiation of nesting. Most were initiated by the Red-winged Blackbird in connection with grackle courtship flights or efforts to feed fledglings in blackbird territories. Seven to 10 days after the beginning of grackle courtship, flights were distinctly oriented to the edges of blackbird territories or areas of poorly defined territories with no penetrations more than 3 m into blackbird territories. Grackles in these

areas were largely ignored or avoided by blackbirds. Blackbirds did not respond to grackle fledglings within their territories, but adults arriving to feed them were displayed to or chased. Courtship, pair formation, and nesting success of the grackle was unaffected by Red-winged Blackbirds although blackbirds may affect the distribution of grackle nests. Grackles were rarely aggressive to blackbirds but dove at them if they approached within 0.6-0.9 m of the nest; blackbirds 1.2 m from the nest were tolerated. Snelling (1968) studied the same wetland and did not observe any spatial segregation of blackbirds and grackles. Home range sizes have not been defined for the Common Grackle, but they may be quite large. It may forage 0.5-1.6 km or further from the nest (Alvo in Gauthier and Aubry 1996; Howe 1979). Birds may also fly considerable distances to their nocturnal roosts.

All information on natal philopatry is from general banding data rather than site-specific return rates. Fankhauser (1971a) reported that 311 of 389 birds (82.1%) banded as young were recovered in the same 10-minute block. Moore and Dolbeer (1989) reported that 76.3% of 955 young were recovered within 20 km of the banding location, with the longest dispersals 2,621-2,640 km from the banding location. Peer and Bollinger (2020) reported that the mean dispersal distance from the natal area was 17.1 km for males and 29.8 km for females. A young banded in Ontario was recovered during the breeding season 6 years later in Nebraska, a distance of 2,084 km (Brewer et al. 2018).

Adult site fidelity appears to be high, with birds probably returning to the same area to breed each year. Ninety-two percent of adults were recovered in the same 10-minute block in which they were banded: 91.1% of males and 94.0% of females (Fankhauser 1971a, 1971b). Moore and Dolbeer (1989) reported that 87.1% of males and 89.3% of females were recovered within 20 km of the banding location. The longest records for dispersal were 2,281-2,308 km for males and 1,221-1,240 km for females. The average dispersal distance for adults was 111.4 km per generation.

Limiting Factors

Eggs have been reported in Ontario nests from the beginning of April until mid-July, with most present in the last 3 weeks of May (Peck and James 1987). In Algonquin Park, nests are under construction from late April to early June, eggs are present from early May to early July, nestlings are present from early June to mid-July, and dependent fledglings have been observed from mid-June to late July (Tozer 2012).

Courtship begins as soon as females arrive. Once pairs are formed, nest-site selection occurs. Of 11 nests that were completed in Ohio, only 4 (36.4%) were used. The time required to build a nest ranges from 4 days to 1.5 months. Nests that take extended periods to build are usually started early in spring and worked at only sporadically. In Wisconsin, it took an average of 11 days to complete a nest in 1 year and 14 days the second year. Egg laying may start the day after the nest is complete but as many as 11 days may elapse before egg laying occurs (average 3 days). In the Maritime Provinces, the initiation of egg laying was 5-7 days after the daily mean temperature reached 6°C. Eggs are laid at the rate of 1 a day, although a day is occasionally skipped. Incubation tends to begin with the laying of the last egg in 3- and 4-egg clutches, and with the fourth egg in 5- and 6-egg clutches. Incubation periods of 11-14 days have been reported in Ontario, mostly 12-13 days. Elsewhere, incubation periods of 11-15 days have been reported (mean 13.5 days). The first 3 eggs usually hatch in close succession within 24 hours, the fourth egg often hatches a day after the first

one, and the fifth egg usually hatches 1-2 days after the first egg. The nestling period is 10-18 days but mostly 12-15 days. Those that leave the nest before age 12 days were probably disturbed and have low survival probability (Erskine 1971; R.W. Ficken 1963; Gross in Bent 1958; Howe 1976, 1978, 1979; Maddox and Weatherhead 2012; Maxwell 1970; Maxwell and Putnam 1972; Maxwell et al. 1976; Peck and James 1987; Peer and Bollinger 2020; Petersen and Young 1950; Wiens 1965).

Although the Common Grackle may raise 2 broods in Illinois, it is single brooded in most areas, including Ontario, Quebec, Michigan, and Wisconsin. Renesting is common if the first nest fails (Alvo in Gauthier and Aubry 1996; Gross in Bent 1958; Howe 1976, 1978; Peck and James 1987; Peer and Bollinger 2020; Wiens 1965). Clutches of 2-6 eggs have been reported in Ontario, with single clutches of 7 and 9 eggs. The 9-egg clutch was probably from more than 1 female. A tenth egg was laying on the ground. Average clutch size was 4.2 eggs; 4-egg clutches were most frequent, followed closely by 5-egg clutches (Peck and James 1987). Overall, clutch sizes of 2-7 eggs have been reported, with clutches of 4 and 5 eggs most frequent. Mean clutch sizes include 5.00 and 4.70 in Nova Scotia, 4.76 and 4.49 in Prince Edward Island, 4.44 and 4.33 in New Brunswick, 4.33 and 5.00 in Saskatchewan, 4.3 and 4.7 in Ohio, 4.9 and 4.26 in Illinois, 4.5 and 4.8 in Michigan, and 4.4 and 4.9 in Wisconsin. Clutch size tends to decrease as the season progresses, but not in every year or location (Bent 1958; Erskine 1977; Gross in Bent 1958; Horsley and Ward 2021; Howe 1976, 1978; Maxwell 1970; Petersen and Young 1950; Wiens 1965). Brood reduction often occurs. Young from the fourth to sixth eggs are frequently one half to two thirds the weight of the first 3 nestlings, due in part to hatching asynchrony. This is despite the fact that later-laid eggs are larger, thereby providing more nutrients and water. The fifth egg in 5-egg clutches is female biased and the sixth egg in 6-egg clutches is male biased. Male nestlings are heavier than female nestlings and require more nutrients for successful fledging. Brood reduction results in differential starvation of males that hatch 1-2 days later than siblings, resulting in a female-biased sex ratio at fledging. Of 20 young that died in Michigan nests, 60% were from the last egg and an additional 15% were from the penultimate egg. No adults that started with a clutch of 6 fledged more than 5 young and broods of 4 and 5 typically lost 1 young before fledging. In 63 nests, 65 of 292 young (22.3%) starved: 0 of 15 from broods of 3, 19 of 88 (21.6%) from broods of 4, 34 of 165 (20.6%) from broods of 5, and 6 of 18 (33.3%) from broods of 6. Only 30% of adults with broods of 5 fledged all young. The grackle has 2 adaptations to rear as many young as possible: increased egg size with the laying sequence and hatching asynchrony. This allows it to maintain the brood for as long as possible, but to allow later-hatching and smaller young to starve if food supplies are inadequate. These young often die by the time they are 4 days old, ensuring an adequate food supply for the remainder of the brood (Howe 1976, 1978; Maddox and Weatherhead 2012).

The age at first breeding has not been determined (Peer and Bollinger 2020), but is probably 1 year. The male is predominantly monogamous, but polygyny occurs. About 50% of males abandon the female while she is incubating and some interact with other females. In Michigan, 2 of 12 males (16.7%) were polygynous in 1 year and one may have had 3 subsequent mates. In the second year, 0 of 15 males were polygynous for a 2-year total of 2 of 27 males (7.4%) being polygynous (Howe 1976, 1978, 1979; Peer and Bollinger 2020). Intraspecific egg dumping is a rare breeding strategy (Bent 1958; Peck and James 1987; Peer and Bollinger 2020). This strategy is unlikely to be successful

because not all eggs would be adequately incubated in extra-large clutches and many young would be lost due to starvation.

The Common Grackle is an omnivore that eats a wide variety of vegetable matter, invertebrates, and vertebrates. It is quite adaptable in its foraging behaviour. It mostly forages on the ground while walking, but also in shrubs and trees. Occasionally, it flies 30 cm up from the ground to capture a flying insect. It uses its bill rather than its feet to uncover food on the ground. The main foraging habitats include woodlot edges, agricultural fields, and urban open spaces and residential areas. Those breeding in marshes mostly forage in adjacent upland habitats, especially woodlots, but capture some dragonflies and damselflies within marshes. In the Boreal Forest Region, it forages mostly in marshes and bogs and this adaptability has allowed it to breed within this area. Its lower density in the boreal forest suggests poorer feeding opportunities than in open arable lands (Bent 1958; Erskine 1971; Howe 1976; Peer and Bollinger 2020; Wiens 1965). In urban areas, it is often a scavenger, picking up crumbs and waste from human foods from the ground, patrolling areas of high human pedestrian concentrations. It also flies into dumpsters to obtain waste food. When bread or crackers are dry and stale, it often soaks them in water to soften them prior to eating them. This appears to be a learned habit, with some birds doing it regularly even if the bread is fresh and others not doing it at all. Dunking by some individuals is common in some areas but does not occur in other areas. Fruits, meat, and insects may be washed by some individuals. On lawns, it often watches robins and steals earthworms that they capture (Bent 1958; Davis 1944; Peer and Bollinger 2020; Pitocchelli 1985; Rand 1967; Wible 1975). There are numerous accounts of the grackle capturing live fish or scavenging dead ones. It uses a variety of fishing techniques. These include flying from a perch near the water and hovering above fish to capture them with the beak, attacking fish from driftwood floating in water, occasionally diving into the water, fishing in deep turbulent water in the manner of gulls and terns, and wading in water and plunging the head under water to obtain fish or crayfish. It appears to prefer live fish to those that are dead. It has captured live golden shiners, common shiners, emerald shiners, threespine sticklebacks, and unidentified minnows. It has eaten dead goldfish, alewives, gizzard shad, and yellow perch (Beeton and Wells 1957; Cahalane 1944; Cottam 1943; Darden 1974; Follett 1957; Iron 1997; Townsend 1919; Zottoli 1976). The Common Grackle often preys upon eggs and nestlings of other birds. It also kills adult birds, often eating only the brain and flesh on the head. This behaviour is most prevalent during winter when food supplies are low, but occurs at all seasons. Its most frequent victim is the House Sparrow, but it has killed American Woodcocks, Barn Swallows, Ruby-crowned Kinglets, American Robins, White-throated Sparrows, and Ovenbirds. It has been observed eating Pine Siskins and American Goldfinches, but it was uncertain whether the grackles killed them (Cummings and Cummings 1989; Davidson 1994; Green 1990; Gross in Bent 1958; Laporte 1974; Middleton 1977c; Taylor 1958). It also attacks, kills, and eats small mammals such as mice and masked and short-tailed shrews. One was observed dive-bombing a bat in mid-air, driving it to the ground, stabbing it with its beak, and flying off with it (Gross in Bent 1958; Mueller 1990; Sparks and Choate 1995). Vogt (1979) observed grackles feeding in association with map turtles in Wisconsin. They removed leeches (the smooth turtle leech) from the leg cavities of turtles while they were basking. The grackle also consumes hatchling turtles in large numbers as they move from their nests to the water. Several other miscellaneous foraging behaviours have been documented. One flock was observed feeding on sphinx moth

caterpillars in a tobacco field. At High Park in Toronto, it captured amphipods in a pond, gathering several together in a pile before eating them. At a small pond, it caught, killed, and devoured small leopard frogs (Gross in Bent 1958). The grackle is highly adapted for opening acorns. It has a specialized keel on its palate that it uses to apply pressure to the acorn, producing an indentation in it. The acorn is rotated and the process repeated until the acorn falls in half. It is capable of opening the acorns of black, Hill's, scarlet, bur, and pin oaks but cannot open the larger acorns of white and red oaks (Schorger 1941). In Niagara Region, it was observed eating chinquapin oak acorns (Sheppard et al. 1936).

In New York, adults often flew 800 m to obtain food for nestlings even though the same food could have been obtained near the nest. Birds at 1 nest flew about 500 m to obtain dead alewives to feed their young even when they were available within a few metres (Hamilton 1951). Females without male assistance are capable of raising a brood of 4 young (Howe 1979; Maxwell and Putnam 1972; Snelling 1968). Young in all nests at a pond in Algonquin Park were fed mostly dragonfly nymphs (Axtell 1955). Young at Michigan nests were fed mostly arthropods, including beetles, odonate nymphs, mayflies, stink bugs, geometer moth caterpillars, crayfish, isopods, spiders, and earthworms; some corn was consumed (Howe 1979). Zottoli (1976) observed adults feeding juveniles pieces of fish. Hamilton (1951) analyzed 130 nestling fecal samples and observed adults feeding their young. Green frog tadpoles were captured in a pond and fed to the nestlings. They were also fed red-backed and dusky salamanders. Parts of a newborn meadow vole and a masked shrew were fed to nestlings. Animal food comprised 89.5% of the volume of nestlings' diet: 48.2% insects, 10.9% earthworms, 8.3% amphibians, 6.6% fish, 5.4% spiders, 0.8% millipedes, 3.4% isopods, 0.3% mammals, and 5.2% snails. Other materials included 3.2% green grass, 1.8% fruit, 1.4% grain, and 4.3% grit. Beetles were the most important insects, appearing in 42.5% of samples. These were predominantly June beetles but ground beetles, click beetle larvae, and small scarab beetles were also consumed. Caterpillars comprised 40.3% of the volume of food and occurred in 52.4% of nestlings that had been fed insects. True bugs, mostly stink bugs, were present in 16.7% of nestlings that had consumed insects. A few ants and a single scorpionfly were consumed. Spiders were frequently fed to smaller nestlings to age 4 days. The grain that was consumed was waste; the fruit was raspberries. Beal (1900) analyzed the diet of 456 nestlings. They had eaten 74.4% animal food and 25.6% vegetation. The animal food consisted of 70% insects and its composition was practically the same as the adult diet. Beetles were fed to older nestlings only, with grubs forming more than 19% of the diet along with 10% ground beetles, 3% weevils, and 5 or 6 other families of beetles totalling less than 1% of the diet. Grasshoppers and crickets were favoured and constituted more than 21% of the diet. Adults selected grasshoppers and other soft-bodied insects for their young and ate beetles and other hard items themselves. Caterpillars comprised 6% of the nestling diet and small amounts of ants, flies, bugs, mayflies, centipedes, and spiders were given to young. Spiders were given to young birds shortly after they hatched. In Wisconsin, Snelling (1968) compared the diets of nestling grackles and Red-winged Blackbirds in a cattail marsh. The nestling period of the 2 species overlapped 23-60% over 6 years with a trend toward decreasing overlap. The grackle was a recent arrival as a breeder in the marsh, so the 2 species may have evolved to minimize the overlap in their nestling periods. Both species were diverse and unspecialized feeders and ate similar-sized prey (mean of 9.79 mm for the grackle and 10.09 mm for the blackbird). There was a 52% overlap in

the diet of the species when they were feeding nestlings. Significant competition for food seemed unlikely. The food for them was abundant and they used somewhat different foraging techniques. Earthworms and scarab beetles were important foods for the grackle but were not eaten by Red-winged Blackbirds. The most important foods for grackle nestlings by volume were 9.13% earthworms, 5.26% skimmers (dragonflies), 27.19% scarab beetles, 13.78% owlet moths, 3.57% geometer moths, 3.55% fulgorid planthoppers, 7.01% fish, and 12.82% bread. Other food items included nematodes, snails, harvestmen and spiders, isopods, crayfish, other beetles (rove, click, darkling, and June beetles and weevils), book lice, other lepidopterans (gossamer-winged butterflies and snout, twirler, and ermine moths), flies (midges and crane, soldier, bristle, and big-headed flies), hymenopterans (ants and sawflies), leafhoppers, true bugs, seeds, and human foods (corn chips, noodles, popped corn, and peanut fragments).

Potvin et al. (1976) summarized the diet of adult Common Grackles in Quebec. During 10-19 May, the diet by volume consisted of 72.5% vegetation, 19.0% animal material, and 8.5% unidentified items. The vegetable matter consisted of 53.0% corn, 12.7% barley, 6.6% smartweed, and 0.2% cherries. The animal food consisted of 15.6% beetles (4.1% ground beetles, 3.3% click beetles, 0.8% rove beetles, 2.5% weevils, 2.5% bark beetles, 1.6% scarab beetles and blister beetles), 2.6% millipedes, and 0.8% isopods. The diet 14-29 July consisted of 43.8% vegetation, 42.8% animal matter, and 8.3% unidentified items. The vegetable matter consisted of 3.5% corn, 27.1% barley, 2.5% oats, 8.3% alfalfa, 1.3% red clover, 0.7% cherries, and 0.5% white sweet clover. The animal food consisted of 2.0% short-horned grasshoppers, 4.0% flies (2.0% parasite flies, 2.0% house flies), 2.0% snout moths, 30.0% beetles (4.0% ground beetles, 4.0% click beetles, 4.0% rove beetles, 8.0% weevils, 8.0% scarab beetles, and 2.0% bess beetles), 3.9% millipedes, 3.8% spiders, and 2.0% earthworms. The diet from 12 August to 16 September consisted of 86.6% vegetation, 9.7% animal matter, and 3.7% unidentified items. The vegetable matter consisted of 79.0% corn, 3.8% barley, 1.7% oats, and 2.1% white sweet clover. The animal food consisted of 1.4% ants, 0.7% snout moths, 0.7% stink bugs, 5.5% beetles (0.7% ground beetles, 1.3% rove beetles, 0.7% scarab beetles, and sap beetles), 0.7% millipedes, and 0.7% spiders. Beal (1897a) analyzed the contents of 2,258 stomachs that were probably included in the 2,346 that Beal (1900) analyzed; 1,890 were adults and the remainder were nestling stomachs. Only 1.6% contained traces of bird eggs and 1 stomach contained the bones of a young bird. Many eggshells were from domestic fowl and were probably obtained from compost piles. Early in spring, it obtains corn from corn cribs and follows plows for insects and grubs. It eats cherries and other fruits as they ripen and corn in the milk stage. In late autumn and winter, it feeds mostly on seeds and grains, becomes more insectivorous in spring, takes small fruits in summer, and attacks ripening corn in September. In all seasons, it probably selects the food items that are most abundant and easily obtained. It eats large quantities of cutworms, June beetles, grasshoppers, crickets, locusts, and pupae and adults of 17-year cicadas and cabbage white butterflies. In late autumn and winter, it eats mast of beech and oaks. There is 1 observation of it killing, skinning, and eating a lizard. The annual diet consisted of 30.3% animal matter and 69.7% vegetable matter. The animal food included insects, spiders, millipedes, crayfish, earthworms, isopods, horsehair worms, snails, fish, treefrogs, newts, lizards, snakes, birds′ eggs, and mice. Insects comprised 27% of the annual diet with a minimum of 3% in February and a maximum of 62.5% in May. Scarab beetles were the most important insects in the diet, including June and rose chafer beetles eaten both as grubs

and adults, with many stomachs crammed full of grubs. Dung beetles and rainbow scarab beetles were common in the diet. It ate weevils every month and they contributed a maximum of 5% of the volume of the diet in June. It ate ground beetles in every month and appeared to prefer them, with a minimum of 7% of the diet in January and 13% in June. Grasshoppers, locusts, and crickets were next in importance in animal foods, particularly grasshoppers which were eaten every month except January with a maximum of 23.4% in August. Caterpillars constituted 2.3% of the annual diet with a maximum of 8% in May. Hymenopterans were represented in the diet mainly by ants. Flies were entirely absent in the samples but have been reported in the diet in other studies. Spiders reached a maximum of 7% in the diet in May. Crayfish were commonly eaten but represented a small proportion of the overall diet. It ate both terrestrial and aquatic snails and a few small clams. The vegetation eaten was very variable and diverse indicating that the grackle is highly opportunistic. Grain consumed included corn, oats, wheat, rye, and buckwheat. Corn was the favourite grain, representing a maximum of 82% of the February diet (all waste grain), 53.2% in September, and 51.5% in October which was crop grain. The fruit consumed included blackberries and raspberries, strawberries, cultivated cherries, mulberries, currants, grapes, apples, blueberries, cranberries, huckleberries, chokeberries, juneberries, and hackberries. Blackberries and raspberries were the favourites and the dominant fruits consumed from May through September, but mostly in July and August. It consumed seeds or nuts of poison ivy, smooth sumac, bayberry, hophornbeam, chestnut, beech, and oaks. Seeds consumed included those of ragweeds, barnyard grass, gromwell, smartweeds, pokeweed, and sheep sorrel. Miscellaneous foods included small bulbs or tubers, galls containing larvae, plant stems, grass and leaves, black locust thorns, and pieces of rotten wood. The overall average diet consisted of 5.6% ground beetles, 4.9% scarab beetles, 2.0% weevils, 1.0% other beetles, 2.3% caterpillars, 7.3% grasshoppers, 2.3% other insects, 1.5% spiders and millipedes, 3.1% crustaceans and molluscs, 0.3% vertebrates, 37.2% corn, 2.9% oats, 4.8% wheat, 1.6% other grain, 2.9% domestic fruit, 2.1% wild fruit, 4.2% weed seeds, and 14.0% mast and miscellaneous. In Algonquin Park, the grackle fed on spruce budworms during an outbreak (Tozer 2012).

Although the ranges and habitats of the 2 species overlap broadly, the Common Grackle is a rare host of the Brown-headed Cowbird. There appear to be a number of reasons for this. The grackle nests earlier than the cowbird. In Illinois, 88.5% of grackle nests were in the incubation stage or later when the first cowbird egg was laid, thereby greatly reducing the potential for parasitism. The grackle is unusual in that it may either accept or reject cowbird eggs, with most species being either acceptors or rejecters. In Illinois, 12.1% of eggs were rejected and 13.4% of Iowa cowbird eggs were rejected. Most eggs are rejected by ejection and the remainder are pierced. Occasional egg rejection is another reason why the grackle is not selected as a host more frequently. Grackles respond aggressively toward cowbirds which may further decrease the incidence of parasitism. Grackle hatchlings weigh more than twice as much as cowbird nestlings, putting the cowbird nestling at a significant disadvantage. Cowbirds are capable of fledging from a grackle nest only when the clutch size has been reduced to allow effective incubation, the cowbird hatches at least 2 days earlier than the grackles, and the cowbird hatchling weighs at least 3 grams. Parasitism has negligible effects on the grackle with the presence of a cowbird nestling having no effect on the grackle nestlings. The only potential negative effect is the removal of grackle eggs by cowbirds (Peer and Bollinger 1997, 2020; Peer and Rothstein 2010; Peer et al. 2010; Rothstein 1975). Peer et al. (2001) reported that there

were only 30 known cases of parasitism, but more may have been documented since. These included 4 of 2,245 nests (0.2%) that were parasitized in Ontario (Peck and James 1998b). Other reported parasitism rates are 0% in Wisconsin (Petersen and Young 1950), 0 of 401 nests in Illinois (Peer and Bollinger 1997), 6 of 727 nests (0.82%) in North Dakota, 3 of 119 nests (3.4%) in Manitoba, 0 of 371 nests in Louisiana (Peer et al. 2001), and 0 of 1,795 nests (Friedmann et al. 1977). Notable are the 3 of 8 nests (37.5%) parasitized in the Saskatoon area (Leighton et al. 2002).

Forest clearing to create agricultural and developed land greatly increased the amount of habitat for the Common Grackle. Its habitat may now be declining or becoming degraded. More intensive farming with subsequent loss of hedgerows reduces nest-site availability. In Nova Scotia, densities were lower in more intensively farmed areas (Erskine 1971) but densities remain high in the extreme southwest of Ontario where agriculture is dominated by large fields of row crops (Zimmerling in Cadman et al. 2007). Modern subdivisions provide little habitat for the grackle because of the high density of houses, small lots, and limited ornamental plantings. Natural succession is occurring in the southern portion of the Canadian Shield, with marginal farmland evolving into forest, thereby reducing the amount of suitable habitat.

In New York, Keller et al. (2003) studied the effects of forest clear-cutting on the grackle. They included it in the sparrow-dominated guild of ground-feeding birds. This guild declined significantly as leaf area increased and the shrub-opening edges it preferred disappeared. This guild represented 37% of the total avian population in 2-year-old clear-cuts and only 9% 6 years after cutting. The grackle was documented in low densities only in clear-cuts 3-5 years old. In southern Ontario, the grackle was equally abundant in uncut forests, those that were selectively thinned, and those where heavy diameter-limit cuts were made (Holmes et al. 2007).

Weather may result in the failure of many nests. Young are often killed in early nests by subfreezing temperatures, and high winds may blow nests out of trees. In the Prairie Pothole Region of Canada, abundance of the grackle was positively correlated with temperature in the previous spring (Forcey et al. 2007; Howe 1976; Maxwell and Putnam 1972; Peer and Bollinger 2020; Petersen and Young 1950).

Human disturbance and predation may result in extensive nest losses and colony desertion. Low reproductive success occurred in a Wisconsin marsh due to researchers. Raccoons followed human trails and depredated nests, food sampling retarded chick growth, adults removed some nestlings with food collars, and many nests were deserted (Snelling 1968). In Ohio, nests disturbed early in the cycle by researchers were abandoned, and nests were deserted when vegetation near the nest was trimmed to afford a better view. No nests were abandoned after the eggs hatched (Maxwell and Putnam 1972). In Illinois, entire colonies were deserted after depredation (Peer and Bollinger 2020). At a Michigan colony, 90% of nests were depredated by domestic cats (Howe 1976). Many grackle nests are closely associated with human dwellings and farm buildings, so cats may be significant predators in much of its range.

Hanowski et al. (1997a) treated Minnesota wetlands with Bti and methoprene to control mosquitoes. This management had no apparent effects on the grackle.

Status

The Common Grackle is much more common now than it was prior to European settlement. There is more habitat available for it now than there ever was in Ontario (McCracken 2003b; Peer and Bollinger 2020). In the Kingston area, it was an abundant summer resident in 1859, 1909, 1965, 1973, and 2008 (Weir 2008). In Elgin County, it was a common breeder in 1891 and 1954 and abundant in 2000 (Lancaster et al. 2004). Baillie and Harrington (1937) considered the grackle one of the most common and widely distributed breeding birds in the province. At that time, it bred from the southern boundaries of the province north at least to Cochrane District and west to Lake of the Woods, and probably considerably further north. The first atlas demonstrated that the breeding range of the grackle encompassed the entire Boreal Forest Region south to the shores of Lake Erie and Lake Ontario. There were also records in the eastern portion of the Hudson Bay Lowland in the Moosonee area north to Attawapiskat. It was an abundant breeder, but became progressively less common northward (Weatherhead in Cadman et al. 1987). James (1991) considered it an abundant summer resident in the south, locally common in the north to Big Trout Lake and Albany, and a vagrant north to Winisk.

The second atlas demonstrated that there had been no significant change in the breeding distribution of the grackle since the first atlas. Its probability of observation decreased province-wide and in all regions except the Hudson Bay Lowland where it experienced a nonsignificant increase. The only significant decline was in the Shield portion of the Great Lakes-St. Lawrence Forest Region. The decline was attributed to natural succession and blackbird control programs in the southern United States. It was most abundant south and east of the Canadian Shield. Its density in this area was surpassed only by densities of the European Starling and Red-winged Blackbird. All these species do well in landscapes dominated by agriculture and urban areas. Density of the grackle decreased in the Shield and northward, probably due to less availability of agricultural lands, settlements, and productive wetlands (Zimmerling in Cadman et al. 2007).

The population of the Common Grackle appears to be declining in the east. Western populations continue to increase and its range is also expanding in the west, due in part to planting of shelterbelts (Campbell et al. 2001; Homan et al. 1996; Peer and Bollinger 2020). There was a considerable increase in its population between the mid-19th and early 20th centuries, probably due to continuing deforestation and planting of grain crops. Population declines may have started early in the 20th century. Extensive planting of corn beginning in the late 20th century increased food supplies and may have levelled off the rate of decline. The grackle has declined at the steepest rate of any blackbird species except the Rusty Blackbird since the Breeding Bird Survey (BBS) was initiated in 1966. By 2003, the population had decreased by 38%, with the decline more severe in the United States at 40%. The decline in the east is attributed to blackbird control programs implemented in the southern United States in autumn and winter. Severe weather in the wintering range may also be a factor (McCracken 2003b; Peer and Bollinger 2020). BBS results indicate that the grackle decreased at annual rates of 0.489% in Canada and 1.17% in Ontario 1970-2021. The trends 2011-21 were annual increases of 2.88% in Canada and 1.03% in Ontario. All results were highly reliable (A.C. Smith et al. 2023). In Great Lakes coastal wetlands, it increased at an annual rate of 8.4% 2011-21 (Tozer et al. 2024).

POSTFLEDGING PERIOD

Young are poor fliers when they leave the nest but quickly become proficient. They usually leave the area of the nest within 1-2 days and disperse as far as 0.5 km to areas of dense vegetation. The duration of parental care is uncertain, but may be several weeks. Young have been observed being fed in early July long after nesting is usually complete. Once the young are independent, family groups coalesce to form flocks. Postbreeding flocks have been observed in Muskoka District as early as 18 June. In late summer and early autumn, grackles join large flocks of other postbreeding species, particularly Red-winged Blackbirds, cowbirds, and starlings (Howe 1976; Mills 1981; Peer and Bollinger 2020; Petersen and Young 1950; Wiens 1965).

During the postbreeding season, the grackle occurs mostly in anthropogenic habitats in the southern portion of the province. These include agricultural fields and farm buildings, rural residential areas, and urban areas. In Algonquin Park, flocks forage on the forest floor, at wetland edges, along shorelines, and in open areas (Sheppard et al. 1936; Tozer 2012). In British Columbia, it prefers human-made clearings in otherwise treed habitats, wetlands, backyards with feeders, homesteads, farm ponds, airstrips, and campgrounds. It also visits farmyards, sewage lagoons, livestock corrals, orchards, harvested cornfields, and riparian woods (Campbell et al. 2001). Agricultural fields close to hardwood forests in bottomland areas appear to be especially attractive (Peer and Bollinger 2020). In Michigan, small numbers occurred both in mature upland and riparian trembling aspen forests (Akresh et al. 2009). Breeding areas may be abandoned by flocks by August in some habitats and areas (Beal 1900).

Communal roosts are an important component of grackle habitat during the postfledging period. Grackles continue to use roosts during autumn migration, winter, and in spring until courtship begins. Numbers of birds at roosts may start to swell 1 or 2 days after the young fledge, beginning as early as mid-June to early July. It roosts with Red-winged Blackbirds, Brown-headed Cowbirds, and European Starlings, with lesser numbers of American Robins, Rusty Blackbirds, and Brewer's Blackbirds. In Niagara Region, roosting occurs regularly in a common reed marsh. In Algonquin Park, grackles roosted in grey alder thickets. Other reported roosting habitats include hardwood woodlots, near food sources such as agricultural fields and orchards, trees along city streets, conifer groves, and cattail and common reed marshes. In Illinois, a family of Barred Owls roosted in a 9-year-old white pine plantation along with 2,500 grackles. An analysis of the owl pellets revealed that they had been eating grackles (Applegate 1975; Black and Roy 2010; Gross in Bent 1958; Lyon and Caccamise 1981; Peer and Bollinger 2020; Stewart 1975b; Tozer 2012).

In North Carolina, roosts were always in or adjacent to urban areas, with few roosting in rural areas. In larger mixed roosts, grackles were the dominant species with most roosts becoming larger and more central after young fledged. By early August, all grackles gathered into a single roost, often returning repeatedly to the same site in successive nights, but also frequently switching roost sites. By early spring, it roosted in scattered sites even when roosting in the same tract of woodland. Some areas were used continually for long periods but specific sites were often different in successive years (Stewart 1975b). Within a 1,000-km^2 area in New Jersey, 22 roosts were located, including 20 in hardwood stands and 2 in common reed. Roosts consisted of 60% starlings, 33% grackles, and lesser numbers of Red-winged Blackbirds, cowbirds, and robins. Hardwood roost sites were 0.13-

10.4 ha, with larger sites supporting more birds. When initially occupied, only a small proportion of the site was used. As the assemblage grew, the roost usually expanded until the entire area was occupied. Important tree species in roosts included maples, gum, oaks, pines, red cedar, and birches. Plantations were used in some sites adjacent to residential areas. Red maple, black gum, and pin oak were the most frequently used hardwoods and red cedar was used in old fields. Tree density in roosts was high (average of 1,741 trees per ha). No sites with a tree density of less than 720 trees per ha were used. Roosts were usually in even-aged stands, and the mean age of roost stands was 18-34 years, with 68% of sites 21-26 years old. There was a significant difference in the average age of roost stands (25 years) and non-roost stands (41 years). The most consistent characteristics of roost sites in addition to stand age were a closed canopy, compact vertical arrangement of twigs, and uniformity of mean twig heights (Lyon and Caccamise 1981). Roosts first became active in early June and the number of active roosts increased through mid-August then declined until the end of the local roosting season in early November. Individual roosts were active 3-20 weeks. The same sites were used each year and their heaviest use occurred over a similar period. Following the population peak in mid-August, the size of individual roosts began to decline, resulting in abandonment of some. Few new roosts were established after mid-August but those that were eventually supported large autumn flights. By early October, few roosts were active; 1-3 became large premigratory roosts while others dwindled until they were abandoned. Before the peak in population, individuals usually remained in a single roosting flock. Later, they switched sites more often as the number of active sites declined, abandoning declining roosts and moving either to developing major roosts or remaining in minor roosts with fewer than 2,000 birds. Roosting sites were not limited because not all were used all the time and some suitable areas were never used (Caccamise et al. 1983). Caccamise and Fischl (1985) identified secondary species that occurred in these roosts in addition to starlings and grackles. They included the Green Heron, Mourning Dove, Common Nighthawk, Chimney Swift, Blue Jay, Purple Martin, Tree Swallow, American Robin, Northern Mockingbird, House Sparrow, Red-winged Blackbird, and Brown-headed Cowbird. The robin was the most abundant secondary species and occurred in every roost except early in the season. Red-winged Blackbirds and Mourning Doves were present for most of the season, but in much lower numbers than robins and not in every roost. The remaining secondary species were less widely distributed and remained for short periods. Morrison and Caccamise (1990) determined that the grackle exhibited fidelity to diurnal activity centres. The mean distance of diurnal grackle sightings was 0.88 km from the centre of the diurnal activity centre and the mean distance moved between sightings was 0.55 km. Four grackles used the same activity centre June to November. One female used 3 activity centres in succession separated by distances of 6.5 and 5.5 km. Although all birds were captured in the same foraging areas, they joined communal roosts at 15 sites. Grackles joined roosts containing both starlings and robins more than 97% of the time. Mean distance between grackle roosts and activity centres was 3.6 km with 2 major roosts more than 4 km away. Grackles switched roosts 15.1% of the time and mostly (39 of 41 cases, 95.1%) switched to roosts within 2 km of the previous night's roost. They switched roosts much more frequently than they switched activity centres. One case of switching activity centres was accompanied by a major shift in the roost.

In the postbreeding period, and also autumn migration and winter, the Common Grackle usually forages in flocks with other blackbirds and starlings. The grackle is one of the most significant

agricultural pest species in North America. It and the Red-winged Blackbird are responsible for most damage to ripening corn and the grackle is the most important species in damaging sprouting corn. It also damages rice crops, other small grains, sunflowers, peanuts, blueberries, and sweet cherries (Peer and Bollinger 2020). Bernhardt et al. (1987) studied how the grackle feeds on ripening corn and found that it had the highest feeding efficiency of the species tested, inflicting the most damage per unit time. It pecked through the husk with the bill closed. Once access to the kernels was obtained, it fed by direct pecking, shearing entire kernels off the cob. Once the husk was open, it would do extensive damage, making 5-10-cm vertical slits in the husk. In field situations, it is more likely to attack ears already damaged by other species. Cummings et al. (1989) summarized damage to sunflower crops by grackles, Red-winged Blackbirds, and Yellow-headed Blackbirds in North Dakota, South Dakota, and Minnesota. Grackles represented 11% of the birds in flocks. Seventy-four percent of damage occurred 3-18 days after antithesis, 70% occurred on sunflower heads with green and green-yellow bowls, and 68% occurred when the heads were half inverted. Soft seeds received 76% of the damage and bird numbers peaked when fields reached the soft-seed stage. Brugger (1988) studied damage to sprouting rice crops in Louisiana by blackbirds. Grackles represented less than 1-8% of the total birds in flocks and did minimal damage compared with female Red-winged Blackbirds. Foraging on rice crops occurred in the winter. Flocks flew as far as 60 km from the roost to forage. Tobin et al. (1982) studied bird damage to apples in New York. Damage to individual crops was less than 1%. The mean percentage of trees receiving at least some damage was 57% and the mean percentage of apples pecked by birds was 5.9%. Most damage was done by the American Crow. The grackle caused minimal damage.

During the postfledging period and autumn migration, acorns are a prominent food (Bent 1958). The grackle also eats wild fruits at this time. In an Illinois woodlot, it gulped fruits whole while foraging in the subcanopy. It foraged an equal amount of time in treefall gaps and forest interior. In 1 year, 100% of the fruit eaten was Virginia creeper. The following year, it ate only fox grapes. It was not observed eating the fruits of red elderberry, pokeweed, poison ivy, greenbrier, or moonseed (Malmborg and Willson 1988). Dennis (1949) reported a flock of 800-900 grackles completely stripping off the fruits of a large stand of flowering dogwood within half an hour in Virginia. They were not well adapted to foraging on dogwood berries. They could easily pull off the fruit but could swallow only a small portion of it, dropping the rest to the ground. Many then fed on the ground, eating both the seed and the fleshy part of the fruit.

MIGRATION

Most Common Grackle populations are migratory except for those breeding in the Gulf Coast states, which are resident birds. Migration occurs diurnally, usually in mixed-species flocks that include Red-winged Blackbirds, starlings, and cowbirds, and less frequently Rusty Blackbirds, Brewer's Blackbirds, and robins. Females tend to migrate about 100 km further south than adult males and juveniles travel 100-300 km further than adult males. Those breeding at latitude 44-45°N migrate about 1,000 km. Those breeding at latitude 34-35°N travel approximately 200 km. The mean distance travelled from the Great Lakes area was 870 km. Severe winter weather may drive birds further south than usual (Dolbeer 1982; Peer and Bollinger 2020). The winter range of Ontario birds covers a broad area from southern Ontario and the Great Lakes states south to the Gulf Coast states, although encounters are rare in Texas and Florida, and along the Atlantic Coast from New Jersey to Georgia

(Brewer et al. 2018). Birds are at the maximum distance from their breeding area in January or February. The mean distance between banding and recovery in a subsequent breeding season for hatch-year birds was 35 km. Mean dispersal distances between years for adults was 26 km for males, 14 km for females, and a mean of 24 km for the sexes. Hatch-year birds dispersed significantly further than adults and 12% moved further than 50 km. Mean distance between successive winters was 357 km for males, 263 km for females, and 282 km overall. Grackles were more faithful to breeding than wintering locations (Dolbeer 1982). Stewart (1975b) analyzed banding recoveries to determine where birds banded in winter in South Carolina were recovered in a subsequent breeding season. A total of 79.4% of birds remained south of Maryland after wintering in South Carolina. Of birds going further north, 6.6% went to Ontario, 5.7% to Pennsylvania, and 4.7% to New York. Birds from New England, more northern states, Ontario, and Quebec wintered in North Carolina rather than moving further south into South Carolina. Eighty-one percent of these birds were from Ontario and 2.0% were from Quebec (Peer and Bollinger 2020).

Males typically arrive 5-10 days before females, but in Hamilton, females did not arrive until a few weeks after the males. Spring flocks are usually comprised of either males or females (Curry 2006; Gross in Bent 1958; Petersen and Young 1950; Wiens 1965). It is possible that males are arriving much earlier now than they did historically and that the gap between the arrival of the sexes has increased. In Hamilton, McIlwraith (1894) reported that males arrived just a few days before females, usually in mid-April. The gap between arrival of the sexes there is now a few weeks and males arrive in late March (Curry 2006). In Manitoba, Murphy-Klassen et al. (2005) analyzed 63 years of migration data and determined that the grackle arrived significantly earlier in the 2000s than in the 1940s. It exhibited the strongest trend toward earlier spring arrival with warmer spring temperatures than any other passerine species. It arrived 2.1 days earlier for every 1°C increase in temperature. In southern Ontario, small numbers arrive in mid- to late February; the peak of migration occurs through March and April. Smaller flocks continue to migrate into mid-May after local breeders are incubating (Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008). In the southern Shield, birds arrive in late March or early April; some arrive in early March (Mills 1981; Tozer 2012).

Wilson and McRae (1993) reported 1 grackle at Longridge on 5 September and another at Moosonee on 2 September. They terminated their fieldwork shortly afterwards, so these records may not represent the latest migrants. In Algonquin Park, most leave during October but a few linger into November, mostly at feeders (Tozer 2012). In Muskoka and Parry Sound districts, peak flocks occur in September and October (Mills 1981). In the Kingston area, autumn migration is obvious during October (Weir 2008). In Elgin County, large flocks have moved on by late November (Lancaster et al. 2004).

Habitat used during spring migration is similar to that used during the breeding season. Migration habitat is closely tied to areas with high abundance of food, with both early spring and late autumn migrants visiting feeders when other food sources are less plentiful. Even after arriving at the breeding grounds, grackles may travel as far as 2.4 km from the nesting area to forage. Autumn migration habitat is similar to that used during the postfledging period, with flocks concentrating in agricultural and urban areas. The major postfledging roosts continue to be used during autumn migration, with numbers swelling in September and October. Communal roosting also occurs

during spring migration, but in smaller numbers (Gross in Bent 1958; Mills 1981; Petersen and Young 1950; Tozer 2012).

In the St. Lawrence lowlands of Quebec and Ontario in early autumn, most birds appeared to be from the local breeding population, with two thirds of the breeding population remaining until late autumn from 1 October to mid-November. Blackbird control methods, if implemented in April and early autumn, would affect local breeding populations and reduce late autumn numbers (Weatherhead et al. 1980).

James (1991) considered the Common Grackle an abundant migrant in Ontario. In Niagara Region, an estimated 90,000 were observed in mid-October mixed with other species (Black and Roy 2010). During spring in Hamilton, 5,000 roosted in the Dundas Marsh and 50,000 were seen on a reverse migration in mid-March. In autumn, it flies along the Lake Ontario shoreline with peak numbers of 5,000-7,400 (Curry 2006). At Presqu'ile, 6,000 roosted in the marsh in late August with other blackbird species (LaForest 1993). In Kingston in autumn, flocks of 3,000 grackles are typical mixed among other blackbird species; 12,000 were seen in mid-October (Weir 2008).

WINTER

In winter, the Common Grackle inhabits mostly agricultural and urban habitats. Those in more northerly locations where snow cover may be deep and prolonged tend to remain around feeders. Nocturnal roosts are important in winter, with it roosting mostly with the Red-winged Blackbird, starling, and cowbird; lesser numbers of several other species may be present. Large winter roosts are concentrated mostly in the lower Mississippi Valley, but also in the Atlantic Coastal Plain from Chesapeake Bay southward and in the southern portion of the Piedmont. There are at least 125 major roosts in the southern United States that each support 1,000,000 or more blackbirds and starlings. Peak winter numbers at a Louisiana roost reached 25,000,000 birds. There is considerable intermingling of birds from different breeding populations within and among species in roosts. Birds wintering in a given area come from a broad area of the breeding range (Brugger 1988; Dolbeer 1982; Peer and Bollinger 2020).

In winter, the grackle subsists mostly on waste grain and other anthropogenic food, but also eats some tree seeds (Peer and Bollinger 2020). In the north, it may use feeders all winter. In the normal wintering range, few visit feeders until February when spring migration may be underway. It is less likely to visit rural than urban feeders, probably because natural food is more abundant there. Its favourite feeder foods are mixed seeds, sunflowers, cracked corn, water, and pet food. It infrequently consumes millet, canary seed, safflower, whole corn, milo, wheat, peanuts, suet, peanut butter mixes, bird puddings, fresh or dry bread, baked goods, sugar water, oats, meat scraps, and popped corn (Dunn and Tessaglia-Hymes 1999). Based on 30,311 feeding observations, it preferred cracked corn and 0.5-mm sunflower chips. It preferred platform feeders over tubes and hopper feeders. The mean number of grackles feeding on different seed types per 5-minute observation period were: 5% black oil sunflowers, 7% cracked corn, 5% 0.3-mm sunflower chips, 5% 0.5-mm sunflower chips, 1% niger seed, 3% red milo, 2% safflower, 5% striped sunflowers, 3% white proso millet, and 4% whole peanuts (Horn et al. 2014; Johansen et al. 2014).

Control of blackbirds at winter roosts appears to be the most significant limiting factor for the Common Grackle. There is pressure to control blackbird numbers because of the damage they do

to crops and roosts may harbour the fungus histoplasmosis, a human respiratory disease that can be fatal. From 1974 to 1992, a detergent that eliminates the waterproofing ability of feathers was sprayed on roosts followed by spraying of cold water. This resulted in birds dying of exposure. Hundreds of millions of birds were killed in this manner. In Kentucky and Tennessee, an estimated 28,000,000 were killed 1974-82. This method of control was banned in 1992. Subsequently, DRC-1339 was applied as bait on the ground or spread on rice grains. This chemical kills birds by shutting down liver and kidney functions. Millions of birds were killed by this organochlorine pesticide. The actual number of grackles that have been and continue to be killed in winter is unknown, but it is undoubtedly several millions (Dolbeer 1982; Gross in Bent 1958; McCracken 2003b; Peer and Bollinger 2020). The impacts of blackbird control at winter roosts have been downplayed, using the rationale that birds disperse from roosts to over much of the breeding range, thereby likely having limited effect on local breeding populations (Dolbeer 1982). It seems more likely that the control program has depressed the entire eastern breeding population (Peer and Bollinger 2020). In Illinois, the grackle is declining at an annual rate of more than 7%. Horsley and Ward (2021) demonstrated that nest and postfledging survival rates were high and attributed the decline to winter control programs and possibly exposure to neonicotinoides on agricultural land during spring migration and the breeding season.

Severe winter weather may result in mortality of the Common Grackle. After a storm in Illinois, 8.7% of grackles within a colony died (Odum and Pitelka 1939). Also in Illinois, Graber and Graber (1979) reported a grackle population decline of 18.9% in bottomland forests and 66.7% in urban residential areas after a severe winter storm. They also found a number of grackle carcasses. Stewart (1978) reported less extensive mortality of the grackle at a Kentucky roost following severe winter weather. Ninety-eight percent of the birds in the roost were grackles, but they represented only 9.4% of the dead birds. About 14,500 birds, 32.2% of the total roost, left the evening prior to the mortality suggesting that many responded to the environmental stress by moving further south.

James (1991) considered the Common Grackle a rare to locally common winter resident in the south and occasional and rare to uncommon in the north to Thunder Bay and Moosonee.

The Common Grackle appears to have increased as a wintering species and extended its winter range northward. Freedman and Riley (1980) examined Ontario Christmas Bird Count (CBC) data for 1929-77. It exhibited a trend toward higher abundance and frequency of occurrence, but total numbers remained low. McIlwraith (1894) stated that there were no winter records for the province. Curry (2006) reported that 1 or 2 are present in the Hamilton area every winter, with a maximum of 12. It is uncommon in winter in Niagara Region, Presqu'ile, and the Kingston area; rare in Elgin County and Muskoka and Parry Sound districts; and very rare in Algonquin Park. These are all areas where wintering birds were historically absent. CBC results indicate that it decreased in Ontario at annual rates of 3.67% 1970-2021 and 1.78% 2009-21 (National Audubon Society 2022).

Ovenbird

Seiurus aurocapilla

BREEDING SEASON

Habitat Requirements

All Ontario Ovenbird nests were in forests. Mixed (45% of nests) and deciduous (41.9%) forests were preferred to coniferous forests (12.6%). Open forests with little understorey were preferred to those with a dense understorey. Wet and dry habitats were used without any evidence of preference. Many nests were at woodland edges or near clearings, or beside paths and logging roads (Peck and James 1987). Tree height does not appear to be important, but it requires a closed canopy. It was much more common in mature forests with dry to mesic conditions where there was limited shrub growth (James 1984b).

In the Hudson Bay Lowland near Moosonee, the Ovenbird was common in all deciduous and mixed forest cover (Wilson and McRae 1993).

In the Ontario Boreal Forest Region, the Ovenbird was in a guild by itself, associated with older, tall, closed-canopy deciduous stands with little interspersion of young and old forests. It preferred

areas of lower disturbance and less age-class interspersion of forest stands. Areas that were predicted to have high occupancy in the Nipigon Forest would have 5.9% more canopy closure, 0.6 m taller canopy, less young habitat, more hardwoods, less edge, and less intact forest than current conditions. The most important variable was the amount of deciduous forest cover (Rempel 2007; Rempel et al. 2007). In boreal mixed-wood and coniferous forests near Hearst, it was absent in all lowland stands and clear-cut upland stands 3-5 and 24 years old. In upland habitats, it occurred in clear-cuts 6-19 years old and in uncut stands (Welsh and Fillman 1980). On the northeast shore of Lake Superior, it preferred drier woods where poplar and birch were the dominant species (Baillie and Hope 1943). In the Clay Belt, it was most abundant in trembling aspen, spruce-aspen, jack pine, and jack pine–black spruce stands. It occurred mostly in dry and mesic stands that were moderate to rich in nutrients (Welsh and Lougheed 1996).

In jack pine stands near Gogama in the Canadian Shield portion of the Great Lakes–St. Lawrence Forest Region, James and Peck (1995a) considered the Ovenbird characteristic of pine stands once trees reached a height of 10 m and of mixed jack pine–deciduous stands once trees became 12 m tall. The main habitat requirements were dense canopy cover; a sparse tall shrub layer, although density occasionally reached 50% coverage; dense coverage by low shrubs and herbaceous species in pine stands; and herbaceous growth in leaf litter in deciduous woods, with these areas growing up with bracken fern later in summer. Jack pine forests mixed with trembling aspen, white birch, white pine, sugar maple, and hemlock near Parry Sound supported low to moderate Ovenbird densities. These stands had low canopy closure of 25-50% or less with numerous openings due to rocks, wetlands, or logging (James 1979a). In Muskoka District and Haliburton County, areas around singing posts and nests had high canopy coverage and low ground and shrub coverage. It was associated with very high canopy volume mixed-wood forests with intermediate tree density, typical of mature undisturbed forest (Clark et al. 1983). In Peterborough County, it consistently chose territories in mature forests with tree heights of 16-22 m, with 60-90% canopy closure. Relative to random sites, it selected nest sites with lower ground cover, larger trees, and flatter areas, where the leaf litter was thick, and at distances of more than 20 m from forest edge (Burke and Nol 1998). In Algonquin Park, it was abundant and well distributed throughout every forest type except wet spruce swamps (MacLulich 1938). It was absent in bogs and in black spruce, balsam fir–black spruce, and black spruce–white cedar stands in Algonquin Park. It was the most abundant species in trembling aspen–white birch stands and was also dominant in aspen-birch–balsam fir stands, but occurred at lower densities. It was the dominant species in immature white pine and balsam fir–

black spruce–hardwoods stands and second in abundance in northern hardwoods stands. It also occurred in stands dominated by hemlock. It was characteristic of deciduous stands where it was consistently one of the most abundant species (Martin 1960). In Algonquin Park, it was least common in stands cut 10-18 years previously and more common in both recently cut stands and those where no logging had taken place. It was one of the most abundant species in white pine stands (Kingsley and Nol 1999). Also in Algonquin Park, it avoided large open areas of bracken fern and grasses in aspen forests but used similar areas in conifer-birch stands. It avoided wet areas in sugar maple stands (Stenger and Falls 1959).

Near Ottawa in the off-Shield portion of the Great Lakes–St. Lawrence Forest Region, high importance habitat features for the Ovenbird were the percent coverage of living ground cover, leaf litter depth, shrub height, canopy cover, and percentage of deciduous trees. Moderately important features were the diameter at breast height (DBH) of trees, tree density, and tree species richness. Tree height was of low importance (Lee et al. 2002). In the Kingston area, McLeish and Robertson (1997) concluded that upland white cedar stands could provide quality breeding habitat. In southeastern Ontario, leaf litter was positively correlated with its density, pairing success, and productivity. Pairing success was correlated with sapling density and canopy cover. Nest success was correlated with percent cover by forbs (Richmond et al. 2012). In Durham Region, it was present in all forest types surveyed, including those with open canopies and a black spruce bog with a red maple–poplar swamp on 1 side. It was a late successional species associated with deciduous tree species (Speirs and Orenstein 1975).

In the Carolinian Forest Region in the South Walsingham Forest in Norfolk County, abundance of the Ovenbird was significantly correlated with the shrub layers 0-0.3 m and 0.3-1.0 m from the ground, and shrub stem density. It was one of the least discriminating species, occurring in all types of forested habitat. It was the second-most abundant species (McCracken et al. 1998).

Throughout its range, the Ovenbird is an obligate forest species, although it occasionally nests in early successional areas created by clear-cutting. In New York, it became a dominant species 24-25 years after clear-cutting in deciduous forest. Mixed and deciduous woods are preferred over coniferous stands, but it may be common in certain types of coniferous woods, particularly those dominated by white pine and balsam fir. It avoids pine-spruce stands, but nests where spruce is mixed with deciduous species or balsam fir. It may be common in coniferous plantations, especially those dominated by white pine. Densities are higher in plantations that have been thinned and have some deciduous undergrowth. In plantations, it may be second in abundance. It is the dominant species in many stand types, or second in abundance. It is particularly abundant in stands dominated by aspen and/or white birch, mixed upland spruce–balsam fir, oak and oak-pine, pines, and sugar maple. In New Jersey pine and oak barrens, it was one of the most abundant species in oak stands, second in abundance in oak-pine stands, and third in abundance in pine-oak. In Wisconsin, it was rare in pine and oak barrens, but common in barrens that were nearly forest (Back 1979; Bielefeldt and Rosenfield 1994; Brooks 1940; Brush 1987; Campbell et al. 2001; Capen 1979; Crawford and Titterington 1979; Drapeau and Darveau in Gauthier and Aubry 1996; Erskine 1977; Falardeau et al. 1999; Hanski et al. 1996; Holmes and Sturges 1975; Keller et al. 2003; Kirk et al. 1996;

Lambert and Hannon 2000; Lent and Capen 1995; McLaren and McLaren 1981; Mossman et al. 1991; Schieck et al. 1995; Sinclair et al. 2003; Sweeney and Dijack 1985; Thompson and Capen 1988).

The Ovenbird is mostly associated with upland mesic stands that are rich in nutrients, but exceptions occur. It tends to prefer woodlands with moderate slopes. In Illinois, floodplain forests usually lack Ovenbirds, but some lowland forests support notable populations on second-level ridges above the floodplain. In Michigan, small populations occurred in forested swamp nearest a river, it avoided the next 2 bands of forested wetland, and significantly higher densities occurred in the outer band of upland forest. It was considered an upland species. In balsam fir–white cedar stands in eastern Quebec, it occurred both in riparian and nonriparian stands, but was significantly more abundant in nonriparian stands. It was also more frequent in nonriparian than riparian stands of balsam fir in Newfoundland. In Missouri, it was absent in mature riparian forest. In Wisconsin upland forests, it was associated with mesic stands and was the most abundant species. It was most abundant in stands of the more mesic half of the moisture gradient and very conspicuously increased in importance and density with increasing mesic conditions (Bond 1957; Campbell et al. 2001; Faanes and Andrew 1983; Flack 1976; Graber et al. 1983; Inman et al. 2002; Kirk et al. 1996; LaRue et al. 1995; Mossman and Hoffman 1989; Pagen et al. 2000; Robbins et al. 1989; Wenny et al. 1993; Whitaker and Montevecchi 1997). The Ovenbird occasionally occurs in treed swamps. In New Jersey, there was no significant difference in its abundance in upland oak-pine forests and hardwood swamps, and it was the most abundant species in both habitats. In other areas, it is equally abundant in upland xeric oak-hickory forests, mesic stands, and lowland deciduous forests (Chapman 1907; Morse 1989; Rich et al. 1994). In Newfoundland balsam fir stands, it was significantly more abundant in rich than poor stands. Observations were equally split between poor and rich sites in 40- and 80-year forests, but significantly more birds were seen in rich sites in 60-year-old stands (Thompson et al. 1999).

The Ovenbird may occur in almost all ages of forest, except for very young stands. It reaches its highest abundance in intermediate to mature stands and is least abundant in very early seral stages and old-growth forests. In Ontario white pine forests in the Canadian Shield in the Great Lakes–St. Lawrence Forest Region, it was more abundant in old-growth than mature stands, but not significantly. In mixed jack pine stands near White River, it was significantly more abundant in 40-100-year-old stands with a large component of jack pine than in stands 3-25 years old. It was 1 of 6 species that were indicators of mature forest. In the Boreal Forest Region of Ontario, it was rare in stands 12 years old and younger and common in stands 18-220 years old. In clear-cuts, it is significantly more abundant in stands 9-10 years old than those 4-5 years old, and abundance increases with increasing stand age until stands are at least intermediate aged. In aspen-birch stands, it is absent in the seedling-sapling stage, first appearing in the sapling-pole stage and increasing through to mature stands. It was absent in stands younger than 15 years. Similar relationships have been documented in pine and mixed stands. In Alberta aspen stands, its relative abundance in different age classes was 2.13 in young stands, 2.78 in mature stands, and 1.71 in old-growth stands. In Wisconsin, it was more than twice as common in climax stands as in pioneer stands. In Newfoundland balsam fir stands, it preferred stands 40 years old to those 60 or 80 years old, but possibly because there was a higher percentage of deciduous growth in the younger forests. In regenerating fields surrounded by forest in New Jersey, the Ovenbird was absent in fields

that had been regenerating for 10 and 20 years, but present in a 40-year-old field. In Quetico Park, its average importance values were 8 in early-successional stands (1-23 years), 28 in intermediate stands (67-73 years), 18 in mature stands (112 years), and 0 in old-growth stands. In Pennsylvania, it occurred in 36.4% of old-growth forests, 74.6% of forests state-wide and 82.7% of forests on the Appalachian Plateau. It had a negative old-growth affinity, probably because of its preference for heavy ground cover which was virtually absent in old-growth forest. It increased over a 30-year period in a New Hampshire forest. During this time, the forest changed from having a dense canopy and low shrub layer to having a more patchy canopy, a denser subcanopy, and a more sparse low shrub layer, which improved habitat (Apfelbaum and Haney 1985; Back 1979; Bond 1957; Capen 1979; Haney 1999; Hoffman 1989a; Holmes and Sherry 2001; Kirk et al. 1996, 2012; Lent and Capen 1995; Pagen et al. 2000; Schieck et al. 1995; Suthers 1988; Temple et al. 1979; Venier and Pearce 2005; Welsh 1993).

In North Dakota, the Ovenbird occurred in areas with 50-75% forest cover (75% was the maximum extent of forest cover) and in areas with 91-100% forest cover in New York. It showed a strong response to increasing forest cover and was the only species that had a sharper positive response in landscapes with more than 30% forest cover. It was absent where there was less than 20% tree cover within 100 m (Cunningham and Johnson 2016, 2019).

Numerous studies identified vegetation parameters correlated with Ovenbird abundance. The most consistently reported habitat parameters are canopy height of 16-22 m, 60-90% canopy closure, deep deciduous leaf litter, and sparse to moderate coverage by short shrubs. Less important vegetation parameters include total basal area (BA) particularly by larger trees, tree density, moss cover, downed woody material, density of snags larger than 20 cm DBH, increasing deciduous cover and decreasing coniferous cover, moderate slopes, herbaceous coverage and species diversity, shrub species diversity, and abundance of invertebrates in the leaf litter (Anderson and Shugart 1974; Askins et al. 1987; Beals 1960; Bushman and Therres 1988; Campbell et al. 2001; Collins et al. 1982; Falardeau et al. 1999; Gross in Bent 1953; Grundel and Pavlovic 2007a; Lynch 1987; Mossman and Hoffman 1989; Niemi and Pfannmuller 1988; Parker et al. 1999; Pérot and Villard 2009; Robbins et al. 1989; Schieck et al. 1995; Stauffer and Best 1980; Sweeney and Dijack 1985; Temple et al. 1979; Thompson and Capen 1979; Thompson et al. 1999; Van Horn and Donovan 1994; Wenny et al. 1993). In New Hampshire and Maine, it was positively correlated with the number of deciduous trees larger than 10 cm DBH, the total foliage density of coniferous trees larger than 10 cm DBH, and the total foliage volume of deciduous trees smaller than 2 cm DBH. It was negatively correlated with the number of coniferous trees larger than 10 cm DBH, the number of woody stems per ha, and the total foliage volume of both deciduous and coniferous trees 2-10 cm DBH (DeGraaf et al. 1998).

Some exceptions to these vegetation preferences have been documented. In Tennessee, the Ovenbird was found in forest stands with open canopy and subcanopy layers and a dense understorey. In Indiana, it was positively associated with tree density, but occurred in open stands with as few as 200 trees per ha. Some authors stated that the Ovenbird occurred in areas of dense shrub growth. It usually avoids areas of very high shrub density and may nest in areas that are devoid of woody vegetation in the understorey. In some cases, it was associated with increasing coniferous coverage rather than deciduous coverage. In Minnesota, it occurred where there was more than

50% coniferous tree coverage. Its association with coniferous coverage might be secondary because it consistently occurred in areas of mixed deciduous-coniferous cover. In Maryland, it was more abundant where coniferous ground cover and hemlock, deciduous, and short shrub coverage were high. In Iowa, its abundance was negatively correlated with herbaceous cover and abundance of snags (Anderson and Shugart 1974; Collins et al. 1982; Gates and Giffen 1991; Grundel and Pavlovic 2007a; Stauffer and Best 1980).

Habitats used by the Ovenbird in Maine and Minnesota were quite dissimilar. In Minnesota, it occupied areas with tall canopies, moderate coniferous cover, few small trees, and more large trees. In Maine, it was associated with high percent canopy cover, variable coniferous cover, and many trees in the smaller age classes (Collins 1983a).

In a Connecticut woodlot over a 59-year period, there was a progressive shift to larger trees, a sparser shrub layer, and a less diverse tree canopy dominated more by oaks and maples as a result of a decline in hemlock. The Ovenbird declined within the woodlot but remained stable throughout the state. Buchanan et al. (2016) considered it a hemlock associate and its decline may have been related to the decline of this tree. In Pennsylvania and New Jersey over a 15-year period, hemlock declined from 56% of the total basal area to 46% due to the hemlock woolly adelgid. The decline in hemlock resulted in an increase in deciduous understorey. The Ovenbird population increased in response to the loss of hemlock (Toenies et al. 2019).

In Missouri, the Ovenbird avoided streams and in New Brunswick its abundance was significantly lower near streams. Density increased with distance from edge and it demonstrated an avoidance reaction to streams (Parker et al. 1999; Wenny et al. 1993). In Maryland, Gates and Giffen (1991) found no evidence of stream avoidance by the Ovenbird. Avoidance of streams in some areas could potentially be related to vegetation characteristics, such as shrub density rather than actual stream avoidance.

The Ovenbird is an area-sensitive species, requiring forests much larger than its territory size. In contiguous forests near Quebec City, Ovenbird territories were aggregated, possibly in response to the clustered distribution of suitable ground cover (Bourque and Desrochers 2006). Similar findings were reported in Missouri, with territories clumped together and areas of apparently suitable habitat remaining unoccupied. The placement of clumped territories may vary annually, and may be a result of social interaction rather than habitat structure. The sociability of the species requires that forests be large enough to accommodate more than 1 pair, although single pairs occur within some woodlots (Van Horn and Donovan 1994). The size of forest required varies regionally, even within the province. Also, a distinction must be made between forests that merely contain Ovenbirds and those that support viable populations. Those residing in small forest fragments may be unpaired or have minimal reproductive success due to predation, parasitism, and low density of prey items. In the Ottawa area, Villard et al. (1993) studied the Ovenbird in woodlots 4.5-25.9 ha and found that pairing success was lower in fragments than in contiguous forest, but not significantly. It may inhabit small patches in this region. It is restricted to forests larger than 100 ha in Elgin County, but is one of the most common species where it is present. It is not found some years even at Springwater Forest, one of the largest and most mature forests in Elgin County (Lancaster et al. 2004). James (1984b) concluded that it required 70 ha or more of contiguous forest in Ontario. In the Region of Waterloo,

it was rare in woodlots 3-4 ha in area. It was more frequent in larger woodlands, but only 50-67% of forests 20-50 ha were occupied (Friesen et al. 1999a). In southern Ontario, its abundance was positively associated with woodlot size, amount of forest cover 100 m or further from edge, and amount of forest cover within 2 km. It was negatively correlated with the amount of regional forest cover. These relationships were not significant (Austen et al. 2001). Burke and Nol (1998, 2000) characterized the amount of forest required in Peterborough County and central Ontario to support a source population. High-quality habitat was not attained until fragments contained a minimum of 20 ha of core habitat (100 m from edge), or at least 80 ha in total. They concluded that it required forests larger than 500 ha to maintain populations. Smith et al. (2011) analyzed point count data for southern Ontario from the second atlas. The amount of forest in the surrounding landscape had an important and consistently positive effect and this was the most important variable for the Ovenbird at all scales examined. In the Ottawa area, its abundance was best predicted by the amount of surrounding forest cover and woodlot size. The amount of surrounding forest cover was a more important variable than patch size, although this was also important (Lee et al. 2002). These studies suggest that the Ovenbird will inhabit smaller woodlands when there is a greater percentage of forest cover. Elgin County has approximately 15.2% forest cover compared with 29.4% for Ottawa (Riley and Mohr 1994).

Forest size requirements for the Ovenbird have been reported from other areas. In South Carolina, its probability of detection was 7% in 0.5-ha and 1.0-ha deciduous forests, 8% in 2.5-ha forests, 9% in 5.0-ha forests and 12% in 10.0-ha forests. The deciduous stands were all surrounded by pine forest. The probability of detection was 0% in all similarly sized forests surrounded by fields and shrubs (Kilgo et al. 1997). In aspen woodlands surrounded by grassland in North Dakota, its probability of occurrence was 45% in 1-ha woodlots, 60% in 5-ha woodlots, 65% in 10-ha woodlots, 80% in 100-ha woodlots, and 90% in 1,000-ha woodlots. It was predicted to reach 50% probability of occurrence in aspen groves 8-20 ha and should almost always be found in larger stands (Grant and Berkey 1999). In the mid-Atlantic states, the maximum probability of detection was reached at 450 ha, the probability was reduced to 50% at 6.0 ha, and the 3 smallest woodlots in which it was detected at least twice were 2.5, 1.2, and 0.8 ha. It was estimated that 2,650 ha were required to maintain a viable population, the highest for all species studied (Robbins 1979; Robbins et al. 1989). Hayden et al. (1985) considered the 2,650 ha to be an overestimate and concluded that 341 ha was the minimum area requirement for it in Maryland. Estimates reported from other areas were 4.0 ha in New Jersey and 24 ha in Illinois (Bushman and Therres 1988). In Maryland, Lynch (1987) reported its probability of occurrence at 10% in 1-ha woodlots, 25% in 3.2 ha, 41% in 10 ha, 60% in 32 ha, 65% in 100 ha, 69% in 320 ha, and 63% at 3,300 ha. In Wisconsin, its frequency of occurrence in differently sized woods was 4.0% in 6.1-14 ha, 20.0% in 16.2-32.4 ha, and 29.5% in woodlands larger than 32.4 ha. The Ovenbird was 45% more common in larger forests. In pioneer stands, it was more abundant in larger patches, but this effect was less pronounced in more climax stands (Bond 1957). In South Dakota, it was absent in small tableland woodlots 0.7-3.5 ha but was present in large riparian forests (Gentry et al. 2006). In Rhode Island red maple stands surrounded by upland forests, it occurred in low density within the swamp and there was no relationship between patch size and abundance. This may have been because the landscape was 60% forest and area sensitivity had broken down (Golet et al. 2001). In Iowa, the minimum width of wooded riparian strip that supported it was 175

m (Stauffer and Best 1980). In Alberta, it inhabited riparian buffer strips 100 and 200 m wide, but not those 20, 40, or 80 m wide (Lambert and Hannon 2000). In Missouri, it occurred in wide (400-530 m) riparian strips, but not in narrow (55-95 m) strips (Porneluzi et al. 2020). In Pennsylvania, Porneluzi et al. (2020) suggested that 1,000 ha may be needed in areas of lower density and that the presence of a forest larger than 5,000 ha was necessary to ensure viable populations in nearby woods. The amount of regional forest was considered important to Ovenbird abundance in Connecticut, Maryland, and the mid-Atlantic states (Askins et al. 1987; Lynch 1987; Robbins et al. 1989), but not in Michigan (Crozier and Niemi 2003). Robinson (1992) found the Ovenbird in woodlots as small as 14 ha in southern Illinois. Woodlots this small in Missouri, central Illinois, and the eastern United States generally lack Ovenbirds. He suggested that the Illinois woodlots might be attractive because there are no large (500 ha) upland forests within a 200-km radius. McShea and Rappole (1997) determined that song rates were higher in larger forests and where the Ovenbird was more abundant. Survey results might underestimate the abundance of the Ovenbird in smaller forest fragments.

Many authors consider the Ovenbird a forest-interior species that avoids forest edge. Freemark and Collins (1992) assumed that it was a forest-interior species because it was area sensitive but Villard (1998) pointed out that there was no information to establish a linkage between area sensitivity and edge avoidance. Mazerolle and Hobson (2003) cautioned that early morning surveys may falsely indicate that Ovenbirds are avoiding edge. During early morning, males spend most of their time defending their territories, with foraging activities occurring later in the day. Males with territories along edges spend the early morning defending the interior portion of their territory because there are no neighbours on the edge side. Edge use varied with the time of day, with the mean time of observation in edge habitat occurring at 1139 hours compared with 0936 hours in the interior. Studies conducted in early morning only are likely to underestimate usage of forest edge habitat. A few studies determined that the density of nesting Ovenbirds is greater in forest interior than edge and concluded that this is due to edge avoidance (Kroodsma 1984; Wenny et al. 1993). In Vermont, densities of Ovenbirds were 40% lower at edges than in forest interior. The proportion of area defended as territories did not differ between edge (39.6%) and interior (36.7%). Ortega and Capen (1999) concluded that lower density near edges was related to variation in territory size and that it did not actively avoid forest edges. In New Hampshire, it was equally abundant at edges of clear-cuts and distant from edge (King et al. 1997).

The Ovenbird is not an obligate forest-interior species. There are occasions when it exhibits an aversion to edge, when it appears indifferent to edges, and when it actively selects edge and avoids forest interior. In Michigan, Hann (1937) did not find any nests closer than 20 m from forest edge. In Peterborough County, the mean distance of nests from forest edge was 125.5 m in forest fragments compared with 81.9 m for random sites. In larger forests, nests averaged 250.8 m from edge compared with 192.1 m for random sites. Burke and Nol (1998) concluded that random sites within small tracts contained little core area and had few sites available for nesting at distances of 190 m from edge. Smith et al. (2011) found that increasing amounts of core area had a stronger positive effect when the amount of forest was low. It is likely that Ovenbirds nesting in small patches or in areas with limited forest cover show a greater tendency to avoid edge. Edges may contain higher densities of predators and cowbirds and lower densities of invertebrate prey. Edge avoidance is more likely in forests within agricultural and urban landscapes than where forests are fragmented

by forestry and natural features such as wetlands, water bodies, and burns. In Saskatchewan, Mazerolle and Hobson (2003) studied Ovenbirds in relation to forest edge in an agricultural landscape. Their results were the opposite of those of Burke and Nol (1998, 2000). More than 20% of Ovenbird observations were less than 25 m from edge and activity centres were closer to edge than randomly derived activity centres. Forty-seven percent of sightings were less than 50 m from edge, and this habitat was only 33.3% of home ranges. Similar results were obtained when edge was defined as 25 m. Nests tended to be closer to edge (44 m) than the mean distance of random points (58 m). In this study area, forest edges had the greatest biomass of insect larvae and arthropod abundance was not correlated with leaf litter or soil moisture, which increased with distance from edge. Burke and Nol (2000) found that invertebrate abundance was low in the edges of the forests that they studied. Differences in the abundance of food relative to edge might partially explain the apparent preference of edge by Ovenbirds in Saskatchewan and edge avoidance in Ontario. In Saskatchewan, there was no evidence that edge habitats were lower in quality than forest interior, but edge habitat was inferior in Ontario. In Alberta, it tended to avoid edges created by clear-cuts but the response was not significant (Villard et al. 2007). In Wisconsin, it tended to nest in higher density near forest clear-cut edges (Flaspohler et al. 2001). The highest nesting density reported for the Ovenbird in southern Illinois was at the edge of a pine plantation (Graber et al. 1983). In a 33-year Pennsylvania study, all territories were on edge and Ovenbirds could not be enticed into forest interior using broadcasts of their calls. There were 14 territories each year, almost always at the same location. The mean litter depth in territories was only 1.64 cm, less than found on any territories in Ontario. It appeared to be avoiding the eastern chipmunk, a known nest predator. Chipmunks were found in 97% of off-territory surveys and it took an average of 2.1 minutes to detect one. On territories, chipmunks were found on only 14% of surveys and it took an average of 7.2 minutes to detect one. One territory was occupied for 2 years and abandoned the third. No chipmunks were detected on it the first 2 years, but chipmunks were present the third year (Morton 2005). In a 15-year study in New York, nests were in locations with significantly lower chipmunk populations (Emmering et al. 2018). It appears as though the Ovenbird does not respond to edge per se, but instead selects areas with a greater abundance of food and low densities of predators and possibly brood parasites. In individual woodlands, it may be more common in the interior or at edges, or be uniformly distributed. Edge avoidance is most likely to occur in agricultural landscapes and in small forest patches due to lower food abundance and higher densities of predators and parasites in edge.

All Ontario nests were on the ground, mostly in areas with deep dead-leaf ground cover. Most nests (50.0%) were among ferns, grasses, and herbaceous plants; 39.1% were at bases of trees, saplings, shrubs, and stumps, often concealed by overhead branches; 7.3% were under fallen branches; 2.7% were in moss hummocks; and 0.9% were under arched tree roots. Most nests were hidden in the surrounding vegetation, but 3 were exposed. Nests were both in depressions in the ground and on level ground (Peck and James 1987). In Peterborough County, nest sites were on mid- to upper slopes and were characterized by a low percentage of bare ground (less than 7%), moderate herbaceous and sapling cover, low seedling and shrub coverage, high canopy cover, deep leaf litter, moderate slopes, and distances of approximately 3 m from the nearest tree (Burke and Nol 1998).

Although nests are rarely closer than 20 m to a forest edge, most are in or near openings in forests. In Michigan, most were less than 10 m from an internal roadway, creek bed, lane, or open spaces within the woods. The average distance of nests from open spaces was 4.4 m. The 7 furthest were 12-20 m away from an edge or opening. If these 7 were omitted from the calculation, the average distance from an opening was 2.8 m. All nests got a little sunshine each day, albeit a very small amount. Nests have been reported in and near openings in Ontario, Quebec, British Columbia, New Jersey, and throughout much of its range. The Ovenbird avoids areas of dense shrubbery for nesting, but nests may be at the base of herbaceous vegetation, saplings, or trees. They may also be hidden under clubmosses, ferns, and low-hanging branches. A high proportion is built in open areas among leaves. All reported nests except one were on the ground; the exception was in the hollow of a large pine log (Beals 1960; Campbell et al. 2001; Chapman 1907; Gross in Bent 1953; Hann 1937; Maciula 1960; Mousley 1916a, 1926; Porneluzi et al. 2020).

Males begin defending a territory as soon as they arrive in spring. When the nest site is selected, territory boundaries undergo some changes, shifting the centre of interest from the male's favourite singing perch to the nest, and there may be an initial shift when females arrive. There is little change in the territory thereafter unless later nests are built. In some areas, there is a buffer between territories and foraging may occur in these undefended areas. In other populations, territories are contiguous and foraging occurs within the territory. Territorial boundaries are usually respected, but territories may overlap in some cases. In Saskatchewan, territories overlapped by 20% in contiguous forest and 34% in forest fragments. During the premating, mating, incubation, and nestling periods, the area used by the male in a day was almost as large as the entire territory. During the nest-building and egg-laying periods, the male uses approximately half the territory on a daily basis. Territory size is influenced by the type of forest community, density of birds, whether the male is paired, whether the territory is on forest edge or in forest interior, whether the territory is in contiguous or fragmented forest, and food availability. Older and larger males have larger territories than those that are younger or smaller. The higher the habitat quality and the more abundant the food resources, the smaller territories were. Habitat quality is also linked to food availability, so food abundance may be the most important criterion in defining territory size. Where birds can forage off the territory, the linkage between food availability and territory size is weak (Drapeau and Darveau in Gauthier and Aubry 1996; Hann 1937; Mazerolle and Hobson 2004; Ortega and Capen 1999; Smith and Shugart 1987; Stenger 1958; Stenger and Falls 1959; Van Horn and Donovan 1994; Zack and Falls 1979). In Vermont, ground cover was significantly less in territories (4.3%) than in unoccupied areas (4.8%). Territory size decreased with decreasing ground cover. Proximity to a road was more important in defining territory size than habitat, suggesting an effect on habitat quality that was independent of vegetation structure. Edge territories were significantly larger (0.53 ha) than those in forest interior (0.39 ha). Overall territory size ranged from 0.20 to 0.69 ha (Ortega and Capen 1999). In Tennessee, occupied territories had a higher percentage of canopy closure, the largest tree classes, and a lower percentage of ground cover, shrub cover, and conifer BA than unoccupied areas (Smith and Shugart 1987). In Quebec, territory boundaries were most often associated with fern cover, vegetation-covered rocks, and shrub diversity, suggesting that these served as landmarks rather than resources (Porneluzi et al. 2020). Territories may contain habitats that are not used. A Pennsylvania site had several areas dominated by large boulders which likely reduced the area of

the forest floor that was suitable for foraging. The average territory size was 1.0 ha in rocky areas compared with 0.5 ha in other areas (Bernard et al. 2001). In Algonquin Park, several territories had open, unforested areas within them that were not used (Stenger 1958).

Five studies examined territories of Ovenbirds in Algonquin Park (Martin 1960; Stenger 1958; Stenger and Falls 1959; Zack and Falls 1975, 1979). In 1 study, most territories were separated by about 18 m and 30 m in sugar maple stands where territories were larger. Some territories were contiguous or overlapped. Territory depth extended from the ground to 8-12 m above ground, which corresponded to the height of the lowest branches in the canopy. These were often used as singing perches. In 1 area, singing perches were scattered throughout the territory with no particular concentrations, and no song posts were used repeatedly. In another area, song perches were patchily distributed within the territory and often occurred in clusters. The density of song perches decreased toward the periphery of the territory. Nests are within the territory, but may be at its edge. In 1 study, territories were 0.02-1.6 ha (average 0.23 ha). Another study found that territory size ranged from 0.3 to 1.7 ha. Territory sizes differed by forest type and averaged 0.7 ha in aspen, 0.9 ha in conifers-birch, 1.0 ha in mixed woods, and 1.3 in sugar maple, suggesting that aspen stands are superior habitat. The territory sizes of 2 males were smaller when they were unmated than when they became mated. The territory location did not change when birds renested. When renesting, 2 males increased the size of their territory and one decreased it: 1.1 to 1.5 ha, 0.6 to 1.4 ha, and 0.6 to 0.4 ha. Territory sizes of first and second nesting attempts for individual males in different habitats were 0.61 and 0.45 ha in aspen, 0.61 and 1.38 ha in mixed forest, and 1.09 and 1.46 ha in mixed woods. Mean territory sizes in nonbudworm years were 0.83 ha (range 0.5-1.1 ha) compared with 0.48 ha in budworm years (range 0.4-0.6 ha) for first nests, and 1.4-1.5 ha in nonbudworm years compared with 0.3-0.5 ha in budworm years for second nests. In nonbudworm years, third nests were not attempted; territory sizes were 0.5-0.6 ha in budworm years for third nests. During budworm years, there was no significant difference in territory size between first and replacement nests, but territory sizes increased significantly for replacement nests in nonbudworm years. During budworm years, territories were more densely packed in addition to being smaller. The average distance between territory centres was 92.3 m in budworm years and 108.6 m in nonbudworm years. At 1 site, the mean area used for foraging was 6,346 m^2 (range 4,600-8,450 m^2), the mean territory size was 5,146 m^2 (range 2,454-8,154 m^2), and the 95% territory size was 3,649 m^2 (range 1,611-5,592 m^2). The mean percent of the foraging search path that was outside the territory was 31.43% (range 14.64-61.66%) and 39.23% (range 18.15-67.90%) was outside the 95% core territory area. Near Lake Nipigon, 9 territories averaged 0.77 ha (range 0.44-1.21 ha; Kendeigh 1947).

In Saskatchewan, the territory size was 1.41 ha in forest fragments and 1.28 ha in contiguous forests. The mean home range size of individuals with territories abutting an edge was 1.95 ha (Mazerolle and Hobson 2003, 2004). In Michigan, territory size was 0.2-1.8 ha, average territory size was 0.26 ha in Wisconsin, average territory size was 0.65 ha in New York (range 0.10-1.21 ha), 13 Illinois territories were 0.5-2.2 ha (averages 1.0 and 1.7 ha over 2 years), 23 Tennessee territories averaged 0.27 ha (range 0.13-0.38 ha), Missouri territories were 0.88-1.40 ha, and Quebec territories averaged 0.27 ha with a range of 0.2-1.8 ha (Drapeau and Darveau in Gauthier and Aubry 1996; Graber et al. 1983; Hann 1937; Kendeigh 1945; Loss and Blair 2011; Smith and Shugart 1987; Van Horn and Donovan 1994). In Quebec sugar maple stands, territories were larger (0.60 ha) in forests

that had declined than in healthy stands (0.34 ha; DesGranges et al. 1987). In response to timber harvesting in Alberta, territory sizes decreased in residual adjacent habitat. In 100-m wide residual strips, territory size decreased from 1.76 to 1.45 ha after harvest. Territories decreased from 1.60 to 1.36 ha in 200-m wide strips (Lambert and Hannon 2000).

Natal philopatry rates appear to be low. In Michigan, 1 of 68 young (1.5%) returned to nest in its natal area. It established a territory 300 m from its natal nest and mated with the female that had been there the year before (Hann 1937).

Adult site fidelity is fairly high. Schlossberg (2009) calculated site fidelity at 32% from a sample of 908 birds from 8 studies. The rate of adult return varies depending upon age of the bird, mating success, and habitat quality. In New Brunswick over a 9-year period, 322 of 525 males (61.3%) returned in at least one of the following breeding seasons (Haché et al. 2016). In Michigan, 24 of 46 adults (54.5%) returned, including 52.4% of females and 56.5% of males. Both sexes returned to their previous territory, if possible. Old males have a good chance of obtaining their former territories either by arriving early or driving away other males. Over several years of study, only 1 male moved its territory. It occupied an adjacent territory that perhaps overlapped the old one. Females go first to their old territory. If the male there already has a mate, she moves to an adjacent territory. Eight females returning to their original territory had nests 2.6-48 m (average 19.2 m) from their previous nest site (Hann 1937). In a 21-year study in Pennsylvania, no Ovenbirds moved between 2 study sites that were 1.5 km apart. Bernard et al. (2011) concluded that long-term dispersal by older birds was rare and that failure to return was probably a result of death. Return rates at the 2 sites were 72.9% and 57.4%. There was no significant difference in return rates for birds that had nested successfully or unsuccessfully the previous year. Despite high rates of territory fidelity, territories tended to drift apart. The distance from the first territory increased each year that a bird returned but the direction of the shift was not constant. Shift distances were different among age classes, with first-year shifts greater than subsequent years. The mean shift distance from centre to centre of territories was 41.6 and 76.5 m for the 2 sites. Nearly all shifts between years were less than a territory width. Birds moved a mean distance of 65.5 m from their first-year territory. Thirty-seven lifetime shifts were beyond 100 m with the furthest 302.8 m. The high site fidelity at these Pennsylvania study areas may have been because Ovenbirds were in high quality, homogenous habitat. Another Pennsylvania study determined that annual return rates for males over a 2-year period were 67% and 62%, with 85% being after-second-year birds (Morton 2009). In Missouri, males that were paired but failed to raise young rarely returned (9.1%), but the return rates of unpaired males (41%) and paired males that were successful (54%) did not differ from each other. Return rates were similar in both fragmented and unfragmented landscapes. Of 47 returning males, 30 (64%) had territories with more than 50% overlap with the previous year's territory, and 12 (26%) were adjacent to or overlapped with less than 50% of the previous territory. The remaining 5 (10%) were not adjacent, but were separated by less than 200 m. Unpaired males returned to essentially the same location the next year. Upon returning, previously unpaired males achieved a rate of pairing success (73%) that did not differ from previously successful males (80%). Territories that were successful were more likely to support successful pairs the subsequent year and unsuccessful territories were more likely to be unoccupied or be settled by an unpaired male the following year (Porneluzi 2003; Porneluzi and Faaborg 1999). In Saskatchewan, 41.0% of 398 males returned to the same site at least once. Return rates were 44.4%

in contiguous forest, 43.1% in forest fragments within a largely forested landscape, and 35.1% in forest fragments within an agricultural landscape. There was no significant difference in return rates among the 3 types of forests, but Ovenbirds in small fragments in agricultural landscapes had lower return and survival rates. The probability of a male returning was dependent upon its pairing success the previous year. Only 11% of unpaired males returned compared with 41% of paired males, but there was no significant difference in the return rates of males that were successful or unsuccessful the previous year. Significantly more yearling males were recruited into forest fragments in agricultural settings (90%) than in fragments in forested landscapes (73%) and contiguous forests (70%). Eighty-eight percent of returning males relocated less than 100 m from their previous territory. There were no significant differences in distances moved by returning males in different landscapes or by successful or unsuccessful birds. Increased immigration into small agricultural woodlots seemed to compensate for the low return rate to these fragments. The larger proportion of older birds in contiguous forest could be due to floaters obtaining territories as they get older rather than from failed breeders dispersing from small agricultural woodlots to larger forests (Bayne and Hobson 2002a). Villard et al. (1992, 1995) studied numerous woodlots near Ottawa and found that this region constituted a metapopulation for the Ovenbird. Local extinctions and recolonizations occurred within individual woodlots but the total number of occupied woodlots remained fairly constant. Patches that experienced population turnovers were smaller than those where it was continuously present, but were not significantly larger than patches where Ovenbirds were never recorded. In New Brunswick where single-tree selection removed 30-40% of the BA of trees, the return rate of males was 69.1%. Return rates were similar in treatment and control plots during the first year after treatment, but were 15.8% and 12.7% lower on treatment plots 2 and 3 years postharvest, respectively. A lower proportion of after-second-year birds returned to treatment than control plots suggesting that the cut plots were of inferior quality. Dispersal movements were short with only 2 males moving more than 100 m from their previous territory. The proportion of first-year birds breeding in control and treatment plots was similar suggesting that they were not forced to breed in suboptimal habitat (Haché and Villard 2010). In New Hampshire, 46% of adults fitted with geolocators returned, similar to the return rate of 53% of adults without geolocators (Hallsworth et al. 2013). In New Jersey, only 3 of 172 adults (1.7%) returned. This was marginal habitat that consisted of a 40-year-old field that had regenerated with second growth (Suthers 1988). In Illinois, only 16.7% of adults returned, indicating a high rate of turnover. These were isolated fragments distant from potential source woodlands where there was a high predation rate. This area was poor habitat (Robinson 1992).

Limiting Factors

Eggs have been found in Ontario nests from the last week of May until the end of July, with most present in the first 3 weeks of June (Peck and James 1987). In Algonquin Park, most eggs hatched between 26 and 28 June and the maximum biomass of invertebrates occurred during the first half of July during the nestling period (Stenger 1958). Nests there are under construction from mid-May until early July, eggs are present from late May to late July but chiefly in June, nestlings are present from early June to early August, and dependent fledglings occur from late June to mid-August. July and August nests are probably replacement nests (Tozer 2012).

The female begins building the nest 1-6 days after she arrives on the territory. The time required to build first nests is 5 days. Successive nests may be completed in 4 days or less. The first egg is laid 1-3 days after the nest is complete. Eggs are laid at the rate of 1 a day. Incubation may begin in the afternoon or evening before the last egg is laid or as late as the day after the last egg is laid. The incubation period at 5 Ontario nests was 11-12 days. In Michigan, the incubation period ranged from 11 days 12 hours to 14 days (average 12 days 5.6 hours). All eggs of a clutch have approximately the same incubation period and there is no difference in the incubation period in cool or warm weather or in parasitized or unparasitized nests. Young may leave the nest in an emergency when they are 6 days old, but typically remain in the nest longer. In Michigan, the average nestling period was 7 days 22.5 hours (range 6 days 13 hours to 8 days 12 hours). In North Carolina, the average nestling period was 7.6 days and was 8.0, 7.8, and 7.0 days over 3 years. Larger broods fledged sooner than smaller broods, with averages of 8 days for 2-nestling broods, 8.1 days for 3 nestlings, 7.7 days for 4 nestlings, and 7.25 days for 5 nestlings. In Minnesota, most young fledged when they were 8 days old, but some fledged on day 7. Abundant food resulted in a shorter nestling period. Increased temperatures in May and June corresponded to a decrease in the nestling period, although this relationship was weak. The nestling period is as long as 10 days in some areas. The short nestling period may be an adaptation to reduce predation risk. Predation rates during the nestling period are double those during incubation. In North Carolina and Tennessee, the average length of the nesting cycle was 31.4 days for first broods and 30.1 days for renesting and second broods. Averages were 7.1 days for nest building (5.8 days for later nests), 2.5 days for egg laying, 13.2 days for incubation, and 8.7 days for the nestling period (Chapman 1907; Gross in Bent 1953; Hann 1937; Harrison 1984; Mousley 1926; Nice 1931; Peck and James 1987; Stodola et al. 2010a; Van Horn and Donovan 1994).

The Ovenbird typically raises a single brood, but there are rare records of second broods, including one from Algonquin Park during a spruce budworm outbreak. Two second broods were reported in Michigan and 3 were documented in Tennessee. A New York population appeared to raise 2 broods. Renesting occurs regularly if a nest is disarranged or lost. The probability of renesting in Tennessee and North Carolina was 75% at the nest construction stage, 67% at the egg stage, and 70% at the nestling stage. The distance of 15 replacement nests from the first nest averaged 42 m in Michigan (range 18-66 m). In Ontario, clutches of 2-6 eggs have been reported, with 4 and 5 eggs most frequent (mean 4.3 eggs). In Algonquin Park, both first and replacement clutches averaged significantly larger in budworm than in nonbudworm years. During budworm years, first clutches averaged 5.0 eggs compared with 4.2 eggs in nonbudworm years; replacement clutches averaged 4.5 and 3.7 eggs, respectively. In budworm years, no clutches contained fewer than 4 eggs and 1 female laid 5 eggs in her third nesting attempt. In nonbudworm years, replacement clutches all contained 3 or 4 eggs. Throughout its range, the Ovenbird lays 3-6 eggs, but mostly 4 or 5. First nests typically have 5 eggs; later nests have 3-5 eggs. In Michigan, all 3-egg clutches and all but a single 4-egg clutch were laid by females that had previously laid a clutch. The maximum number of eggs laid by an individual bird in a season was 10 eggs (Chapman 1907; Gross in Bent 1953; Hann 1937; Kendeigh 1945; Peck and James 1998a; Podolsky et al. 2007; Zach and Falls 1975, 1976a).

The age of first breeding is 1 year. Birds nest every year thereafter if they can find a mate. The sex ratio is male biased so there are unpaired males in all populations, even within contiguous forest. One unpaired Illinois male defended 2 territories 200 m apart. The mating system is typically

monogamous, but rare cases of bigamy and polyandry have been reported. If an adult receives no fledglings to care for or loses them, it may remate if it is not too late in the season. Pairs usually do not remate in subsequent years, but this happens occasionally. Remating occurs only if both birds return to the same territory and another female has not mated with the male by the time the original female arrives (Hann 1937, 1940; King et al. 2000; Robinson 1992; Van Horn and Donovan 1994; Villard et al. 1993).

The Ovenbird forages by walking on the ground, picking food from the substrate, and hunting among dead leaves. Most food is obtained in the leaf litter on the forest floor. It does not scratch with its feet, but occasionally turns over a leaf with its bill. It gleans some insects from low ground vegetation or from sides of decaying logs. In Vermont, 90% of prey attacks were by gleaning and 10% were aerial. Foraging substrates were 77.5% ground, 2.5% foliage, 2.5% air, 2.5% tree trunk, and 1.0% branch. Over 2 years in Algonquin Park, only once was one observed attempting to feed in a tree, and it was extremely awkward at this. During a spruce budworm outbreak in the same area, it frequently fed in infested white spruce and balsam fir, taking larvae, pupae, and adults. More than 100 observations of arboreal feeding were made. It searched in small conifers that could be reached from the ground and also along the main branches of larger trees. Spruce budworm moths that it flushed were often pursued and captured aerially. In Algonquin Park, the distribution of prey was patchy and foraging sites contained significantly more food than areas that were not searched. The Ovenbird is responsive to the distribution of its food supply and concentrates searches in areas of high food abundance. It systematically forages along pathways, avoiding areas that have already been searched. Areas of high prey density are remembered, and initial foraging bouts on subsequent days focus on sites that previously supported abundant prey. In Tennessee, prey abundance was correlated with percent canopy cover and density of trees 15.3 cm DBH and larger, and negatively correlated with the density of shrubs, density of trees 2.5-7.5 cm DBH, and the BA of conifers. Stands dominated by larger trees with a closed canopy and few shrubs in the understorey supported the greatest abundance of prey. The Ovenbird usually takes larger prey in preference to smaller prey, but size selection is less important with familiar prey. The close relationship between prey density and territory size in some populations suggests that food supply limits the size of the breeding population in some areas (Lent and Capen 1995; Morse 1989; Stenger 1958; Smith and Shugart 1987; Zach and Falls 1975, 1976b, 1976c, 1979). Burke and Nol (2000) concluded that food availability was probably a limiting factor in small woodlands in central Ontario.

Stomachs of 5 nestlings in Algonquin Park contained 35.4% caterpillars, 17.3% unidentified larvae, 15.4% weevils, 12.3% snails, 9.2% lepidopteran adults, 10.8% unidentified beetles, 6.1% fly larvae, 1.5% flies, and 1.5% bugs. In Michigan, the food brought to young nestlings consisted of green and brown geometer moth larvae and small earthworms. As the young grew, adult insects were added to their diet, including crane flies, moths, ants, and beetles. Nestlings have eaten spruce budworm larvae, click beetles, and fireflies. In Ohio, there was little evidence that fledglings adopted a frugivorous diet and they appeared to eat a variety of arthropods. In Algonquin Park, the Ovenbird exhibited a low preference for eating ants. Several young collected a few days after they left the nest had a diet similar to that of the adults (Hann 1937; Mousley 1926; Stenger 1958; Zach and Falls 1975, 1979).

A sample of 98 adult stomachs collected over an 11-year period in Algonquin Park consisted, by weight, of 24.0% unidentified larvae, 20.7% ground beetles, 10.7% unidentified beetles, 19.9% weevils, 12.3% ants, 6.1% spiders, and 4.4% miscellaneous beetles. Other items that constituted less than 5% of the diet included rove beetles, beetle larvae, fly larvae, snails, millipedes, hymenopterans other than ants, flies, bugs, and lepidopteran and fly pupae. The major invertebrate groups in the diet occurred in similar proportions as the litter samples from the forest floor. Some soil invertebrates were eaten less than their abundance, but these were subsurface species that were not generally available to Ovenbirds. There was no selectivity for food items from the forest floor. The diet varied annually, providing further evidence for lack of selectivity. Caterpillars occurred in the diet in greater proportion than they occurred in leaf litter indicating that some were gleaned from trees, that there is selectivity for caterpillars, or that an increased number occur on the ground during the shortest period of greatest abundance. Near Lake Nipigon, the diet of 8 adults included 39.0% beetles (8.5% ground beetles, 8.2% click beetles, 4.8% scarab beetles, 0.4% weevils, and 17.2% unidentified). Hymenopterans were second in abundance at 19.4%, including 9.4% ants, 5.0% sawflies, 1.1% ichneumonid wasps, a parasitic wasp, and unidentified species. Spiders were third in abundance (11.4%), followed by flies (fungus gnats and marsh flies) at 5.1%, 1.9% harvestmen, 0.1% lacewings, and 5.4% unidentified invertebrates. In Quebec sugar maple forests, 93% of food items were beetles and a high proportion of these were brown leaf weevils. Other items included slugs, centipedes, earthworms, aphids, crickets, mosquitoes, and black flies. The Ovenbird does not exhibit a strong vagrancy response to outbreaks of the spruce budworm. When an outbreak occurred in Algonquin Park, food supply remained high after 15 July, territories were smaller and more densely packed, and there was a greater tendency to replace lost nests. A laboratory study demonstrated that it fed both on early and late-instar gypsy moth larvae and that it was more likely to feed on larger larvae. Four birds collected in Maine during a spruce budworm outbreak had eaten 14% budworm larvae and pupae by volume (DesGranges et al. 1987; Gross in Bent 1953; Hann 1937; Kendeigh 1947; Mitchell 1952; Mousley 1926; Patten and Burger 1998; Stenger 1958; Vitz and Rodewald 2012; Whelan et al. 1989; Zach and Falls 1975, 1979). The Ovenbird responds positively to spruce budworm outbreaks and may increase its population slightly (Morris et al. 1958; Venier et al. 2009).

The Ovenbird is a common host of the Brown-headed Cowbird. It typically accepts cowbird eggs, but occasionally abandons the nest and builds a replacement nest. As many as 7 or 8 cowbird eggs have been found in a single Ovenbird nest, but usually only 1 or 2 cowbird eggs are laid in a nest. Early nests are parasitized more frequently than later nests due to the cowbird's early laying period and the presence of more potential hosts later on. The female cowbird often removes an Ovenbird egg after laying her own egg. Parasitized nests contain fewer Ovenbird eggs than unparasitized nests: 2.7 compared with 4.1 eggs in Massachusetts, and 3.0 compared with 4.8 eggs in Minnesota. In Michigan, 18% of Ovenbird eggs were lost due to removal by cowbirds. Some nests were deserted and replaced resulting in a net loss of 13.5% of eggs. The incubation periods of the cowbird and Ovenbird are similar. The cowbird does not have a significant advantage by hatching earlier but a single cowbird nestling consumes as much food as 2 Ovenbird nestlings. There is no evidence to suggest that Ovenbird nestlings starve, and a high proportion of nests fledge both Ovenbirds and cowbirds. One Michigan nest fledged 2 cowbirds and 4 Ovenbirds, and nests with 2 cowbirds fared as well as those with only one. Due to egg removal and loss of some young from

competition with cowbirds, parasitized nests fledge fewer Ovenbirds than unparasitized nests: 1.7 compared with 4.1 fledglings in central Ontario, 2.4 compared with 3.8 fledglings in Massachusetts, and 2.5 compared with 4.4 fledglings in Minnesota. In central Ontario, 67% of parasitized nests produced at least 1 Ovenbird fledgling. The cowbird has a longer nestling period than the Ovenbird, remaining in the nest an additional 1-2 days. The host parents continue to feed the cowbird nestling until it leaves the nest. Of 40 cowbird eggs laid in Ovenbird nests in Michigan, 22 hatched, 10 fledged, and only 5 left the woods. Cowbird survival from egg laying to independence was 12.5% compared with 24.2% for the Ovenbird. In Minnesota, 1 fledgling from a parasitized nest and fledglings from unparasitized nests were radiotracked. The fledgling from the parasitized nest died 26 days after fledging and showed no signs of predation but its stomach was empty. All fledglings recovered from nonparasitized nests had signs of predation and their stomachs contained food. An adult was observed accompanying the fledgling from the parasitized nest on 33.3% of observations compared with 68% of observations for fledglings from nonparasitized nests. It was suggested that parasitism could affect survival of fledglings because of parents spending additional time feeding cowbird fledglings (Burke and Nol 2000; Hann 1937, 1947; Harrison 1984; Hersek et al. 2002; Lowther 1985, 1997; Peterson et al. 2012; Robinson 1992).

Cowbird parasitism rates on the Ovenbird range from 0% to 100%. The rate of parasitism depends upon local abundance of the cowbird and landscape and forest-size characteristics. Parasitism rates are higher in agricultural than forested landscapes and in smaller than larger woodlands. Parasitism rates frequently approach 0 in contiguous forest. In Ontario, 34 of 298 nests (11.4%) were parasitized, comparable to the 10% rate reported in Quebec. In Manitoba, Saskatchewan, Alberta, and the Northwest Territories combined, 36.8% of nests were parasitized. Parasitism rates in fragmented landscapes include 72% in Missouri, 40% in Illinois, 19% in Wisconsin and Minnesota, 29% in Massachusetts, 17% in Saskatchewan, 80% in Wisconsin, 52% in Michigan, 0% in Georgia and South Carolina where no ground-nesting species were parasitized, 33% in Connecticut, 36% in Ohio, and 100% in Iowa. In Missouri, 32 of 65 nests (49.2%) were parasitized in 890-ha and 1,146-ha forests, but the dominant cover in the larger landscape was not described. In 3 Missouri woodlots 575-1,146 ha, 50 of 94 nests (53.2%) were parasitized. Parasitism rates reported in forested landscapes include 6.1% in Minnesota, 4% in Wisconsin and Minnesota, 1.6% and 5.0% in Minnesota, 4% in Missouri, and 0% in Ontario, New Brunswick, North Carolina, Minnesota, Tennessee, New Hampshire, and Saskatchewan (Brittingham and Temple 1996; Burke and Nol 2000; Drapeau and Darveau in Gauthier and Aubry 1996; Gross in Bent 1953; Hann 1937; Hanski et al. 1996; Harrison 1984; Hersek et al. 2002; Jenkins and Faaborg 2016; Jenkins et al. 2016; Kilgo and Mossman 2003; Manolis et al. 2002; Peck and James 1998a; Pérot and Villard 2009; Peterson et al. 2012; Podolsky et al. 2007; Porneluzi and Faaborg 1999; Porneluzi et al. 2020; Robinson 1992; Sodhi 1995; Van Horn and Donovan 1994).

South of the Canadian Shield, habitat loss and fragmentation are the greatest limiting factors for the Ovenbird, and this is true through most of its range. Effects of fragmentation are significantly greater in landscapes dominated by agricultural or urban land uses than in forested landscapes. The Ovenbird has been described as one of the most sensitive species to alteration of its habitat. Fragmentation has effects at different scales: at the landscape scale, at the local scale where

reduction in forest size can have impacts, and as a result of fragmentation of individual woodlots by roads, utility corridors, and other disturbances.

At the landscape scale, fragmentation reduces the amount of forest cover in a given region and increases distances among wooded areas. Smith et al. (2011) concluded that the overall negative effects of fragmentation were more important where the amount of habitat was low in southern Ontario. This has a direct effect on area sensitivity, with Ovenbirds requiring larger forests in landscapes with less forest cover. In southern Ontario, there was about a 12% reduction in its probability of occurrence in woodlands with every 1 km increase in distance from a large forest. Colonization of sinks is predominantly through natal dispersal. Occupied forest fragments were mostly less than 14 km from large forests and much less than this on average (Nol et al. 2005). Bélisle et al. (2000, 2007) translocated territorial males in Quebec and Alberta and measured the time it took them to return in different areas. The amount of forest cover was the only factor that affected return rates and timing. The probability of a male returning to its territory increased by 1.06% for each 1.0% increase in forest cover. A bird translocated in a landscape with 80% forest cover would be 99% more likely to return than one in an area of 20% forest cover. Reduction of the percent coverage of forest may disrupt habitat selection processes, reduce colonization of isolated forest patches, and ultimately alter population structure and dynamics. In the eastern United States, only about 17% of detections of the Ovenbird on Breeding Bird Survey (BBS) routes were in fragmented landscapes (Donovan and Flather 2002). In Peterborough County, densities of singing males were 25 times higher in the largest than the smallest woodlots, and density increased significantly with increasing core area (forest habitat 100 m or more from edge; Burke and Nol 1998). In the Hull-Ottawa area, densities in contiguous forest were approximately twice those in fragments (Villard et al. 1993). Density of the Ovenbird was lower in large than small patches near Ottawa, however (Lee et al. 2002). Higher territorial density in larger forest fragments and contiguous forests than in small woodland fragments has been reported from Saskatchewan, Missouri, New Jersey, and Pennsylvania (Gibbs and Faaborg 1990; Hobson and Bayne 2000; Keller and Yahner 2007; Mazerolle and Hobson 2002; Porneluzi and Faaborg 1999; Porneluzi et al. 1993; Van Horn and Donovan 1994; Villard et al. 1993). In Pennsylvania, parameters that were most important in defining density were the percentage of forest within 2 km, forest size, core area, and distance to a large forest. Densities were higher in Saskatchewan where there was a higher percentage of forest cover within 5 km (Hobson and Bayne 2000; Porneluzi et al. 1993). Forest fragments either have larger proportions of their area that are unsuitable habitat or they are less saturated with males (Mazerolle and Hobson 2004). In Missouri and the Midwest, the proportion of edge habitat occupied by males is less than in forest interior, and this relationship has also been observed in Ontario (Burke and Nol 1998; Porneluzi and Faaborg 1999). If some birds avoid edge or have to have larger territories to obtain sufficient food, then smaller woodlots would have lower densities of males. This is because a higher proportion of the habitat of small woodlots is near edge. In contrast, Flaspohler et al. (2001) found no differences in density between forest edge and interior in Wisconsin, but there was a tendency for greater density at edge. In this area, the potential ecological trap of high nest density and low nest success in edge was partially offset by larger clutch sizes in edge.

Even in contiguous forests, there may be unpaired males but the percentage of unpaired males increases as forest size decreases. In eastern Ontario, less than 25% of males were paired in small

woodlots; most pairs were paired in large woodlots (Brenner and Nol 1996). In the Hull-Ottawa area, pairing success over 2 years was 82.4% and 76.5% in contiguous forests and 58.6% and 58.3% in forest fragments. Pairing success was greater in denser populations but the relationship between pairing success and density levelled off and became weak once densities exceeded 4 males per 10 ha (Villard et al. 1993). Also in the Ottawa area, mean pairing success was significantly higher in 3 extensive forests than in 22 forest patches. Pairing success was unrelated to landscape forest cover (Lee et al. 2002). In Peterborough County, pairing success increased most significantly with increases in woodlot core area and ranged from 0% in the smallest woodlots to 100% in the largest. Pairing success was correlated with the density of territorial males. Lower male pairing success in smaller woodlots has also been documented in Saskatchewan, Pennsylvania, Missouri, New Jersey and Illinois (Bayne and Hobson 2001b; Gibbs and Faaborg 1990; Mazerolle and Hobson 2002; Robinson 1992; Van Horn and Donovan 1994; Van Horn et al. 1995). In Saskatchewan, the proportion of paired males was positively correlated with density in woodlots in agricultural landscapes, negatively correlated with density in forest fragments within forested landscapes, and uninfluenced by density in contiguous forests. The effects of fragmentation in agricultural settings on pairing success are most severe where the density of males is lower (Bayne and Hobson 2001b). Most studies that demonstrated an increase in pairing success with increasing forest size were undertaken in agricultural landscapes. This relationship does not appear to occur in woodlots in landscapes dominated by forest. In Missouri, New Brunswick, and Pennsylvania, there were no significant differences in pairing success in forest fragments and contiguous forests in forested landscapes. Fragmentation effects on Ovenbird pairing success appears to be largely restricted to agricultural and urban landscapes (Porneluzi and Faaborg 1999; Porneluzi et al. 1993; Rodewald and Yahner 2000; Sabine 1996; Sabine et al. 1996). In Saskatchewan, males further from edge had a greater probability of attracting a mate. In Vermont, pairing success was lower within 150 m of roads than in forest interior. In Missouri, there were more paired males with territories further than 300 m from edge, but this was not always a significant relationship (Bayne and Hobson 2001b; Ortega and Capen 1999; Van Horn et al. 1995). In another Saskatchewan study and at a Pennsylvania site, pairing success of males was as high on edges as in forest interior (Mazerolle and Hobson 2003; Morton 2005).

Habitat quality and food abundance are often lower in smaller than larger woodlands and in territories of unpaired than paired males. In many areas, the food supply is limited such that habitat quality and food abundance are synonymous. In Peterborough County, the biomass of leaf-litter invertebrates was significantly higher within territories than in random areas and significantly higher in large than small woodlots. Woodlands with more than 20 ha of core area had 10-36 times more invertebrate biomass than woodlots with less than 20 ha of core area. The average invertebrate biomass was higher at random sites in large woodlands than at nest sites in small woodlots. Smaller forests contained significantly lower percentages of leaf litter, more bare ground, and significantly reduced seedling and shrub layers than larger forests. Small tracts lacked deep litter which is important in nest-site selection and abundance of invertebrates. Small woodlots appeared to have poor habitat in terms of food supply. Even in large woodlands, Ovenbirds preferentially selected areas with high food abundance. Desiccation of leaf litter is most pronounced near forest edge. This leads to a decline in food availability which may result in lower density of birds and reduced pairing

success near edge (Burke and Nol 1998). Also in Ontario, small woodlots contained less food in the litter, a possible cause of low pairing rates. It appeared to choose nest sites in smaller fragments that had a sparser shrub layer and denser canopy layer than random sites, and larger fragments may have contained more of these suitable nest sites (Brenner and Nol 1996). Similar results were documented in Missouri, Vermont, and Pennsylvania, with habitat quality and food abundance probably being the most important factors in defining pairing success and distribution of the Ovenbird in small and large fragments and in relation to edge (Ortega and Capen 1999; Rodewald and Yahner 2000; Van Horn et al. 1995; Wenny et al. 1993). In a forested landscape in New Brunswick, there were no significant differences in invertebrate biomass in contiguous forests and forest fragments or in territories of paired and unpaired males. Leaf-litter invertebrate biomass was correlated only with canopy cover (Sabine et al. 1996). In Saskatchewan, there was no difference in the invertebrate biomass in territories in forest fragments and contiguous forests, although the composition of the invertebrates varied. Vegetation structure varied significantly between fragments and contiguous forests and this was the most important factor in determining pairing success and possibly predation rates. Contiguous forests had more hardwood stems, taller trees, larger diameter trees, and more shrubs taller than 2 m, and fewer shrubs shorter than 2 m and less coarse woody debris than forest fragments. Females prefer mature forests with large hardwood trees, so the vegetation differences could affect pairing success. The vegetation parameters that were correlated with invertebrate biomass were leaf-litter depth, increasing shrub density, and decreasing coarse woody debris (Mazerolle and Hobson 2002).

Nest predation rates are typically higher in small than large forest fragments, but this is not always the case. In central Ontario, Burke and Nol (2000) reported predation rates of 55.4% in small woodlots, 41.0% in large woodlots, and 20.0% in contiguous woodlands. Predation rates declined significantly with an increase in the amount of woodland core area. Brenner and Nol (1998) found no relationship between forest size and predation rates in southern Ontario. In Saskatchewan, artificial nests were depredated at higher levels in forest fragments than in extensive woodlands (Mazerolle and Hobson 2002). In Pennsylvania, nest survival rates were lower in agricultural than forested landscapes due to differential effects of predation. Squirrels were significantly more abundant in agricultural landscapes 1 year, but not the other. There were no significant differences in population densities of chipmunks and Blue Jays between landscape types, but there were significantly more American Crows in agricultural than forested landscapes. Lower survival in agricultural landscapes was best explained by the greater abundance of some avian and mammalian predators (Rodewald and Yahner 2001). In central Ontario, Burke and Nol (2000) found no difference in nest predation rates in relation to distance from forest edge. Predation rates were 29% 0-50 m from edge, 56% 50-100 m from edge, 16% 101-200 m from edge, and 32% more than 200 m from edge. Predation rates were unaffected by edge due to the lack of avian predators near edge and the presence of small predatory mammals throughout forest fragments. In Pennsylvania, there was no difference in survival rates in relation to edge (Rodewald and Yahner 2001). In Saskatchewan, artificial ground nests at edges of woodlots in agricultural settings were 25% more likely to be destroyed than those at the edges of woodland fragments in forested landscapes or of contiguous forests (Bayne and Hobson 2001b). In Illinois, artificial Ovenbird nests 20 m from edge had significantly higher egg predation rates than those 200 and 400 m from edge (Linder and

Bollinger 1995). Predation rates are higher in small than large woodlots and in agricultural than forested landscapes. There may or may not be higher predation rates closer to forest edge depending upon the predators that are present. Porneluzi et al. (2020) concluded that predation across 17 states increased with the amount of fragmentation within a 10-km radius.

Parasitism rates of the Ovenbird by the Brown-headed Cowbird are higher in small than large woodlots. In central Ontario, 29.3% of nests were parasitized in small woodlots, 16.4% in large woodlots, and 0% in contiguous forests. In 6.76% of nests in small fragments only cowbird young were produced compared with 1.56% in large fragments (Burke and Nol 2000). Also in Ontario, parasitism was greatest in small- and intermediate-sized woodlots and rare in large woodlands (Brenner and Nol 1996). In Missouri, 6% of Ovenbird pairs raised cowbird young in forest fragments, significantly more than the 1% in contiguous forests (Porneluzi and Faaborg 1999). In Saskatchewan, no nest parasitism occurred in contiguous forests or in forest fragments within forested landscapes. In forest fragments in agricultural landscapes, 17% of nests were parasitized, with all but 1 nest parasitized 1 year (Bayne and Hobson 2002a). In suburban woodlots ranging from 10 to 132 ha in Massachusetts, a higher percentage of nests was parasitized in small (37.5%) than large (34.7%) woodlots, but not significantly (Hersek et al. 2002). In Missouri, Wisconsin, and Minnesota, nest failure due to parasitism was only a factor in forest fragments where 16.7% and 5.27% of the daily mortality rate was attributed to parasitism. In contiguous forests, 2.5% and 4.0% of nests were parasitized compared with 80% and 58% in forest fragments (Donovan et al. 1995). In Ontario, the parasitism rate was significantly higher within 100 m of edge than more distant from edge (Burke and Nol 2000) and this relationship has been observed in other locations (Ford et al. 2001; Ortega and Capen 1999). Porneluzi et al. (2020) concluded that brood parasitism across 17 states increased with the amount of fragmentation within a 20-km radius.

Reproductive success is lower in smaller than larger forests, and smaller populations are frequently sinks with adults failing to produce enough young to replace themselves. In central Ontario, woodlot size was the most important factor affecting reproductive success. Significantly more young were fledged per nest in contiguous forests than in either small or large forest fragments. Ovenbirds in contiguous forests produced almost 2 times as many young as those in large fragments and almost 7 times as many as those in small fragments. The number of nesting attempts required to maintain populations were 4.1 in small fragments, 1.3 in large fragments, and 0.8 in contiguous forests. Populations were sinks in small forests, close to maintenance levels in large fragments, and sources in contiguous forests. Populations remained constant over the study, suggesting a source-sink population. Most fragments with nesting Ovenbirds produced at least 1 fledgling over the course of the study and some fragments occasionally functioned as sources. Sink populations can have a positive influence on metapopulation size and longevity provided that source populations remain. Only 1% of forest fragments in central Ontario are sources (woodlands larger than 200 ha), and 82% have no core area and are sinks (Burke and Nol 2000). In Ontario, 6 nesting attempts were required to produce a single young in small woodlots compared with 1 in a contiguous forest. Woodlots with less than 50 ha of core area resulted in no Ovenbirds being produced despite the high density of singing males (Benner and Nol 1996). Similar results have been reported from other areas, but the size of forest that is required to be a source varies. In Missouri, the average clutch size and proportion of pairs raising young in contiguous forests were significantly

higher than in forest fragments. Some of these effects in forest fragments may have been mitigated by renesting. Populations in contiguous forests were self-sustaining, but those in forest fragments as large as 2,000 ha were not (Porneluzi and Faaborg 1999). In Massachusetts, woodlands as small as 120-132 ha acted as sources. These woodlands were surrounded by a forested suburban landscape so that edge effects were not as extreme as for isolated woodlots in agricultural landscapes (Hersek et al. 2002). Podolsky et al. (2007) cautioned that not accounting for renesting and double brooding in models can greatly underestimate annual productivity and that these activities may account for 40% or more of annual fecundity. In Pennsylvania, the proportion of successful males was significantly higher in contiguous forests (59%) than forest fragments (5.9%). Only 1 male in forest fragments was successful in raising young and he was in the largest (126.5 ha) fragment. It was concluded that forests as large as 183 ha did not support sustainable Ovenbird populations (Porneluzi et al. 1993). In Saskatchewan, nest survival rates were lower in small woodlots in agricultural settings, intermediate in woodlots in forested landscapes and highest in contiguous forests (Bayne and Hobson 2001b, 2002a; Hobson and Bayne 2000).

Fragmentation may affect survivorship of males. In Saskatchewan, the apparent survivorship of males was significantly higher in woodlots larger than 20 ha (58%) than in those smaller than 15 ha (34%). Although the probability of recapture rate was higher in forest fragments in agricultural landscapes, male survival rates were significantly lower in these forests than in forest fragments in forested landscapes and contiguous forests (Bayne and Hobson 2002a).

Linear corridors through forests are the final type of fragmentation effects. In Vermont, Ortega and Capen (1999) studied the effects of narrow (7-10-m wide) dirt and gravel roads through forests on the Ovenbird. They concluded that habitat quality for it may be lower within 150 m of unpaved roads in extensively forested landscapes, affecting territory density and possibly reproductive success. In New Jersey, Rich et al. (1994) examined the distribution of the Ovenbird in relation to 8-m wide corridors for unpaved roads, 16 m for paved roads, and 23 m for hydro corridors. Its abundance was significantly reduced on edge transects of corridors 16-23-m wide, but not along those 8-m wide. Corridors 16-23-m wide created an edge effect. Edges also attracted avian predators and parasites. In the Northwest Territories, Machtans (2006) examined the response of Ovenbirds to seismic lines, which were 6-m wide clear-cuts. It was the most sensitive species to this type of disturbance, declining in abundance and shifting territories away from seismic lines. It was not observed crossing these lines. Bayne et al. (2005a, 2005b) examined the effects of seismic lines 6-10 m wide in Alberta. All but 1 Ovenbird was observed on both sides of a line, but birds spent significantly more time than expected on 1 side of the line. The average percentage of the territory on the predominantly used side of the line was 78%. There was no change in abundance or density of the Ovenbird as a result of the lines, but they tended to act as territory boundaries. There was little evidence that it declined in response to seismic lines but there is potential for population-level effects as the density of lines increases. Lankau et al. (2013) continued this research and concluded that Ovenbirds excluded seismic lines from their territories due to a lack of protective cover (lower tree and shrub coverage) and because of reduced food resources due to large areas of bare ground. These effects appeared to be mitigated only once the depth and extent of leaf litter was restored and the amount of woody vegetation returned to forest-interior conditions. Bayne et al. (2016) compared its abundance near energy sector disturbances and in adjacent forest interior in the

western boreal forest. It was 2-19% less abundant along seismic lines, 2-24% less abundant along pipelines, and 11-69% less abundant at well pads than in adjacent forest interior. In Michigan, Valentine et al. (2019) used artificial Ovenbird nests to determine if forest fragmentation due to well pads had an effect on predation. Predation rates on nests 5, 20, and 35 m from edge were similar to those at nests in forest interior and in control woodlots. In West Virginia, it avoided well pads, access roads, and pipelines and was significantly less abundant close to them. Over time, it shifted its distribution within the forest to avoid the area most heavily affected by well pad development and, to a lesser extent, away from linear infrastructure. It declined by 35% in response to these features (Farwell et al. 2019).

Forest management may have detrimental effects on the Ovenbird. It is considered by most authors to be one of the most adversely affected species when forestry practices are implemented. Other studies found few effects. In the Boreal Forest Region of Ontario, Rempel et al. (2007) modelled the effects of forest management on the Ovenbird. Even when all guides for habitat maintenance were adhered to, a decline was predicted because of a decline in hardwoods. A decline was also predicted due to natural disturbances, but this decline was markedly less than declines due to forestry. Vanderwel et al. (2009) summarized the effects of partial harvesting of late-successional forests in the Boreal Forest Region of Ontario. A decrease in population was observed when 50-70% of the forest cover was retained. When only 30% of the forest cover was retained, it became locally extirpated. It declined by 25% when 15% of the forest cover was removed, by 50% when 30% of the forest cover was removed, and by 75% when 45% of the forest cover was removed. Partial harvesting negatively affects habitat by removing canopy trees, reducing litter depth, and promoting growth of understorey shrubs (Vanderwel et al. 2007). Near Sault Ste. Marie, Holmes and Pitt (2006) examined the effects of single and group selective harvesting on the Ovenbird. It declined significantly in 2 of 3 cut-blocks, but showed signs of recovery 3-6 years later. Its abundance was positively associated with canopy cover, BA (especially of trees larger than 50 cm DBH), and leaf litter, and negatively associated with grass and sedge cover, low shrub cover, downed woody cover, and density of tall shrubs. Reduced canopy cover due to thinning could result in a drier leaf-litter layer and lower prey densities. Densities declined after harvesting and the productivity of the remaining individuals was also reduced. In Algonquin Park, it was 50% less abundant in recently logged stands and stands logged 15-20 years previously. The reduced canopy cover and increased shrub growth as a result of thinning was detrimental. Higher air and soil temperatures and lower soil moisture result in reduced beetle populations that serve as prey for the Ovenbird (Tozer 2012). In Algonquin Park, Kingsley and Nol (1999) concluded that the Ovenbird was not adversely affected by uniform shelterwood logging in white pine stands. Also in Algonquin Park, Tozer et al. (2010) examined the effects of group-selection logging. In typical group-selection, 5% of the stand area was removed; intensive group-selection removed 20% of the stand area. The Ovenbird decreased slightly in the second year due to typical group-selection and showed no response to intensive group-selection. The decrease was likely due to a reduction in leaf litter and an increase in ground cover. Numbers did not change with intensive group-selection because birds crowded into the residual forest where the canopy was left intact. In Algonquin Park, its abundance was 50% lower in areas harvested by single-tree selection and in stands logged 15-20 years previously than in uncut stands. It was positively associated with deciduous canopy cover and density of trees 10-20 cm DBH (Jobes et al. 2004). Leblanc (2010)

studied responses of the Ovenbird to single-tree-selection in Algonquin Park hardwood forests. No differences were detected in daily nesting success, pairing success of males, or in nesting behaviour among treatments. In recently (1-15 years) harvested stands, it was selective for nest sites with deep leaf litter and BA associated with larger trees because these microhabitats were limited. After 20-25 years, nest site and total BA were the only microhabitat parameters that remained below preharvest levels. In the Carolinian Forest Region, selective harvesting and diameter limits cuts had no effects on the Ovenbird (Holmes et al. 2004). In the Canadian Shield in Ontario, it was equally abundant in early successional clear-cuts and burns but significantly less abundant in mid-successional clear-cuts than mid-successional burns. It was significantly less abundant in early successional than mature stands but significantly more abundant in mid-successional than mature stands (Zimmerling et al. 2017).

Effects of forest management on the Ovenbird have been reported from other areas. In Quebec, strip-cutting had a detrimental effect; it took 12-15 years for its abundance to reach the levels of neighbouring uncut areas (Drapeau and Darveau in Gauthier and Aubry 1996; Falardeau et al. 1999). In New Brunswick, lower breeding density and reproductive success occurred as a result of single-tree selection and in selection cuts that removed 30% of tree cover every 20 years. The return rate of males was negatively affected by single-tree selection. The Ovenbird was the species most affected by forestry (Bourque and Villard 2000; Haché and Villard 2010; Pérot and Villard 2009). In Nova Scotia, it was one of the most abundant species in unharvested forests, was absent in recent clear-cuts and on thinned plots, and occurred in much lower densities in strip-cut plots than in uncut forests (Freedman et al. 1981). In Saskatchewan, it was significantly more abundant in sites that were at or below rotation age, so forests were not harvested before they provided optimum habitat (Cumming and Diamond 2002). In Alberta, Lambert and Hannon (2000) examined the effects of harvesting trembling aspen stands, leaving riparian buffer strips of 100 or 200 m where trees averaged 60-70 years old. The harvest did not affect numbers within 100-m strips, although territories shifted toward the lake. The 200-m wide buffers retained the Ovenbird at preharvest levels. There was no change in pairing success in either width of buffer, and the authors concluded that the effects of forest fragmentation may be considerably less in areas of extensive forest. In Alberta, it declined in cut-blocks but numbers recovered by the third year after harvest. It increased with increasing BA after cutting and with increasing retention of trees in cut-blocks. There was evidence for an effect of harvesting on the Ovenbird, but it was short lived (Tittler et al. 2001). Another Alberta study determined that it decreased when 25% of trees were removed in deciduous forests and became extirpated when 50% or more of trees were removed. In deciduous forests with a shrubby understorey, it declined when 25-50% of trees were removed and became extirpated when 80-100% of trees were removed (Harrison et al. 2005). In New York, it showed a decline in population with increased intensity of logging. Habitat became less and less suitable as the intensity of logging increased. The population recovered substantially over 6-7 years, but only to half the level of unharvested forest (Webb et al. 1977). Declines in numbers of Ovenbirds as a result of selective logging have been documented in Missouri, Arkansas, Illinois, Wyoming, Minnesota, and Pennsylvania (Hanowski et al. 2002, 2005; Niemi and Hanowski 1984a; Porneluzi et al. 2020; Robinson and Robinson 1999; Yahner 2003). In Pennsylvania, areas where snags were retained in improvement cuts supported lower densities of Ovenbirds than where snags were removed. There was

significantly greater coverage by shrubs in stands where snags were retained and this may have created less favourable breeding habitat (Stribling et al. 1990).

Three studies were conducted on the effects of clear-cutting in forested landscapes. In New Hampshire, clear-cuts were 12 ha or less and cowbirds were absent. There was no evidence of edge avoidance or lower pairing success on edges. Although nest survival was lower on edge, the proportion of pairs fledging young and the condition of fledglings did not differ between edge and interior nests. King et al. (1996) concluded that the effect of small-scale clear-cutting on the Ovenbird was slight in this extensively forested area. Edge effects could be further minimized by making clear-cuts as close to circular as possible and by creating fewer but larger clear-cuts to minimize edge creation. In Minnesota, there was strong evidence for an edge effect on Ovenbirds nesting near regenerating clear-cuts in a forested landscape. Nesting success increased with distance from the nearest clear-cut edge. Differences in nest success rates were due to increased predation rates near edge (Manolis et al. 2002). In Minnesota, territory density in patches that were recently thinned or near clear-cuts was 1-3% greater than in uncut and interior patches. Territory density increased by 19% as upland openings increased from 1% to 22%. Pairing success decreased from 92% to 88% as territory density increased from 0.7 to 2.5 males per ha. Territory settlement patterns were inconsistent with an ideal distribution where densities are highest in the least fragmented landscapes which should contain high quality patches. The reason for this is that the costs of dispersing from a low-quality patch may exceed the costs of remaining (Mattsson and Niemi 2008).

Loss and Blair (2011) studied the effects of invasion of woodlands by common earthworms on the Ovenbird in Wisconsin. Earthworms consume leaf litter and organic layers below the litter, mix soil horizons, reduce the abundance of mycorrhizal fungi and arthropods, and alter nutrient dynamics. Presence of earthworms was not directly associated with Ovenbird daily survival rate, but earthworms affected vegetation. There was a significant positive correlation between presence of earthworms and sedge cover and a significant negative relationship with average litter depth. At 0% sedge coverage, nest success rate of the Ovenbird was 74% compared with 37% for 100% sedge coverage. Nest concealment decreased with increasing sedge coverage, mostly by Pennsylvania sedge. This sedge thrives in response to earthworms because it has a competitive advantage in the absence of other plants, tolerates disturbed soils, and does not depend on mycorrhizal fungi. Ovenbird success rates were 84% with 9.7 cm litter depth compared with 45% at 0 cm. Decreased litter depth can result in decreased arthropod abundance, reduced food availability, and more exposed nests. Earthworms significantly affected the productivity of Ovenbirds. In Ontario, it is likely that a high proportion of woodlands south of the Shield are infested with earthworms and there are local earthworm infestations further north.

Near Peterborough, 14 of 27 of Ovenbird nests (51.9%) failed due to predation. Nests in sites with more cover were more likely to fledge young. Abundance of raccoons and squirrels was positively correlated with housing density. Eastern chipmunks were negatively correlated with housing density. The effects of housing extended only 100 m for chipmunks and squirrels, but 2 km for raccoons. Squirrels were positively associated with the percentage of understorey vegetation. Forest fragments surrounded by greater amounts of less intensive agriculture (hay, pasture, old field) within 2 km tended to have greater invertebrate biomass. Nests are more likely to survive if more

seedlings and forbs are present regardless of the type and relative abundance of mammalian predators, and more invertebrates are likely to be present under these conditions (Richmond et al. 2011).

Acid precipitation and other air pollutants that affect tree health or soil acidity may have adverse effects on the Ovenbird. In Quebec, many sugar maple forests are declining, which results in a loss of crown foliage. Density of Ovenbirds was 42% lower in stands affected by dieback than in healthy stands. Insect abundance appeared to be lower in dieback forests (DesGranges et al. 1987). In Maine, there was no difference in territory size in acidified and control watersheds. Territory size decreased as calcium concentrations in potential prey (adult beetles) increased. Calcium limitation can be a determinant of territory size (Pintar and Olsen 2021). In Pennsylvania, Pabian and Brittingham (2011) added lime to forest plots to increase soil calcium concentrations. Where calcium was added, territory density was 1.8 times higher and clutch size was 1.1 times larger than in control sites. Two times as many young were produced from limed than control plots. At high calcium concentration areas, nests were initiated earlier and as many as 3 replacement clutches were laid. Ovenbirds in low calcium areas rarely laid replacement clutches. Snail abundance was positively correlated with calcium concentrations. Snails may be important in the diet to aid in eggshell formation. Soil acidification due to acid precipitation has the potential to decrease its productivity, especially in the Canadian Shield in Ontario.

Natural disturbances that affect canopy closure may affect the Ovenbird. A decline occurred in Vermont due to changes in habitat structure from an extensive ice storm. In Minnesota, a dramatic decline in density occurred following loss of elms to the Dutch elm disease. This resulted in an increase in density of ground vegetation and light levels that made habitat less suitable (Porneluzi et al. 2020). It is possible that loss of ash trees due to the emerald ash borer will further degrade Ovenbird habitat.

In central Ontario, Clark et al. (1983) concluded that the Ovenbird could be expected to occur near cottage lots in mature woods provided that the forest was not disturbed. Cottages lots where only a few trees were removed and the ground and shrub layers were left intact would probably deter Ovenbirds from nesting. Stauffer and Best (1980) considered the Ovenbird intolerant of any habitat alterations. They predicted that it would be reduced in numbers if the canopy was partially removed or if the woody understorey was thinned.

Woodlots were formerly frequently grazed by livestock. This was highly detrimental to Ovenbirds because it removed both herbaceous and woody cover in the understorey and inhibited tree regeneration (Graber et al. 1983; Hann 1937). These practices have largely been abandoned in Ontario, but grazing by the white-tailed deer creates a similar problem (Vitz and Rodewald 2011). In Delaware, Tymkiw et al. (2013) found no significant differences in the abundance of the Ovenbirds in areas of low, moderate, and high deer density.

Prescribed burns and other fires in forests are highly detrimental to the Ovenbird. In Georgia, it was the species most negatively affected by fire and this was also true in pine-oak forests in North Carolina. Burns opened up the canopy and reduced shrub coverage. Habitat may be degraded for many years following a high-intensity fire. Six years after a fire in Georgia, densities were only about half those before fire, or even much lower in some areas. In addition to reducing shrub density, leaf-

litter depth is greatly reduced by fire, thereby reducing food availability and nest cover. In Indiana, maximum abundance of the Ovenbird occurred when the frequency of fires within a 15-year period was 0. Abundance dropped to 0 when fire frequency reached 4 in 15 years (Grundel and Pavlovic 2007a; Klaus et al. 2010; Porneluzi et al. 2020; Rose and Simons 2016).

In Waterloo Region, woodlands adjacent to houses supported fewer forest-dwelling bird species than those without houses nearby. This relationship was not particularly strong for the Ovenbird (Friesen et al. 2005). In North Carolina, its abundance declined significantly with increases in housing density (Lumpkin and Pearson 2013).

In Alberta, the Ovenbird's song frequency overlapped that of noise from compressor stations, potentially causing masking of songs. Significantly more males were paired at control sites (92%) than at compressors (77%). Densities of males were greater at controls than at compressors. The noise may have interfered with intersexual communication. Noise level may be 1 factor that females use in mate selection (Habib et al. 2007). In Alberta, Bayne et al. (2008) found no significant difference in its abundance at quiet well pads and noisy compressor stations.

Streby et al. (2009) determined that blow flies appeared to have no effects on nestlings, but the survival rate and minimum first-detection distance from the nest were significantly lower for fledglings from infested nests. Of 9 infested fledglings, 8 died within 3 days of leaving the nest. Seven exhibited no signs of predation and the eighth was apparently depredated by a small mammal. Seventy-four percent of non-infested fledglings survived the same period. Infected broods were more active with nearly constant scratching and twitching, and this may have attracted predators. Non-infested broods remained chiefly motionless. The adverse effects of blow fly infestations are not manifested until the fledgling stage.

In Minnesota, young forced to fledge early by researchers experienced a significantly higher survival rate than those that fledged at a typical fledging age. Premature fledging did not adversely affect survival rates and the ability to fledge early may be a predictor of higher probability of fledgling survival (Streby et al. 2013).

Blake et al. (1992) examined the effects of drought on the Ovenbird in Wisconsin and Michigan. It declined over a 5-year period and its abundance varied significantly among years in both states. Abundance was influenced by drought or drought-related factors with declines in drought years. Drought effects were less severe early in the year when temperatures were mild and moisture from winter snowfall was still present.

Price (2004) concluded that the Ovenbird's range could contract in southern Ontario if the average summer temperature increased by 2°C. In North Carolina, Lumpkin and Pearson (2013) determined that its abundance increased with increasing temperatures.

Status

The Ovenbird has always been common to abundant in Ontario. Highest densities occur in mature deciduous forests in Ontario, New Brunswick, Maine, Wisconsin, and Minnesota (Mattsson and Niemi 2008; Van Horn and Donovan 1994). McIlwraith (1894) considered it present in suitable habitat throughout the province. In eastern Ontario, it was very common in deciduous forests in the 19th and 20th centuries, and it is still an abundant breeder in the Kingston area (Weir 2008). Baillie and

Harrington (1937) described it as a common summer resident throughout most of Ontario north to southern Kenora District and James Bay and concluded that it likely bred throughout this range. It had also been documented during the breeding season at Lake of the Woods and at latitude 52°N along the Manitoba-Ontario border. Fleming (1907) considered it a rare breeder in the Toronto area; it is likely that this area had been largely deforested by that time. In the Dorset area in the 1960s, it was the second most abundant species (Mills 1981). During the first atlas, it was common and widespread throughout Ontario, except in the northern portion of the Hudson Bay Lowland, where it was scarce or absent. It was most abundant in the Great Lakes–St. Lawrence Forest Region, particularly in the southern Canadian Shield (Armstrong in Cadman et al. 1987). James (1991) considered it an abundant summer resident across the province, becoming rare through the Boreal Forest Region north to Big Trout Lake and Fort Albany, and occasional somewhat further north. In heavily forested areas in south and central Ontario, the Ovenbird is very abundant and is usually outnumbered only by the Red-eyed Vireo. In Peterborough County and white pine stands in Algonquin Park, it was the most ubiquitous species (Burke and Nol 1998; Kingsley and Nol 1999). In the Shield portion of the Great Lakes–St. Lawrence Forest Region, the Ovenbird was the most abundant species in white pine stands and constituted 11.9% of all birds (Kirk et al. 2012). In the South Walsingham Forest in Norfolk County, it was second in abundance to the Red-eyed Vireo, and represented 12.56% of all bird records (McCracken et al. 1998). It is much less common in southwestern Ontario where there is less forest cover. In Elgin County, it was common to very common until 1954 but an uncommon breeder by 2000 and apparently absent some years (Lancaster et al. 2004). Black and Roy (2010) considered it an uncommon breeder in Niagara Region.

The second atlas demonstrated that there had been no change in the breeding distribution of the Ovenbird since the first atlas. In the Hudson Bay Lowland, it was restricted to river corridors where there were suitable stands of mature balsam poplar and trembling aspen. Habitat distant from rivers is unsuitable. Province-wide, there was no significant change in its probability of observation. A significant decline occurred in the Carolinian Forest Region, possibly due to continuing forest fragmentation. It is absent in many areas of the extreme southwest because the existing woodlots are very small and the percentage of regional forest cover is very low. Heavy logging has likely contributed to its decline in portions of Huron, Lambton, and Middlesex counties. Significant increases were documented in the Boreal Forest Region and the Great Lakes–St. Lawrence Forest Region in the Shield. It was predicted that continued declines or losses would occur in many areas due to forest disturbance and fragmentation. Highest densities occurred in the Great Lakes–St. Lawrence Forest Region in the Shield, and high densities also occurred on Manitoulin Island and the Bruce Peninsula. Areas of moderate density south of the Shield included the Oak Ridges Moraine, Norfolk Sand Plain, Niagara Escarpment, and eastern Ontario north of the St. Lawrence River (Burke in Cadman et al. 2007).

Based the BBS, the Ovenbird experienced an initial increase followed by a decline. Overall, it increased 1965-79, but declined 1978-87. BBS data for 1980-89 indicated significant population declines at the periphery of its breeding range, but significant increases in the core of its range (Porneluzi et al. 2020; Van Horn and Donovan 1994). BBS data indicate that it decreased at annual rates of 0.188% in Canada and 0.461% in Ontario 1970-2021. Trends 2011-21 were annual decreases of 0.335% in Canada and 1.42% in Ontario. All results were highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Fledglings go through 4 phases: the hopping stage at 8-11 days of age, the early flying stage at 11-20 days, the semi-dependent phase at 20-30 days, and the independent phase at 30-40 days. During the hopping stage, young can travel on the ground about as fast as a person can walk. During this phase, fledglings may remain in practically the same place for several days. During the early flying stage, young can fly 5-30 m, but go in a circle if flushed and return to the same area. During the semi-independent stage, young walk with their parents, picking up food as they go, but continue to be fed by the adults. During the independent phase, the adults leave the young and usually leave the woods that were used for nesting. At this time, the young wander solely or occur in small groups of 2-3, occasionally in the company of an adult. Young birds associated together at this time are not necessarily from the same brood. When the first chick leaves the nest, either the male or female leads it away and the other mate is left responsible for the remainder of the brood. Young are initially led 15-25 m from the nest and are subsequently taken further. Fledglings under the care of an individual adult are kept separate from each other. The male and his young tend to remain in the nesting territory until the young are independent, but the female and her young may move considerable distances (Hann 1937; Streby et al. 2011a, 2013b; Van Horn and Donovan 1994; Vitz and Rodewald 2010).

Shortly after the young leave the nest, adults and fledglings move to areas with denser vegetative cover. In Ohio, postfledging habitat was significantly different from nesting habitat and had 1.8 times as many woody stems, 14% less canopy cover, and 11% fewer small trees. There were no differences in the number of medium- or large-sized trees at postfledging and nesting sites. There were significant differences in postfledging habitat and random sites, with 40% more woody stems and 8% more canopy cover at postfledging sites compared with random areas. Surviving fledglings used habitats with 15% more woody stems than those that perished, mostly due to predation. Some fledglings used regenerating clear-cuts, but these were not preferred. More frequently used habitat was dense understorey in mature forest, including riparian thickets, forest edges, tree-fall gaps, and dense foliage of recently fallen trees (Vitz and Rodewald 2011). In Missouri, habitat used by fledglings differed significantly from habitat at nest sites. Juveniles occurred in areas with denser foliage 0-2 m from the ground (72.0% compared with 58.9%), less litter depth (2.0 cm compared with 2.6 cm), higher shrub density (2,363 compared with 1,677 per ha), higher ground cover, and more live tree stems (1,263 compared with 959 per ha) than nest sites. Juveniles occurred closer to edge (mean 132 m compared with 168 m) than nests (Jenkins et al. 2016). Stoleson (2013) captured 38 adults and 20 fledglings in clear-cuts compared with 19 adults and 16 fledglings in adjacent mature forest. The capture rate of Ovenbirds was significantly higher in forest. The Ovenbird preferred mature forests to clear-cuts during the postfledging season. In many areas, postfledging Ovenbirds make heavy use of regenerating clear-cuts and it is frequently the most abundant forest-breeding bird found in this habitat. Fledglings rarely use clear-cuts until they are independent of their parents, usually around age 24 days. Simultaneous capture of adults and young is not a reliable indicator of family groups because the young move to shrubby habitat after they are independent. In Ohio clear-cuts, capture rates were 2 times higher in areas with a canopy taller than 4.5 m than those with a canopy shorter than 2.5 m. In Minnesota clear-cuts, the strongest predictors of adult abundance were density of shrub- and ground-level invertebrates with canopy

height and woody debris being less important parameters. The strongest predictor for fledgling abundance was availability of shrub-level invertebrates, which was twice as important as the next strongest predictor of leaf-litter depth. In Ohio, there was no significant difference in capture rates in small (4-9 ha) and large (13-18 ha) clear-cuts, although clear-cut edges may be avoided to reduce predation risk (Marshall et al. 2003; Streby et al. 2011a, 2011b; Vitz and Rodewald 2006, 2007). In New Hampshire, areas occupied by fledglings had fewer large trees and more understorey structure than nest sites and random points. Fledglings selected habitat with a dense understorey of shrubs and saplings. These were mostly dense areas of regeneration of canopy species such as beech and hemlock, but also included patches of hobblebush, raspberries, and blowdown. There was no association between fledgling presence and litter depth. Mature hardwoods and mixed woods were most preferred; coniferous forests and regenerating forests were much less preferred. Pole-sapling stands and non-forested habitat were not used (King et al. 2006). In Michigan, Akresh et al. (2009) studied the abundance of adults and fledglings in upland and riparian forests. The upland habitat was an even-aged aspen stand. The riparian forest had an aspen overstorey and a shrubby understorey of alder and honeysuckles. Adults did not nest in the riparian forest, but after the young fledged, adults were captured less in upland forest and more in riparian forest. Seventy-three percent of juveniles were captured in riparian forest indicating that both young and adults quickly dispersed to the area with denser shrub coverage.

Porneluzi et al. (2014) netted in Missouri during the postfledging period 2-15 years after an oak-pine-hickory forest was clear-cut. Ovenbird capture rates showed a significant curvilinear trend that increased gradually to a peak 7-10 years after harvest followed by a decline. In Missouri, Burke et al. (2017) radiotracked juvenile Ovenbirds that were captured in deciduous clear-cuts 3-6 years old. The mean distance between moves was 133.5 m. Seventy-five percent of birds remained in the clear-cut where they were captured. The probability of use was much greater for stands in the small-tree class than in pole or sawtimber classes. The probability of use was much greater for clear-cuts than for partial cuts or unharvested stands. One bird travelled 1.14 km to another study area and returned the same day where it remained for another 10 days. It used early successional habitat for all its stops.

Streby and Andersen (2012, 2013a) radiotracked fledglings from nests in mature deciduous and mixed forests in Minnesota. Every fledgling made 1-day movements ranging from 300 m to 3 km 5 days or less after becoming independent. Within 24 hours of fledging, fledglings were 3-108 m (average 36 m) from their nests. Fifty-eight to 74% of fledglings were outside their natal territory within 24 hours. Within 5 and 10 days of fledging, 98% and 100% of fledglings were outside their natal territory, respectively. Stands occupied after these movements differed from habitat in the natal areas. Of birds from the deciduous stand, which had a sparse shrub layer, 50% moved to sapling-dominated clear-cuts, 40% moved to forested wetlands, and 10% moved to mature deciduous forests. Of birds leaving the mature mixed woods, 10% moved to sapling-dominated clear-cuts, 30% to forested wetlands, and 60% to mature mixed woods. Birds spent 1-10 days (mean 5 days) in these stands before making a second 1-day long-distance movement of 300 m to 6.1 km. Birds made a third long-distance movement after another 1-10 days (mean 4 days). Only 10% of birds tracked for 5 or more days did not make use of sapling-dominated clear-cuts or forested wetlands. Birds from the deciduous site selected among cover types. Usage of sapling-dominated

clear-cuts was more than twice as much, forested wetlands 6 times as much, and mature forest less than half as much as expected based on availability. Birds from the mixed forest also selected, using mature forest, sapling-dominated clear-cuts, and forested wetlands more than shrub-dominated clear-cuts. There was a disproportionately low use of shrub-dominated clear-cuts. All fledglings used areas with dense woody undergrowth. Regenerating clear-cuts can be important habitat for fledglings, but not until saplings become established.

Areas of dense shrub or sapling coverage are very important to Ovenbirds during the postfledging period. Areas that are potentially suitable nesting habitat may not be occupied if birds do not have access to dense woody cover once the young leave the nest. These dense areas are probably most important in providing protection from predators, but they may also be rich in invertebrates and fruit (King et al. 2006; Streby et al. 2011a; Vitz and Rodewald 2010, 2012).

In Ohio, Vitz and Rodewald (2013) captured young Ovenbirds in regenerating hardwood clear-cuts. Fledglings were released in the clear-cut where they were captured, in a different clear-cut, or in mature forest. Birds that survived the 52-day monitoring period inhabited areas containing 1.5 times the number of woody stems as those that did not survive. Birds released in clear-cuts had the highest survival rates, but not significantly greater than in mature forest. Juveniles used areas with 1.4 times the number of woody stems than occurred in random areas. Birds were most often found in mature forest (80% of observations), followed by regenerating clear-cuts (11%), and mid-successional stands (9%). Of mature-forest locations, 16% were in riparian thickets and 6% in treefall gaps. Birds released into mature forest were later found in this habitat 91% of the time, but also in mid-successional forests (6%) and clear-cuts (3%). For fledglings released into clear-cuts, 76% of subsequent locations were in mature forest, 14% in clear-cuts, and 10% in mid-successional stands. Survival of young Ovenbirds was not determined by access to large patches of early successional habitat. They used a variety of habitats that provided dense understorey vegetation, including within mature forests, and did not appear to be especially attracted to regenerating clear-cuts.

In Saskatchewan forests, male Ovenbirds did not avoid forest–clear-cut edges during the postfledging period and were more abundant at forest edges. The percentage of positions within 50 m of edge (75%) was greater than expected if males randomly used areas within the forest (58%). The proportion of observations within 25 m of edge was also greater than expected (46% compared with 30%). Males without young had a higher percentage of observations within 50 m of edge (80%) than those with young (65%) but there was no difference in the percentage of observations within 25 m of edge. Forest edges may be a barrier to movement, resulting in a concentration around edges (Bayne and Hobson 2001a).

Fledglings may move considerable distances from the nest to postfledging habitat. In Ohio, the mean time of dispersal between these 2 habitats was 29.2 days (range 24-34 days). The centre of the natal home range was separated from the postfledging habitat by an average of 1.3 km (maximum 3.7 km). There was no evidence that presence of dense vegetation near the nest reduced the distance travelled (Vitz and Rodewald 2010). The range of distance moved by independent fledglings in Ohio was 0.07-18.2 km. Birds gradually moved greater distances over the first 4 weeks after capturing them in clear-cuts. Birds released in mature forests moved the furthest (mean 975 m). Those released in different clear-cuts moved a mean of 855 m compared with 468 m for those

released in the same clear-cut. No birds attempted to return to the original capture location (Vitz and Rodewald 2013).

In Missouri, there was no difference in the overall numbers of male and female nestlings or in the survival rates of male and female fledglings. Twenty days after fledging, females moved 350-750 m further than males from the nest. Prior to this, male and female movements were similar. Some females moved as far as 1 km from their nest. The maximum distance travelled by male fledglings was 250 m (Jenkins et al. 2017).

In Minnesota, Streby and Andersen (2013b) determined survival rates of Ovenbird fledglings 1-8 and 9-16 days after leaving the nest and correlated the results with habitat. During the first 8 days after fledging, young that crossed a logging road at least once during this period were twice as likely to be depredated as those that did not cross a road. Next in importance in defining survival was the habitat adjacent to the mature forest where they fledged. Survival was lower for fledglings adjacent to young regenerating clear-cuts and higher for those near older regenerating clear-cuts and forested wetlands. Road crossing had the greatest impact on survival 9-16 days after fledging. Young that crossed logging roads were 33% less likely to survive than those that did not. Reclamation of abandoned logging roads could have a positive effect on populations of Ovenbirds.

In New Brunswick, Haché et al. (2014) studied survival and movements of postfledging Ovenbirds in plots treated 4 and 5 years earlier by selection harvesting and in control plots. Shrub density was higher in treated plots than in controls. Of 55 fledglings, 45.5% were still alive on day 14; 60% of mortality occurred 2-10 days after fledging. Some fledglings moved as far as 355 m during the first 2 weeks, but most remained near their nest. Mean distances between the nest and location on day 14 were 138.5 m in treated plots and 212.2 m in controls. Only 3 fledglings moved from control plots. They moved into plantations or coniferous riparian areas with open ground cover. Postfledging movement rate was not influenced by habitat variables, predator abundance, or body condition. Variations in eastern chipmunk and red squirrel abundance were key factors influencing fledgling survival, and they were responsible for 80% of predation events.

In Saskatchewan, Bayne and Hobson (2001a) examined whether forest fragmentation affected dispersal of adult males during the postfledging period. Males without young were more likely (83%) to cross gaps in the fragmented landscape than those with young (14%). Four birds without young permanently left the woodlot where they were first encountered and moved to 2 or more fragments 1.05-5.63 km away. The widths of gaps crossed by them was 100-300 m. Six males left their original woodlot, crossing at least 50 m of adjacent cropland to another woodlot, and returned the following day. Only 1 was seen attending young. In contiguous forest, there was no difference in the frequency in which males with young (33%) and those without young (30%) crossed gaps less than 25 m wide. Males with young in contiguous forest frequently crossed small gaps but those with young in forest fragments rarely left. Forest fragmentation did not affect dispersal of adults without young and did not constrain movement patterns of successful breeders. Although the Ovenbird is capable of crossing gaps, it may preferentially move through forested areas when dispersing from the breeding territory. The fact that successful breeders usually did not disperse from small forest fragments suggests that these woodlots must have habitat that is suitable both for breeding and postfledging to accommodate nesting Ovenbirds.

Not all fledglings maintained a stable home range in New Hampshire (King et al. 2006). In Ohio, the mean home range of fledglings while they were still in the natal area was 5.0 ha. This far exceeded the size of breeding territories. The use of large areas after fledging may contribute to patterns of area sensitivity, at least in fragments smaller than the natal home range. Once a patch exceeds this size, these effects are likely to be reduced because family groups may have overlapping home ranges (Vitz and Rodewald 2010). In Saskatchewan, there was no difference in home range sizes of males during the postfledging period among woodlots in forested and agricultural landscapes. Males without young had significantly larger home ranges (7.2 ha) than those with young (2.2 ha). Most males remained within a few 100 m of their capture location regardless of landscape type. Males with young remained in a 2-3 ha area around the capture site, suggesting they remained near their territory. Home ranges during the breeding season in forest fragments (1.8 ha) and contiguous forests (1.6 ha) were similar to those of males with young during the postfledging period (Bayne and Hobson 2001a).

Jenkins and Faaborg (2016) studied the effects of cowbird fledglings on Ovenbird fledglings in Missouri. There was no significant difference in mortality rates of Ovenbirds from parasitized and unparasitized nests. Ovenbirds from unparasitized nests moved further from the nest (150 m) than broods with a cowbird fledgling (60 m). The negative effects of cowbird parasitism did not extend into the postfledging period.

MIGRATION

The Ovenbird appears to be a nocturnal migrant. During spring, males migrate before females. In Michigan, male arrival was spread out over a few days and they arrived 9-14 days before the first female. The average time between arrival of all males and females was 7 days; females arrived simultaneously. The age classes may migrate separately in spring and autumn. Some studies indicate differential timing and others do not. The length of stopover during migration is significantly briefer in spring than autumn. During spring in Louisiana, the average length of stopover was 1.68 days (maximum 3 days). Lean birds stayed longer than fat birds. In Maine, the minimum length of stopover was 2.4 days in spring and 5.1 days in autumn. During autumn migration in New York, Ovenbirds stayed 1-14 days. The fat content of birds remaining only 1 day was at least 11% of the total body mass but all with fat content of less than 6 percent remained at least 4 days. One bird stored sufficient fat to continue migration after 8 days, yet remained an additional 6 days. The wind was from the north on the night it departed, but was from the south previously. This bird possibly waited 6 days for favourable flying conditions (Brewer et al. 2018; Hann 1937; Moore and Kerlinger 1987; Morris et al. 1994; Seewagen and Guglielmo 2010; Van Horn and Donovan 1994).

The Ovenbird mostly arrives in Ontario at the beginning of May and migration is over by the end of May; it may arrive as early as mid-April. Peak migration occurs during the second and third weeks of May (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008). During 1975-2000, the midpoint of Ovenbird migration at Long Point was 15 May and there was no difference in timing of spring migration in relation to climate change when either the date of first arrival or the quartile method was used (Mills 2005a).

Determination of the timing of autumn migration is confounded by the fact that birds move to shrubby, atypical breeding habitat once the young have fledged. It is difficult to distinguish between birds that are occupying postbreeding habitat from those that are migrating. Records of autumn migrants in July and early August probably represent birds in postfledging habitat. In the southern Shield, migrants are on the move from late August to mid-September, with some remaining until early October (Mills 1981; Tozer 2012). In southern Ontario, the peak of migration occurs in the first 2 weeks of September. Birds may arrive in late August and most have left by late September or early October, with stragglers remaining until mid-December (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008). Throughout its range, the Ovenbird begins autumn migration in early to mid-August and the northern breeding grounds are vacated by the end of September (Gross in Bent 1953).

Several studies examined habitat preferences of the Ovenbird during migration. In Pennsylvania, it was detected more frequently in less fragmented landscapes and was more likely to occur in larger than smaller woodlots. It was found in smaller habitat patches during migration than during the breeding season (Keller and Yahner 2007). In oak savannahs and woodlands in Indiana, abundance of spring migrating Ovenbirds was positively associated with tree density. Relative abundance was 0.5 at 400 trees per ha and reached almost 1.0 at 600 trees per ha (Grundel and Pavlovic 2007a). In British Columbia, migrants may inhabit floodplains, fields, trembling aspen sapling forests, brushy thickets, areas of thick undergrowth, and occasionally suburban areas and city parks (Campbell et al. 2001). In Saskatoon, it occurs primarily in wooded areas such as riverbank parks, but may venture out of shrubbery and walk across lawns (Leighton et al. 2002). In Illinois, spring migrant populations were highest in bottomland forests in the southern portions of the state and in upland forests centrally. In autumn, highest densities were in bottomland forests in the south but it was equally common in bottomland and upland forests centrally. It used all types of woody habitats that were surveyed during autumn (Graber et al. 1983). During spring migration in Wisconsin and Minnesota, it was significantly more abundant in upland than riparian forests (Kirsch et al. 2013). During spring migration in Pennsylvania, Smith and Hatch (2008) observed and captured significantly more Ovenbirds in forest than shrub habitat. In Pennsylvania during spring, it was significantly more abundant in mature upland forest than in mature riparian forest. The main differences in the habitats were that the upland forest had 74% canopy closure and 39% shrub coverage compared with 83% canopy closure and 19% shrub coverage in the riparian forest (Rodewald and Matthews 2005). Spring migrants prefer forests to shrublands; forests with dense shrub coverage are preferred to those with sparse coverage. Rodewald and Brittingham (2002) examined the distribution of autumn migrating Ovenbirds in Pennsylvania woodlands. In decreasing order of abundance, it occurred in forest interior followed by suburban forest, forest edge, forest-agricultural edge, pole-stage forest, and shrub-sapling-stage forest. There was no difference in its abundance in these habitats. Rodewald and Brittingham (2004) updated this study. Significantly more Ovenbirds were found during autumn migration in forest interior than in shrub-sapling-stage forest. Numbers within the other habitat types were not significantly different from those occurring in forest interior or shrub-sapling-stage forest.

In North Carolina, Parnell (1969) studied habitat and substrate preferences of the Ovenbird during spring migration. It was absent in wet and dry thickets and occurred in most forest types, but

selected pine-hardwoods, pine, and oak-hickory stands over floodplain and beech forests. Forty-six percent of observations were in a low tree, 22.6% in a shrub, 21.7% on the ground, and 9.7% in the canopy. Birds occurred at heights of 0-7 m (average 1.2 m). In low trees, 0% of observations were at the top of the crown, 13.7% in the inner crown, 32.3% in the lower crown, and 0% on the bole. In shrubs, 3.2% of observations were at the top of the crown, 7.3% were in the inner crown, 0.8% in the lower crown, 7.3% in dense thicket, 4.0% in brush piles, and 0% in grasses. On the ground, 4.0% of observations were in dense thicket, 0.8% in grasses, 0% at the edge of water, and 16.9% in the open. In the canopy, 0% of observations were at the top of the crown, 1.6% in the inner crown, and 8.1% in the lower canopy.

Tozer (2012) reported a case of site fidelity in a grey alder thicket in Algonquin Park. An Ovenbird banded on 30 August 1960 was recaptured in the same location on 27 August 1961, 27 August 1962, and 19 August 1963.

The autumn of 1975 was unusually cold in Ohio. During migration that year, Tramer and Tramer (1977) reported an Ovenbird eating fruit from a yew. Arboreal arthropods and insects were scarce that year, forcing it to eat fruit. During autumn migration in New York, Lebbin et al. (2007) suspected that Ovenbirds were foraging nocturnally at a site illuminated by football-stadium lights.

Massive kills of the Ovenbird frequently occur during migration. These are usually associated with frontal movements, most frequently cold fronts in association with high pressure systems. Under these conditions, it may strike tall structures such as office buildings and television and communication towers. Many are killed by flying into windows of houses. At the Lennox generating station chimneys near Kingston, 1,127 were killed 1972-82. Probably more Ovenbirds have been killed at central Illinois television towers than any other species (Graber et al. 1983; Leighton et al. 2002; Van Horn and Donovan 1994; Weir 2008). Loss et al. (2014) summarized bird-building collision data for the United States. At all building types combined, the Ovenbird was 21.8 times more at risk of collisions than average for bird species. At 1-3 storey residences, it was 112.1 times more vulnerable, 30.4 times more vulnerable at low-rises, and 43.7 times more vulnerable at high-rises. It is one of the species most vulnerable to striking high-rise buildings in Toronto (Colling et al. 2022).

Strode (2003) studied the effects of climate change in Illinois and North Dakota on the timing of spring migration by the Ovenbird. Over 100 years, there was no significant change in temperature in southern Illinois, but over a 40-year period spring advanced an average of 8.6 days in North Dakota. The Ovenbird arrived earlier on its breeding grounds, suggesting that it was responding to climate change.

James (1991) considered the Ovenbird a common to abundant migrant. This is true for most of the province, but it is an uncommon migrant in Niagara Region, Elgin County, and sparsely forested areas in the southwest (Black and Roy 2010; Lancaster et al. 2004).

Hussell et al. (1992) summarized trends in numbers of Ovenbirds banded at the Long Point Bird Observatory 1961-88. It experienced a significant decline of 2.9% per year. Numbers fluctuated considerably with a decrease during the first decade and a weak increase the following decade, followed by a large decline. This pattern was exhibited by several other species and may be influenced by spruce budworm outbreaks.

WINTER

The Ovenbird is rare and irregular during winter in Ontario (James 1991). Most winters, it is likely that there are no Ovenbirds present in the province. It is uncertain if an Ovenbird has ever survived an entire winter in Ontario. One remained in an urban Hamilton garden from 26 November until 12 January. It survived by eating high-fat foods put out for it (Curry 2006). One was at Presqu'ile on 2 January where it sought shelter under large spruce trees. It was last seen 2 days later following a heavy snowstorm (LaForest 1993). One was observed in Toronto on 6 February and was last seen on 7 March. It took shelter under spruce trees and near a washroom that emanated warm air. It was observed feeding on peanut particles at a feeder. Another Ovenbird survived at an Ottawa feeder until 28 February (Bryant 2002).

The Ovenbird normally winters as far north as North Carolina, but there are casual winter occurrences north to the Great Lakes and New England. It usually does not winter where the average January temperature is less than 0°C and is most abundant where this temperature is 10°C or higher. Mulvihill and Leberman (1977) reviewed 80 extralimital winter records: 61% in December, 25% in January, 9% in February, and 9% in March. Multiple records occurred in winters or portions of winters that were unusually mild with little snow cover. Deaths typically coincided with periods that had both cold temperatures and significant snow accumulations.

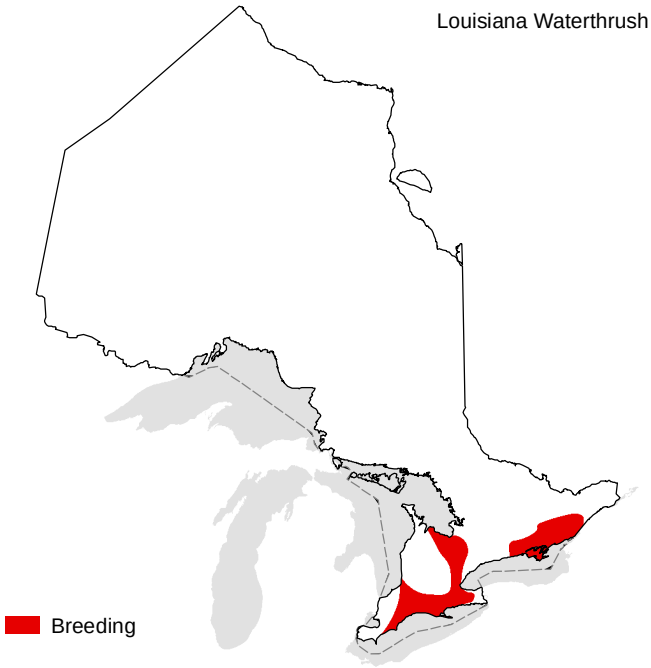
Louisiana Waterthrush

Parkesia motacilla

BREEDING SEASON

Habitat Requirements

Breeding habitat of the Louisiana Waterthrush in Ontario consists of deciduous woodlands that are swampy or contain flowing streams with more or less vertical earthen banks. Two nests were in a mixed forest dominated by hemlock in Elgin County (Peck and James 1987, 1998a). It prefers heavily wooded ravines with running water, particularly in east Elgin where the soils are sandy. One nest was along a small tributary at the bottom of a steep hemlock-dominated ravine (Lancaster et al. 2004). In the Hamilton area, it occurs in rocky ravines containing streams, particularly where there are larger waterfalls along the Niagara Escarpment (Curry 2006; McIlwraith 1894). In southern Ontario, its distribution is dictated by climate, the presence of forested creek and river valleys, and abundance of large swamps that contain ponds and vernal pools. It occurs at elevations lower than 300 m and in regions above the 6°C isotherm for annual temperature. It prefers mature deciduous and mixed forests where there are shaded watercourses with underbrush and old logs lining stream banks. It prefers steep-sided talus slopes facing southward and selects cold, clear streams most frequently for nesting. The forests that are inhabited are often late successional and dominated by



sugar maple and hemlock. Less frequently, it inhabits mature deciduous and mixed swamps with standing pools of open water. Closed forest canopies and presence of water are essential habitat components (Austen et al. 1994; McCracken 1991, 2006). At Chesney Bog, it nested in a mature mixed swamp surrounding a bog. The swamp was dominated by white pine and red maple, with lesser amounts of white cedar and yellow birch. This habitat supported 593 trees per ha that were 7.6 cm or larger in diameter and 87 trees per ha 22.9 cm or larger. The total basal area (BA) was 16.1 m^2 per ha. Canopy closure was 85% and the average canopy height was 16.8 m (range 9.1-27.4 m). There were 17,890 shrub stems per ha with the 5 most frequently occurring species being winterberry holly (29.7% of total shrub stems), white cedar (23.3%), red-osier dogwood (8.0%), black ash (5.5%), and yellow birch (5.4%). Portions of the swamp are quite hummocky and support vernal pools (personal observation). At Former Camp Ipperwash, it nested in mature, mixed mesic forest dominated by sugar maple and hemlock with numerous vernal pools. There was also extensive mature deciduous swamp dominated by pumpkin ash, silver maple, and cottonwood adjacent to and interspersed within the mixed forest (personal observation). It also nested at Vanessa Swamp, a mature deciduous swamp with vernal and semi-permanent pools (personal observation).

Throughout its range, preferred habitat of the Louisiana Waterthrush is along watercourses in mature deciduous and mixed forests. Preferred streams are clear and cold, often with springs, and have a steep gradient. These watercourses have a series of riffles and pools, and waterfalls are often present. Typical stream substrate is cobbles and gravel, with cobblestones optimal because the interstitial spaces provide habitat for aquatic macroinvertebrates and the stones provide foraging perches for this waterthrush. Most selected streams are permanently flowing, but some may be reduced to isolated pools by the time the young fledge. Its presence in Georgia was correlated with the percentage of mayflies, stoneflies, and caddisflies in the benthic macroinvertebrate population and also to the invertebrate Family Biotic Index. Waterthrush presence is used as an indicator of high stream quality in that state. Streams it inhabits are frequently in ravines and may have talus slopes and often undercut banks, exposed tree roots, and logs along the shoreline. Watercourses that it uses are typically small first- to third-order headwater streams, but it occasionally inhabits larger streams and small rivers. In Minnesota, there were several streams populated with this waterthrush, but it avoided areas where the valley became broad and flat with limited forest canopy. Much less frequently, it may nest along slow-flowing streams through swamps, and these watercourses typically have a soft substrate of silt or mud (Bent 1953; Chapman 1907; Coffin and Pfannmuller 1988;

Eaton 1958; Eliason and Fall 1989; Graber et al. 1983; Mattsson and Cooper 2006; Mattsson et al. 2011, 2020; Mossman 1988; Mossman and Hoffman 1989).

Upland forests inhabited by the Louisiana Waterthrush are most often dominated by sugar maple and often have a component of basswood, mountain maple, and conifers, especially hemlock or white pine. The conifers provide essential cover in the spring prior to the leaf-out of deciduous trees. In both upland and swamp forests, it is restricted to mature, late-successional stands. It prefers low to moderate shrub density in the understorey and avoids areas with dense, woody undergrowth (Buffington et al. 1997; Bushman and Therres 1988; Eaton 1958; Eliason and Fall 1989; Noon et al. 1979; Prosser and Brooks 1998).

Prosser and Brooks (1998) prepared a habitat suitability index (HSI) model for the Louisiana Waterthrush in Pennsylvania. It was designed to be used in areas containing first- to third-order streams in the mid-Atlantic states. It preferred high-quality headwater streams with well developed pool and riffle sequences; large blocks of forest-interior habitat where herbaceous cover was sparse and shrub coverage was moderate to sparse; areas of fallen trees with exposed root masses; and riparian banks with abundant crevices. It was absent in highly fragmented landscapes and where sediments from agricultural and urban lands had negatively affected water quality and stream substrates. The HSI model ranked habitats on a scale of 0 (unsuitable) to 1 (optimum). The model for forest canopy closure was: more than 80%, 1.0; 60-80%, 0.7; 40-59%, 0.2; and less than 40%, 0. The model for percent shrub cover was: for 0.1-1.5 m tall shrubs, 75% or more coverage 0.1, 24-74% coverage, 0.3, and 25% or less, 0.5; for shrubs taller than 1.5 m, 75% or more coverage, 0.4; 24-74% coverage, 1.0; and 25% or less, 0.8. The model for percent deciduous forest cover was: 0-29%, 0.5; 30-69%, 1.0; 70-100%, 0.5. The model for percent herbaceous cover less than 20 cm tall was: 75% or more, 0; 24-74%, 0.3; 25% or less, 1.0; for percent herbaceous cover 5-20 cm tall, 75% or more, 0.3; 24-74%, 0.7; 25% or less, 1.0; and for percent herbaceous cover less than 5 cm tall, more than 75%, 0.7; 24-74%, 1.0; 25% or less, 1.0. The model for stream type was: first- or second-order stream with well developed pool and riffle areas, 1.0; first- or second-order streams with steep topography, continuous rapid riffles, a straight channel or run, or flat water, 0.7; third-order stream comprised mostly of riffles and pools, 0.5; and third-order stream that was mostly a run or greater than third-order stream, 0.2. The model for stream substrate was: clear streams with coarse or sandy substrate, 1.0; clear streams with fine substrate, 0.5; turbid streams with coarse or sandy substrate, 0.5; turbid streams with fine substrate, 0. The model for stream bank slope and cover type was: a mix of soil, roots, and rocks forming crevices with an overhanging bank with more than 60° slope, 1.0; the same bank type with 30-60° slope, 1.0; the same bank type with less than 30° slope, 0.7; more than 75% rock banks, 0.1 for all slope categories; and more than 70% herbaceous coverage, 0.1 for all slope categories. The landscape model was: forest with interior habitat larger than 350 ha, 1.0; within 100 m of the edge of a large forest but within the forest, 0.8; shrubland or highly fragmented forest, 0.5; emergent wetland, agricultural field, or open water, 0.2; and urban, 0.

The other habitat type used by the Louisiana Waterthrush consists of mature treed swamps. These may contain either streams or small ponds and vernal pools. The presence of water is essential to this species in both upland forests and swamps. In most regions, swamps are much less preferred than watercourses in upland forests and it tends to be uncommon to rare in swamps. The exception

is in Missouri where it is uniformly distributed in swamps. In swamps in South Carolina, it occurred exclusively in late-successional stands dominated by black gum, red maple, and tulip tree. These stands had an average of 92.5% canopy closure, 18.3 m canopy height, 36.0% green ground cover, 35.8% coverage by water, 139 shrubs per ha, and a BA of 43.7 m^2 per ha. In the mid-Atlantic states, its probability of observation was positively correlated with BA, forest area, moisture gradient, and foliage density between 0.3 and 1.0 m from the ground. It was negatively correlated with the percentage of the canopy that was occupied by conifers (Bent 1953; Buffington et al. 1997; Chapman 1907; Graber et al. 1983; Robbins et al. 1989).

In North Carolina, the Louisiana Waterthrush was not observed in the canopy or in low trees; 62.5% of observations were in shrubs and the remaining 37.5% were on the ground. It was observed at heights of 0 m to more than 15 m, with an average of about 4.5 m for singing males, 0-6.9 m for other activities, and an overall average of 1.2 m from the ground. It was associated with the ground and low tree layer in beech and floodplain forests (Parnell 1969).

In Connecticut, Craig (1985) compared habitat use by the Louisiana and Northern waterthrushes. The 2 species occurred together and their territories overlapped widely with no apparent signs of aggression. In Louisiana Waterthrush territories, the percent coverage by herbaceous species was 6.7% cinnamon fern, 8.7% sensitive fern, 9.2% skunk cabbage with a total of 17.4% forbs, 17.9% ferns, and 19.9% moss. Louisiana Waterthrush territories had significantly more fast-flowing water, were less densely vegetated with trees and shrubs, and had less coverage by conifers, moss, ferns, and alders than those of the Northern Waterthrush. The amount of fast-flowing water may be the most important difference between the habitat of the 2 species, with Louisiana Waterthrush territories containing 23.7% fast-flowing water compared with 3.8% in Northern Waterthrush territories.

The Louisiana Waterthrush appears to be area sensitive throughout its range. In Maryland, the smallest woodland it occurred in was 42.2 ha and it did not reach 100% occurrence until woodlands were larger than 340 ha. In Maryland and the mid-Atlantic states, the critical forest size was estimated at 100 ha. Its probability of detection was 10% at 75 ha, 20% at 1,000 ha, and 25% at 3,200 ha. The forest size where its probability of detection was greatest was larger than 3,000 ha and the probability declined to 50% at 200 ha. The 3 smallest forests where it was detected at least twice were 24.7, 24.7, and 184.1 ha (Bushman and Therres 1988; Hayden et al. 1985; Robbins 1979; Robbins et al. 1989). In Illinois, all forests studied by Robinson (1992) were relatively small (maximum size of 65 ha), yet supported the Louisiana Waterthrush. In riparian forests in Maryland and Delaware, its probability of detection increased significantly with forest width: 9% in 50-m wide forests, 11% in 100-m wide, 15% in 200-m wide, and 65% in 800-m wide forests (Keller et al. 1993).

Some authors (Bushman and Therres 1988; Freemark and Collins 1992; Hayden et al. 1985) considered the Louisiana Waterthrush a forest-interior species. There appear to be no strong data to support this. Nests averaged 58 m from a transmission line corridor in Maryland and Bushman and Therres (1988) considered this evidence of edge avoidance. Given that the average distance from edge was only 58 m, many nests must have been much closer than this to edge. No information was provided on the minimum distance from edge. The forests studied by Robinson

(1992) in Illinois contained abundant edge and there were no woodlots where birds could nest more than 250 m from edge.

The female roosts in the nest at night from the start of incubation until the young are fledged. Males have roosted in hemlock trees and on exposed roots under overhanging creek banks (Eaton 1958; Mattsson et al. 2020).

Ontario nests were in depressions in earthen banks of streams and pools and in natural cavities in stumps surrounded by water. Five nests were 0.2-1.2 m above water (average 0.7 m). Nests in banks were concealed by roots and overhanging vegetation (Peck and James 1987). Another Ontario nest was on a sloping bank of a stream 0.9 m above the creek surface under live and dead fronds of Christmas fern (Peck and James 1998a).

Nests in upland forests are typically imbedded in the bank of a stream, often among tree roots, in cavities in the bank, on bedrock shelves, or under the edge of a ledge. Nests in swamps are usually in roots of upturned trees, often at the edge of a pond or pool of water. In Georgia, 162 nests were oriented in every direction, but many faced southwest and few faced east. In New York, 10 of 13 nests faced south and the others faced east. In Illinois, 5 nests faced south, 5 west, and none east or north. Preferred nest sites are adjacent to streams and are in small hollows or cavities within the root mass of an upturned tree or under a fallen log. Cavities where the nest is protected from above are preferred, but some nests are only partially covered or even completely exposed. Nests in stream-bank cavities were 0.2-7 m above a stream, but most are less than 2 m above water. In swamps, where most nests are in upturned tree roots, the nest may be as high as 1.8 m above ground or water. Nests are not reused, but nest cavities may be. Of 113 nest cavities used the previous year in Georgia, 7 were reused by a different pair and 3 were used by the same male mated to a different female. Four Pennsylvania nest sites were used in multiple years by different birds. One nest cavity was used twice in the same breeding season in 2 years following a flood event in both cases (Bent 1953; Chapman 1907; Eaton 1958; Eliason and Fall 1989; Forbes and O'Regan 1960; Graber et al. 1983; Harrison 1984; Mattsson et al. 2020).

The Louisiana Waterthrush is strongly territorial, mostly before the females arrive and again during incubation. Males sing in tree perches 5-12 m from the ground or on talus slopes, but usually about 9 m from the ground, and rarely on the ground. For birds nesting along a watercourse, only the stream is defended and it is used as a travel corridor within the home range. In Ontario, territories are rarely, if ever, contiguous to one another. The size of territories within swamps in Ontario was 2 ha. In Connecticut swamps, territories averaged 0.67 ha. In upland habitats, territories were linear and followed the watercourse. In New York, territories extended approximately 400 m along a watercourse. Nests tended to be near the centre of territories so that nests were spaced about 400 m apart. Nests were only 200 m apart on 1 stream where a waterfall formed territory boundaries. One male included 2 streams that were close to each other in his territory. In Illinois, stream territories averaged 930 m in length. They averaged 358 m in Connecticut, 520 m in Georgia, and 283 m in northeastern Pennsylvania, with an overall range in territory length of 90-1,200 m. Stream quality affects territory length, with streams that are acidified or degraded due to other pollutants or sediments supporting longer territories and lower densities of waterthrushes. In Pennsylvania, territories averaged 630 m in length on acidified streams compared with 370 m on circumneutral

streams. The average area of stream territories is 2 ha, assuming an average width of 50 m and average length of 400 m. The accuracy of these assumptions is uncertain. Some authors stated that it rarely uses the upland habitat adjacent to streams. In Minnesota, a pair nested along a river that was more than 100 m wide and the male often flew across the river to forage on the opposite shoreline. It was unknown if the far side of the river was an undefended feeding area or part of the territory. It has been estimated that a home range size of about 25 ha is required over the course of the breeding season to successfully raise young (Craig 1984; Eaton 1958; Eliason and Fall 1989; Friis and Brett 2012; Mattsson et al. 2020; McCracken 2006; Mulvihill et al. 2002, 2008).

Natal philopatry rates are low. In Tennessee, 0 of 49 nestlings returned. At the same site, 113 fledglings were banded and 4 (3.5%) returned. Three were banded in July when they may have been dispersing, but the fourth bird probably hatched locally. In Pennsylvania, 1 nestling returned to breed the following year and a male banded as a nestling in New York was collected 2 years later 4 km from its natal site (Goodpasture 1977; Mattsson et al. 2020; Mulvihill et al. 2002). In West Virginia, Frantz et al. (2019) banded 222 nestlings over 6 years. Natal site fidelity was consistently low and ranged from 0% to 5.1% annually, with an overall return rate of 1.7%. Highest return rates occurred in years when adult breeding densities were lowest, suggesting that natal dispersal might be density dependent. When areas are saturated with breeding birds, dispersal by yearlings may enhance individual survival or the prospects of finding unoccupied suitable breeding habitat.

In Tennessee, 20 of 152 adults (13.2%) returned. Some made multiple returns with 1 returning after 8 years, 1 after 5 years, 3 after 4 years, 8 after 3 years, 10 after 2 years, and 17 after 1 year (Goodpasture 1977). Of 201 Pennsylvania territories, 18% of males and 15% of females returned at least once, and 13% of males and 7% of females returned at least twice (Mulvihill et al. 2009). Also in Pennsylvania, females exhibited high territorial fidelity, with as many as 50% reoccupying their previous year's territory (Mulvihill et al. 2002). In Illinois, 2 of 3 adults returned the next year in 1 area and 0 of 4 returned at another site (Mattsson et al. 2020; Robinson 1992). In West Virginia, Frantz et al. (2019) banded 187 adults over a 6-year period. Adult return rates were 63% in the first 2 years but declined to 32% at the end of the study. Habitat quality declined during the study due to disturbances from shale gas extraction.

Limiting Factors

Eggs have been reported in Ontario nests from 1 June to 8 July (Peck and James 1998a). McCracken (1991, 2006) concluded that eggs could be present in Ontario nests from early May until mid-July, including renesting attempts.

Nest-site searching may be delayed 1-2 weeks after pair formation unless this occurs later in the season. The delay appears to be related to food availability. Nest building begins about the same time that spring vegetation begins to leaf out. Most nests are completed in 2-5 days but replacement nests may be built quicker. In some nests, there is a delay of 1-7 days before the first egg is laid. Egg laying begins immediately in other nests. One egg is laid per day. Incubation may begin the day before the last egg is laid. The incubation period is 11-14 days, mostly 12-14 days. All young hatch over a 24-hour period. Young may leave the nest when they are 9-12 days old, but mostly when they are 11 days old. The nest cycle length was 22.9 days in Pennsylvania and 21.7 days in Georgia. In Pennsylvania over several years, the breeding season extended 107 days from the

earliest clutch initiation to the latest observation of provisioning of fledglings. Initiation of egg laying in first clutches ranged over more than 6 weeks. A total of 48-55 days were required from clutch initiation to fledgling independence, approximately half the breeding season (Eaton 1958; Forbes and O'Regan 1960; Harrison 1984; Mattsson et al. 2011, 2020; Mulvihill et al. 2009).

The Louisiana Waterthrush typically raises a single brood in a season (Eaton 1958), but rare cases of double brooding have been reported further south in its range. It is highly unlikely that any second broods are raised in Ontario. In Pennsylvania, 5.6% of pairs that successfully fledged young from their first nest attempted a second brood; 4.8% and 8.4% of birds attempted second broods in 2 Georgia studies. In Pennsylvania, the mean date of first clutch initiation was significantly earlier for birds attempting to raise a second brood (29 April) than for birds raising a single brood (4 June). Only those birds that initiate nesting shortly after arrival have an opportunity to raise a second brood. Of 24 pairs that initiated nesting early, 8 attempted a second brood and 5 were successful. Pairs attempting second broods fledged an average of 7.0 young compared with 2.3 for single-brooded pairs. No individual attempted a second brood in more than 1 year and double brooding did not occur every year. At least 58.9% of females attempting second broods were experienced breeders returning to the same territory. Only 1 yearling female was involved in a second brood and all males attempting a second brood were after-second-year birds. Almost all cases of double brooding occurred along high-quality circumneutral streams, suggesting that food availability may be a factor influencing the incidence of double brooding. Only 1 case of double brooding occurred along a stream that was moderately affected by acidification. Prey levels at the end of fledging of the first brood may be important determinants in defining the incidence of second broods (Eaton 1958; Mattsson and Cooper 2007; Mattsson et al. 2011, 2020; Mulvihill et al. 2009). It commonly renests if the first nest is lost. The replacement clutch may be initiated 1-6 days after the first is lost (Eaton 1958; Mulvihill et al. 2002). In Pennsylvania and Georgia, its probability of renesting was 65.8% and 54.2%, respectively. The higher incidence of renesting further north was because of greater food availability due to the longer daylight hours (Mattsson et al. 2011). In Pennsylvania, 38.2% of pairs that had their first replacement nest fail attempted a third nest (Mulvihill et al. 2020). In Georgia, 36 of 75 first nests (48.0%) that failed were followed by a replacement nest. Third and fourth nesting attempts were uncommon: 3 of 26 pairs (11.5%) attempted third nests and 1 of 1 attempted a fourth nest. Of 10 abandoned nests, replacement clutches were laid in 4 cases and adult mortality was involved in the other 6 cases. Loss of the first nesting attempt was more influential on productivity because replacement nests contributed little to productivity (Mattsson and Cooper 2006). Clutches of 4-5 eggs were reported in Ontario (average 4.5; Peck and James 1998a). Elsewhere, it lays 3-6 eggs with 5 eggs the most frequent clutch size. The size of first clutches was 4.8 in Pennsylvania and 4.7 in Georgia; the size of replacement clutches was 4.3 and 3.8, respectively. In Pennsylvania, clutches of nests along circumneutral streams were significantly larger (4.8 eggs) than those along acidified (4.5 eggs) streams (Bent 1953; Chapman 1907; Eaton 1958; Graber et al. 1983; Mattsson and Cooper 2007; Mattsson et al. 2011; Mulvihill et al. 2008). Presumably streams affected by organic pollution and sediments would also contribute to smaller clutch sizes.

The age at first breeding is 1 year and birds nest every year thereafter provided they can find a mate (Mattsson et al. 2020). The mating system is typically monogamous. Of 283 males (1.4%) were polygynous in Pennsylvania. Polygyny may be promoted by females' high site fidelity. Females may

mate with the territorial male even if he has another mate. The sex ratio may be female biased, contributing to the potential for polygyny. In 1 case, the primary female lost her clutch. The male extended his territory by 250 m, drove off the male that was defending this area, nested with the female of the male that he had ousted, and renested with the primary female. One male nested with another female 1 km away. One male was polygynous in 2 successive years. Nests of secondary females overlapped only with the late stages of fledgling care of the first nest. One female was polyandrous and double brooded, switching mates between broods. In 6 other cases of double brooding, the pair remained united for both broods. Occasionally mates reunite in subsequent years. In Georgia, 9 of 29 matings (31.0%) comprised of individuals present the previous year consisted of birds mated with their previous mate (Mattsson et al. 2020; Mulvihill et al. 2002, 2009).

Early in the season, the Louisiana Waterthrush forages entirely in streams. Later in the season, if streams dry up, it may feed in adjacent upland forests or along lakeshores and exposed riverbeds. Swamp-dwelling birds forage at edges of pools and ponds. The male and female often forage together prior to incubation, but forage alone during the incubation and nestling stages. One adult flies downstream and the other upstream to forage and birds move upstream while feeding. It forages by wading and walking along logs, flat bare rocks, on branches, and at the water's edge. The use of microhabitats for foraging changes as the breeding season progresses. In Illinois, from territory acquisition until the end of laying, 90% of foraging manoeuvres were directed at water; 7% at soil, rocks, or dry leaf litter (ground); 2.5% at foliage; and 0.5% at flying insects. During incubation, 60% of foraging was directed at water, 19% at the ground, 20% at foliage, and less than 1% at flying insects. During the nestling period, 63.5% of foraging was directed at water, 23% at the ground, 11% at foliage, and 2.5% at flying insects. In Connecticut prior to leaf-out, 80% of foraging was directed at water and 20% at the ground, with no foraging observed on foliage or flying insects. After leaf-out, 53.3% of foraging was directed at water, 28.3% at the ground, 14.2% at foliage, and 4.2% at flying insects; these differences were significant. It captures both submerged and floating organisms. It finds prey items by flipping leaves to pick up animals beneath, poking its bill into crannies, picking food items directly out of the water by wading, and jumping from the ground to capture flying insects. It takes prey from water 2 cm or less in depth. When feeding on woody plants, it walks on stout branches and picks prey from foliage and stems. During a stonefly outbreak in New York, it foraged along deciduous and coniferous branches several metres above ground. Foraging techniques include picking prey from rocks, mud, moss, leaf litter, and vegetation; leaf-pulling (pulling dead leaves from water or litter to inspect them for prey); hawking (sallying upward for flying insects); and hovering. In Connecticut, foraging methods changed significantly as the season progressed. Prior to leaf-out, 53.3% of foraging attacks were by picking, 44.0% by pulling, 0% by hawking, and 2.6% by hovering. After leaf-out, 86.6% of foraging attacks were by picking, 5.5% by pulling, 30% by hawking, and 4.9% by hovering (Craig 1984, 1987; Eaton 1958; Eliason and Fall 1989; Mattsson et al. 2020).

Craig (1984) compared the foraging ecology of the Louisiana and Northern waterthrushes. Both species exhibited similar behaviours when foraging, had similar attack rates, and fed on submerged and floating organisms. The 2 species foraged similarly prior to leaf-out but there was a significant divergence in the foraging sites used after leaf-out. The Louisiana Waterthrush foraged mostly on the ground and at aquatic sites. The Northern Waterthrush had a wider range of foraging substrates

including ground, water, and foliage. There was an overlap in use of foraging sites of 98% before leaf-out and 92% after leaf emergence. The foraging methods of the 2 species overlap to a greater degree than for other closely related species.

Small items are initially fed to nestlings, but by the time they are 5 days old, they may be brought prey as large as cicadas. At 1 nest, most food items brought to nestlings were mayfly nymphs or adults. Along an acidified watercourse where mayflies were almost completely absent, young were fed novel prey items such as terrestrial salamanders. In New York, 1 nestling′s stomach contained 85% insect fragments by volume, 5% snails, 5% adult beetles, and 5% grit. Another contained 85% insect fragments, 10% beetle adults, and 5% grit. In Arkansas and Pennsylvania, DNA sequencing was used to determine nestlings′ diet. The researchers hypothesized that the nestling diet would be comprised predominantly of mayfly, stonefly, and caddisfly taxa and that the diet would change over the course of the nesting season in response to changes in the aquatic insect community. Contrary to predictions, lepidopterans occurred in 92% of fecal samples and they were significantly more common in the diet than any other order in Pennsylvania and any other order other than flies in Arkansas. Flies (70% occurrence) and mayflies (61% occurrence) were frequent in the diet. Among the mayfly, stonefly, and caddisfly orders, mayflies were most frequently represented, contributing to 93% of taxonomic units. Stream mayflies, whose nymphs typically occur in rapidly flowing water, occurred in 58% of Arkansas fecal samples and 61% of Pennsylvania samples and were the only family of mayflies found in the diet in Arkansas. Stoneflies and caddisflies were detected in only 9 samples from Pennsylvania, representing 7% and 1% of taxa, respectively. These orders were not detected in samples in Arkansas. The diet included aquatic megalopterans and terrestrial spiders, beetles, true bugs, hymenopterans, orthopterans, and book lice. The frequency of occurrence of flies in the diet did not vary seasonally at either study area. Frequency of occurrence of lepidopterans and mayflies did not vary seasonally in Arkansas but differed significantly from late May to early June in Pennsylvania. The Louisiana Waterthrush is less dependent upon aquatic prey than previously thought, with only mayflies being important in the diet. In these study areas, it did not rely predominantly on pollution-sensitive aquatic species. The usefulness of using the Louisiana Waterthrush as a predictor of high-quality streams, and the contention that water quality impairment is a significant threat to it may be overstated or incorrect (Craig 1984; Eaton 1958; Trevelline et al. 2016).

In New York, fly larvae (midges, soldier flies, and crane flies) and beetles (water-scavenger and click beetles and weevils) were the dominant foods of adults, but the Louisiana Waterthrush highly preferred mayflies and stoneflies. Nymphs of these orders were taken 1-2 days before they emerged and waterthrushes feed heavily on subimagos and adults during emergence. Other prey consisted of caddisflies, bugs, earthworms, millipedes, and alderflies. In Connecticut, 96.0% of prey was aquatic. The diet consisted of 40.7% caddisflies, 20.3% flies, 13.6% mayflies, 13.6% oligochaetes, and 3.4% isopods based on observations of prey captures. Other food items included dragonfly nymphs, predaceous diving beetle larvae, crane fly larvae, snails, mosquito larvae and adults, terrestrial millipedes, and caterpillars. Other items that the Louisiana Waterthrush eats include locusts, ants, scale insects, small fish, cicadas, geometer moths, scorpions, bugs, small frogs, and larval salamanders. Compared with prey availability, it strongly preferred fly larvae, especially midges, and strongly avoided isopods. It selected prey more than 13-19 mm in length, took prey longer than 19

mm in proportion to its availability, and underutilized prey 7 mm or shorter and 7-13 mm in length. It ate prey as large as 30 mm (Bent 1953; Craig 1984, 1987; Eaton 1958; Harrison 1984; Mattsson and Cooper 2006; Mattsson et al. 2020; Mulvihill et al. 2009).

Craig (1984, 1987) compared the diet of the Louisiana and Northern waterthrushes. The Louisiana Waterthrush ate significantly more caddisfly larvae and fewer flies (mostly midges) than the Northern Waterthrush. The most significant difference between the diet of the 2 species was the size of prey consumed. The Northern Waterthrush showed no size preferences; the Louisiana Waterthrush preferred prey 13-19 mm in length. Caddisflies comprised 52% of prey larger than 13 mm in Louisiana Waterthrush territories compared with 31% in Northern Waterthrush territories. The biomass of aquatic insects larger than 13 mm was 15% higher in Louisiana Waterthrush territories than in Northern Waterthrush territories. The 2 species were not ecologically separated by interspecific territoriality, divergence in foraging sites, or divergence in foraging methods. They appeared to select territories with different sizes of aquatic invertebrates. Fast-flowing water supports a higher density of larger invertebrates which may explain the Louisiana Waterthrush's preference for fast-flowing streams.

The Louisiana Waterthrush is a common host of the Brown-headed Cowbird. Cowbirds remove a waterthrush egg prior to laying one of their own. Young waterthrushes are occasionally jostled out of the nest by cowbird nestlings and 1 young cowbird killed 3-4 young waterthrushes just before they fledged. The cowbird occasionally lays before the Louisiana Waterthrush does, and these eggs are sometimes buried in the nest. Most cowbird eggs are laid during the waterthrush's laying period and these eggs are either accepted or punctured and ejected. The Louisiana Waterthrush frequently fledges both species. Parasitized nests may produce 50% fewer waterthrush fledglings than unparasitized nests due to egg loss and lower success rates. Nests with greater exposure from above and those with a larger gap between the top of the nest and the cavity roof are more likely to be parasitized. Nests nearer forest edge were more likely to be parasitized in southern Illinois. In Ontario, 2 of 11 nests (18.2%) were parasitized. Two of 9 (22.2%) and 9 of 16 (56.3%) were parasitized in 2 New York studies. In Illinois, 81% of nests were parasitized in 1 study, but only 33% were parasitized at a site 35 km away. In Pennsylvania, 7% of 74 nests were parasitized in the northeast, 0% of 31 centrally, and 3% of 117 in the southwest. In Georgia, 0 of 173 nests were parasitized (Bent 1953; Eaton 1958; Hahn and Hatfield 1995; Mattson and Cooper 2007; Mattsson et al. 2020; Peck and James 1998a).

Habitat loss does not currently seem to be a major limiting factor for the Louisiana Waterthrush in southern Ontario, although habitat degradation is taking place in some areas. It is likely that considerable habitat was lost historically due to forest clearing. This, in turn, may have dried up some streams that potentially provided habitat in the past. Due to past land management practices, there are few swamp forests remaining in southern Ontario large enough to support the Louisiana Waterthrush. The remaining swamps are under pressure from agricultural drainage and drainage may dry up vernal pools and ponds that are essential within its territory (Austen et al. 1994; McCracken 1991, 2006).

Habitat degradation is the most significant limiting factor for the Louisiana Waterthrush. Degradation may result from opening up the forest canopy, air and water pollution, and changes in stream hydrology.

Friis and Brett (2012) and McCracken (1991) stated that forest thinning was a medium threat because this opens up the canopy, increases water temperature and sedimentation, results in erosion, and decreases the diversity and biomass of aquatic invertebrates. It is possible that this threat is overstated. To have any appreciable effect on water temperature, considerable lengths of the streams' banks would have to be deforested (Barton et al. 1985). Buffer strips are typically left along watercourses when forest management approved by the Ontario Ministry of Natural Resources or a registered professional forester is undertaken. These threats are likely to be realized only if extensive and unauthorized forest thinning takes place. Friis and Brett (2012) recommended, for streams supporting the Louisiana Waterthrush, that 75% of the stream length be maintained in natural vegetation, with a riparian buffer of at least 100 m. In West Virginia, forest removal due to shale gas development was detrimental. As a result of the development, forest cover declined from 95% to 91% over a 6-year period. Study streams had a mean of 23% of their length disturbed (range 0-67%). Territory density declined and territory length increased over time. Daily nest survival declined over time and all parasitism by cowbirds occurred in later years after disturbance. Nest survival averaged 37% in undisturbed areas and 31% in disturbed areas. Birds in disturbed areas fledged significantly fewer young. In addition to direct habitat change, streams in disturbed areas were affected by sedimentation. Nests were predominantly in forested habitat (94%) with 2.3% of the canopy disturbed. Disturbances related to shale gas development resulted in declines in its territory density, nest survival, nest productivity, and riparian habitat quality. Individuals breeding in disturbed areas potentially inhabited sink habitat. Declines occurred despite less than 5% forest cover loss in a predominantly forested area suggesting that factors other than forest cover also influenced demography (Frantz et al. 2018). In West Virginia, well pads, access roads, and pipelines in contiguous forest did not have any effects on this waterthrush (Farwell et al. 2019). Forest thinning in swamp habitats used by the Louisiana Waterthrush may be detrimental. Bushman and Therres (1988) reported a 50% decline due to selective logging that resulted in the understorey becoming too dense.

Mulvihill et al. (2008) studied the effects of stream acidification on the Louisiana Waterthrush in Pennsylvania. Although stream acidification is not an issue in Ontario, this research is important for 2 reasons. The first is that effects due to sedimentation and organic pollution that may result from urbanization, agricultural practices, or other disturbances will be similar to those resulting from acidification, but probably more severe. The second is that reductions in Louisiana Waterthrush populations in adjacent states due to stream acidification may reduce immigration from those areas to southern Ontario. Acidification had numerous effects in Pennsylvania. Although the mean abundance of macroinvertebrates was similar in acidified and circumneutral streams, their mean biomass was significantly lower and mayflies, a preferred food, all but disappeared in acidified streams. The average length of waterthrush territories was significantly longer on acidified (630 m) than circumneutral (370 m) streams and consequently breeding density was much lower on acidified streams. Extensive areas of habitat were unoccupied on acidified streams but occupancy gaps were rare on circumneutral streams. Significantly fewer males were paired on acidified (84%)

than circumneutral streams (92%). Acidified streams had a higher proportion of second-year birds and fewer of these birds returned to nest in subsequent years. Some birds moved from acidified to circumneutral streams. Acidified streams were occupied only as secondary or suboptimal habitat when high quality habitat was not available. Older and more experienced birds may exclude second-year birds from nesting along circumneutral streams. Pairs successfully raised young along acidified streams by decreasing density and foraging over a longer distance of stream.

Sedimentation may be the worst type of water pollution. It enriches the water and fills up the interstices among cobblestones and boulders and, in extreme cases, may bury coarser substrates. High sediment loads eliminate stoneflies and mayflies and other sensitive invertebrates. A significant limiting factor to the Louisiana Waterthrush in Ontario is fording of streams by off-road vehicles. This results in increased sedimentation which can affect food supplies. This is a growing problem on the Norfolk Sand Plain, which is where the largest population of this waterthrush occurs in Ontario (Friis and Brett 2012; McCracken 2006).

Urbanization within watersheds of streams that support the Louisiana Waterthrush may potentially to affect it, although the current threat level from this is low. Urbanization tends to result in delivery of sediments and organic nutrients to streams, which depress aquatic invertebrate populations. Urbanization often alters the hydrology of streams with resulting lower baseflow during dry periods and high peak flows during runoff events. This may cause premature drying of intermittent streams, stream bank erosion with subsequent sedimentation problems, and flooding. Flooding may result in the loss of nests either by their being washed out or by bank failure. Highly fluctuating water levels have adverse effects on aquatic invertebrates and may alternately flood or dry out waterthrush feeding areas (Eliason and Fall 1989; Friis and Brett 2012; Mattsson and Cooper 2007; Mattsson et al. 2020; McCracken 1991, 2006).

Friis and Brett (2012) concluded that irrigation or other water uses that reduced stream flows or drained swamps were a threat to the Louisiana Waterthrush.

Widespread use of neonicotinoid pesticides in southwestern Ontario agricultural lands is a threat. These persistent chemicals are especially toxic to mayflies and caddisflies which are important prey for the Louisiana Waterthrush (Heagy 2015).

A few localized threats to the Louisiana Waterthrush have occurred in Ontario. These include residential development close to its habitat; disturbance of nesting birds by fishermen, hikers, and dog-walkers along streams; and forest clearing for ski runs along the Niagara Escarpment (Heagy 2015).

Drought may have adverse effects on the Louisiana Waterthrush. Although a dry year was beneficial to it in Minnesota by exposing beaches suitable for foraging along a large river (Eliason and Fall 1989), it is not known to inhabit such areas in Ontario where it would benefit from lower water levels. Adverse effects due to drought have been observed at several sites in Norfolk County, which were abandoned following a succession of drought years (McCracken 1991, 2006).

In the Great Smoky Mountains, loss of riparian hemlocks due to the hemlock woolly adelgid did not affect Louisiana Waterthrush foraging habitat selection or adult survival rates. It selected nest sites in areas with more exposed live roots, but only where hemlocks were in poor condition. Nest

survival was lower where deciduous rather than coniferous species dominated the understorey, suggesting a potential long-term effect of hemlock decline (Bryant et al. 2020).

Eaton (1958) stated that late snowstorms appeared to have no effects upon the Louisiana Waterthrush in New York. Curry (2006) concluded that one seen on 6 April and the following 2 days in Hamilton probably perished in a late winter storm.

Price (2004) predicted that the range of the Louisiana Waterthrush might expand in southern Ontario if the average summer temperature increased by 2°C. McCracken (2006) and Friis and Brett (2012) pointed out that any northward range expansion due to climate change would likely be negated by decreased availability of water. Increased temperatures would probably contribute to lower groundwater levels and lower stream baseflows. It is more likely that the range and population of the Louisiana Waterthrush will contract due to climate changes.

Status

Until recently, the breeding distribution of the Louisiana Waterthrush was underestimated. Many breeding areas were overlooked until at least after the first atlas. Breeding was first confirmed in Aylmer in 1895 and at Rondeau in 1933. Baillie and Harrington (1937) stated that it occurred in small numbers north to Middlesex and Frontenac counties and that its only known nesting areas at that time were at Rondeau, where it was numerous, and in Middlesex and Wentworth counties. During the first atlas, breeding evidence was obtained in the Long Point area north to Cambridge, in the Bayfield River valley along Lake Huron, in ravines along the Niagara Escarpment in Grey County, and in the Kingston region. More intensive surveys after the first atlas found many more nesting in Haldimand, Norfolk, and Elgin counties. The first evidence of breeding in the Kingston area occurred in 1975 and it has bred there annually since 1980 (Austen et al. 1994; Eagles in Cadman et al. 1987; McCracken 1991). James (1991) considered it a rare and local breeder in the Carolinian Forest Region and occasional and rare in the Kingston area. McCracken (1991) stated that its centre of abundance was in the Norfolk Sand Plains, with secondary populations occurring locally along the Niagara Escarpment and in the Kingston area. The total Ontario population at that time was estimated at 150-313 pairs.

The second atlas confirmed that the breeding range of the Louisiana Waterthrush had not changed significantly since the first atlas, and the largest populations were concentrated in the same areas. It was documented occurring locally along portions of the Oak Ridges Moraine and in the Rideau Lakes area. There was no significant change in its probability of observation, and the population was believed to have remained stable at 105-195 breeding pairs since the first atlas. This population estimate is lower than the 1991 estimate, but is essentially the same because the earlier estimate did not account for intermittent use of habitat (McCracken 2006; McCracken in Cadman et al. 2007).

The breeding range of the Louisiana Waterthrush expanded northward through New England beginning in the 1920s. This was probably in response to reforestation of areas that were heavily lumbered in the late 1800s and early 1900s. It is unknown if this general increase occurred in Ontario because the species appears to have been largely overlooked in many areas until the late 1980s. The exception is the population at Kingston, which apparently did not become established until about 1975. In Elgin County, it occurred sparingly in 1891. By 2000, it was a very local summer breeder but

occurred wherever there was suitable habitat. This suggests that much of its habitat was lost in that county and that it is less common now than formerly. It was quite common north and northeast of Point Pelee in 1924 but is now virtually extirpated in Essex and Chatham-Kent. Peak numbers occurred in the Hamilton area in the late 1950s and 8 were present at Tiffany Falls in Ancaster in 1956. In Niagara Region, it formerly nested at Beamer's Falls in Grimsby, but breeding has not been confirmed there since 1960 and it was not recorded in Niagara at all during the second atlas. Despite these apparent declines in the 20th century, the Louisiana Waterthrush population appears to have been stable since the 1980s (Austen et al. 1994; Black and Roy 2010; Craig 1985; Curry 2006; Lancaster et al. 2004; Mattsson et al. 2020; McCracken 1991, 2006). The management plan objective for the Louisiana Waterthrush in Ontario is to maintain the current size and distribution of the population. It was acknowledged that population changes at the continental level could have significant effects on it in Ontario (Friis and Brett 2012).

The southwestern Ontario population is concentrated in the Norfolk Sand Plain. In 2014, it was estimated that this area supported 47-94 breeding pairs, about two thirds of the 2005 estimate of 81-133 pairs. The 2014 population estimate for south-central Ontario was 40-100 pairs, but new sites were found along the Niagara Escarpment. Probably fewer than 5 pairs nest in southeastern Ontario. The 2014 population level was similar to the 2005 estimate. Occupancy is intermittent at most Ontario sites (Heagy 2015).

The Louisiana Waterthrush is listed as threatened in Canada and Ontario. The Canadian population is estimated at 235-575 adults. The objective of the recovery strategy is to maintain or increase the size and distribution of its population in Canada. It is likely that maintaining the current population will require more than 235 adults (Brett 2023).

POSTFLEDGING PERIOD

By the second day after fledging, the young can fly about 15 m and can fly and perch skillfully 4 days after fledging. Fledglings begin feeding themselves when they have been out of the nest for approximately a week. At this time, their foraging methods are restricted to picking and they do not attempt leaf-pulling until 3 weeks postfledging. In New York, the young remained near the nest 2-3 days after fledging, where they perched in shrubbery. They occasionally moved out of the ravine into the adjacent oak forest, but this was exceptional. One brood of 4 was split between the parents with all remaining within 70 m of the nest and near the stream for the first 10 days after fledging. One young was seen 1 km from the nest being fed by an adult. One young left the nest on 12 June and was observed 4.8 km away on 19 July. Another fledged on 9 June and was 2.0 km away on 14 July. Fledglings may begin feeding themselves about a week after leaving the nest but may continue to be fed by adults until 4 weeks after fledging (Eaton 1958). One bird moved 1.5 km from the nest to an adjacent tributary 5.5 weeks after fledging (Mattsson et al. 2020).

Vitz and Rodewald (2006, 2007) captured both adults and juveniles in regenerating clear-cuts in Ohio during the postbreeding season. There was no indication that breeding had taken place in this habitat. Dense shrubby areas may be important to both adults and fledglings during the postfledging period. In a Missouri oak-pine-hickory forest, Porneluzi et al. (2014) captured 4 Louisiana Waterthrushes 2-15 years after it was clear-cut.

MIGRATION

The Louisiana Waterthrush migrates mostly, if not entirely, by night. Birds travel singly and usually appear in spring on a morning after a warm night with strong south winds. Females tend to arrive later than males in spring. Some arrive on the same day as males but others appear a week or more later. In New York, females arrived over a span of 9 days; males arrived over a 15-day period (Eaton 1958; Mattsson et al. 2020).

The Louisiana Waterthrush is one of the earliest warblers to arrive in the province. The average date of first arrival at Long Point is 20 April. In Elgin County, it arrives in the second or third week of April. In the Hamilton area, average spring arrival is in late April, with early birds in late March and migrants present until late May. In the Kingston area, it mostly arrives in late April, with earliest birds in mid-April (Curry 2006; Lancaster et al. 2004; McCracken 1991; Weir 2008).

Throughout its range, the Louisiana Waterthrush leaves its breeding range as early as July, but most leave in August and a few may linger into early October in the southern portion of its range. In Pennsylvania, double-brooded birds and their fledglings were the last to migrate, probably not leaving before the end of August. It defends a winter territory, so double-brooded birds may be at a disadvantage on the wintering grounds because of their late arrival (Mattsson et al. 2020; Mulvihill et al. 2009). Most Ontario birds have migrated by mid-August, with some remaining until early September (Curry 2006; McCracken 1991; Weir 2008).

Migration habitat is similar to that used during the breeding season, but the Louisiana Waterthrush may also occur near stagnant or open-water habitats and away from forested areas. It may forage in parks, gardens, and shrubby thickets where water is available. In Illinois, spring migrants were particularly abundant in rich bottomland forests, so these areas may be preferred habitat. During spring migration in North Carolina, it was observed only in beech and floodplain forests. It was not observed in pine-hardwoods, pine, oak-hickory, wet thicket, or dry thicket habitats. No particular selection for habitat was made within the general types of habitat that it used (Graber et al. 1983; Mattsson et al. 2020; Parnell 1969).

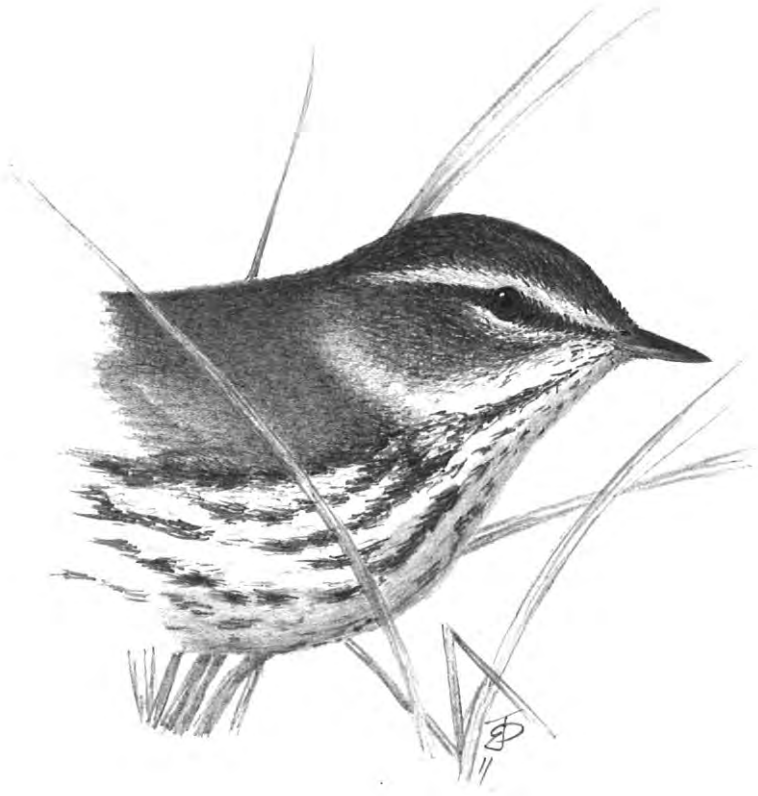
Parnell (1969) examined where the Louisiana Waterthrush spent its time during spring migration in North Carolina. Overall, 7.6% of observations were in the canopy, 31.7% in low trees, 15.8% in shrubs, and 44.8% on the ground. In the canopy, 2.3% of observations were in the inner crown and 5.3% were in the lower crown; it was not observed at the top of the crown or on tree boles. In low trees, 5.3% of observations were at the top of crowns, 5.3% in the inner crown, 21.1% in the lower crown, and 0% on tree boles. In shrubs, 2.6% of observations were at the top of the crown, 0% in the inner and lower crowns, 13.2% in dense thickets, and 0% in brush piles and grasses. On the ground, 8.3% of observations were in dense thickets, 0% in grasses, 20.8% at water's edge, and 8.3% in the open.

During migration, the Louisiana Waterthrush occasionally strikes tall buildings and communication towers. It also collides with windows and vehicles during migration (Mattsson et al. 2020). It was at high risk of colliding with buildings across the United States. At low-rise buildings, it was 46.4 times more likely to collide with a building than average for all species. It was not on the lists of the 20 most vulnerable species for striking 1-3-storey residences and high-rises (Loss et al. 2014).

The Louisiana Waterthrush is a rare migrant in Ontario. It occurs regularly in spring along the north shore of Lake Erie at Point Pelee, Rondeau, and Long Point, but is uncommon even at these migration concentration areas (James 1991; McCracken 1991, 2006).

Northern Waterthrush

Parkesia noveboracensis

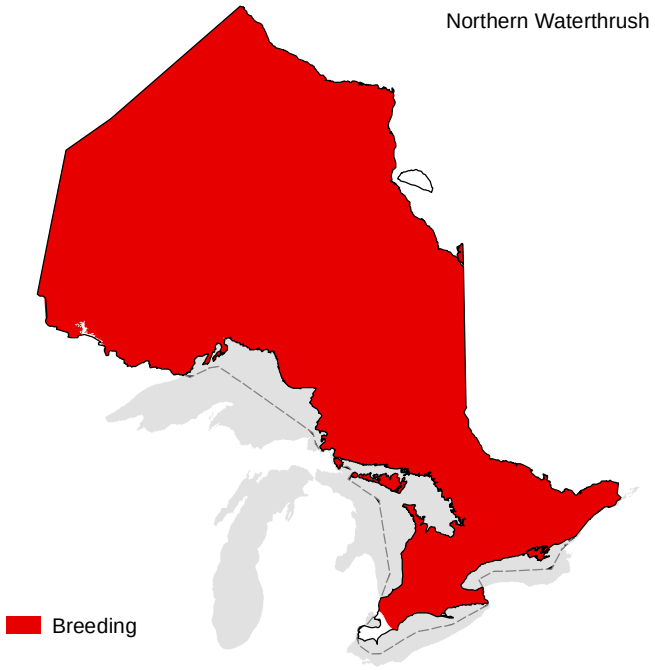


BREEDING SEASON

Habitat Requirements

In Ontario, the Northern Waterthrush has nested in moist or flooded forests (64.4% of nests), preferring mixed stands to deciduous and coniferous stands; in forested areas beside lakes, ponds, rivers, and streams (18.6%); at margins of marshes and beaver ponds (3.4%); in black spruce and sphagnum bogs (3.4%); in a dry forest (1.7%); and in unspecified woods (8.5%; Peck and James 1987). Its breeding habitat consists of mixed, deciduous, or coniferous forests; swamps; margins of isolated pools and ponds; and riparian edges. Trees within nesting habitat may be sparse and range in height from short to tall. It requires a dense shrub layer (James 1984b).

Although the Northern Waterthrush is often characterized as a forest bird associated with swamps, woodland ponds and vernal pools, or margins of forested lakes or watercourses, it may be locally common in shrub thickets. Along the western James Bay and southern Hudson Bay coasts, it was evenly distributed in willow thickets at edges of spruce woods. Most were observed in tall



willow thickets (Manning 1952). It occurred along the Brant River in willow thickets (Wilson and McRae 1993).

Near Pickle Lake in the Boreal Forest Region, the Northern Waterthrush occurred regularly in small numbers in shrubs at lake and river shorelines (James 1980). In the Pickle Lake, North Caribou Lake, and Little Sachigo Lake regions, highest densities were in deciduous shrubs followed by deciduous forest, mixed shrubs, coniferous shrubs, coniferous forest with understorey, and coniferous forest without understorey. It was absent in mixed forest, heath, and tundra (McLaren and McLaren 1981). Near Hearst, it occurred in clear-cuts 13-24 years old (Welsh and Fillman 1980). In the Clay Belt, it occurred mainly in wet habitats with poor to rich nutrient status. It occurred in black spruce, tamarack–white cedar, white birch–white spruce, and balsam poplar stands (Welsh and Lougheed 1996).

In Muskoka and Parry Sound districts, the Northern Waterthrush nested in alder thicket swamps, ash swamps, and undisturbed lakeshores (Mills 1981). In white pine shelterwood cuts in Algonquin Park, Kingsley and Nol (1999) reported it in 8.3% of 2-9-year-old cuts; in 0-18.2% of 10-16-year-old cuts; and in 20-21.4% of old cuts. In Algonquin Park, it nested along margins of lakes, streams, and flooded areas (MacLulich 1938). Also in Algonquin Park, it nested in black spruce and black spruce–white cedar stands. It was absent in wet or dry bogs, white birch–poplar, white birch–poplar–balsam fir–spruce, balsam fir–spruce, immature white pine, balsam fir–spruce-hardwoods, hardwood, and hemlock stands (Martin 1960).

In Durham Region in the Great Lakes–St. Lawrence Forest Region south of the Shield, the Northern Waterthrush nested in a young forest with an open canopy and much standing water, and in a sugar maple forest sloping down to a stream bordered by white cedar, balsam fir, and spruce with a dense undergrowth of raspberries and nightshade. Speirs and Orenstein (1975) considered it associated with balsam fir. It preferred wet forests at Presqu'ile (LaForest 1993).

Throughout its range, the Northern Waterthrush is strongly associated with the presence of water and dense shrub growth. It commonly nests in shrub thickets, treed swamps, treed bogs, and riparian forests. Occasionally it nests in upland forests along watercourses, but usually only in mountainous regions (Bent 1953; Brooks 1940; Chapman 1907; Harrison 1984; Whitaker and Eaton 2020).

Although the Northern Waterthrush is often considered an obligate forest species, it frequently nests in shrub thickets. It commonly nests in willows, dogwoods, and alders bordering rivers and lakes. Willow or alder thickets along watercourses are favoured habitat in Quebec. In British

Columbia, it prefers dogwood thickets that provide dense cover near water and frequently inhabits flooded vegetation, especially willow, trembling aspen, and alder mixed with spruce. Highest densities occur in alder-fern shrubbery and alder–skunk cabbage thickets. Near Fort Nelson, it occurs mainly in alders and willows along streams. In the Yukon, it is found in dense shrubbery along rivers, creeks, and sloughs, often at the edge of an area bordering open water. Highest densities in North Dakota occurred in willow shrub thickets. In Minnesota and Wisconsin, the primary habitats included alder thickets and sedge meadows that were regenerating with shrubs, especially dogwoods (Campbell et al. 2001; Faanes and Andrew 1983; Lemieux et al. in Gauthier and Aubry 1996; Manning and MacPherson 1952; Sinclair et al. 2003; Whitaker and Eaton 2020).

The Northern Waterthrush nests in a wide range of moist to wet forest types. These include stands dominated by balsam fir, white cedar, black or white spruce, trembling aspen, northern hardwoods, lowland hardwoods, tamarack, nutrient-poor jack pine, and red maple. It is characteristic of swamps and floodplain forests, and also of tundra with boreal forest near the northern extent of trees. It prefers forests with vernal or permanent pools of water or those that are along the bank of a river or lake. Nesting may also occur in forested habitat at edges of beaver ponds. Its abundance in forests is significantly correlated with the density of shrubs in the 0.3-1.0-m stratum. In 2 different Newfoundland studies, it occurred at higher densities in balsam fir stands with denser understorey. All 7 territories on the main island of Newfoundland contained open water, but only 1 of 7 on an adjacent island had open water (Campbell et al. 2001; Dawson 1979; Erskine 1977; Faanes and Andrew 1983; Golet et al. 2001; Kirk et al. 1996; La Rue et al. 1995; Morgan and Freedman 1986; Mossman 1988; Noon et al. 1979; Robbins et al. 1989; Samson 1979; Temple et al. 1979; Thompson et al. 1999; Vassallo and Rice 1982; Whitaker and Eaton 2020; Whitaker and Montevecchi 1997; Wiebe and Martin 1998). In Newfoundland, the climate provides unusual conditions and creates areas of nonriparian surface water in upland balsam fir stands. These areas support suitable habitat for abundant arthropods that provide suitable habitat for the Northern Waterthrush (Warkentin et al. 2003a).

Golet et al. (2001) and Freemark and Collins (1992) classified the Northern Waterthrush as a forest-interior species, but provided no supporting documentation. In southern Ontario, its abundance was significantly correlated with the amount of forest cover more than 100 m from edge (Austen et al. 2001). Most studies found that it is a riparian specialist that avoids forest interior. In Newfoundland, Whitaker and Montevecchi (1997, 1999) considered it a riparian habitat specialist. It was rarely seen away from water and travelled linearly along shorelines. It was rare in forest interior, with relative abundance of 8% in the interior compared with 85% in riparian habitat. In Quebec balsam fir and white cedar stands, La Rue et al. (1995) found it in 7 of 8 riparian plots and in no nonriparian plots. There was no difference in vegetation communities between riparian and nonriparian plots except for the presence of alder–reed canary grass wetlands in riparian habitat. In British Columbia, Wiebe and Martin (1998) studied riparian areas along second-order streams in mature to old-growth coniferous forests. Its presence was positively associated with riparian habitat. The percentage of birds seen in intervals from the willow or alder riparian habitat was: 0-50 m, 32.6%; 50-100 m, 18.6%; 100-150 m, 18.6%; 150-200 m, 10.5%; and 200-250 m, 19.8%. The distribution of birds differed significantly from random. It was recorded at least 250 m from a stream 2 km upstream from a lake, indicating that it may use a zone wider than the riparian vegetation itself. In Alaska, it

was largely restricted to the floodplain terrace landform (Handel et al. 2009). It is unlikely that the Northern Waterthrush can be classified as a forest edge or interior species. Its distribution within a forest is probably related more to the presence of water and dense shrub coverage than edge.

It is uncertain whether the Northern Waterthrush is an area-sensitive species. In southern Ontario, its abundance was significantly correlated with forest size, the amount of forest cover within 2 km, and the amount of regional forest cover, all suggesting that it is area-sensitive (Austen et al. 2001). In the mid-Atlantic states, Robbins et al. (1979) determined that its abundance was correlated with forest size and considered it area sensitive. Its maximum probability of occurrence occurred in forests larger than 3,000 ha, probability declined to 50% at 200 ha, and the 3 smallest woodlots in which it was observed at least twice were 187, 187, and 24.1 ha. In Rhode Island red maple swamps, it regularly occurred in swamps as small as 1 ha. This was not a good test of area sensitivity because the swamps were surrounded by upland forest. Its abundance was not related to forest size, probably because 60% of the landscape was forested (Golet et al. 2001). The Northern Waterthrush is not considered an area-sensitive species in Ontario. It was not identified as such by James (1984b) or Coleman et al. (2000).

Craig (1985) compared habitat use by Northern and Louisiana waterthrushes in Connecticut. The habitat consisted of rocky ravines containing watercourses, one of the less frequented habitats of the Northern Waterthrush. Although there was great overlap in the territories of the 2 species, Northern Waterthrush territories were much more densely vegetated; had more evergreen coverage in the form of mosses, shrubs, and trees; possessed typical swamp characteristics such as abundant hummocks, ferns, and alders; and had less fast-flowing water than Louisiana Waterthrush territories. Northern Waterthrush territories had significantly fewer forbs (12.5%) and significantly more ferns (31.9%) than those of the Louisiana Waterthrush (17.4% and 17.9%, respectively). Northern Waterthrush territories had significantly less fast-flowing water (3.8% compared with 23.7%) and more hummocks (45.8 compared with 30.9) than Louisiana Waterthrush territories. Northern Waterthrush territories had significantly higher total shrub density and higher densities of shrubs in the 1-2-m and 2-3-m strata than those of the Louisiana Waterthrush. Much of the difference was due to the presence of significantly more hemlock saplings in Northern Waterthrush territories. There were significantly more trees per ha (average 913, range 503-1,238) in Northern Waterthrush than Louisiana Waterthrush (average 666, range 470-948) territories, and Northern Waterthrush territories had a higher evergreen to deciduous ratio, higher density of hemlock, and a higher density of grey alder than Louisiana Waterthrush territories. Typical northern Connecticut habitats for the Northern Waterthrush were mixed deciduous-hemlock swamps traversed by meandering streams. In the south, it was found in pure deciduous or cedar swamps. In the mid-Atlantic states, abundance of the Northern Waterthrush was significantly correlated with percent canopy cover by conifers. It was negatively associated with slope, consistent with the fact that there is little fast-flowing water within its territories. Its abundance was positively correlated with foliage density between 0.3 and 1.0 m. It was negatively correlated with canopy closure suggesting that presence of dense shrubs is more important than tree coverage (Robbins et al. 1989).

Of 77 Ontario nests, 44.2% were in upturned roots of trees, 28.6% were among roots or in cavities near bases of standing trees and stumps, 13.0% were in depressions in earthen banks of streams and

rivers, 10.4% were in moss-covered hummocks and logs, 1.3% were under a log, 1.3% were under balsam fir branches, and 1.3% were in the side of a water-filled depression in a swamp. Nests were usually well concealed; 53.7% were either on the ground or in stream banks and 46.3% were elevated 0.2-1.2 m above water or occasionally above ground. One nest was reused the following year and another was situated just below a previous year's nest (Peck and James 1987). One nest in Sudbury District was in the side of an old beaver dam and hidden by grasses (Peck and James 1998a).

The nest is usually in complete shade and often not visible from above. Preferred nest sites are in cavities in root systems of wind-blown trees in forested swamps, under roots or other cover along stream banks, and on the ground in the base of a fern clump or in a cavity at the base of a tree or stump, or under logs, mosses, a clump of sod, driftwood along shorelines, or debris. Elevated nests are usually above water at heights as high as 80 cm, but usually less than 30 cm. Nests in upturned roots usually are directly over a small pool of water. One was on the ground and completely exposed, but there is usually cover over the nest with an opening to 1 side (Bent 1953; Campbell et al. 2001; Chapman 1907; Harrison 1984; Sinclair et al. 2003; Whitaker and Eaton 2020).

Territories are defended as soon as males arrive in spring, but territoriality ceases 3-4 days after the young leave the nest. In swamps, territories are often clumped in 1 area, usually in the thickest undergrowth, rather than being uniformly distributed. Even in large areas of apparently suitable habitat, territories are found near nest-support structures or cover such as roots of upended trees, stream banks, hollow stumps, or mossy logs. New York territories averaged 1.0 ha (range 0.8-1.5 ha). In Connecticut, the mean territory size was 0.47 ha; territory size may be halved if another territorial male arrives. In black spruce forests in Algonquin Park, territories extended from the ground to a height of 3 m, which corresponded to the top of the shrub layer and the bottom of the canopy. In mature balsam fir stands in Newfoundland, territory sizes at the 50% isopleth averaged 1.2 ha (range 0.1-4.6 ha). At the 70% isopleth, territories averaged 2.3 ha (range 0.1-8.2 ha), and territories averaged 4.3 ha (range 0.2-15.5 ha) at the 90% isopleth. Territory size was affected by the proportion of harvested versus naturally unforested land at the landscape scale and varied by greater than 2 orders of magnitude. Birds frequently foraged outside their territories and incorporated both natural and anthropogenic openings into their home ranges. They regularly flew directly across large lakes, peatlands, patches of harvested forest, and roads. Home range size at the 50% isopleth averaged 3.5 ha (range 0.8-10.6 ha). At the 70% isopleth, home ranges averaged 6.3 ha (range 1.6-19.5 ha), and home ranges averaged 13.3 ha (range 3.5-35.9 ha) at the 90% isopleth. Home range size was not affected by the amount of harvested versus naturally unforested habitat in the landscape (Craig 1984, 1985, 1987; Leonard et al. 2008; Lemieux et al. in Gauthier and Aubry 1996; Martin 1960; Whitaker and Eaton 2020).

Limited information is available on natal philopatry. In Newfoundland, 7 of 103 fledglings (6.8%) were resighted or recaptured in subsequent years. The median dispersal distance was 1,200 m (range 230-2,500 m; Whitaker and Eaton 2020).

In New York, 2 of 4 males returned to the same breeding site for 2 years. In Massachusetts, 67.8% and 71.4% of 2 groups of adults returned (Whitaker and Eaton 2020). In Newfoundland, 16.3% of adults returned, but these were mostly males due to their higher responsiveness to broadcast calls. The overall return rate was probably higher. Seventy-five percent of 20 adults were observed in 3 or

more years, which was likely more reflective of the return rate. Twenty-five percent of returning individuals were detected more than 1 km from their capture site, indicating some breeding season dispersal (Whitaker and Eaton 2020).

Limiting Factors

Eggs have been found in Ontario nests from mid-May until the second week of July, with most present in the last week of May and first week of June (Peck and James 1987). In Algonquin Park, eggs are present from late May to early June, nestlings occur in early June, and dependent fledglings have been observed from mid-June to early July (Tozer 2012).

One replacement nest was built in 3 days. One egg is laid per day and incubation is initiated after laying the third egg. The incubation period at 1 Ontario nest was not more than 14 days. Other authors reported incubation periods of 12 or 13 days. The young leave the nest before they can fly, at age of approximately 9 days (Harrison 1984; Peck and James 1987; Wander and Wander 1985; Whitaker and Eaton 2020).

The Northern Waterthrush raises a single brood per season. There are no records of second broods. Renesting commonly occurs if a nest is lost. Two Newfoundland birds started replacement nests 10-15 m from the original nest. In Ontario, clutches of 3-5 eggs have been reported (average 4.15 eggs, mode 4 eggs). Overall, clutches of 3-6 eggs have been reported, with most birds laying 4 or 5 eggs (Bent 1953; Campbell et al. 2001; Chapman 1907; Eaton 1995; Peck and James 1998a; Warkentin et al. 2003a).

The Northern Waterthrush first breeds when it is 1 year old and breeds thereafter. It is typically monogamous, but there is evidence for occasional polygyny. Two females with young in their nests were found in a male's territory in New York. In another case, 2 occupied nests were found under a stump with 1 nest close above the other (Eaton 1995). One male in Newfoundland was nonterritorial and did not appear to have a mate or nest (Leonard et al. 2008). Extra-pair copulations have not been confirmed. Males have been observed as far as 1 km from their territories, suggesting that they were seeking extra-pair copulations (Whitaker and Eaton 2014).

From spring arrival until the end of incubation, approximately 80% of foraging occurs in water. In aquatic habitat, the Northern Waterthrush alternately wades and walks along logs, on branches sloping down to the water, and at the water's edge, where it feeds on both submerged and floating organisms. It occasionally flutters over water to capture prey from the surface. Ground feeding includes capturing prey on mud, in leaf litter, on rocks, and on moss. When feeding on woody plants, it walks on stout branches and picks prey from the foliage and stems. The 2 major foraging methods are picking and leaf-pulling, which consists of pulling dead leaves from water or the litter with the bill and inspecting it for prey. These foraging techniques are used both on the ground and in water. It has been observed chasing but not catching adult mayflies and flies. In Connecticut, foraging substrates prior to leaf-out were 74.1% in water, 22.2% on the ground, 1.9% in foliage, and 1.9% in the air. After leaf-out, 38.3% of foraging occurred in water, 23.4% on the ground, 34.0% in foliage, and 4.3% in the air. The 2 waterthrush species foraged similarly prior to leaf-out, but the Northern Waterthrush used a wider range of substrates after leaf emergence. Both species commonly fed by picking and leaf-pulling prior to leaf-out, but picking was the dominant technique after leaves emerged. The Louisiana Waterthrush prefers prey larger than 13 mm; the Northern Waterthrush

prefers shorter prey items. Of 154 prey items, 35.1% were 7 mm or less, 38.3% were 7-13 mm, 22.1% were 13-19 mm, and 4.5% were longer than 19 mm (Craig 1984, 1987; Whitaker and Eaton 2020).

In Connecticut, the diet of both waterthrushes was highly aquatic with only 4.0% terrestrial prey items. The Northern Waterthrush most strongly preferred flies and strongly avoided isopods. Of prey items it caught, 54.7% were flies (mostly midges, but also mosquitoes), 11.0% were caddisflies, 13.6% were mayflies, 5.1% were oligochaetes, and 4.2% were isopods. In addition, it consumed dusky salamanders, adult moths, alderfly nymphs, crane fly larvae, ants, millipedes, centipedes, caterpillars, and snails (Craig 1984, 1987). Whitaker and Eaton (2020) summarized the diet of 25 birds during the breeding season in New York by volume and occurrence: fly adults and larvae, 50.5% and 48%; predaceous diving beetles, 7.5% and 8%; water scavenger beetles, 11.0% and 8%; ground beetles, 5% and 4%; weevils, 3% and 12%; caterpillars, 50% and 8%; stoneflies, 8.5% and 8%; unidentified insects, 51.9% and 88%; snails, 4% and 16%; and leeches, 2% and 4%. Other prey included crawling water beetles, springtails, true bugs, soft-winged bugs, leaf beetles, crane flies, fungus gnats, caterpillars, adult dragonflies, mayflies, alderfly nymphs, dobsonflies, isopods, centipedes, oligochaetes, water boatmen, damselflies, spiders, weevils, owlet moth caterpillars, slugs, and orthopterans. After leaf emergence, it may feed extensively on caterpillars. During migration, it has eaten small fish. During a spruce budworm outbreak in Quebec, it fed budworm larvae to its young (Bent 1953; Lemieux et al. in Gauthier and Aubry 1996; Warkentin et al. 2003a; Whitaker and Eaton 2020).

The Northern Waterthrush is a uncommon host of the Brown-headed Cowbird, partially because much of its breeding range is outside that of the cowbird's. It accepts cowbird eggs and both waterthrushes and cowbirds may fledge from parasitized nests. In Ontario, 11 of 94 nests (11.7%) were parasitized; 17% of 18 nests were parasitized in Quebec; in British Columbia, 0 of 17 nests were parasitized (Campbell et al. 2001; Lemieux et al. in Gauthier and Aubry 1996; Peck and James 1998a; Whitaker and Eaton 2020).

Much suitable habitat for the Northern Waterthrush must have been lost when European settlers cleared the land. Direct habitat loss is less of a threat now, but indirect losses of woodland pools and ponds due to agricultural drainage still occur. Wetlands may accumulate toxins, and the effects of these on it are unknown. Sedimentation and organic enrichment of streams has the potential to reduce its prey base (Eaton 1995). Near Montreal, it declined due to wetland drainage and channelization of watercourses. Increased cottaging on some lakes in southern Quebec has been detrimental (Lemieux et al. in Gauthier and Aubry 1996). Wintering habitat is threatened due to loss of mangrove forests (Whitaker and Eaton 2020).

Much work has been conducted on the effects of forest management on the Northern Waterthrush. In Newfoundland, Whitaker et al. (2008) compared survival rates in landscapes characterized by natural forest openings (mainly peatlands) or those created by clear-cuts. The annual survival rate was 36.5% in natural landscapes and 33.8% in cut landscapes. It was resilient to moderate amounts of clear-cutting. Also in Newfoundland, its occurrence was similar across different levels of forested cover within harvested landscapes, but not in natural landscapes. In harvested landscapes, it exhibited a constant occurrence of 30-35% in 10-100% forest cover. In natural landscapes, it was absent in areas with less than 10% forest cover, had an occurrence rate of

less than 10% in areas with 10-45% forest cover, and had 40% occurrence in 45-100% forest cover. Occurrence rates averaged 30% in cut landscapes, 34% in natural landscapes, and 32% overall. It was relatively insensitive to changes at the local (25 m) and neighbourhood (300 m) scales. Taylor and Krawchuk (2006) concluded that it could fulfill some of its resource needs in clear-cut portions of harvested landscapes but not in non-forested areas in natural landscapes, which consisted of bogs and rock barrens. Species packing may occur in harvested landscapes, whereby birds become more concentrated in residual uncut areas. Vanderwel et al. (2009) summarized studies that examined the effects of partial timber harvesting in the Boreal Forest Region. Its abundance did not change when 30%, 50%, or 70% of trees were removed. In Ontario in the Canadian Shield, there was no difference in its abundance in early and mid-successional clear-cuts compared with the same ages of forests after fire. Abundance was similar in early regenerating and mature stands, but significantly less in mid-successional than mature stands (Zimmerling et al. 2017).

Leonard et al. (2008) studied the effects of clear-cutting in the Newfoundland Boreal Forest Region on territory size of the Northern Waterthrush. There were more occupied territories in natural than harvested habitats. Only 2 settled in territories where gaps in woodland cover were due solely to harvesting. Territories were largest in the most heavily harvested landscapes. At the 70% isopleth, the mean territory size decreased from 3.9 to 0.8 ha as the proportion of unforested land in the landscape due to harvesting increased from 4% to 60%. Territory size increased where the proportion of harvested land was more than 60% to a maximum territory size of 6.5 ha. This represents territory shrinkage of 488% with increasing amounts of clear-cut openings up to a threshold near 60% of the landscape and subsequent territory expansion by 813% when more than 60% of the openings in the landscape were created by clear-cutting. The highly variable territory size may have been due to density and resource availability. In harvested areas, it tends to crowd into riparian buffer areas, thereby increasing density and decreasing territory size. At higher levels of harvest, foraging areas outside territories could be lost resulting in a requirement for larger territories to obtain adequate resources.

In Newfoundland, Whitaker and Montevecchi (1999) compared usage of undisturbed shorelines and those with retained 20-50-m riparian buffers adjacent to clear-cuts. There was no evidence that the Northern Waterthrush was less abundant in buffers than in undisturbed shorelines. They attributed this to the fact that it was associated only with the riparian habitat along shorelines and concluded that increasing the width of the buffer zone would not likely increase usage by waterthrushes.

Warkentin et al. (2003a) examined the effects of clear-cutting in Newfoundland on the Northern Waterthrush. They studied intact riparian and upland habitats and riparian and upland habitats adjacent to clear-cuts. Riparian habitat had consistently greater numbers and higher biomass of prey items even if aquatic organisms were not considered. Despite the variability in food supply, territory numbers in each of the 4 treatments was highly consistent year to year. Similar numbers of territories were present in intact riparian and upland habitats, but fewer Northern Waterthrushes occupied disturbed upland habitat and large numbers packed into disturbed riparian habitat. Birds in disturbed riparian habitats moved longer distances and more frequently than birds in the other 3 habitat types. Territory packing was still evident 5-10 years after clear-cutting, but did not appear to

have any effect on reproductive success. Crowding of disturbed riparian strips may lower foraging success and these retained habitats may not be viable over the long term.

Whitaker and Eaton (2020) suggested that aerial spraying for spruce budworms could reduce the biomass of prey available to Northern Waterthrushes, or kill birds if nonbiodegradable toxins were used. It has been found to carry high concentrations of blood methylmercury, presumably from foraging in contaminated water (Whitaker and Eaton 2020).

In Alberta, the Northern Waterthrush was significantly more abundant at seismic lines than in adjacent forest interior. It was significantly less abundant at pipelines than in adjacent forest interior, and there was no difference in its abundance at well pads and adjacent forest interior (Bayne et al. 2016).

The Northern Waterthrush may be vulnerable to the effects of climate change. In Quebec, it was associated with a low number of growing-degree temperatures (cooler sites), breeding season precipitation, and an early start to the growing season (DesGranges and LeBlanc 2012). Price (2004) predicted that the Northern Waterthrush might no longer breed in southern Ontario if the average summer temperature increased by 2°C. Increased summer temperatures are likely to result in increased evapotranspiration rates and loss of woodland vernal pools and ponds.

Status

McIlwraith (1894) stated that the Northern Waterthrush bred throughout the province and considered it as abundant as the Ovenbird. Manning (1952) reported that a survey completed in 1896 determined that it was very abundant all the way down the Moose River to Moosonee. Fleming (1907) concluded that it was possibly a rare summer resident in the Toronto area. Baillie and Harrington (1937) stated that it bred north to Lake of the Woods and James Bay and probably throughout the province. The first atlas confirmed that it was common and that its range covered the entire province except for the intensive agricultural areas of the southwest and much of Niagara Region and Haldimand County. Its abundance was highest in Peterborough and Haliburton counties, Nipissing District, and the Algonquin Park area (Eagles in Cadman et al. 1987). James (1991) concluded that it was a common summer resident throughout the province except in southern agricultural areas, where it was rare. In Elgin County, it was not known to be a breeder in 1891 or 1954, but was an extremely rare breeder in 2000 (Lancaster et al. 2004).

The second atlas indicated that there had been no change in the distribution of the Northern Waterthrush in Ontario since the first atlas. It was not found in some squares where it previously occurred in the vicinity of Sault Ste. Marie and Sudbury, and in some squares in southwestern Ontario. It was found in many new squares in the south on Manitoulin Island, south of the Bruce Peninsula, southwest of London, and east of Ottawa. Its probability of observation increased significantly province-wide since the first atlas. Increases occurred in all atlas regions and were significant in the Canadian Shield and Hudson Bay Lowland. Highest densities occurred in the Hudson Bay Lowland and the northwestern portion of the Boreal Forest Region. Densities in southern Ontario were much lower, with highest densities in this area occurring in the Kawartha Lakes area north to Algonquin Park and east to Perth County, along the Niagara Escarpment south to Halton Region, and in the Dundalk uplands (McLaren in Cadman et al. 2007).

Breeding Bird Survey results indicate that the Northern Waterthrush increased at an annual rate of 1.07% in Canada and decreased at an annual rate of 0.302% in Ontario 1970-2021. Trends for 2011-21 were an annual decrease of 3.26% in Canada and an annual increase of 0.97% in Ontario. All results were of medium reliability except that the short-term Canadian trend was of low reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Once young leave the nest, brood division occurs with each adult caring for half the brood. Fledglings hide under dense vegetation for 2-3 days after leaving the nest and can fly proficiently by the time they have been out of the nest for 8 days. Each adult feeds half the brood for 4-5 weeks after they fledge. One fledgling was completely independent 30 days after leaving the nest (Whitaker and Eaton 2020).

In Quebec, Major and Desrocher (2012) caught 2 Northern Waterthrushes in regenerating clear-cuts during the postfledging period. In Minnesota, Streby et al. (2011b) captured 5 adults and 13 juveniles in 2-10-year-old clear-cuts during the postfledging period. No waterthrushes were captured in this habitat during the breeding season. At least some juveniles and adults move to dense shrubbery in clear-cuts during the postfledging period. Although it prefers dense shrub cover year-round, it may move to upland sites devoid of water once the young are independent.

In Michigan, Akresh et al. (2009) studied avian usage of mature trembling aspen–large-toothed aspen stands during the postfledging period. The canopy composition of riparian and upland stands was similar, but riparian stands had a shrub layer of alders and honeysuckles. They captured 5 adults and 4 juveniles, all in riparian forests.

MIGRATION

The Northern Waterthrush migrates long distances nocturnally, probably in loosely associated homogenous flocks (Whitaker and Eaton 2020; Winker et al. 1992). Birds captured at Thunder Cape (83%) and Long Point (78%) were strongly represented by deuterium levels in the northern Boreal Forest Region and Hudson Bay Lowland in Ontario, the prairies west to southern British Columbia and north to the Yukon, Northwest Territories, and Nunavut. Forty-eight percent of birds captured at Long Point were representative of birds breeding in the Great Lakes–St. Lawrence and Boreal Forest regions in Ontario and Quebec. There is a strong southeastern migration in autumn and many Ontario and western Quebec breeders move southeastwards toward the Atlantic coast, bypassing Long Point to the north. It tends to move more north-south in spring than autumn and more directly to the breeding grounds (Dunn et al. 2006).

In Minnesota, there was sexual segregation in the spring but not in autumn, with males preceding females in spring. More stayed longer than 1 day in autumn than spring (Winker et al. 1992). In Maine, 2 spring birds stopped over for 6 days; 41 autumn migrants stopped over an average of 4.3 days (range 1-6 days; Morris et al. 1994).

The Northern Waterthrush is one of the earliest warblers to arrive in spring. In southern Ontario, it arrives at the end of April, with some arriving in early April. Most have left by the end of May, but spring migrants have been seen in early June (Black and Roy 2010; Curry 2006; LaForest 1993;

Lancaster et al. 2004; Weir 2008). In the southern Shield, average arrival is in the first week of May with the earliest records in late April (Mills 1981; Tozer 2012).

Autumn migration begins early, well before the end of July, soon after the young are independent (Bent 1953; Campbell et al. 2001; Harrison 1984). In the southern Shield, the Northern Waterthrush is one of the earliest birds to move south, with migrants observed from late July to mid-September (Mills 1981; Tozer 2012). In the south, significant southward movement occurs in July, although the main passage is in late August to mid-September (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008).

During migration, the Northern Waterthrush occurs in similar habitats to those that it uses during the breeding season. It is less selective in its habitat preferences during migration and may occur in sites that would not be used during the breeding season. These include mature upland forests, gardens and about dwellings, open muddy areas in pine barrens, oak meadows, dug-out ponds and water-filled ditches surrounded by shrubs, and freshly turned soil in a livestock corral. At Point Pelee in 1908, it occurred in several habitats including low, damp spots in woods, in upland walnut stands, in red cedar thickets, in brush piles, and in patches of herbaceous plants in cottonwoods (Bent 1953; Brush 1987; Campbell et al. 2001; Chapman 1907; Graber et al. 1983; Leighton et al. 2002; Sinclair et al. 2003; Whitaker and Eaton 2020). Migrants show a consistent preference for riparian thickets and swamps where they are usually found close to water. In Illinois, it shows a strong preference for bottomland forests during both spring and autumn migration. During spring migration in North Carolina, the average number of birds observed per hour was 0.69 in wet thicket, 0.21 in floodplain forest, and 0.04 in oak-hickory forest. It was not observed in pine-hardwoods forest, pine forest, beech forest, or dry thicket. During autumn in New Jersey, it occurs in shrubs along tidewater creeks and at rainwater or dried-up pools. In Minnesota in spring, there were higher capture rates in swamps and floodplains than in willows and upland habitat. In autumn, higher capture rates occurred in floodplains than willows and uplands, and it used swamps more than uplands. During spring migration in Wisconsin and Minnesota, it was observed significantly more in floodplain forests than in upland forests (Campbell et al. 2001; Chapman 1907; Graber et al. 1983; Kirsch et al. 2013; Leighton et al. 2002; Parnell 1969; Sinclair et al. 2003; Whitaker and Eaton 2020; Winker et al. 1992).

During spring migration in North Carolina, 4.2% of Northern Waterthrush observations were in the canopy, 20.9% in low trees, 37.5% in shrubs, and 37.4% on the ground. Of the canopy observations, all were in the inner crown with none at the top or lower crown or on the bole. In low trees, it was not observed at the top of the crown, 4.2% of observations were in the inner crown, 16.7% in the lower crown, and 0% on the bole. In shrubs, none were seen at the top or inner crowns, 4.2% of observations were in the lower crown, 16.6% in dense thicket, 12.5% in brush piles, and 4.2% in grasses. On the ground, 8.3% of observations were in dense thickets, 0% in grasses, 20.8% at water's edge, and 8.3% in open areas. It occurred at heights of 0-5.5 m (mean 1.2 m). It foraged on the ground and flew to low perches to sing (Parnell 1969).

During spring migration, some birds establish territories in swamps around shrubby edges of small ponds. These territories are defended and may prevent some individuals from finding satisfactory foraging areas. Birds defend a territory from 1 to 5-7 days, foraging and accumulating

enough fat to continue migrating. Individuals unable to establish a territory are forced to move on quickly. Migration feeding territories are 0.1-0.5 ha (Graber et al. 1983; Morse 1989; Whitaker and Eaton 2020).

A bird banded in Illinois on 9 September 1967 was recovered at the same location on 7 September 1969 (Graber et al. 1983). This suggests that some individuals may exhibit site fidelity during migration.

During migration, the Northern Waterthrush is frequently killed at television towers and other tall structures. Near Kingston, 189 were killed at the Lennox generating station chimneys 1972-82, including 80 on 6 September 1981 (Graber et al. 1983; Weir 2008; Whitaker and Eaton 2020). In the United States, it was particularly vulnerable to striking residences 1-3 stories tall and was 22.5 times more likely to suffer a collision than average for birds. It was not on the lists of the 20 most vulnerable species for striking low-rises or high-rises (Loss et al. 2014).

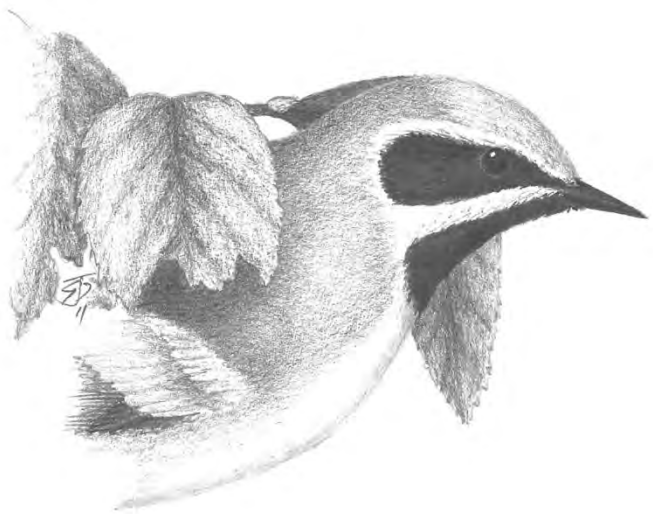
Seewagen (2013) examined the effect of mercury on autumn migrant Northern Waterthrushes in New York. Blood mercury levels averaged 0.42 ppm (range 0.09-2.08 ppm). Mercury did not appear to affect its foraging efficiency or other factors that reduced its stopover refueling rate. Most had blood mercury levels above the means reported from Northern Waterthrushes and numerous other long-distance passerines elsewhere in the eastern United States, but well below the level of 0.7 ppm that is used as an indicator of risk in passerines.

James (1991) considered the Northern Waterthrush a common migrant in Ontario. It is a common migrant at Point Pelee and Rondeau, but is rarely observed in Elgin County and seldom occurs during migration in Niagara Region (Black and Roy 2010; Lancaster et al. 2004).

The number of Northern Waterthrushes banded at Long Point 1961-88 declined significantly at a rate of 4.0% per year. Changes by periods were: 1961-70, −6.1%; 1970-79, −1.7%; and 1979-88, −10.0%. It was 1 of 4 neotropical migrants that exhibited a continuous decline (Hussell et al. 1992).

Golden-winged Warbler

Vermivora chrysoptera



BREEDING SEASON

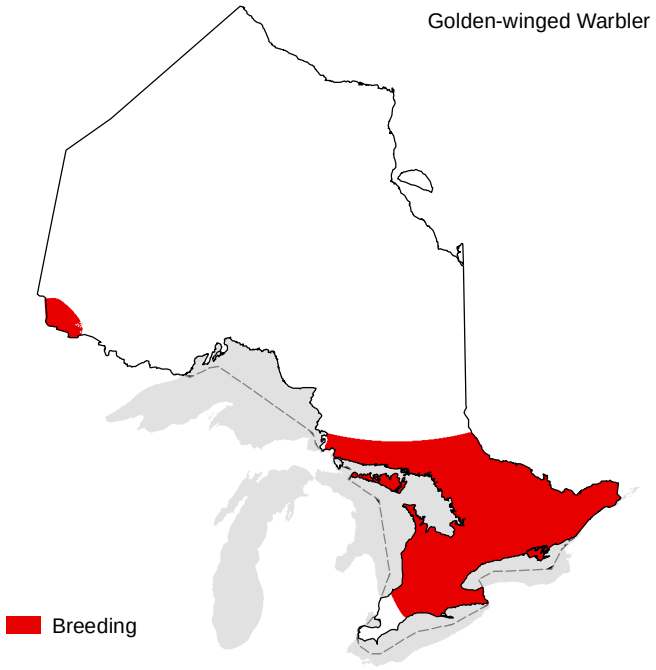
Habitat Requirements

In Ontario, the Golden-winged Warbler nests in fields of tall grasses and forbs overgrown with raspberries, shrubs, and saplings; in or at edges of open conifer plantations; in overgrown clearings and edges of deciduous and mixed woods; near roadsides and hedgerows; at edges of alder thicket swamps; and in an alder-willow-dogwood thicket swamp. Most territories were in dry habitat, but 3 of 33 nests (9.1%) were in wet areas (Peck and James 1987).

In the Canadian Shield in the Great Lakes–St. Lawrence Forest Region, the Golden-winged Warbler inhabits alder thickets, alder-spruce swamps, and tamarack bogs. Alder-spruce swamps appear are preferred habitat in Muskoka and Parry Sound districts (Fraser 2006; Mills 1981). Territories south of the Shield contain patches of herbaceous plants and shrubs with scattered trees, plus a forested edge that it uses for foraging and song perches. Most vegetation within territories is less than 3 m tall. Preferred areas include utility rights-of-way, shrubby field edges, recently logged areas, beaver meadows, and shrubby areas along streams (Fraser 2006; King et al. 2009; McIlwraith 1894; Weir 2008). Near Kingston, an open area maintained by late-summer cattle grazing that left more gradual edges to forests was the best habitat for the Golden-winged Warbler. Vegetation in most other areas in this region consisted either of tall, closely spaced trees or abrupt edges between meadows and forests. These habitats were suboptimal (King et al. 2009). In Durham Region, it nested

in a forest with an open canopy. There were some overgrown logging roads through it and much of the forest floor was under water. The lack of a canopy over much of the site resulted in a rank growth of ferns and raspberries (Speirs and Orenstein 1975).

Where the 2 species co-exist, the Golden-winged Warbler and Blue-winged Warbler readily hybridize. The F1 generation of hybrids comprises 2 hybrids known as Brewster's Warbler and Lawrence's Warbler. The hybrids are reproductively viable and mate with phenotypically pure Golden-winged or Blue-winged warblers and, less frequently, with other hybrids.



In agricultural landscapes, the Golden-winged Warbler nests predominantly in early successional habitats that include a mix of grasses, herbaceous plants, shrubs, scattered trees, and a forest edge. These include meadows, lightly grazed pastures, and utility rights-of-way passing through forested habitat. It occasionally used road rights-of-way, but the incidence of this is now rare. Abandoned farmland provides suitable habitat 10-35 years into succession. Younger areas do not support a sufficient density of trees and saplings to be attractive; older sites are too densely stocked with trees. In eastern Ontario, edge creation experiments documented that it will move into an area of suitable habitat within 3 years of its creation. Utility corridors may be suitable for longer periods because they are maintained to remain in early successional stages. The periodic maintenance results in a cycle of rights-of-way being unsuitable shortly after clearing and evolving into good habitat until they are cleared again. Rights-of-way that are 20 m or less in width are unoccupied unless there are other openings on either or both sides. Most occupied rights-of-way are 60 m or more wide. In more southern areas of its range, it has nested on open wooded dunes, in sandy savannahs where the dominant trees were bur oak and sassafras and there was dense shrub growth, on reclaimed surface mines, and in pine and oak barrens (Aldinger and Wood 2014; Buehler et al. 2007; Bulluck and Buehler 2008; Canterbury et al. 1993; Fraser 2006; Graber et al. 1983; Hands et al. 1989c; Kubel and Yahner 2008; Marsi 1980; Mossman et al. 1991). In West Virginia, numbers decreased in the shrub to forest stages. Highest densities occurred in the first stage of succession which included farms and recently abandoned farmland, reclaimed and abandoned surface mines, and open fields dominated by goldenrods and other weedy species. The next stage of succession supported lesser numbers. This habitat was shrubby with small shrubs and saplings plus goldenrods, and included species such as multiflora rose, blackberries, white pine, black locust, and staghorn sumac. The third stage of succession supported the lowest numbers. It was characterized by very shrubby habitat and trees 3-4.5 m tall, as well as Carolina rose and late-successional species such as maples (Canterbury et al. 1993).

Not only is the Golden-winged Warbler confined to a narrow successional range, it is highly specialized in its habitat requirements in meadows and thickets. Its requirement for few tall trees within its territory restricts it almost entirely to fields that were last farmed 10-35 years previously. Territories in this type of habitat have a consistent structure of a forested edge and an open patchwork of clumps of shrubs and short trees (usually under 6 m) within a mosaic of herbaceous vegetation. In New York, all 75 territories had a forested edge and territories extended 5-30 m into the forest. The minimum tree cover along a territory edge consisted of an old fence line with a dense row of trees and shrubs, with some 10-15 m tall. Some territories may contain large open spaces such as mowed or sprayed areas, bare soil, or marshy areas. Within the territory, there are few trees except for those in the forested border, and these are frequently used as singing perches. Too few or too many trees in the open portion of the territory result in it not being used. If an area is large enough to support many territories but there are no trees in the opening, territories are restricted to the treed edges. In 1 New York field, 35% of the habitat was open with tall grasses and scattered hawthorns and dogwoods, 45% was covered with dense shrubs 2-4 m tall, 15% was covered with trees as tall as 10 m, and 5% was wet and swampy. All New York upland nesting areas included patches of goldenrods, grasses, and patches of shrubs such as dogwoods, raspberries, poison ivy, and Asiatic bittersweet. In Kentucky, plant species characteristic of territories included orchard grass, green ash seedlings and saplings, and black locust saplings. Species indicative of sites supporting both the Golden-winged and Blue-winged warblers were bush-clovers, goldenrods, clematis vines, and blackberries. Results from many studies combined show a preference by the Golden-winged Warbler for low to moderate canopy cover (6-45%) and moderate (45-69%) shrub and herbaceous (48-73%) coverage (Buehler et al. 2007; Confer and Knapp 1977, 1979, 1981; Confer et al. 2003, 2010, 2020; Ficken and Ficken 1968a, 1968b; Frech and Confer 1987; Patton et al. 2010).

Within agricultural landscapes, the Golden-winged Warbler nests in habitats other than abandoned agricultural land. It nests within openings in forests where seepage areas prevent tree growth, and this is probably representative of habitat that was used before large-scale forest clearing occurred. It may also nest in shrubby growth along watercourses and has nested in abandoned gravel pits. In New York and Rhode Island, it commonly nests in treed swamps dominated by red maple or black ash. These wetlands had 60-80% canopy closure with a shrub layer consisting of spicebush, northern arrowwood, and wild raisin. Tussock sedge strongly dominated the ground layer and was the principal substrate for nests in the wetlands. Some wetlands contained dense patches of common reed that it avoided, although 1 nest was found in this habitat. Breeding in this type of habitat has not been confirmed in southern Ontario, but wetlands and beaver meadows may have been used historically. Wooded areas that are highly disturbed due to storms, fire, or excessive thinning may create temporary suitable habitat. Wide-scale disease or insect infestations of trees may create suitable habitat. In the mid-1940s, the Golden-winged Warbler was characteristic of decimated stands of American chestnut. Chestnut blight resulted in stands comprised of scattered dead chestnuts with a dense understorey of sprouting chestnut saplings. Young plantations may temporarily provide suitable habitat until the conifers become dominant. It formerly inhabited old orchards (Brooks 1940, 1947b; Confer and Knapp 1979; Confer et al. 2003, 2010, 2020; Golet et al. 2001; Hands et al. 1989c; Mossman and Hoffman 1989; Noon et al. 1979; Tyler in Bent 1953).

In forested landscapes, the Golden-winged Warbler commonly nests in wetlands or at open interfaces of forests and wetlands. It frequently nests in wetlands dominated by alders or willows and occasionally in tamarack bogs and swamps. It occasionally nests in forests. In central Minnesota, it historically nested in dense deciduous forests and may also nest in forested stands at elevations above 580 m. In North Carolina in 1886, it was characteristic of open oak woodlands where it occurred at elevations as high as 1,200 m. In Tennessee, it inhabited northern hardwoods and mesic oak-hickory stands less than 20 years old at elevations higher than 1,000 m. In Minnesota, average habitat characteristics of territories were 92.3% ground cover, 45.0% shrub cover, 31.4% canopy closure, 10.5 m canopy height, 10.4% coniferous cover, and number of trees of different size classes per 0.04 ha: smaller than 7.5 cm diameter at breast height (DBH), 3.2; 7.5-15 cm DBH, 5.7; 15.1-23 cm DBH, 4.6; 23.1-30 cm DBH, 2.7; 30.1-38 cm DBH, 1.0; 38.1-53 cm DBH, 0.5; 53.1-68 cm DBH, 0.3; and larger than 68.1 cm DBH, 0.1. It preferred deciduous edge vegetation and open areas with dense ground coverage and moderate shrub coverage. In Pennsylvania wetlands, its abundance was negatively correlated with canopy cover and positively correlated with the density of shrubs 1-2 m tall at the 100-m scale. At the landscape level, it was positively correlated with the amount of emergent wetland cover and percent wetland shrub edge (Collins et al. 1982; Confer et al. 2003, 2020; Hands et al. 1989c; Klaus and Buehler 2001; Martin et al. 2007; McNeil et al. 2018; Patton et al. 2010).

At the landscape level, abundance of the Golden-winged Warbler was strongly correlated with total forest cover, especially deciduous forest dominated by aspen. It was negatively associated with habitat edge density and patchy, perforated, and transitional forests. There was a lack of a positive association with edge and mesic forest conditions. It may achieve higher density in more forested situations in low-forest, high-edge landscapes. In high-forest, low-edge landscapes, highest density occurs where forest is less abundant and most fragmented by early successional patches. As forest cover increased in the landscape, the Golden-winged Warbler was more abundant as forest edge declined (Thogmartin 2010).

Crawford et al. (2016) examined landscape-level habitat and climate attributes of the Golden-winged Warbler at scales of 2.5 km and 500 m and compared them with those of the Blue-winged Warbler. They studied the Appalachian Mountain and Great Lakes populations, but did not include Ontario data in their analysis. In both areas combined at the 2.5-km scale, compared with the Blue-winged Warbler, Golden-winged Warblers were associated with higher elevations, cooler breeding season temperatures, and forests dominated by aspen. Golden-winged Warblers were found at an average elevation of 427 m (370 m for Blue-winged Warblers) and a mean maximum May temperature of 20.1°C (21.3°C for Blue-winged Warblers). Both species were found in roughly equal numbers in grassland mosaic landscapes (12.7% for the Golden-winged Warbler and 8.5% for the Blue-winged Warbler). Golden-winged Warblers were more than twice as likely to be found in woodland landscapes (20.2%) than Blue-winged Warblers (9.6%). The greatest extent of Golden-winged Warbler locations (39.5%) were associated with landscapes where trembling aspen was present compared with 7.0% for the Blue-winged Warbler. Fewer Golden-winged Warbler locations (4.5%) were associated with agricultural landscapes than Blue-winged Warbler locations (10.2%). At the 2.5-km scale in the Great Lakes population, Golden-winged Warblers were correlated with elevation, summer breeding temperature, land-cover type, and percent deciduous forest cover.

Golden-winged Warbler locations had a mean elevation of 335.2 m (240.9 m for the Blue-winged Warbler) and a minimum May temperature of 4.7°C (7.2°C for the Blue-winged Warbler). Fifty-eight percent of Golden-winged Warbler locations contained aspen compared with 26% for the Blue-winged Warbler; 16% of Golden-winged Warbler locations were associated with areas with no trees compared with 32% for the Blue-winged Warbler. Golden-winged Warblers occurred less in agricultural landscapes (6.8%) than Blue-winged Warblers (23.9%). Golden-winged Warblers preferred forests with an open or broken canopy with a greater percentage of locations in woodland landscapes (30.7%; 14.3% for Blue-winged Warblers). At the 500-m scale in the Great Lakes region, variables most strongly associated with the 2 species included percent deciduous forest, percent agriculture, and elevation. Both species were strongly associated with yellow birch–sugar maple forests, although the Golden-winged Warbler was also found in forests dominated by aspen-birch, jack pine, black spruce–tamarack, and swamp forests. The Blue-winged Warbler was also associated with beech–sugar maple–basswood forests and occurred in agricultural land types at lower elevations. In New York, the Golden-winged Warbler occurred more often in oak-pine and swamp forests than their availability; 10% of locations were associated with fallow pasture. In both the eastern and western portions of the Great Lakes range, it was most commonly associated with yellow birch–sugar maple forests. It occupied higher elevations (367 m) in Michigan, Minnesota, and Wisconsin than in New York (135 m), higher than for the Blue-winged Warbler (303 m and 154 m respectively). The Golden-winged Warbler was associated with a cool dry climate at elevations of 350-1,500 m and habitats comprised of at least 60% deciduous forest cover. In the Great Lakes area, its occurrence was best predicted by the distribution of aspen forest. At finer scales, it was negatively correlated with agriculture and human disturbances, which were more indicative of the presence of the Blue-winged Warbler.

In West Virginia, Aldinger et al. (2017) modelled Golden-winged Warbler density at 4 scales representing annual dispersal (5-km radius), extraterritorial movement (1.5-km radius), intraterritorial movement (100-m radius), and local resource utilization (11.3-m radius). The objective was to identify habitats that supported the highest densities at the various scales. In addition to the 4 scales, they sampled 4 habitats along a successional gradient including herbaceous areas, shrublands, young forests, and late succession forests. Five km was the longest between-season movement they recorded, 1.5 km was the maximum distance travelled by males within season, and 100 m corresponded with the territory size (2.4 ha) and matched their point count radius. At the 5-km scale, its density was negatively correlated with altitude. At the 1.5-km scale, density peaked at elevation 804 m, near the midpoint of elevations they sampled. At the 100-m scale, density was negatively associated with elevation and peaked at 540 m, the lowest elevation they sampled. These mid- to high-elevation landscapes may buffer Golden-winged Warbler populations from contact with the Blue-winged Warbler. At the 100-m scale, the amount of shrubland was important. The Golden-winged Warbler was not detected where shrubland cover was less than 11% but density did not reach higher than average levels until shrubland cover was greater than 52%; density was greatest where shrubland cover was 100%. Managing roughly circular or regularly shaped patches of contiguous shrubland cover of 9.0-12.6 ha surrounded by older-class forests may ensure that it uses the entire patch. Higher densities may be achieved within each patch by arranging multiple patches in a network with less than 2 km between patches. Irregularly shaped patches or patches with

embedded islands of trees may be preferred to create habitat. Densities were higher in shrublands than in young forests. Selective or diameter-limit harvesting of older forests usually does not remove enough tree cover to create suitable nesting habitat. The most important variables for high density included elevations of 602-1,006 m at the 1.5-km scale, elevations of 540-914 m at the 100-m scale, and shrubland cover of 52-100% at the 100-m scale.

Clear-cuts in New York did not provide habitat for the Golden-winged Warbler. Succession in clear-cuts did not provide the patchy distribution of vegetation that it prefers. The dense growth of saplings produced after clear-cutting was unsuitable habitat (Confer and Knapp 1981). In other areas, clear-cuts have provided suitable habitat and some of the highest densities ever recorded were in aspen clear-cuts in Wisconsin (Roth and Lutz 2004). In regenerating aspen clear-cuts in Minnesota, it used sites with residual trees unless the residual canopy exceeded 25% (Patton et al. 2010). In Tennessee, it used stands with a median age of 11 years (range 8-16 years) at 1 site and 10 years (range 3-13 years) at another site. Stand age and composition was critical in determining habitat suitability. Occupied sites had a lower basal area (BA) (10 compared with 40 m^2 ha) than unoccupied sites and were associated with unimproved logging roads. Occupied sites had lower sapling densities (4,445 compared with 5,271 stems per ha) and greater tree heights (11 m compared with 10 m) than unoccupied sites. There were no significant differences between occupied and random sites for other habitat characteristics such as percent grass cover, height of blackberries, elevation, slope, canopy cover variation, herbaceous cover variation, or aspect (Klaus and Buehler 2001). In Pennsylvania, clear-cuts in aspen and mixed oak stands created habitat for the Golden-winged Warbler. It was absent in uncut stands. Only 50% of the oak stands were cut but 75% of the aspen stands were cut. In oak stands, the dominant plant species were oak, red maple, grasses, and ferns, especially hay-scented fern. Dominant plants in aspen stands were aspen, oak, tartarian honeysuckle, grasses, and forbs, especially goldenrods. Almost all territories occurred in aspen clear-cuts, probably because of the higher cutting intensity and because it appears to prefer aspen regeneration (Kubel and Yahner 2008; Yahner 2003). It occurred in young, dense northern hardwoods occasionally interspersed with snags that regenerated shortly after clear-cutting in Wisconsin (Hoffman 1989a). Highest densities reported in North America occur in managed trembling aspen–large-toothed aspen–white birch stands in Wisconsin. Stands older than 25 years did not support the Golden-winged Warbler. It colonized newly created aspen clear-cuts in the first breeding season following harvest. It was not abundant during the seedling stage and persisted in low densities through the sapling and pole stages until 25 years after harvest. In older stands, it occurred largely in forest gaps, in areas of poor regeneration, along edges bordering shrub cover, and along utility and road rights-of-way. High abundance was correlated with the density of aspen suckers, which explained 60% of the variation in abundance. Shrub density explained an additional 17% of variation. Unlike territories on abandoned farmland, those in clear-cuts rarely contained patches of differing vegetation, with sites characterized by uniform regeneration. Territories were also not associated solely with forest edge and occurred in the middle of aspen stands. In other studies, the association demonstrated with edges may be simply because most shrublands are small and situated around the periphery of edges (Roth and Lutz 2004). Also in Wisconsin, it was most abundant in young aspen stands 1-4 years old and least abundant in ecotones between swamps and mature mixed upland forests. Intermediate numbers occurred in jack pine, swamp-upland

aspen ecotones, and shrub swamps. In harvested aspen stands, there was an increase in density from 1-2 years to 4-5 years, and a decline from 6-7 years to 9-10 years. Densities in age class 6-25 years were significantly lower than in 1-4-year-old stands. Aspen density was significantly correlated with its abundance and it was more than 2 times as abundant in young aspen stands as in other habitats. Conditions were most suitable when stands were 3-7 years old. One regenerating aspen stand on sandy soils did not attract the Golden-winged Warbler because it had fewer aspen stems and less woody and herbaceous cover at ground level (Martin et al. 2007). In the upper Midwest, alder wetlands and aspen clear-cuts were 2.7 and 1.5 times more likely to be occupied than other habitats that were sometimes used. Aspen had no significant effect on the probability of use suggesting that the vegetative structure created by clear-cuts was more important than the presence of aspen (Confer et al. 2020).

Peterson et al. (2016a) determined nesting success and fledgling survival rates at 2 sites in Minnesota and 1 in Manitoba, and modelled the effects of landscape-level habitat on full-season productivity. Productivity was 51% higher in upland than wetland habitats. At 1 site, succession of grassland to upland shrub cover was predicted to increase the area available for nesting and to increase productivity by 30%, despite a 12% decrease in the number of surviving fledglings. The models were sensitive to the size and landscape context of the proposed management and the site-specific configuration of the landscape. The relationship between edge and productivity varies substantially depending on landscape structure and composition and amount of edge. The amount of edge was positively related to full-season productivity until a threshold of approximately 0.5 km of shrubby edge within 50 m of any given point was attained. Increasing the amount of edge beyond this threshold decreased productivity. The edges they assessed were those between shrublands and forests and not smaller micro-edges within shrublands.

In Kentucky, the percent coverage by grasses was 42.2% where the Golden-winged Warbler occurred allopatrically and 35.7% where the Blue-winged Warbler was present. Canopy cover was 44.8% and 33.0% under these conditions, respectively. For Golden-winged Warbler management purposes, it was recommended that there be approximately 40% coverage by a mix of grasses and forbs, scattered mature trees with a BA of 2-8 m^2 per ha beyond the forest edge, aggregate sapling heights of as much as 45 m per 5 m^2, and approximately 20% shrub coverage (Patton et al. 2010). In Pennsylvania, vegetative structure differed between territories and unoccupied areas. Territories had a higher percent coverage of herbaceous cover (33% compared with 11%), fewer saplings, and more trees than unoccupied areas. Unoccupied areas had a higher percent coverage of blueberry (33% compared with 7%) and mountain laurel (29% compared with 2%) and a lower percent coverage by blackberry (0% compared with 39%) than territories. There was no difference in percent shrub coverage in territories and unoccupied areas. Black locust, chokecherry, pin cherry, black cherry, white pine, and red pine were indicators of territories. Sassafras, chestnut oak, and red oak were indicators of unoccupied areas. Territory placement and foraging locations were influenced by plant species composition and associated prey abundance. Woody plants that were indicators of territories had the highest abundance of caterpillars and were selectively foraged upon. In addition to the tree species, blackberry was an important habitat component. Plant species composition needs to be considered during management by preferentially maintaining or encouraging the

growth of black locust, pin cherry, white oak, and blackberry while discouraging sassafras, mountain laurel, and blueberry (Bellush et al. 2016).

In Pennsylvania and West Virginia, Frantz et al. (2016) compared the habitat characteristics of Golden-winged Warbler territories and home ranges. In Pennsylvania, there were significantly more saplings in home ranges than in territories. In West Virginia, there were significantly more trees in home ranges, and home ranges were significantly closer to a forest edge (14.3 m) than territories (44.8 m). Distance to shrubland averaged 45.9 m. Forest cover was important at the home-range scale, although actual visits to forests were rare (25 of 2,067 locations, 1.2%). Forest cover where individuals were observed was 20-110 years old and contained canopy gaps resulting in heterogeneous vegetative structure, with growths of shrubs, saplings, and herbaceous ground cover. Movements into forest may act as reconnaissance trips to identify areas suitable for raising fledglings. A male with fledglings progressively ventured further into closed-canopy forest away from his territory.

In West Virginia pastures, nests were significantly closer to the nearest shrub stem (87.0 cm) than random sites (149.5 cm). Within 11.3-m radius circles, the distance to forest edge was significantly less (28.9 m) at nests than at random sites (64.7%; Aldinger and Wood 2014). Therhune et al. (2016) studied nest-site habitat selection by the Golden-winged Warbler in the Appalachian (North Carolina, New York, Pennsylvania, Tennessee, and West Virginia) and Great Lakes (Minnesota and Wisconsin) populations. They compared habitat characteristics at nest sites to random plots 25-50 m away in the same territory. Consistent habitat characteristics used across its breeding distribution included patches of herbaceous cover, shrubs and saplings, and mature forest edges. Nests were associated with limited bare ground (0-10%), less than 55% grass cover, 40-80% herbaceous cover, and 15-35% woody cover. Nest sites contained less bare ground and greater woody cover than random sites. Nests in areas undergoing succession to forest cover had less grass than random sites. The opposite was true of nests in areas that originated from forest following timber harvest or fire. Blackberry cover was greater at nests in sites undergoing succession to forest than in random areas. It selected nest sites with vegetation density of 10-35%. Successful nests in forest-harvested areas had greater grass cover than unsuccessful nests. Average habitat characteristics at Tennessee nest sites in clear-cuts were: 889 saplings per ha (range 0-25,400), 38.8% canopy cover (range 5.0-73.8%), and 150 blackberry stems per ha (range 0-2,258). Nest sites had significantly lower sapling density and canopy cover than perch sites. Dominant plant species at Tennessee nests included bluestems, orchard grass, asters, goldenrods, and blackberry. Nest sites had more grass cover (52.3% compared with 39.3%) and forbs (49.3% compared with 39.9%) at the 1-m scale, fewer saplings (31.4% compared with 44.5%) at the 11.3-m scale, and less woody cover (34.5% compared with 47.2%) at the 1-m scale, than random sites (Aldinger and Wood 2014; Bulluck and Buehler 2008). At New York nests, there was an average of 127 trees with a DBH of less than 2.5 cm within 12.5 m, 190 shrubs within 80 m^2, 86% ground cover, and 56% grass coverage. The mean height of stems 1 m around the nest was 0.52 m (Confer et al. 2020).

Aldinger et al. (2015) examined microhabitat variables at 388 nests on 62 sites in 7 states and related these to daily nest survival rates. Percent grass cover affected daily survival rates, with rates constant up to 50% grass cover, after which survival rates declined. Daily survival rate declined to

88% at 90% grass cover. The Golden-winged Warbler preferred 5-50% grass cover within 1 m of the nest. Coverage by raspberries influenced survival rates, declining as coverage increased from 0-30% but then increasing steadily as coverage by raspberries increased. Survival rate at 50% raspberry coverage was similar to that at 0% and survival increased as raspberry coverage increased above 50%. Distance of nests to forest edge affected daily survival rate, declining from 0 m through 500 m then gradually increasing with increasing distance. The daily survival rate did not reach the level that it was at 0 m distant from forest edge until 900 m from forest. Management for percent grass cover had the most potential for creating or enhancing habitat; sedges or rushes could provide comparable coverage to grasses.

Bakermans et al. (2015) determined the effects of microhabitat features on the abundance of the Golden-winged Warbler in north-central Pennsylvania, northeastern Pennsylvania, and a south-central region that consisted of south-central Pennsylvania and western Maryland. Across all 3 regions in the 222 stands that they sampled, there were significant differences between stands where it was and was not detected. Significant differences between occupied and unoccupied stands occurred for size of clear-cut, years since harvest, perimeter-to-area ratio, percent forest cover within 1 km, percent urban cover within 1 km, and percent young forest cover within 1 km. Within the central Appalachian Mountains, abundance was best explained by the proportion of young forest within 1 km of a regenerating stand and size of the stand. Abundance was greatest between 5% and 15% young forest cover. Abundance was related to the total amount of forest but decreased with an increase in the size of the regenerating stand. Its abundance increased as herbaceous cover increased. The percent herbaceous coverage was 1.6 times greater in occupied stands (13.1%) than in unoccupied stands. Distance to a microedge, shrub cover, number of saplings per ha, and residual BA were also important, with greatest abundance at 7 m^2 per ha residual BA. Occupied stands had a mean BA of 6.3 m^2 per ha of residual trees compared with 8.3 m^2 per ha for unoccupied stands. In northeastern Pennsylvania, distance to the nearest regenerating stand was the most important factor determining abundance, with abundance decreasing with increasing distance to the nearest regenerating stand. Coverage by herbaceous species was also important. Other features contributing to its abundance in the northeast included residual BA, number of saplings per ha, shrub cover, and distance to a microedge. When creating habitat for the Golden-winged Warbler, managers should strive for 15% young forest within a heavily forested landscape (more than 70% forest cover) and regenerating stands should be clustered within 1-2 km of other young forests. Habitat for foraging, nesting, and territory delineation activities should be provided within regenerating stands. This can be accomplished by creating or maintaining patchy habitat that provides a mix of interspersed residual trees, saplings, forbs, grasses, and bare ground. Approximately 3-12 m^2 per ha of dominant or codominant crown-class trees should be maintained with at least 40% of these larger than 38 cm DBH.

In Pennsylvania, Leuenberger et al. (2017) characterized habitat features of 62 territories in a hardwood forest regenerating after a fire 19-20 years previously, and 28 territories in old-field habitat. Probability of occupancy in the regenerating forest increased with increasing coverage by raspberries. Occupancy rates of 95% were associated with 40% coverage by raspberries in 1 year and 20% coverage in another year. Maximum occupancy of the regenerating forest occurred with 0 BA in 1 year and 2-12 m^2 per ha in the other year. In the old field, occupancy was unrelated to

raspberry coverage and maximum occupancy occurred with a BA of 0-7 m^2 per ha. Probability of occupancy decreased as vegetation patchiness decreased regardless of territory type. Unoccupied patches had a BA greater than 12 m^2 per ha in both habitat types. Nests were in patchy areas where the average distance to a microedge was less than 2-3 m.

Two studies examined song perch characteristics of the Golden-winged Warbler. The North Carolina study (Rossell 2001) was conducted in a floodplain with a complex system of natural and disturbed wetlands and uplands. The Tennessee study (Klaus and Buehler 2001) was undertaken in a clear-cut. In North Carolina, 78% of song perches were in the upper 25% of the tree canopy. One of 87 perches was at the top of a tree and none were in the bottom 25% of the canopy. The remaining 21% of perches were evenly distributed between the second and third quartiles of the canopy. Ninety percent of song perches were in forest canopy trees compared with 33% of randomly selected potential perches. Perch trees were significantly closer to forest edge (0.6 m compared with 2.3 m) and water (29.3 m compared with 32.9 m) than randomly selected perches. Fifty-one percent of perches were within 15 m of water. There was no significant correlation between proximity to water and distance to a forested edge. Males selected an overwhelming majority of perches in the upper quarter of large trees on the edge of wooded areas. Perches were closer to water than expected and all but 1 bird had a perch 11 m or less from water. Males often sang above or adjacent to water. The ecological significance of water is uncertain. Areas near water may have a greater abundance and diversity of insects but it frequently nests where water is absent. In Tennessee clear-cuts, the average habitat characteristics around song perches were: 4,445 saplings per ha (range 0-32,258), 63.8% canopy cover (range 5.0-97.5%), and 44 blackberry stems per ha (range 0-600). There was a significant difference in habitat characteristics between perches and nest sites for sapling density and percent canopy cover. Nests were mostly in openings dominated by grasses and herbaceous species.

Some studies attempted to differentiate the habitat preferences of the Golden-winged and Blue-winged warblers based on moisture regime. These characterizations failed because the Golden-winged Warbler inhabits wetter areas than the Blue-winged Warbler in some regions and drier areas in other regions. The Golden-winged Warbler appears to be indifferent to soil moisture and nests in conditions from wet swamps with standing water to the driest hillsides (Canterbury et al. 1993; Confer and Knapp 1979, 1981; Ficken and Ficken 1968b; Hands et al. 1989c; Harrison 1984; Murray and Gill 1976).

Several studies compared the habitat preferences of the Golden-winged and Blue-winged warblers, particularly in agricultural landscapes. The Blue-winged Warbler nests in the same old-field habitats as the Golden-winged Warbler, and the territories of the 2 species frequently overlap. Ficken and Ficken (1968b) and Patton et al. (2010) found no significant differences in the old-field habitat used by the 2 species in New York and Kentucky. In New York, Confer and Knapp (1977, 1979, 1981) found no differences in the densities of herbaceous vegetation and shrubs in the territories of Golden-winged and Blue-winged warblers. There were significant differences in tree density, with the mean tree value for Golden-winged Warbler territories less than half that of Blue-winged Warbler territories. The variance of the tree value differed even more, with the Golden-winged Warbler variance less than 5% of that of the Blue-winged Warbler. Wood et al. (2016) compared the habitats

of Golden-winged Warblers in New York, where they are associated with the Blue-winged Warbler, with those in Pennsylvania where the Blue-winged Warbler is absent or rare, and the habitat of the hybrids. New York Golden-winged Warblers occupied structurally heterogeneous territories surrounded by homogeneously structured contiguous forests that were far from urban areas. Blue-winged Warblers exhibited opposite associations and hybrids' habitat associations were intermediate. Habitat associations of Golden-winged Warblers and cryptic hybrids were remarkably similar in Pennsylvania and New York. The Golden-winged Warbler declined in later successional stages in West Virginia. Areas characterized by very shrubby habitat with late-successional tree species such as maples had the lowest numbers of Golden-winged Warblers and highest numbers of Blue-winged Warblers. The Golden-winged Warbler was confined to old-field habitats that were abandoned 10-35 years ago. The Blue-winged Warbler inhabited these same fields, but also nested in young second-growth forest in areas abandoned 30-70 years ago. The Golden-winged Warbler is a habitat specialist whereas the Blue-winged Warbler is a comparative habitat generalist (Canterbury et al. 1993). There are 2 habitats used by the Golden-winged Warbler that are rarely used by the Blue-winged Warbler, and these may potentially provide sanctuary for isolated populations of the Golden-winged Warbler. The Golden-winged Warbler nests in treed and shrub swamps and these appear to be avoided or used very rarely by the Blue-winged Warbler, even when there is an adjacent population nesting in upland old fields. In New York, approximately 40% of Golden-winged Warblers nested in treed swamps. This habitat was rarely used by Blue-winged Warblers. The Golden-winged Warbler nests at higher elevations than the Blue-winged Warbler (Confer et al. 2010; Frech and Confer 1987; Patton et al. 2010).

Some studies suggested that the Golden-winged Warbler is area sensitive. In upland forest habitat in Wisconsin, it rarely or never occurs in patches smaller than 40 ha (Mossman and Hoffman 1989). In New York, it almost always occurred in large tracts of suitable habitat that were 10-50 ha, even though the territories occupied only a small proportion of the entire area. Many small areas that appear suitable are not used. The tendency for several birds to nest together in loose aggregations presents an additional habitat requirement. Nonetheless, Confer and Knapp (1981) found a single Golden-winged Warbler nesting in a small forest opening that corresponded to the size of its territory. Treed swamps in New York supported 1-3 pairs and these wetlands were only 0.5-5 ha (Confer et al. 2010). In Ontario, the Golden-winged Warbler is not considered area sensitive (Coleman et al. 2000). It is possible that it exhibits area sensitivity in some regions and not in others. It is also possible that not all habitat that is unoccupied is actually suitable given its exacting microhabitat requirements.

Most Ontario nests were on the ground, but 6 were 7.5-30.5 cm from the ground. They were concealed in clumps of tall grasses and other plants, especially goldenrods, and were often at the base of shrubs or tree seedlings. One nest was hidden in skunk cabbage leaves (Peck and James 1987, 1998a). A Hamilton nest was in a clump of showy lady's-slippers (Curry 2006).

Within old-field habitat, nests are usually at the periphery of the territory and near the interface of open and forested habitats. Nests are usually within the open habitat but close enough to the forest to be in the shade. Nests may also be in forests within 10 m of edge. They may also be along edges of logging roads, paths, or trails, in small woodland openings, or low areas where saturated

soils have retarded woody growth. In Minnesota and Manitoba, more than 95% of 226 nests were within 100 m of either side of an edge. One hundred West Virginia nests were supported by a total of 21 plant species, but 93% were in raspberries, goldenrods, or other woody-stemmed plants. Hawthorn was recorded most frequently as the nearest shrub stem. All nests were at a microedge between dense vegetation and an herbaceous opening such as fencerows, cattle trails, browse lines, and recently mowed strips. Successful nests had higher woody cover (16.6% compared with 12.6%) and less cover by raspberries (25.0% compared with 31.4%) than unsuccessful nests. Most nests are on the ground, often at the base of a large raspberry, sapling, or woody seedling stem. They are often in a clump or rosette of a herbaceous species, especially goldenrod and occasionally meadow-rue. They may be hidden by fern fronds or be deep in a clump of grasses or sedges. The nest is typically concealed from above by leaves or other vegetation. Some nests are above ground, often in a blackberry cane or rose bush. They are usually 0.3 m or less from the ground, but 1 Tennessee nest was 1 m up (Adkisson and Campbell 1977; Aldinger and Wood 2014; Bulluck and Buehler 2008; Chapman 1907; Confer et al. 2020; Ficken and Ficken 1968a, 1968b; Graber et al. 1983; Hands et al. 1989c; Klaus and Buehler 2001; Martin et al. 2007; Streby et al. 2014; Tyler in Bent 1953).

In Minnesota and Manitoba, Streby et al. (2014) studied the relationships between nest location relative to forest edge and fledgling survival. Nest success was lowest (10%) 100 m from forest edge in shrubland and highest (60%) 100 m from edge within forest. Fledgling survival was greatest (90%) 100 m from forest edge in shrubland and lowest (10%) 100 m from edge in forest. Early nest sites were in shrublands where fledgling survival was greater than nest success. Later nests were in forests where nesting success was greater than fledgling survival. This suggested that individuals risk early nest failure in exchange for greater fledgling survival. After early nests fail, they select sites where nests are likely to be more successful.

Males maintain a territory where they sing persistently before the arrival of females. Territories are maintained until the young fledge, and then territorial boundaries break down. Territory establishment may be somewhat irregular. In Michigan, 1 male sang regularly in 1 area 7-12 May, then disappeared and established another territory about 400 m away. Territory establishment continued through late May and early June. Late-arriving birds establish territories in peripheral areas or challenge existing territory holders. This may result in the compression of territories established by early arriving birds and a shifting of singing perches. Some birds had disjunct singing areas. Trespassing occurred on adjacent territories and birds were occasionally as far as 400 m from their territory. Territories usually do not overlap. If there is a small area of overlap, it is under dispute until territoriality wanes. In Kentucky, 4 of 25 territories (16%) overlapped by 0.7-17%. The Golden-winged Warbler may nest singly, but often occurs in loose aggregations of as many as 10 pairs, and an aggregation of 31 pairs occurred in Tennessee. Within these aggregations, territories are not densely packed and there may be undefended areas between territories. It is uncertain whether all suitable habitat is used. Nests of neighbours are frequently within 30 m of each other (Confer and Knapp 1977; Confer et al. 2020; Ficken and Ficken 1968a, 1968c; Fraser 2006; King et al. 2009; Klaus and Buehler 2001; Murray and Gill 1976; Patten et al. 2010).

The Golden-winged Warbler has a large territory size for a warbler. Extremes in territory sizes of 0.16-5.3 ha have been reported, but most are 1-2 ha. In Kentucky, the average territory size was 1.3

ha where the Blue-winged Warbler was present and 1.7 ha where it was absent. In Michigan, mean Golden-winged Warbler territory size was 1.9 ha (range 0.8-5.3 ha) at 1 site and 1.4 ha (range 0.4-3.2 ha) at another. New York territories were 0.4-0.8 ha. Birds nesting on utility rights-of-way in Pennsylvania had linear territories 100-175 m long that were 0.6-1.05 ha. Territories averaged 1.53 ha in a regenerating forest and 1.47 ha in old fields in Pennsylvania. In aspen clear-cuts in Wisconsin, mean territory sizes were 0.82 ha in seedlings, 0.28 in small saplings, 0.16 ha in large saplings, and 0.54 ha in pole-sized aspen. Territories were smaller than reported elsewhere, which may indicate high quality habitat. In the seedling stage, territory size may have been constrained by neighbours. In older stands, territories occurred in openings and were approximately the same size as the opening. Territory size may increase during the incubation period if the male attempts to court a second female (Confer and Knapp 1977; Ficken and Ficken 1968a; Fraser 2006; Graber et al. 1983; Hands et al. 1989c; Kubel and Yahner 2008; Leuenberger et al. 2017; Murray and Gill 1976; Patton et al. 2010; Roth and Lutz 2004). The large range in reported territory sizes may be related to the fact that it may frequent areas outside of the territory and have a larger home range. Frantz et al. (2016) used spot mapping and radiotelemetry to determine territory and home range sizes in Pennsylvania and West Virginia. Forty percent of radiotelemetry locations fell outside the mapped territory. In both states, the 100% minimum convex polygons were significantly larger for home ranges than for territories: a mean of 6.3 ha (range 1.4-19.8 ha) for home ranges and 1.7 ha (range 0.65-3.7 ha) for territories in Pennsylvania, and a mean of 11.8 ha (range 2.3-48.0 ha) for home ranges and 2.4 ha (range 0.80-4.8 ha) for territories in West Virginia. Using 50% minimum convex polygons, mean home ranges were also significantly larger: 0.5 ha (range 0.13-1.03 ha) for home ranges and 0.3 ha (range 0.12-0.69 ha) for territories in Pennsylvania and a mean of 0.6 ha (range 0.20-1.28 ha) for home ranges and 0.3 ha (range 0.13-0.63 ha) for territories in West Virginia. In Pennsylvania, home ranges overlapped an average of 2.1 territories (range 0-6) with an average overlap of 1.3 ha (range 0-4.53 ha). Territories overlapped an average of 0.7 territories (range 0-3) with an average overlap of 0.2 ha (range 0-0.54 ha). In West Virginia, home ranges overlapped an average of 2.4 territories (range 0-9) with a mean average of 2.6 ha (range 0-12.48 ha). Territories overlapped an average of 1.0 territory (range 0-2) with a mean average of 0.4 ha (range 0-1.18 ha). Most overlapping territories were those of Golden-winged Warblers (33 of 39 overlaps), but 1 overlap was with a Blue-winged Warbler and 5 were with hybrids. Home ranges determined by radiotelemetry were 3-4 times larger than spot-mapped territories. One Pennsylvania male travelled 1.6 km outside his territory in the afternoon, but was back the following morning. Territories may be larger in low-density populations. Spot-mapping was effective at determining 50% core areas, but underestimated 100% core areas. The high overlap in home ranges suggests that areas between territories are shared by neighbours and may provide undefended foraging areas. Three males foraged within a 10-m radius with no aggressive interactions. Territories had little overlap but home ranges overlapped extensively. Because of the larger home ranges, locations where singing males are detected may be only loosely associated with the breeding territories. Streby et al. (2012) used spot-mapping and radiotelemetry to determine home ranges and territories in Minnesota. Home ranges determined by spot mapping averaged 0.16 ha compared with 0.45 ha for those determined by radiotelemetry. Home ranges contained more mature forest (37%) than territories determined either by radiotelemetry (22%) or spot-mapping (5%). Seventy-five percent of afternoon perches were in mature forest and birds rarely returned to their territories during that period. Zero of 28 spot-mapped territories overlapped, 2

territories of radiotracked males overlapped by 5%, and home ranges of radiotracked birds included the entirety or a portion of 4-7 other territories.

Where the Blue-winged Warbler is present, there may be a brief period when these species are aggressive toward each other. This occurs for a few days when at least one and often both males become paired. The territories of the 2 species overlap widely and they generally ignore each other after the initial brief period of interspecific aggression. Where territories of the 2 species overlap, birds tend to occupy the same areas at different times. Both species may sing near each other simultaneously, but they tend to use different singing perches (Confer and Knapp 1977; Confer et al. 2003; Ficken and Ficken 1968a, 1968b, 1968c, 1968d; Frech and Confer 1987; Murray and Gill 1976; Patten et al. 2010).

Both the Golden-winged and Blue-winged warblers have 2 song types. Type 1 is for mate attraction and species recognition, Type 2 is for territorial defence during aggressive interactions. The Type 2 song of both species is virtually identical. Hybrids may sing the song of either species, both species have been known to sing the other species' Type 1 song, and rarely Golden-winged and Blue-winged warblers sing both species' song. The postures and displays associated with territorial defence are similar in the 2 species and their hybrids. The flexibility in song choice creates opportunities for hybridization and determines which individuals a male will defend his territory against. Birds with similar songs and plumages have non-overlapping territories; birds with different songs and plumages have overlapping territories. Brewster's Warblers with similar songs had non-overlapping territories and 1 Lawrence's Warbler with a Blue-winged Warbler song had a territory that overlapped extensively with that of a Blue-winged Warbler (Ficken and Ficken 1968a, 1968c, 1968d; Harper et al. 2010; Murray and Gill 1976).

Natal philopatry rates are low with the highest reported rates from the Kingston area. Sixteen of 368 nestlings (4.3%) returned to the natal area and some nested as close as 500 m to their natal site. Of the 16 returning young, 11 were males and 5 were females. In 1 Michigan study area, 0 of 51 nestlings and 2 fledglings returned and 0 of 88 young returned in another Michigan study. In West Virginia, 3% of young returned. In New Jersey, 1 young returned (Confer et al. 2020; Fraser 2006; Hands et al. 1989c).

Adult site fidelity rates are high in Ontario and some other locations. Near Kingston, 50-88% of adult males and 33-53% of adult females returned. During a 3-year study, 5 males and 6 females nested in 2 years and 3 males were present in all 3 years (Fraser 2006; McKinnon and Robertson 2008; Vallender et al. 2007b). In other areas, both males and females returned to the same area for as long as 7 years. In Michigan, 50% of adult males and 10% of adult females returned the year after they were banded. In total, 24 of 63 of adults (38%) returned. In New York, return rates in various studies were 30 of 63 adult males (48%), 31 of 81 adult males (38%), and 30% of adults. Only 16% of adults returned in West Virginia. Brewster's Warblers have similar return rates (Carter 1944; Confer and Knapp 1979; Confer and Larkin 1998; Confer et al. 2010, 2020; Fraser 2006; Hands et al. 1989c). In Tennessee and Minnesota, Peterson et al. (2015) banded adult Golden-winged Warblers and installed geolocators on a subsample of them. In Tennessee, 47% with geolocators returned compared with 42% of control birds. In Minnesota, 45% of birds in both groups returned. Geolocators weighing 0.45-0.51 g did not affect return rates.

Limiting Factors

Eggs have been found in Ontario nests from mid-May until the third week of July, with most present from the last week of May until the third week of June (Peck and James 1987). Near Kingston, the mean date of nest initiation for 86 nests was 23 May (Bulluck et al. 2013).

Pair formation begins immediately after the females arrive. Early arriving females wait 1-2 days before starting to build the nest. Late-arriving females may initiate nest building the day of arrival. Cold weather may delay nest building by as long as 10 days. Nest building usually takes 2-3 days but may rarely be completed in a single day. Egg laying is often initiated the day after the nest is completed but may be delayed during wet springs. During warm, dry springs, the interval between nest completion and egg laying was 1-4 days (mode 1 day). During a warm, wet spring, the interval was 4-6 days (mode 5 days). Usually 1 egg is laid daily but occasionally a day may be skipped. Incubation may begin in the afternoon that the penultimate egg is laid. The eggs usually hatch in 10-11 days, but occasionally in 12 days. The incubation period of 1 Ontario nest was at least 12 days. The nestling period is 8-10 days and young typically leave the nest within 24 hours of each other, rarely over 2 days (Buehler et al. 2007; Chapman 1907; Confer et al. 2020; Ficken and Ficken 1968c; Hands et al. 1989c; Klaus and Buehler 2001; Peck and James 1987; Tyler in Bent 1953).

One brood is raised annually; there are no records of attempted second broods. Renesting is common in Ontario, but rare in Manitoba where birds arrive on the breeding grounds as much as 2 weeks later than in Ontario. Clutches of 3-5 eggs have been reported in Ontario (average 4.17 eggs). Near Kingston, the average clutch size of first nests was 5.0 eggs for Golden-winged Warblers and 4.8 eggs for hybrids in 1 study and 5.06 and 5.00 eggs respectively, in another study. Another study near Kingston examined 86 nests and reported clutches of 2-6 eggs (average 4.95 eggs). Mean clutch sizes were 4.30 and 4.51 eggs in 2 Tennessee studies, 5.2 eggs in Michigan, and 4.39 eggs in New York. Clutch size declines with the season and replacement clutches are smaller than first clutches. Overall, clutches of 3-7 eggs have been reported, but 4-6 eggs is the normal clutch size with 5-egg clutches most frequent. In New York, clutch size increased with the amount of herbaceous cover within the territory (Bulluck and Buehler 2008; Bulluck et al. 2013; Chapman 1907; Confer et al. 2003, 2020; Fraser 2006; Hands et al. 1989c; Klaus and Buehler 2001; Peck and James 1987; Reed et al. 2007; Tyler in Bent 1953; Vallender et al. 2007b, 2012).

The age at first breeding is 1 year and birds breed annually thereafter. The mating system is typically monogamous, but polygyny rarely occurs. Confer et al. (2003) reported 3 bigamous males. In New Hampshire, 2 nests were 32 m apart and within a single male's territory, suggesting polygyny. In New York, 2 of 61 territorial males (3.3%) fed young at 2 nests, indicating polygyny. In a Kentucky population, the sex ratio was male-biased so that only 67% of males were able to attract a mate. Such highly skewed sex ratios have not been reported elsewhere. The pair bond typically lasts only a single breeding season, but remating of pairs in subsequent years has been reported in Ontario. In 3 cases, the same birds paired in consecutive years and in 1 case the same birds paired in 2001 and 2003. A high rate of extra-pair copulation occurs. Near Kingston, 30 of 54 broods (55.5%) contained at least 1 extra-pair young and all young were extra-pair in some broods. Of 240 nestlings, 75 (31.8%) were extra-pair. In 21 cases (72%), the extra-pair sire was the closest male to the breeding territory. Most broods had only a single extra-pair sire, but 5 broods had 2 and 2 broods had 3. More

broods than expected contained only within-pair or extra-pair young and fewer than expected contained both within-pair and extra-pair young. Another study near Kingston found at least 1 extra-pair young in 13 of 17 nests (76%) and 24 of 62 nestlings (39%) were extra-pair. Females may gain genetic diversity or superior male genes or both for their offspring by mating with multiple males. This may hasten the rate of genetic introgression (Carter 1944; Confer et al. 2003, 2020; Ficken and Ficken 1968d; Fraser 2006; Harper et al. 2010; Reed et al. 2007; Vallender et al. 2007b).

The Golden-winged Warbler feeds by gleaning, hovering, and hanging upside down and probing into a bud, flower, or curled leaf. In May in New York, 84% of foraging was by probing, 6% by gleaning, 1% by hovering, and 9% by hanging. During June and early July, it fed mostly in flowers and occasionally gleaned caterpillars from leaves. The primary trees used for foraging were apple, black cherry, and hawthorn. Some feeding was done near the ground by clinging to small herbaceous species. Fifty-eight percent of foraging occurred in the upper quarter of trees, 27% in the third quarter from the ground, 15% in the second quarter, and 0% in the bottom quarter. It fed only in the peripheral portions of trees and shrubs. There were no significant differences in the foraging methods, rates, and locations of the Golden-winged, Blue-winged, and Brewster's warblers. Ficken and Ficken (1968b) concluded that it was doubtful that the Golden-winged and Blue-winged warblers could coexist because of their similar ecological requirements. Bellush et al. (2016) studied tree and shrub species that were used for foraging by the Golden-winged Warbler. Of 7 tree species used at least twice for foraging, it foraged more on black locust and pin cherry than black cherry. It foraged more on white oak than sassafras and sweet birch compared with their respective availabilities. Only 4 shrub species occurred within territories, but no foraging was observed on blueberry or sweet fern. It selectively foraged on blackberry compared with mountain laurel. Among trees, black locust, pin cherry, and black cherry had the highest caterpillar abundance; sassafras, sweet birch, and white pine had the lowest. Blackberry and sweet fern had similar caterpillar abundances that were higher than for mountain laurel and blueberry.

In Minnesota, 94% of food items fed to nestlings were caterpillars (mostly of leafroller moths); they were also fed spiders. Adult Golden-winged Warblers eat predominantly leafroller moths and their larvae, other moths and caterpillars, moth pupae, other winged insects, and spiders and spider egg sacs. It occasionally extracts spittlebug larvae from their cocoons while foraging close to the ground. It rarely eats flying insects or nectar. It is uncertain if it actually consumes nectar. It is most likely capturing insects when it feeds in flowers (Confer et al. 2020; Fraser 2006; Hands et al. 1989c; Reed et al. 2007; Streby et al. 2014; Tyler in Bent 1953).

Parasitism by the Brown-headed Cowbird is one of the 3 main threats to the Golden-winged Warbler, although it is not nearly as significant a limiting factor as the other threats. If other factors are suitable, it is usually able to overcome the effects of parasitism. Where Golden-winged Warbler recruitment and replacement rates are nearly equal, parasitism may be the additional factor that leads to its decline. In Ontario, 13 of 33 nests (39.4%) were parasitized, but only 3.8% of nests near Kingston were parasitized. Parasitism rates are around 30% in New York and Michigan. It was estimated that this rate of parasitism results in a 17% decline in its reproductive productivity. In New York, 68% of unparasitized nests fledged warblers compared with 32% of parasitized nests. In Tennessee, 0 of 23 nests were parasitized and 0 of 100 West Virginia nests were parasitized. An

examination of nests over much of the eastern United States revealed almost identical parasitism rates of Golden-winged Warbler nests (11 of 113 nests, 9.7%) and Blue-winged Warbler nests (20 of 232 nests, 8.6%). Parasitized nests of the 2 species reached the nestling stage with equal frequency: 15.3% for the Golden-winged Warbler and 19.1% for the Blue-winged Warbler. The proportion of nests that were abandoned due to parasitism was identical at 14.3% for both species. In New York, parasitism rates increased with increasing herbaceous cover in territories, although clutch size also increased. Parasitism occurred in 47% of nests with above average herbaceous cover compared with 18% of nests with below average herbaceous cover (Aldinger and Wood 2014; Buehler et al. 2007; Coker and Confer 1990; Confer et al. 2003, 2010, 2020; Fraser 2006; Klaus and Buehler 2001; Hands et al. 1989c; Peck and James 1998a).

Habitat loss is a major threat to the Golden-winged Warbler throughout its range. The early successional habitat that it uses is ephemeral and becomes unsuitable as soon as grassy and herbaceous cover is replaced by shrubs and saplings. In the 1840s, millions of hectares of farmland were abandoned creating large expanses of suitable habitat. Most of this habitat has since been lost due to natural succession, tree planting, further clearing for agriculture, and conversion to residential areas. Fire suppression inhibits creation of habitat through natural processes. In some areas, it nests in swamps and these are threatened due to drainage, agriculture, and invasion by common reed. This invasive plant replaces tussock sedge and other native wetland plants, rendering the habitat unsuitable for nesting. Active habitat management by humans is required for it to persist in much of its range (Buehler et al. 2007; Canterbury et al. 1993; Confer 2006; Confer and Knapp 1979, 1981; Confer et al. 2003, 2020; Fraser 2006; Klaus and Buehler 2001; Kubel and Yahner 2008; McCracken 1994; Roth and Lutz 2004).

The other major threat to the Golden-winged Warbler is hybridization with the Blue-winged Warbler. This is a significant threat wherever the 2 species are sympatric, and this now includes almost the entire Golden-winged Warbler's range except for portions of Manitoba and some high altitude areas. Once the 2 species come in contact, there are 5 predictable stages of population dynamics: mostly Golden-winged Warblers with few Blue-winged Warblers and hybrids; balanced populations of Golden-winged and Blue-winged warblers with some Brewster's Warblers; mostly Blue-winged Warblers with few pure Golden-winged Warblers and many Brewster's Warblers, and the first appearance of Lawrence's Warbler; introgressed Blue-winged Warblers with few hybrids and no Golden-winged Warblers; and introgressed Blue-winged Warblers and Lawrence's Warblers. This entire evolution may take place over 50 years but may be completed in as few as 4-5 years. This has happened everywhere the 2 species are sympatric except for a population in the Hudson Highlands of New York where the 2 species have coexisted for over a century. The Golden-winged and Blue-winged warblers are sister species that diverged approximately 1.5 million years ago. Historically, they were geographically separated, with the Blue-winged Warbler originally occurring only west of the Appalachian Mountains. Extensive forest clearing in the early to mid-1800s allowed the Blue-winged Warbler to expand eastward into the range of the Golden-winged Warbler, and both species have been expanding northward as well. Hybrids were first reported in 1874 when Brewster's and Lawrence's warblers were described as full species. There are numerous similarities in the biology of the 2 species that facilitate hybridization. There is great genetic similarity in the species which helps explain why they hybridize so readily and why hybrids appear to have high fitness. The 2 species

occupy identical habitat, although the Blue-winged Warbler uses a wider range of habitat, and the territories of the species may overlap or be adjacent to each other. The songs of the 2 species are very similar and each may occasionally sing the other's song. The courtship displays and sexual reactions of the species are similar. Sex ratios of one of the species may be temporarily biased due to differential timing of spring arrival of the species or sexes, or when 1 species is locally rare and this promotes hybridization due to lack of conspecific mates (Bledsoe 1985; Buehler et al. 2007; Canterbury et al. 1993; Confer 2006; Confer and Knapp 1977; Confer and Tupper 2000; Ficken and Ficken 1968b, 1968c, 1968d; Fraser 2006; Frech and Confer 1987; Gill 1980, 1987, 2004; Harper et al. 2010; King et al. 2009; Patton et al. 2010; Vallender et al. 2007a, 2009).

The mechanisms by which hybridization results in the local extirpation of the Golden-winged Warbler were the subject of many studies, but much is yet to be learned. Interspecific mating of the 2 species is uncommon, but mating of pure species and hybrids is common. Male Golden-winged Warblers dilute their genes by mating with hybrids more frequently than male Blue-winged Warblers do, although the reverse may be true where the Blue-winged Warbler is rare. Male Blue-winged Warblers pursue female Golden-winged Warblers at a higher frequency than male Golden-winged Warblers pursue female Blue-winged Warblers resulting in asymmetry in the transfer of genes. These factors favour introgression of ancestral Blue-winged Warbler into Golden-winged Warbler phenotypes. It was originally thought that the gene flow was unidirectional from the Blue-winged Warbler to the Golden-winged Warbler, resulting in genetic swamping of the Golden-winged Warbler. More recent research demonstrated that gene flow is bidirectional and that the genetic compliment of the Blue-winged Warbler also becomes introgressed. There appears to be a mosaic of pure and mixed populations throughout the sympatric range of these species, with varying amounts of introgression. The rate of introgression depends upon the length of contact of the 2 species and their relative population sizes. The long-term persistence of the Golden-winged Warbler in 1 area of New York may be because introgression may not have been enough to swamp the local population, or this population might be continually augmented by immigration. Genetic swamping of the Golden-winged Warbler is hastened through extra-pair copulations that result in broods of mixed parentage and genetic compliments. Several studies concluded that male hybrids are at a disadvantage in obtaining a mate, probably due to lack of the facial patterns that may be important in attracting a female. Some studies determined that facial patterns are important in attracting females. Others have found that facial patterns are unimportant. Ontario studies demonstrated that hybrid males were as likely to attract a mate as males of either of the 2 species. There was no difference in clutch size, food-provisioning rates, or fledgling success of nests with male hybrids or males of pure species. Earlier studies were based on smaller sample sizes, but it is possible that there is regional variation in mating success of hybrid males based upon local population structures. Once mated, hybrids are likely to be as successful as males of either species (Buehler et al. 2007; Confer 2006; Dabrowski et al. 2006; Ficken and Ficken 1968d; Fraser 2006; Gill 1980, 2004; Leichty and Grier 2006; Parker 1951; Reed et al. 2007; Shapiro et al. 2004; Vallender et al. 2007b, 2009). Wood et al. (2016) determined that the habitat preferences of hybrids were intermediate between those of the Golden-winged and Blue-winged warblers. Even populations that are isolated from Blue-winged Warblers contain cryptic hybrids that appear to be pure Golden-winged Warblers. The pattern of habitat occupancy by these hybrids may promote contact with

Golden-winged Warblers and thus facilitate genetic introgression even where the Blue-winged Warbler is absent.

The rate of genetic introgression in the Golden-winged Warbler is alarming. Most studies estimate the proportion of pure Golden-winged Warblers and hybrids in populations by plumage characteristics. Short (1963) examined 1,028 museum specimens and concluded that 312 of 431 definite hybrids (72.3%) would be identified as a pure species in the field. Vallender et al. (2007a) analyzed the genetic make-up of Golden-winged Warblers from Manitoba, Kentucky, Tennessee, and Ontario and found that almost a third of phenotypically pure individuals had experienced cryptic past hybridization. The number of pure populations is probably much smaller than field studies indicate. Genetic analyses conducted in 9 states and 3 provinces revealed that all populations except those in Manitoba and Quebec showed some level of introgression. No introgression was found in populations from southern Ontario near Long Point or Quebec, but it was concluded that this was likely due to small sample sizes rather than actual absence of introgression. At Rainy River, 7.1% of birds were introgressed and 22.2% of Barrie birds were introgressed or were clear Brewster's Warblers. Manitoba appears to support the only pure populations of the Golden-winged Warbler, but this province supports less than 1% of the global population. Samples from southern Ontario had the highest rates of introgression at 43%. The Kingston population was allopatric until the Blue-winged Warbler was first observed in the late 1980s. By 2004, 17% of the breeding population was comprised of hybrid phenotypes although Blue-winged Warbler occurrence remained low at 1%. The most common route of introgression at Kingston was mating by advancing male Blue-winged Warblers with females of the established Golden-winged Warbler population. The continued advancement of Blue-winged Warblers and hybrids into the current breeding range will perpetuate declines in Golden-winged Warbler populations. As of 2007, approximately 33% of the Kingston Golden-winged Warbler population was introgressed despite the relatively short contact period and low incidence of observed hybridization. There are varying opinions on the future of the Golden-winged Warbler, but all concur that it looks bleak. One prediction is that the Golden-winged Warbler will be very rare by the end of the 21st century, persisting in early stage successional habitats at high elevations and latitudes, and perhaps in swamps. There are signs of co-existing populations in southern New York, Michigan, and West Virginia that suggest that the Golden-winged Warbler will likely escape total replacement by the Blue-winged Warbler. A second opinion suggests that complete genetic swamping of the Golden-winged Warbler is not a foregone conclusion. This is due to site-specific differences in patterns of introgression. The third opinion is that the only currently genetically pure populations are in Manitoba and that it is likely that Blue-winged Warbler genes will eventually become prevalent even in these populations. By 2010-12, 8 of 128 Golden-winged Warblers (6.3%) in Manitoba had DNA mismatches indicating that introgression is proceeding rapidly there. In this event, the Golden-winged Warbler may become genetically extinct. All these predictions may be correct. It is possible that isolated populations of birds will persist that have plumage characteristics typical of pure Golden-winged Warblers, but that all populations will exhibit some introgression and genetically pure populations will become extinct (Confer et al. 2010; Dabrowski et al. 2005; Fraser 2006; Gill 1980, 2004; Reed et al. 2007; Vallender et al. 2007a, 2007b, 2009, 2012; Vallender and Bull 2016).

It was originally thought that the Blue-winged Warbler had a competitive advantage over the Golden-winged Warbler and that interspecific competition was a factor in the decline of the Golden-winged Warbler. Blue-winged Warbler males regularly harass Golden-winged Warbler males in West Virginia and Michigan. Golden-winged Warblers nesting close to Blue-winged Warblers in New York laid smaller clutches than those without a Blue-winged Warbler neighbour. In New York, however, Golden-winged Warblers were dominant in more than half the interactions with Blue-winged Warblers. Intense aggression appeared to occur only in relation to nest defence or mate guarding. Experiments involving removal of adjacent Blue-winged Warblers determined that Golden-winged Warblers did not expand their territories. Blue-winged Warblers do not drive Golden-winged Warblers into inferior habitat and interference competition is not a cause of Golden-winged Warbler decline. There are single records of the male of each species feeding the young of a pair of the other species and, in both cases, aggression was directed toward the intervening male. In 1 case, the intruding Blue-winged Warbler male was dominant to the Golden-winged Warbler male (Adkisson and Campbell 1977; Coker and Confer 1990; Confer and Larkin 1998; Confer et al. 2003, 2020; Gill 1980, 2004; Rayner 1988c).

The habitat selected by the Golden-winged Warbler for nesting may affect reproductive success. In West Virginia, 86% of nests in early stages of succession were successful compared with 33-52% in areas of dense shrub and sapling growth. Nest success declined with increasing shrub and sapling growth in New York. In Tennessee, nest success increased with increasing shrub cover and decreased with sapling density. Daily survival rates of nests decreased as daily minimum temperatures increased, possibly because higher temperature may increase activities of predators such as snakes. In Pennsylvania, nest predation rates were significantly lower in clear-cuts than along utility rights-of-way. Clear-cuts had a greater interspersion of shrubs and herbs; rights-of-way were abrupt edges. In New York, nest success was 65% in swamps and 37% in upland habitat, which supported a high density of chipmunks and snakes (Bulluck and Buehler 2008; Canterbury et al. 1993; Confer et al. 2003, 2010; Kubel and Yahner 2008).

Vallender et al. (2012) sampled Golden-winged Warblers in Manitoba, Ontario, and Quebec to determine the prevalence of blood parasites in them. These are intercellular sporozoans that complete part of their life cycles within circulating red blood cells in birds. Infections are chronic and tend to resurface during periods of stress, particularly during the breeding season. None of the birds sampled showed clinical signs of illness. The rates of infection were 0% in Quebec and at Barrie, 7.1% at Rainy River, and 30% in Manitoba. The infection rates were considered an underestimate. The higher rate of infection in Manitoba is of conservation concern because infections may reduce fitness. In Manitoba, birds with more grassland or marsh cover within 200 m were more likely to be infected with blood parasites (Enslow et al. 2023).

The Golden-winged Warbler readily deserts its nest if disturbed while building it. Even nests with incomplete clutches may be abandoned. Once incubation starts, females often stay on a nest despite considerable disturbance (Confer et al. 2020). In Minnesota, young that were forced to fledge experienced a higher survival rate than those that fledged naturally. Premature fledging did not adversely affect survival rates and the ability to fledge early may be a predictor of higher probability of fledgling survival (Streby et al. 2013).

In Virginia, Albrecht-Mallinger and Bulluck (2016) broadcast calls of the Golden-winged Warbler to determine if this method could be used to attract breeding males to a site. Males did not respond strongly to conspecific attraction in a low-density and highly fragmented system. Male increases near treatment areas resulted in a decline in previously occupied areas. Other studies in dense and less-fragmented populations have demonstrated conspecific attraction.

In Pennsylvania, a severe hailstorm produced 2.5-cm hail and caused the failure of 8 of 9 nests (88.9%). Seven of the 8 nests contained damaged eggs and all nests sustained damage. Two females were found dead within 0.5 m of their nests. The storm may have had greater effects than what was observed because little territorial or renesting activity occurred in the following weeks. Climate change has the potential to increase the frequency of damaging severe storms (Fiss et al. 2019).

The potential effects of climate change on the Golden-winged Warbler are uncertain. Price (2004) predicted that its range in southern Ontario might contract if the average summer temperature increased by 2°C. Thogmartin (2010) noted that moths and their larvae are a favoured food and that there is evidence that moths are responding to climate warming. This may result in a gradient in food abundance that at some point may become asynchronous with Golden-winged Warbler habitat as the climate changes. Confer et al. (2020) stated that it had experienced major range changes in the last century and that it uses a wide range of altitudes. They concluded that it may be adaptable to a wide range of temperatures.

Status

Prior to European settlement, the Golden-winged Warbler was probably present in very low numbers in the extreme south, which would have been at the northern extent of its range. The first record for the province was from Hamilton in 1860. At the end of the 19th century, it occurred regularly at London and had been recorded at Port Rowan and Dunnville in addition to Hamilton. Middlesex County was one of its early strongholds, with the first nests found there in 1912 and 1914. It was fairly common there and in Norfolk County in the 1930s. In the Hamilton area, it was documented in 1929 and every year thereafter, with breeding first occurring in 1935. By the 1950s, its breeding range had extended northward by 250 km to include the Region of York and Peterborough and Simcoe counties. In the early 1960s, the breeding range included Kingston, the Bruce Peninsula, and southern Muskoka District and the range continued to expand northward to Parry Sound, Manitoulin Island, and near Sudbury. By 1980, there was evidence of its becoming established in the Rainy River area. During the first atlas, there was a population at Rainy River and it occurred throughout south of a line from Sault Ste. Marie to North Bay, except in Essex County. The stronghold of the species was in a broad band along the southern edge of the Canadian Shield. Distribution in much of the southwest that was its former stronghold was spotty by then. Its centre of abundance had shifted considerably northward (Baillie and Harrington 1937; Curry 2006; McCracken 1994; McIlwraith 1894; Mills in Cadman et al. 1987). James (1991) considered the Golden-winged Warbler an uncommon to locally common resident in the south.

In the 1990s, there was no evidence that overall numbers of the Golden-winged Warbler were declining and they may have been increasing. It has exhibited a pattern of extending its range northward and abandoning areas further south where it was formerly common. This pattern has been continuing for about 1.5 centuries (King et al. 2009; McCracken 1994). The evidence of

withdrawal from the southern portion of the province was evident well before the first atlas. Breeding numbers in the Hamilton area peaked in the 1960s and Curry (2006) predicted that it might not be long before the Golden-winged Warbler disappeared as a breeding species near Hamilton. In Elgin County, it was a common breeder in 1891, a regular but not common breeder in 1954, and possibly extirpated as a breeder in 2000 (Lancaster et al. 2004). McCracken (1994) predicted that it would be largely extirpated from many areas south of Toronto by the end of the 20th century, and this prediction was correct.

The second atlas demonstrated that there had been no change in the overall distribution of the Golden-winged Warbler since the first atlas. It was not found in many squares where it was present during the first atlas. It declined in all atlas regions except in the Rainy River area, and declines were significant in the Carolinian Forest Region and the Great Lakes–St. Lawrence Forest Region in the Shield. It was most abundant along the southern edge of the Shield, especially near Georgian Bay and north of Kingston on the Frontenac Axis. Smaller areas of high density occurred east of Sudbury, east of Algonquin Park, and near Gravenhurst (Vallender in Cadman et al. 2007).

Preliminary results of the third atlas indicate a further decline in the Ontario Golden-winged Warbler population. There were few records in the southwest and the population in the Parry Sound area and east of Algonquin Park almost disappeared completely. The population in the Rainy River area increased from being in 5 squares in the second atlas to 28 squares by 2024 (Cadman 2024).

Both hybrids are rare in Ontario. The Brewster's Warbler is found most often around the southern Niagara Escarpment, on the Oak Ridges Moraine, along the southern edge of the Shield, and in the Long Point area. The Lawrence's Warbler was found in only 5 locations during the second atlas, mostly in or just north of the Carolinian Forest Region but one was found in southeastern Ontario (King et al. 2009; Vallender and Leckie in Cadman et al. 2007).

No northward expansion of the Golden-winged Warbler's range occurred between the first and second atlases. Further northward expansion may be inhibited by lack of suitable habitat. The Boreal Forest Region, with its dominance by spruce and fir, is marginal habitat at best for it (Buehler et al. 2007; King et al. 2009). The lack of northward range expansion coupled with declines in the south is likely to result in precipitous declines in the Ontario population.

Golden-winged Warbler populations have not been stable for at least the past 150 years. Population trends are characterized by localized expansion, establishment of regional populations of moderate abundance, and subsequent declines. The population expanded its range northward while contracting southward, disappearing in more southerly areas where it was formerly fairly common. The northward range expansion appears to have stalled now that populations have reached the southern edge of the Boreal Forest Region. Until the 1990s, it may have been increasing in Ontario, but it is now declining significantly. Breeding Bird Survey (BBS) data for 1998-2007 suggested a decline of 4.4% per year in Ontario and 11.3% per year in the Great Lakes–St. Lawrence Forest Region in the Shield. The rate of decline in Ontario is increasing and was as high as 14.4% per year 1992-2002. Although the rates of decline in Ontario are alarming, they are not as pronounced as declines in the United States. It is declining at rates greater than for most other North American passerine species (Confer 2006; Confer et al. 2020; Fraser 2006). Rosenberg et al. (2016) mapped the range of the Golden-winged Warbler during 1880-1920, 1980, and 2013. Its range shifted northward

until the 1980s, with limited expansion to the north since then except in Manitoba. Its range was originally contiguous through the Appalachians and the Great Lakes region. Due to its disappearance in many Great Lakes states, the Appalachian and Great Lakes populations are now isolated from each other. In the Appalachians, it is becoming restricted to high-elevation sites where the Blue-winged Warbler is absent.

Bulluck et al. (2013) used adult survival and fledging success rates to estimate population trends of the Golden-winged Warbler near Kingston. They concluded that this population was declining rapidly at a rate of 24% per year, a higher rate of decline than BBS data indicated (8.01% per year for the entire province). The number of birds remained fairly constant at the Kingston site, suggesting that this high-quality habitat receives immigrants on a regular basis. Based on the Golden-winged Warbler Atlas Project and eBird results, the 2013 range in southern Ontario contracted to exclude most of the area west of Hamilton and areas north to central Bruce and Grey counties. In these areas, it has largely been replaced by the Blue-winged Warbler and hybrids (Rosenberg et al. 2016).

BBS data indicate that the Golden-winged Warbler increased at annual rates of 0.561% in Canada and 0.436% in Ontario 1970-2021. Trends for 2011-21 were an annual increase of 0.1% in Canada and an annual decrease of 1.36% in Ontario. The long-term trends were of medium reliability; the short-term trends were of low reliability (A.C. Smith et al. 2023).

The Golden-winged Warbler is designated threatened in Canada and special concern in Ontario. The population and distribution objectives identified in the recovery strategy are to maintain self-sustaining populations in Manitoba, Ontario, and Quebec while maintaining, at a minimum, the current population of approximately 35,000 pairs (Friis et al. 2016).

POSTFLEDGING PERIOD

During the postfledging period, adults and juveniles may occur both in open successional habitat and in forests. Dense vegetation in these areas, particularly forest edges, may provide important foraging opportunities and possibly cover from predators. In northern Minnesota, broods were observed in the interior of forests. In Michigan, 8 juveniles but no adults were captured in mature riparian trembling aspen forests with an understorey of alder and honeysuckle. No Golden-winged Warblers were captured in mature upland trembling aspen–large-toothed aspen forests with minimal understorey. In clear-cuts in Minnesota, 30 were caught in mist nets during the breeding season. During the postfledging period, 53 adults and 108 juveniles were caught in the same location. In other areas, adults with broods have been observed in dense thickets of dogwoods and alders. In Minnesota and Manitoba, adults usually moved their fledglings into forest within 10 days of leaving a nest in open habitat, or kept them near the nest if it was in forest (Akresh et al. 2009; Hands et al. 1989c; Patton et al. 2010; Streby et al. 2011b, 2014).

In Minnesota, fledglings were 8-66 m (average 26 m) distant from their nests within 24 hours. Thirteen percent of fledglings were outside their natal territory by this time. Five days after fledging, young were 25-346 m (average 156 m) from the nest and within 10 days they were 126-510 m (average 252 m) from the nest. This suggested that 85% and 100% of fledglings were outside their natal territory within 5 and 10 days, respectively (Streby and Andersen 2013a). In Pennsylvania 1-5 days postfledging, sub-broods made average daily movements of 38.7 m (range 5.3-127.5 m) and 44.9 m (range 3.0-104.7 m) at 2 sites. During days 6-28, sub-broods made average daily movements

of 155.9 m (range 61.1-322.8 m) and 156.7 m (range 56.9-369.1 m). One to 5 days after fledging, sub-broods averaged 92.5 m (range 6.1-278.9 m) and 106.0 m (range 4.1-266.1 m) from the nest. Average distances from the nest 6-28 days postfledging were 749.3 m (range 207.4-2,042.8 m) and 694.3 m (range 38.9-3,600.2 m; Fiss et al. 2020).

Brood division occurs, with the male and female each caring exclusively for individual fledglings. In Minnesota and Manitoba, 98.5% of broods were divided with equal parental care whereby the male and female cared for similar numbers of young. Both sexes were equally likely to care for male or female offspring. Both male- and female-reared sub-broods moved similar distances from the nest in the early postfledging period. In the last 5 days of the postfledging period, female-reared sub-broods were 461 m from the nest and 354 m from the natal patch edge; sub-broods reared by males were 164 m from the nest and 108 m from the natal patch. Male-reared sub-broods appeared to change directions in a manner that kept them closer to the nest. Female-reared broods exhibited a period of directional movement 8-10 days postfledging that took them further from the nest. Following 10 days postfledging, sub-broods cared by both sexes made movements more than 90° in direction in successive days, keeping them in appropriate brood-rearing habitat (Peterson et al. 2016b, 2022).

In Minnesota and Michigan, male- and female-reared sub-broods used areas with similar vegetation characteristics (vertical cover, shrubland, lateral vegetation density, and forest strata) throughout the postfledging period. Vegetation characteristics of sites used by sub-broods changed with time. From fledging to independence, the percentage of vertical cover in inhabited areas increased from 40% to 60%, nonshrub forest use increased from 45% to 85%, the frequency of fledglings perched on the ground decreased from 35% on day 1 to 0% by day 13, and the frequency of use of the midstorey increased from 0% to 15%. Lateral vegetation density of fledgling locations remained constant at 65% and understorey use remained constant at 60%. There was no difference in survival rates of fledglings raised by males and females. Managing for postfledging cover types as far as 700 m from a managed shrubland would provide postfledging habitat for 95% of the broods that were studied. Many unoccupied areas that appear to be suitable breeding territories may not be surrounded by adequate postfledging habitat at a scale used by females to rear their broods (Peterson et al. 2016b, 2022). In Pennsylvania, sub-broods selected for even-aged stands harvested less than 10 years previously over all other cover types 1-5 days postfledging and avoided edges between early successional and mature forests. At 6-28 days postfledging, sub-broods selected the same forests plus those harvested 10-25 years previously with trees less than 15 cm DBH. At 1 site, they also selected upland shrubland (Fiss et al. 2020). In Pennsylvania, fledglings consistently selected for greater lateral and overhead vegetation density and lower basal area than available in stands. Nests were associated with abundant herbaceous vegetation, but fledglings preferred areas with greater structural complexity provided by taller woody plants. Herbaceous cover at nests averaged greater than 40% but fledglings used areas with less than 30% herbaceous cover in all stands. Sapling height averaged 2 m at nests and more than 3 m at fledgling locations, especially in mature and forested wetlands where sapling heights averaged more than 4 m. In even-aged stands harvested less than 10 years previously stocked with trees less than 15 cm DBH, fledglings strongly selected for increased cover by raspberries. Raspberry coverage greater than 80% was associated

with greater than 70% probability of use; coverage less than 25% was associated with less than 60% probability of use (Fiss et al. 2021).

In Pennsylvania, polygynous and monogamous males moved fledglings under their care in different manners. One nest was attended by a female Golden-winged Warbler and a male Brewster's Warbler. The fledglings remained within 40 m of the nest for the first 2 days; brood division occurred on the third day. The male and female travelled in different directions with their fledglings, with the female entering a nearby closed-canopy forest and the male remaining in the timber harvest area where the nest was located. On day 4 after fledging, the male led the young 166 m to a nest attended by a female Brewster's Warbler. Over the next 12 days, the male regularly fed his fledgling, the second female, and her nestlings, with the fledglings remaining within 36 m of the second female's nest. The first female and her fledglings remained an average of 275 m from the second female's nest during this period. After the second female's nest failed, the male moved away from it. His movements were then unbiased by its location. Both adults led their sub-broods away from the natal nest, but the female led her sub-brood 30% further than the male. The female and her sub-brood moved an average of 122 m per day compared with 86 m per day for the male sub-brood. The next year, the same male was monogamously mated to a female Golden-winged Warbler. In that year, he moved his sub-brood into the adjacent closed-canopy forest, similar to what his mate of the previous year did. In the second year, he moved his sub-brood an average of 160 m per day compared with 86 m the previous year. Results suggested that polygynous males may constrain their postfledging movements by approximately 50% when they are attending a second nest (McNeil et al. 2019).

Streby et al. (2016) studied survival rates of Golden-winged Warbler fledglings in relation to habitat in Minnesota and Manitoba. Forty-eight percent of fledglings were depredated before they became independent of their parents at age 25 days; 75% of predation occurred in the first 3 days after fledging and 86% occurred in the first 8 days. Fledgling survival was greatest from nests in forests, lowest from nests in shrublands, and intermediate from nests closest to forest-shrubland edge. Fledgling survival was least in shrublands and greatest in forests for the first 8 days after which fledgling survival was generally high. The probability of a fledgling surviving to day 25 was 84% in sapling-dominated clear-cuts, 75% in mature forests, 46% in wetland shrublands, and 40% in shrub-dominated clear-cuts. In the first 8 days after fledging, young selected for mature forests and sapling-dominated clear-cuts over all other cover types, selected against roads and grasslands, and used shrub-dominated clear-cuts, wetland shrublands, firebreaks, and forested wetlands in accordance with their availability. Older fledglings selected for mature forests over all other cover types and for shrub-dominated clear-cuts over all other cover types except mature forests. They selected against roads and grasslands and used wetland shrublands, firebreaks, and forested wetlands in accordance with availability. First-day movements of fledglings from shrubland nests were oriented toward shrubland-forest edges but first-day movements from forest nests were not oriented toward shrubland-forest edges. The best predictor of survival was location of the nest relative to a forest-shrubland edge. Fledgling survival is strongly influenced by nest-site choice, which may explain why the Golden-winged Warbler rarely nests in areas that maximize nest success. Adults direct or lead their fledglings to forest cover, or keep them in forest cover, regardless of the location of the nest. Crossing roads had no significant effects on fledgling survival because they

crossed roads quickly by flying. Young fledglings use shrubs and understorey trees while their parents forage elsewhere, often more than 300 m distant. Early postfledging habitat might be limited in landscapes with primarily closed-canopy forests with limited shrub and sapling growth. Two potential management strategies include forest canopy thinning to promote shrub and sapling growth and maintaining close associations between shrublands and sapling-dominated regenerating stands through rotational harvest.

MIGRATION

Judging by kills at television towers, migration may be nocturnal. Males migrate first in spring and arrive on the breeding grounds 2-7 days before females (Confer et al. 2020). The differential in timing of migration by the sexes may be greater in Ontario. Males appear in early May in the province, with peak numbers in mid-May; some arrive at the end of April. Females arrive 1-2 weeks later (Fraser 2006; King et al. 2009). In the southern Shield, spring migrants occur from mid-May to early June (Mills 1981; Tozer 2012).

Autumn migration in the southern Shield extends from mid-August to early September, with some remaining until early October (Tozer 2012). In the south, migration peaks in late August and early September, with stragglers until early October (Fraser 2006; Weir 2008).

During migration, the Golden-winged Warbler is much less exacting in its habitat requirements than during the breeding season. In addition to thickets, it may occur in open woodlands and closed-canopy forests. During migration in Michigan, it occurred in the forested strip nearest a river in a large riparian woodland, but was absent in the next 2 wetland bands distant from the river and in the outer band of upland forest. During spring migration in Wisconsin and Minnesota, it was equally abundant in floodplain and upland forests. In Algonquin Park, migrants usually occur in alder swales, in swamps, and along shrubby edges of forests. During the breeding season, it avoids conifers, but may forage in white pine during migration (Chapman 1907; Fraser 2006; Inman et al. 2002; Kirsch et al. 2013; Tozer 2012; Tyler in Bent 1953).

Ficken and Ficken (1974) considered the Golden-winged Warbler a social mimic of the Black-capped Chickadee during migration. The 2 species have similar plumages, both often forage by hanging upside down, and both forage on buds in spring. Although only 5% of warblers present during 1 spring migration were Golden-winged Warblers, 50% of warblers seen within 5 m of a chickadee were that species. Interactions between the 2 species involved close approaches and following with little sign of aggression. Both species may benefit by this close association. The warbler may benefit by following the chickadee because it is a resident species that presumably knows the best foraging areas and might also be aware of predators. The chickadee gains access to buds opened by the warbler, which may not prey on all the available insects because it is rapidly displaced by the chickadee.

The Golden-winged Warbler occasionally strikes television towers and other tall structures during migration. Ten were killed at the Lennox generating station chimneys near Kingston on 4 and 7 September 1984. Over an 11-year period, 52 deaths were reported at a Florida television tower. Although numbers of mortalities during migration appear low, they are disproportionately high given its low population. At regularly monitored communications towers, 542 mortalities were reported at 15 of 47 surveyed sites. This mortality rate was exceptionally high compared with other

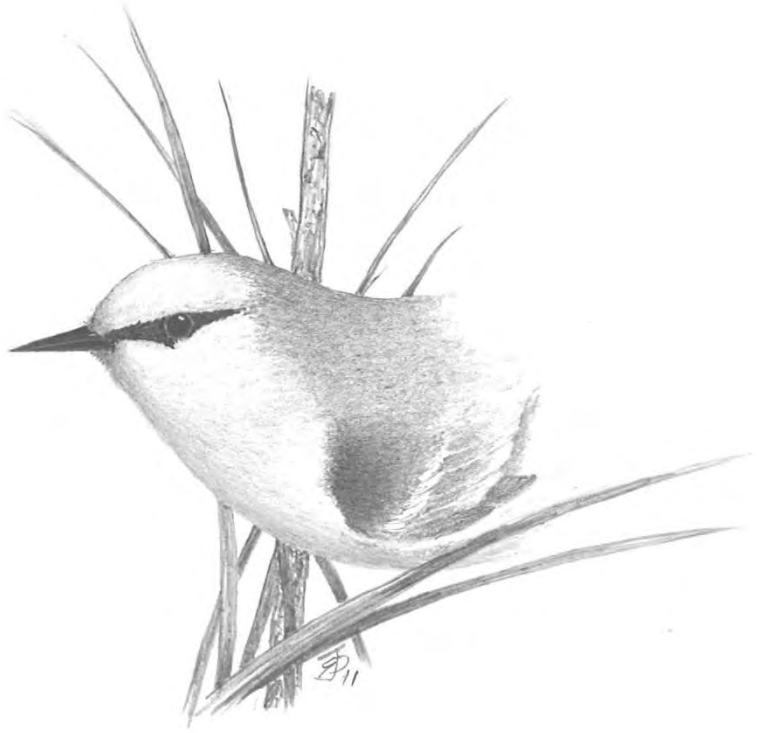
species that are orders of magnitude more abundant but that had only slightly higher mortality (Confer et al. 2020; Hands et al. 1989c; Weir 2008). Loss et al. (2014) examined bird collisions with buildings in the United States. The Golden-winged Warbler was 35.3% more vulnerable to colliding with buildings than birds on average, regardless of the type of building. At low-rise buildings, it was the most vulnerable species, being 141.7 times more likely to strike a building than average. At high-rise buildings, it was 23.1 times more likely to suffer collisions than birds on average. It was not on the list of the top 20 most vulnerable species for striking residences 1-3 stories tall.

James (1991) considered the Golden-winged Warbler a rare migrant in the province and all books summarizing regional populations concurred.

Long Point Bird Observatory data from 1960 to 1989 indicated that the number of Golden-winged Warblers captured increased during this period, but the ratio of Golden-winged to Blue-winged warblers decreased. The number of Golden-winged Warblers captured 1960-69 was 13, 18 were caught 1970-79, and 37 were caught 1980-89. The ratio of Golden-winged Warblers to Blue-winged Warblers captured was 2.6:1 in 1960-69, 1.4:1 in 1970-79, and 0.5:1 in 1980-89 (McCracken 1994).

Blue-winged Warbler

Vermivora cyanoptera



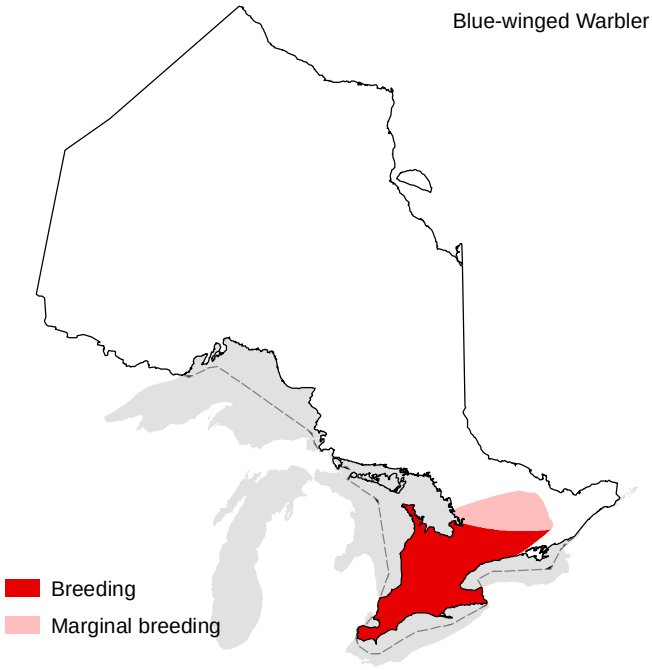
BREEDING SEASON

Habitat Requirements

In Ontario, the Blue-winged Warbler has nested near edges of mixed and deciduous woods, or in open, treed habitats. These areas were vegetated with grasses or mixed grasses and sedges and were overgrown with shrubs and small trees such as hawthorns, apples, and planted conifers. Three of 7 nests were near wet areas (Peck and James 1987). In Elgin County, nesting occurred in a semi-circular opening on the edge of mixed deciduous woods (Rayner 1988c). Near Kingston, it nested in an old field where early succession was maintained by late-summer grazing by cattle (King et al. 2009).

The most common nesting habitat for the Blue-winged Warbler is old fields and pastures with some shrub and tree growth. Utility rights-of-way may provide suitable habitat. Optimum habitat consists of clumps of vegetation, with patches of grasses and herbaceous plants, shrubs, and trees less than 10 m in height. Old-field areas that it inhabits typically are bordered on one or more sides by deciduous forest. It uses trees within and at territory edges as singing perches and for foraging. It also nests in young second-growth forests; on sand dunes; in shrub thicket swamps; in red maple swamps with 60-80% canopy closure and an understorey of spicebush, northern arrowwood, and

tussock sedge; in oak-hickory clear-cuts 2-10 years old; in young pine plantations; in oak savannahs; in pine barrens, particularly pine stands with a dense understorey of oaks; along shrubby margins of watercourses; and occasionally in forest interior (Bent 1953; Bielefeldt and Rosenfield 1994; Brooks 1940; Brush 1987; Chapman 1907; Confer 2006; Confer and Knapp 1981; Confer et al. 2010; Ficken and Ficken 1968a, 1968b, 1968d; Gill et al. 2020; Golet et al. 2001; Graber et al. 1983; Harrison 1984; Lehnen and Rodewald 2009a; Mossman 1988; Mossman and Hoffman 1989; Mossman et al. 1991; Patton et al. 2010; Rich et al. 1994).



Old fields that the Blue-winged Warbler uses tend to have a mix of grasses and herbaceous species, shrubs, and trees growing in a patchy distribution. In 2 New York study areas, grass and forb coverage was 10% and 21%, shrub coverage was 15% and 25%, and coverage by trees shorter than 5 m was 33% and 23%. In West Virginia, highest site occupancy occurred at 50-100% shrubland cover within 100 m. Occupancy was negatively correlated with basal area, decreasing by 93% as basal area within 100 m increased from 0 to 30 m^2 per ha. In Connecticut, it preferred clear-cuts with dense shrubs 0.5-1.5 m tall, a canopy height less than 7 m, and territories close to road or utility rights-of-way. In West Virginia, 33% of territories were covered by dense herbaceous cover; trees covered only 10% of territories. One New York breeding site was characterized by 35% open habitat dominated by tall grasses with scattered hawthorns and dogwoods, 45% was covered with dense shrubby growth 2-4 m tall, and 15% was covered with taller trees (10 m) with an understorey of shrubs. In Kentucky, occupied habitat consisted of patches of herbaceous plants, shrubs, and saplings, with grass cover averaging 34.6%. Plant species characteristic of territories included bush-clovers, goldenrods, clematis, and blackberries. In Indiana oak savannah-type habitats, its density was negatively correlated with tree height. Highest densities occurred at tree heights of 4 m and dropped off to almost 0 at 10 m. Average habitat around nest sites consisted of 100 trees less than 10 cm diameter at breast height (DBH) within 12.5 m of the nest in Michigan, 112 trees of similar size in West Virginia, and 105 in Ohio. The number of shrubs in 80 m^2 transects within 12.5 m of nests averaged 190 in Michigan, 205 in West Virginia, and 198 in Ohio. On West Virginia reclaimed surface mines, it was most abundant in areas planted to shrublands and was next abundant in grassland habitats. It occurred at low densities in remnant and intact forests (Confer and Knapp 1977; Gill et al. 2020; Grundel and Pavlovic 2007a; Margeneau et al. 2019; Oliver et al. 2023; Patton et al. 2010). In Pennsylvania, core home ranges had greater grass cover (68.5% compared with 58.6%) and goldenrod cover (43.9% compared with 27.3%) than total home ranges. Total home ranges had

greater overhead cover (74.1% compared with 61.9%) and leaf litter cover (51.9% compared with 32.2%) than core home ranges. There were no differences in coverage by forbs, ferns, and raspberries in core and total home ranges. Core home ranges had greater average shrub density (9,872 compared with 7,106 stems per ha), lower average sapling density (5,114 compared with 6,052 stems per ha), lower snag density (31 compared with 39 per ha), and lower basal area (6.8 compared with 13.6 m^2 per ha) than total home ranges. The average DBH did not differ between core and total home ranges. Core and total home ranges all contained forest, shrubland, and ecotones. Core home ranges had less forest cover (24.8%) than total home ranges (43.9%). There were no differences in core and total home ranges for ecotone cover (22.4% and 16.8%, respectively) and shrubland cover (52.9% and 39%, respectively). In core home ranges, males used shrublands and ecotones relative to their abundance and selected against forest cover. In total home ranges, males used shrublands relative to their abundance, selected for ecotones, and selected against forest cover. Habitat management based solely on vegetation within core areas could overlook important habitat components that the Blue-winged Warbler selected in total home ranges. Core home ranges were mostly shrubland with a patchy mosaic of vegetation 1-5 m tall. Total home ranges were more forested, with greater overhead cover, basal area, tree density, and tree height (Fuoco et al. 2024).

In old-field habitats, there is little difference in the habitat preferences of the Blue-winged Warbler and the Golden-winged Warbler and the 2 species frequently have overlapping territories. Some studies failed to find any differences in habitat between the 2 species. The greatest difference appears to be in the amount of tree cover in the territories of the 2 species. Cover by herbaceous species and grasses tends to be lower in Blue-winged than Golden-winged warbler habitat and there is considerably more tree cover within Blue-winged Warbler territories. In New York, the mean tree value for Blue-winged Warbler territories was more than twice that of Golden-winged Warbler territories. The variances for tree value differed even more, with the Golden-winged Warbler value less than 5% that of the Blue-winged Warbler. The range of tree values in Blue-winged Warbler territories (2-54) encompassed the entire range for Golden-winged Warbler territories (3-12). Blue-winged Warbler territories had considerable tree growth (30%); Golden-winged Warblers were confined to more open areas with 10% or less tree cover. The Golden-winged Warbler was restricted to areas that were 10-35 years into succession after cropland abandonment. The Blue-winged Warbler occupied these same fields as well as areas 60-70 years into succession. The Blue-winged Warbler is a habitat generalist and the Golden-winged Warbler is a specialist. In New Jersey, the Blue-winged Warbler occurred in fields 10, 20, and 40 years old, but disappeared once the fields became overgrown with trees at age 50 years. In high elevation areas, the Golden-winged Warbler may prefer areas that support heavier tree growth than the Blue-winged Warbler. The 2 species may be separated elevationally, with the Blue-winged Warbler restricted to areas below 530 m and the Golden-winged Warbler occurring at much higher elevations. In Kentucky, however, the Blue-winged Warbler nested at an elevation of 738 m (Confer and Knapp 1977, 1979, 1981; Confer et al. 2003; Gill et al. 2020; Parkes 1951; Patton et al. 2010; Suthers 1988).

Some authors concluded that the Blue-winged Warbler and Golden-winged Warbler are separated by their differing preferences for moisture regime. It was generally thought that, in the east, the Blue-winged Warbler preferred low, wet areas and the Golden-winged Warbler occurred in drier, upland areas. The reverse appeared to be true in the west and reversal of these apparent

habitat preferences was occasionally recorded in the east. Of 29 New York Blue-winged Warbler territories, 26 were wet and contained standing water or a stream. In a later year when the Golden-winged Warbler was absent, the Blue-winged Warbler occupied most of the drier areas where Golden-winged Warblers formerly held territories. It has since been concluded that the Blue-winged Warbler occupies both wet and dry sites independent of the presence or absence of water. In West Virginia, unmated males defended territories in wetter areas than mated males (Ficken and Ficken 1968b; Gill et al. 2020; Short 1963).

Crawford et al. (2016) examined landscape-level habitat and climate attributes of the Blue-winged Warbler at scales of 2.5 km and 500 m and compared them with those of the Golden-winged Warbler. Their study included the area of the Appalachian Mountains and Great Lakes populations of the Golden-winged Warbler, excluding Ontario. In both areas combined at the 2.5-km scale, compared with Golden-winged Warblers, Blue-winged Warblers were associated with lower elevations, warmer breeding season temperatures, and less use of aspen forests. The Blue-winged Warbler was found at an average elevation of 370 m (427 m for Golden-winged Warblers) and a mean maximum May temperature of 21.3°C (20.1°C for the Golden-winged Warbler). Both species were found in roughly equal numbers in grassland mosaic landscapes (8.5% for Blue-winged Warbler and 12.7% for Golden-winged Warblers). Blue-winged Warblers were less than half as likely to be found in woodland landscapes (9.6%) than Golden-winged Warblers (20.2%). The Blue-winged Warbler probability of occurrence was 7.0% in landscapes where trembling aspen was present compared with 39.5% for the Golden-winged Warbler. More Blue-winged Warbler locations (10.1%) were associated with agricultural landscapes than Golden-winged Warbler locations (4.5%). At the 2.5-km scale in the Great Lakes population, Blue-winged and Golden-winged warblers differed in their preferences for elevation, summer breeding temperature, land use, and percent deciduous forest cover. Blue-winged Warbler locations had a mean elevation of 240.9 m (335.2 m for Golden-winged Warbler) and a minimum May temperature of 7.2°C (4.7°C for Golden-winged Warblers). Twenty-six percent of Blue-winged Warbler locations contained aspen compared with 58% for Golden-winged Warblers; 32% of Blue-winged Warbler locations were associated with areas with no trees compared with 16% for Golden-winged Warblers. Blue-winged Warblers occurred more in agricultural landscapes (23.9%) than Golden-winged Warblers (6.8%). Blue-winged Warblers preferred grassland landscapes (34.6% of locations, 15.5% for Golden-winged Warblers) compared with forests with an open or broken canopy (14.3%, 30.7% for Golden-winged Warblers). At the 500-m scale in the Great Lakes region, variables most strongly associated with the 2 species included percent deciduous forest, percent agriculture, and elevation. Both species were strongly associated with yellow birch–sugar maple forests, although Blue-winged Warblers were also found in beech–sugar maple–basswood forests and in agricultural land types at lower elevations. The Golden-winged Warbler was also associated with forests dominated by aspen-birch, jack pine, black spruce–tamarack, and swamp forests. The Blue-winged Warbler occupied higher elevations (303 m) in Michigan, Minnesota, and Wisconsin than in New York (154 m), lower than for the Golden-winged Warbler (367 and 135 m respectively). At finer scales, the Blue-winged Warbler was positively associated with agriculture and human disturbance. The Golden-winged Warbler was negatively associated with these features and positively associated with the distribution of aspen forest.

Cunningham and Johnson (2019) determined that the Blue-winged Warbler preferred areas that were 2-58% forested in New York.

In southern Ontario woodlands, abundance of the Blue-winged Warbler was positively correlated with the amount of forest cover 100 m or more from edge and the amount of forest cover within 2 km. It was negatively correlated with woodlot size and the amount of regional forest cover. These relationships were not significant (Austen et al. 2001). In New Jersey forests, it was equally likely to be detected at forest edges with unpaved roads 8 m wide, paved roads 16 m wide, and power-line rights-of-way 23 m wide. There was no difference in its abundance at forest edge and in forest interior (Rich et al. 1994).

In shrublands in Ohio, Rodewald and Vitz (2005) netted birds 20, 50, and 80 m from mature forest edge. Adult Blue-winged Warblers appeared to avoid the forest edge and were 2.3 times more abundant 80 m from edge than 20 m from edge. Results were less conclusive for juveniles, which were 1.7 times more abundant at 50 m and 1.4 times as abundant at 80 m as they were 20 m from forest edge.

Confer and Knapp (1981) suggested that the Blue-winged Warbler may be area sensitive in New York, where it was found only in tracts of old fields that were 10-50 ha. There is no evidence of area sensitivity from any other areas, and it was specifically noted that it was not area sensitive in Connecticut. In New Jersey, it nested in fields that were 1.8, 2.3, and 6.5 ha. In Ohio, it nested in clear-cuts as small as 4 ha and patch size was not a good predictor of annual survival or juvenile recruitment. There was no evidence of area sensitivity. Another Ohio study found no differences in its abundance in small (4-8 ha) and large (13-16 ha) clear-cuts. In Rhode Island, it nested in red maple swamps that were less than 1 ha in area, although these were surrounded by upland forests that potentially provided additional habitat (Gill et al. 2020; Golet et al. 2001; Lehnen and Rodewald 2009a; Rodewald and Vitz 2005; Suthers 1988).

Ontario nests were on the ground among grasses. One was adjacent to goldenrod stalks, one was in a clump of goldenrods, and another was at the base of a small dead sapling (Peck and James 1987). A nest in Elgin County was 2 m from the edge of an open area and was surrounded by several saplings. The dead top of a bracken fern rested across the nest and concealed it (Rayner 1988c).

Most nests outside Ontario were at edges of old fields near a deciduous forest, often close enough that the adjacent trees shaded the nest. Nests have also been found at the edge of and in the interior of upland deciduous forests and in deciduous treed swamps. Nests may be along deer trails. Most nests are on the ground but they may be as high as 30 cm from the ground in blackberries or sturdy herbaceous species. Most frequently, nests are well hidden within a clump of goldenrods or at the base of a goldenrod or raspberry plant. They are typically attached to upright stems of a clump of forbs or grasses. One nest was buried in a clump of skunk cabbage in a wet swamp. Most are well concealed by grasses, herbaceous material, or ferns. One in a mixed-wood forest was between the exposed roots of a decaying stump and concealed by ferns (Bent 1953; Chapman 1907; Ficken and Ficken 1968a, 1968b; Gill et al. 2020; Harrison 1984; Murray and Gill 1976; Patton et al. 2010; Short 1964).

The Blue-winged Warbler may nest in loose colonies that contain as many as 10 breeding pairs, but it is not a true colonially nesting species. It frequently nests solitarily as well. During the first week after arrival, males sing infrequently and respond poorly to playback, but restrict their movements to the area that later becomes their territory. During this period, they occupy an area of 1-8 ha. Some birds establish territories in areas other than where they first settled. One bird moved 180 m. Territory establishment continues through late May into early June. Later arrivals either establish territories in peripheral, unoccupied areas or challenge a territory holder and claim a portion of his territory. Males confine most, if not all, of their activities to their territory but some infrequently trespass on their neighbour's territory. In old-field habitat, most territory boundaries are defined by a row of trees or an edge. One New York bird had a territory that was bisected by a strip of trees. Territorial disputes are usually confined to a narrow boundary between territories. Territories of Blue-winged and Golden-winged warblers frequently overlap. Territorial aggression between the 2 species occurs only briefly in the spring, only when one or both males are mated and before they settle into their final territories. Once the breeding season is underway, the 2 species largely ignore each other, although they tend to use different singing perches within shared areas. Hybrids may sing the song of either the Blue-winged or Golden-winged warbler, and these may either be attacked or ignored depending upon which song they sing. Birds with similar songs or plumages have non-overlapping territories. Birds with different songs or plumages may have territories that overlap. The Blue-winged Warbler has a large territory size for a warbler. The smallest territories of less than 0.4 to 0.8 ha were reported in New York, but this was an unbanded population and some individuals may have been mistaken as 2 birds. Another New York study reported territory sizes of 1.0-2.0 ha (average 1.3 ha). In Michigan, territories ranged from 0.4 to 3.0 ha (average 1.8 and 2.0 ha) at 2 sites. In northeastern Ohio, territory size averaged 1.1 ha (range 0.3-5.0 ha). Territories were larger in years of lower density. In Pennsylvania, the median 50% core home range size was 2.9 ha (range 0.6-16.5 ha) and the median 95% total home range size was 12.9 ha (range 2.3-90.6 ha). Six of 27 core home ranges (22%) and 16 of 27 total home ranges (59%) overlapped (Confer 2006; Confer and Knapp 1977; Confer and Larkin 1998; Confer et al. 2003; Ficken and Ficken 1968a, 1968c, 1968d; Fuoco et al. 2024; Gill et al. 2020; Meyerriecks and Baird 1968; Murray and Gill 1976; Patton et al. 2010; Short 1963).

Natal philopatry rates for the Blue-winged Warbler are variable. In Ohio, 11 of 353 (3.4%) juveniles were encountered as adults and 8 (2.3% or 72.7% of returning birds) returned to the natal site (Lehnen and Rodewald 2009b). In New Jersey, 19 of 216 young (8.8%) returned and 3 returned in multiple years (Suthers 1988). Zero of 35 juveniles in Michigan and 0 of 41 in West Virginia and another Ohio area returned (Gill et al. 2020).

Adult site fidelity rates vary and may be lower where the range is expanding northward. Some males returned to the same area for as many as 4 years. At 2 Michigan study areas, 5 of 10 males returned at 1 site, but one established a territory 9.6 km from where it was banded. One of 5 returned at the other site. In Ohio, 62 of 323 adults (19.2%) were re-encountered and 61 (98.4%) returned to the same site. Other adult return rates include 16 of 51 (31.4%) in West Virginia, 10 of 17 (58.8%) in Michigan, and 8 of 18 (44.4%) in New York. Numbers of birds returning for the second year were 11 of 23 (47.8%) in Michigan, 12 of 51 (23.5%) in West Virginia, and 6 of 10 (60.0%) in Ohio. Numbers returning for the third year were 5 of 17 (29.4%) in Michigan and 7 of 17 (41.2%) in West Virginia. Return rates of adult females were 10% in Michigan, 14.3% in West Virginia, and 65.8% in Ohio. A

Michigan male moved 9.6 km between successive breeding seasons and 2 in West Virginia moved 12 km. Birds do not necessarily move to larger habitat patches but may be forced to move if natural succession of habitat becomes too advanced (Gill et al. 2020; Lehnen and Rodewald 2009b; Murray and Gill 1976).

Limiting Factors

Eggs have been reported in Ontario nests from the last week of May until mid-August, with most present from mid-June to early July (Peck and James 1987). Pair formation begins shortly after the arrival of females, often within 12 hours. Nest building starts soon after pair formation, often on the same day for late-arriving females. Early females may wait 1 or 2 days before initiating nest building. It usually takes 2-4 days to build the nest, occasionally 5 days, and rarely as long as 12 days during cold, wet weather. Egg laying usually starts the day after the nest is completed but longer intervals occur during inclement weather. The interval between nest completion and initiation of egg laying is 1-4 days during dry, warm springs (mode 1 day); as long as 5 days during wet, warm springs; and 8 days during wet, cool springs. One egg is laid per day. Incubation begins with the laying of either the penultimate or last egg. The incubation period is 10-12 days. The young leave the nest when they are 8-10 days old. Usually all young leave the nest within an hour but fledging may rarely extend over a 2-day period (Bent 1953; Chapman 1907; Ficken and Ficken 1968a, 1968c; Gill et al. 2020; Harrison 1984).

The Blue-winged Warbler raises a single brood per year but replacement clutches are common if the first one is lost. Nests are not known to be reused. Clutches of 2-6 eggs were documented in Ontario. Throughout its range, clutches of 2-7 eggs were reported, but mostly 4 or 5 eggs. Clutches of 2, 3, and 7 eggs are rare. The mean clutch size is 4.55 eggs and 3.65 eggs for clutches containing cowbird eggs. Replacement clutches may be smaller with only 2 or 3 eggs. These later nests are also subject to higher rates of cowbird parasitism (Bent 1953; Chapman 1907; Gill et al. 2020; Peck and James 1987).

The age at first breeding is 1 year. The Blue-winged Warbler is typically monogamous, but may occasionally be polygynous. No studies have been done on extra-pair copulation, but this is probably prevalent and may promote introgression with the Golden-winged Warbler (Gill et al. 2020).

In May in New York, 98% of feeding was by probing which consisted of inserting the bill into a bud, cluster of leaves, flower, or curled leaf, then opening it slightly to spread the vegetation. An additional 2% of foraging was by gleaning. Birds were not observed hovering or hanging upside down to feed during that month. In July, foraging consisted of 27% probing, 31% gleaning, 5% hovering, and 36% hanging upside down. During 1 day in late July, 2 birds foraged entirely by probing in curled dead leaves. Birds foraged 47.7% of the time in the top quarter of the tree, 53% in the second quarter from the top, 9% in the second quarter from the bottom, and 0% in the bottom quarter. The main trees used for foraging were apple, hawthorn, and black cherry. Some feeding was done near the ground by clinging to small herbaceous species. Most foraging was done near the tops of trees and shrubs and only in the peripheral portions of woody vegetation. The Blue-winged Warbler had a tendency to forage lower than the Golden-winged Warbler, but not significantly. The similarity in foraging methods and locations by the 2 species suggests that they

are eating the same food items. It is doubtful that the 2 species can remain sympatric because of their similar ecological requirements (Ficken and Ficken 1968b).

In West Virginia, young were fed mostly caterpillars and this has been observed elsewhere; small flying insects may also be fed to nestlings. Adults eat predominantly caterpillars, small crickets and grasshoppers, and spiders. Beetles, moths, ants, flies, small locusts, and spittlebug larvae may be consumed. The diet is probably very similar to that of the Golden-winged Warbler and it is likely that most of the caterpillars eaten are those of leafroller moths (Chapman 1907; Ficken and Ficken 1968b; Gill et al. 2020).

The Blue-winged Warbler is commonly parasitized by the Brown-headed Cowbird. Coker and Confer (1990) examined nest records over a wide geographic area and 20 of 232 nests (8.6%) were parasitized. Nine of 47 parasitized nests (19.1%) reached the nestling stage; 2 of 14 parasitized nests (14.3%) were abandoned. Parasitism rates are higher in fragmented than intact landscapes. In highly fragmented habitats in Ohio, 8 of 12 nests (66.7%) were parasitized. In intact habitats in West Virginia, only 1 of 212 nests (0.5%) was parasitized. Reproductive success decreased by as much as 67% in the fragmented Ohio habitats, although both warblers and cowbirds may fledge from a nest (Gill et al. 2020). In New York, 2 of 9 nests (22.2%) were parasitized (Hahn and Hatfield 1995). In Ontario, 2 of 6 nests (33.3%) were parasitized and 1 nest contained only cowbird eggs (Peck and James 1987).

Throughout most of its range, habitat loss is a significant limiting factor for the Blue-winged Warbler. Populations have a history of waxing and waning in response to the availability of early successional habitat. This type of habitat is declining over much of its range due to urbanization, decreased abandonment of farmland, and natural succession. The effects of habitat loss have not yet been manifested in Ontario because it is still expanding northwards. Once it becomes established throughout southern Ontario to the southern edge of the Canadian Shield, it is likely that it will start to experience population declines due to habitat loss. Although the Blue-winged Warbler is a habitat generalist compared with the Golden-winged Warbler, it is still reliant predominantly on ephemeral habitat. Its preferred habitat is the type of habitat that is most likely to be converted to other uses (Confer and Tupper 2000; Gill et al. 2020; McCracken 1994; Morse 1989; Shapiro et al. 2004).

The Blue-winged Warbler and Golden-winged Warbler regularly hybridize wherever they co-exist. They produce 2 recognizable forms of hybrids known as Brewster's Warblers and Lawrence's Warblers and backcrossing between the species and hybrids occurs frequently. There are a number of factors that facilitate hybridization of the 2 species. They are genetically very similar and no more different in their level of enzyme differentiation than morphologically indistinguishable populations of passerine birds. The 2 species occupy the same habitat types and their territories may be adjacent to each other or overlap. Their songs are similar and individuals of 1 species may sing the other's song. The courtship displays and sexual reactions of the 2 species are similar and they are attracted to each other sexually. Males of both species readily mate with hybrid females, thus increasing the incidence of genetic introgression. Both species are shifting their ranges northward and hybridization may be encouraged when 1 species is rare compared with the other and has difficulty finding a conspecific mate. Birds that arrive late in spring may also not be available to find a suitable mate. Most hybrid pairings consist of a pure male pairing with a hybrid female, with pairs of 2 hybrids

or the 2 pure species uncommon. The 2 species may be too similar ecologically to co-exist (Confer 2006; Confer and Larkin 1998; Ficken and Ficken 1968c, 1968d; Gill 1987; Morse 1989; Parkes 1951; Vallender et al. 2007b).

The Blue-winged and Golden-winged warblers are sister species that separated 1.5 million years ago. Historically, they were geographically separated with the Blue-winged Warbler occurring mainly west of the Appalachian Mountains where it nested along the prairie-forest ecotone. Large-scale forest clearing by European settlers followed by anthropogenic shrub growth allowed it to expand its range eastward and northward, thus coming into contact with the Golden-winged Warbler. Once sympatry occurs, the Blue-winged Warbler typically replaces the Golden-winged Warbler within 50 years, but occasionally in as few as 4 years. There is a population in New York, however, where the 2 species have co-existed for over a century. There are 5 stages in the replacement of the Golden-winged Warbler by the Blue-winged Warbler: a population that is predominantly Golden-winged Warblers with few Blue-winged Warblers and hybrids; equal numbers of Golden-winged and Blue-winged warblers with some Brewster's Warblers; mostly Blue-winged Warblers with few Golden-winged Warblers, with a broad range of hybrids and the first appearance of the Lawrence's Warbler; a conspicuously introgressed Blue-winged Warbler population with few hybrids and no Golden-winged Warblers; and a Blue-winged Warbler population with some variation in wing-bar colouration and the occasional Lawrence's Warbler (Confer 2006; Confer and Tupper 2000; Gill 1980).

Although much has been written about how detrimental hybridization is to the Golden-winged Warbler, it also adversely affects the Blue-winged Warbler through genetic introgression and reduction in the number of pure Blue-winged Warblers. The rate of introgression is greater than originally thought, with early determinations being based upon visual inspections in the field. Short (1963) examined a large number of Blue-winged Warbler, Golden-winged Warbler, and hybrid museum specimens and concluded that 312 of the 431 specimens (72.4%) that he considered hybrids would have been identified as pure species in the field. Introgression had occurred in a Long Island population of Blue-winged Warblers that was allopatric. By analyzing mitochondrial DNA, Vallender et al. (2007b) found that some hybrids were morphologically indistinguishable from one of the parental species, but contained genes from both parental taxa. In Pennsylvania, gene flow as a result of hybridization was unidirectional from the Blue-winged Warbler to the Golden-winged Warbler, resulting in the genetic swamping of the Golden-winged Warbler and eventual replacement of it by the Blue-winged Warbler. Studies of other populations have demonstrated that hybridization is more often bidirectional so that both species are compromised by introgression. Patterns of introgression vary geographically depending upon the relative abundance of the species and hybrids and the historical context of interactions between the species (Dabrowski et al. 2005; Gill 2004; Shapiro et al. 2004; Vallender et al. 2009b).

Vallender et al. (2009b) examined 145 Blue-winged Warblers that appeared to be pure based upon plumage characteristics. They were collected from 7 states and 2 provinces (8 birds from Ontario and 1 from Quebec). Fourteen (9.6%) had a mismatch between their pheonotype and their mitochondrial DNA, which was higher than for the Golden-winged Warbler at 8.0%. The Ontario samples showed the highest level of introgression at 45%. Of the 8 Ontario birds, 4 had ancestral

Blue-winged Warbler DNA and 4 had ancestral Golden-winged Warbler DNA. There was no sign of introgression in Kentucky. Dabrowski et al. (2005) analyzed the genetic makeup of birds in this complex from Ontario and New York. In Ontario, all Brewster's Warblers had ancestral Golden-winged Warbler DNA. Lawrence's Warblers had equal numbers of ancestral Golden-winged and Blue-winged warbler haplotypes. Introgression was rare at Kingston and the most common route of introgression was mating by advancing male Blue-winged Warblers with females of the established Golden-winged Warbler population. In New York, 13 of 15 Blue-winged Warblers (86.7%) had ancestral Blue-winged Warbler DNA and the others had ancestral Golden-winged Warbler DNA. Vallender et al. (2007b) examined samples from Ontario and Kentucky. One apparent Blue-winged Warbler could not be assigned to either ancestral population, suggesting that it was a hybrid. Another Blue-winged Warbler had ancestral Blue-winged Warbler DNA. One of 49 Golden-winged Warblers (2.0%) had ancestral Blue-winged Warbler DNA, 9 of 10 Brewster's Warblers had ancestral Golden-winged Warbler DNA and the other had ancestral Blue-winged Warbler DNA. Four 4 Lawrence's Warblers were equally split between ancestral Golden-winged and Blue-winged warbler DNA. All 12 Blue-winged Warbler samples from Kentucky had ancestral Blue-winged Warbler DNA. Shapiro et al. (2004) examined specimens from Missouri, Ohio, and West Virginia. All Blue-winged Warblers from Missouri and Ohio were pure, and these populations are allopatric. In West Virginia, 15.3% Blue-winged Warblers had Golden-winged Warbler DNA; 12.4% Golden-winged Warblers had Blue-winged Warbler DNA; of 9 Brewster's Warblers, 4 had Blue-winged Warbler DNA and 5 had Golden-winged Warbler DNA; and of 4 Lawrence's Warblers, 3 had Blue-winged Warbler DNA and 1 had Golden-winged Warbler DNA. In New York, the hybridization rate for pure Blue-winged Warblers (4.8%) was less than for the Golden-winged Warbler (8.1%), but not significantly (Confer and Larkin 1998). This study relied on plumage characteristics rather than genetic analyses.

Farwell et al. (2019) studied the effects of shale gas infrastructure (well pads, access roads, and pipelines) on the Blue-winged Warbler in contiguous forest in West Virginia. It exhibited no significant response to these features.

Price (2004) predicted that the Blue-winged Warbler might become extirpated in southern Ontario if the average summer temperature increased by 2°C.

Status

The Blue-winged Warbler is a recent addition to Ontario's avifauna. The first record was one collected at Point Pelee in the autumn of 1908. The primary route of colonization appears to have been through the Niagara Peninsula. The first record for the Hamilton area was in 1937 and it began to be seen regularly there in the mid-1950s. Prior to 1950, there were only a handful of records for the entire province. The first nest was found at Ancaster on 3 July 1956 and a week later another nest was found at Milton Heights. By 1961, 5 nests had been documented in the Hamilton area and one had been found at Glen Morris in Brant County. Many early nests had mixed pairings of Blue-winged Warblers and Golden-winged Warblers. The Blue-winged Warbler was a rare breeder in the province in the 1960s, but had been recorded during the breeding season in Middlesex County, at Toronto, in Caledonia, in Durham Region, and at Kitchener. In the Kingston area, the first record was in 1957 but it did not appear as a regular migrant at Prince Edward Point until 1970. By 1979, it had increased so much in parts of the south, such as in the Kitchener area, that it was more abundant than the Golden-winged Warbler. At this time, it occurred during the breeding season north to Kingston and the Oshawa-Scugog area, and vagrants were appearing in Wellington County. By

the 1980s, it was fairly common in Haldimand, Norfolk, Middlesex, and Oxford counties and occurred in even greater numbers in the southwest. Its distribution at that time was from Pelee Island to the Bruce Peninsula east to Gravenhurst and Brockville. In the 1980s, the Blue-winged Warbler was more abundant than the Golden-winged Warbler in Waterloo Region and the counties of Oxford, Haldimand, and Norfolk. The first nesting record for Elgin County was not until 1985, although the first observation there was in 1963. In the Kingston area, the average number of summer sightings was 0.8 in 1981-90, 1.6 in 1991-2000, and 4.8 in 2001-05. Near Chaffey's Locks north of Kingston, it likely arrived in very low numbers in the late 1980s, but was not confirmed breeding until 2005. In the Hamilton area, highest populations occur in Flamborough Township. There is considerable shrubby and early successional habitat there due to the presence of alvars (Baillie 1963, 1967; Curry 2006; King et al. 2009; Lancaster et al. 2004; McCracken 1994; Rayner 1988c; Weir 2008). James (1991) considered it rare to locally uncommon in the south north to Georgian Bay and Kingston.

The second atlas indicated that the range of the Blue-winged Warbler had expanded somewhat to the northeast in areas such as the Oak Ridges Moraine between Orangeville and Trenton and southern portions of Hastings, Lennox, Addington, and Frontenac counties. There were scattered observations in the southern Canadian Shield in Muskoka, Haliburton, and Renfrew. Within southwestern Ontario, there was considerable infilling of its range and it was widely distributed in the Carolinian Forest Region. Its probability of observation increased significantly province-wide and in all atlas regions where it occurred. It was most abundant in the Norfolk Sand Plain, particularly in Norfolk County (Vallender in Cadman et al. 2007).

The continental population of the Blue-winged Warbler started to increase around the 1900s in response to creation of shrublands following forest clearing by European settlers. Forest clearing allowed it to expand its range northeastward. This expansion is still occurring, although it is nearing the limit of suitable habitat at the southern edge of the Boreal Forest Region. The typical scenario is that it increases its population northeastward, but declines in more southerly areas where it was formerly common. Once an area becomes saturated with Blue-winged Warblers, populations tend to decline due to natural succession and habitat loss. Breeding Bird Survey (BBS) data from 1966 to 1993 indicated that the overall population was stable (Confer and Tupper 2000; Gill et al. 2020; Morse 1989). BBS results indicate that it increased at annual rates of 3.48% in Canada and Ontario 1970-2021 and 0.548% 2011-21. All results were of low reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

The brood is divided by the adults. The female takes care of 1-2 fledglings if that is all that is produced and the male cares for any additional young. The parents may move the young out of the male's territory or remain within it for 2-5 days. Fledglings remain motionless in shrubby thickets waiting for the adults to bring food. The 2 family groups remain close to each other for a few days after fledging, often within 100 m (Gill et al. 2020).

In Ohio hardwood clear-cuts, Vitz and Rodewald (2006) mist-netted 118 adults and 209 juveniles during the postfledging period. It was the most abundant species that they captured. Netting was not conducted during the breeding season so it was uncertain if these were local breeding birds or if they had moved in from other areas.

In Missouri, Porneluzi et al. (2014) netted during the postfledging period 2-15 years following a clear-cut in an oak-pine-hickory forest. The Blue-winged Warbler was the seventh most abundant early

successional species captured. Peak numbers occurred 2-3 years after cutting with few present 10 years or more after harvesting.

MIGRATION

The frequent mortalities at communication towers and tall buildings indicate that nocturnal migration occurs.Males usually arrive on the breeding grounds 2-9 days before females. At a Michigan breeding area, males continued to arrive during the entire month of May, but some late arrivals may have moved in from surrounding areas rather than having just returned from migration (Ficken and Ficken 1968c; Gill et al. 2020; Murray and Gill 1976). In southern Ontario, spring migrants arrive mostly in the last week of April or first week of May. Birds continue to move through until the end of May (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008).

Throughout its range, the Blue-winged Warbler may begin autumn migration in late July (Gill et al. 2020). In southern Ontario, autumn migration normally extends from late August until mid-September. A few birds remain until late September or rarely into November (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008).

During migration, the Blue-winged Warbler prefers early successional habitat and open forests, similar to the breeding season, but it may also be found in denser forests. In Illinois, spring migrants were most abundant in forest-edge habitat, but also occurred in mature upland and lowland forests. In Texas, migrants occur in scrub forests, thorn forests, and lowland riparian forests. During spring migration in Pennsylvania, significantly more detections per 100 m of transect occurred in shrub habitat (0.42) than in forest (0.02). The capture rate per 1,000 hours of netting was significantly higher in shrubs (8.6) than in forest (0.6); 146 Blue-winged Warblers were captured in shrubs compared with 8 in forests. During spring migration in Ohio, there was no difference in its abundance in upland and riparian forests. During spring migration in Minnesota and Wisconsin, it was significantly more abundant in upland forests than in floodplain forests (Gill et al. 2020; Graber et al. 1983; Kirsch et al. 2013; Rodewald and Matthews 2005; Smith and Hatch 2008).

Prolonged winter weather during spring migration may kill some migrants. The Blue-winged Warbler is frequently killed by striking buildings and communication towers during migration. This rarely occurs within the breeding range, but is more prevalent in the south (Gill et al. 2020).

In Pennsylvania, an outbreak of the viburnum leaf beetle resulted in almost complete mortality of southern arrowwood, formerly the third most abundant shrub species. Prior to the infestation, spring migrating Blue-winged Warblers gained significant mass after sunrise, but no weight gains occurred after the infestation (Smith and Hatch 2017).

The Blue-winged Warbler is a rare migrant in Ontario (James 1991), but its numbers are increasing. At the Long Point Bird Observatory, 5 were banded 1960-69, 13 in 1970-79, and 81 in 1980-89. The ratios of Blue-winged Warblers to Golden-winged Warblers during these periods were 0.38:1, 0.71:1, and 2.0:1, respectively (McCracken 1994). In Niagara Region, the number counted during spring migration increased significantly from 1966-75 to 1977-2006 (Black and Roy 2010). At Presqu'ile, there were only 5 records of the Blue-winged Warbler from 1960 to 1979. Numbers increased dramatically during spring migration in 1983 after which it occurred regularly, but in low numbers (LaForest 1993). In the Kingston area, an average of 2.1 birds were observed in spring 1971-80 compared with 5.5 1981-90, 7.4 1991-2000, and 8.3 2001-08 (Weir 2008).

Black-and-white Warbler

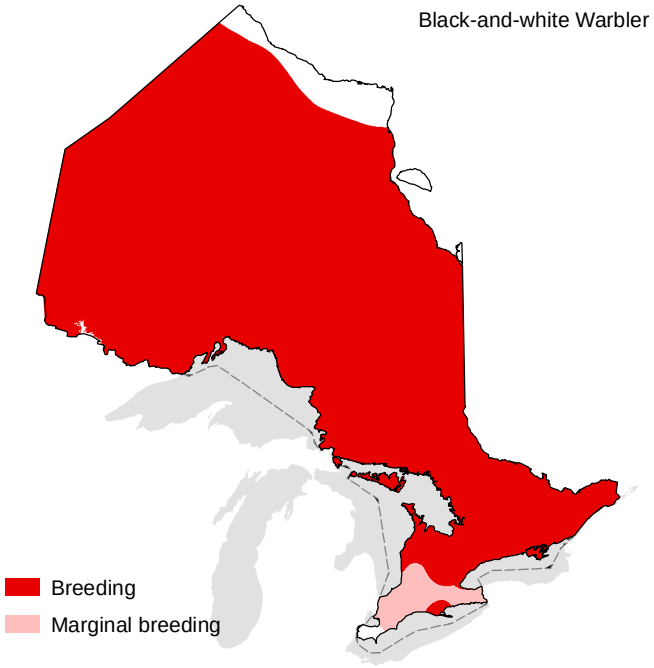
Mniotilta varia

BREEDING SEASON

Habitat Requirements

In Ontario, the Black-and-white Warbler has nested in mixed (37.0% of nests), coniferous (7.4%), deciduous (3.7%), and unspecified (44.4%) woods; in a black spruce bog (3.7%); and in an alder swamp (3.7%). Eleven nests were at edges of woodlands or clearings, or were near roads or fencerows. Eight were in wet habitats with the remainder in dry or unspecified habitats (Peck and James 1987). James (1984b) concluded that it was tolerant of a wide range of forest conditions. It nests mostly in mixed or deciduous forests and less frequently in coniferous forests. It requires a dense understorey of deciduous shrubs in open forests, edges, or openings. It shows no preference for tree height, and may nest in wet riparian forests and swamps as well as dry upland forests.

In the Hudson Bay Lowland, the Black-and-white Warbler nested in lichen-rich spruce forests along streams (Wilson and McRae 1993).



In the northwest portion of the Boreal Forest Region, it was most abundant in mixed and deciduous scrub. It was much less abundant in deciduous forest and present in low density in mixed forest and coniferous forest with a woody understorey. It was absent in coniferous scrub, coniferous forest without an understorey, and in heath and tundra habitats (McLaren and McLaren 1981). In the Boreal Forest Region of Ontario, it was associated with immature to younger hardwoods that were more open in character, and with high disturbance and edge levels (Rempel 2007; Rempel et al. 2007). Welsh (1993) considered it a mid-successional species. It was most abundant in 12-year-old clear-cuts, occurred in cuts as young as 5 years and declined in abundance from 12 to 33 years. It also occurred in stands 150-200 years old, but at lower density than in 12-year-old stands. Near Hearst, it was much more abundant in mixed stands where it occurred in clear-cuts 3-24 years old (the entire range of ages of stands sampled) and in an uncut upland stand. There was little difference in its abundance among stands from 5 years of age to unharvested mixed stands. In lowland conifers, it was present in 9- and 24-year-old clear-cuts but absent in other-aged clear-cuts and in uncut stands (Welsh and Fillman 1980). Near White River in jack pine stands, it was most abundant in stands that had been cut 8-10 years previously. It was not significantly more abundant in this age class and was not an indicator species for any age class of forest (Venier and Pearce 2005). In the Clay Belt, it was most abundant in trembling aspen and balsam poplar stands, but was also common in white cedar–tamarack stands, uncommon in balsam fir–white spruce–jack pine stands, and least abundant in black spruce stands. It occurred mostly in wet stands rich in nutrients, but it was present in stands that represented the full spectrum of nutrient levels and moisture regime (Welsh and Lougheed 1996).

In the Great Lakes–St. Lawrence Forest Region in the Canadian Shield, the Black-and-white Warbler regularly nests in mature and old-growth white pine stands. It is more abundant in old-growth than mature stands. Its abundance in white pine stands was significantly associated with the basal area (BA) of deciduous species and age of the stand (Kirk et al. 2012). Near Gogama, it rarely nested in jack pine stands. One pair nested in a uniform stand of young jack pines 8-10 m tall where there was dense ground cover of blueberries and sheep laurel with a sparse growth of taller deciduous shrubs. It was usually associated with the deciduous component of mixed forests, where it was uncommon. It was found mostly in stands approximately 20 years old or at edges of taller woods where tall shrubs covered most of the ground below or among taller deciduous trees (James and Peck 1995a). In Quetico Park, it occurred only in early successional stands resulting from fire 1-23 years previously. It was not observed in stands 67-370 years old (Apfelbaum and Haney 1995).

Near Parry Sound, it nested in open jack pine stands mixed with deciduous species, reaching its highest density in stands 10-15 m tall (James 1979a). In Algonquin Park, Martin (1960) recorded it in black spruce, black spruce–white cedar, white birch–poplar, balsam fir–spruce, white birch–poplar–balsam fir–spruce, and hemlock stands. He did not observe it in bogs or immature white pine stands. In white birch–poplar stands, it was active from the ground to a height of 9 m which was just below the top of the canopy. In black spruce–white cedar, its activities extended from the ground to 11.9 m, which was just below the top of the cedars but about 10 m below the top of the spruce canopy. In balsam fir–spruce stands, it was active from the ground to the tree tops. In hemlock stands, it was active from the ground to a height of 6 m, about 3 m below the bottom of the canopy. It was not considered characteristic of any habitat type. In white pine stands in Algonquin Park, Kingsley and Nol (1999) found it in all age classes including 2-9-year-old cuts, 10-16-year-old cuts, and uncut stands. Also in Algonquin Park, it strongly favoured mature forests over early successional habitats and the presence of large trees was critical (Tozer 2012). Near Sault Ste. Marie, it was most abundant in areas of advanced regeneration of shrubs in gaps created by selection thinning (Holmes and Pitt 2007). In the southern portion of the Shield, it was associated with high tree density (the highest of all species studied), a high amount of understorey woody vegetation, and moderate to high canopy volumes. Habitat that it occupied was typical of areas that had been cleared and allowed to regenerate to an early successional stage. It was considered a species of deciduous forest, but was associated with high conifer composition (Clark et al. 1983).

In the off-Shield portion of the Great Lakes–St. Lawrence Forest Region in Durham Region, Speirs and Orenstein (1975) considered the Black-and-white Warbler associated with white cedar. They documented it in wet, open stands with heavy growths of raspberries, in a black spruce bog with an adjacent red maple–poplar swamp, in a mature white cedar–elm swamp, and an open riparian stand of white cedar, balsam fir, and spruce. Near Kingston, McLeish and Robertson (1997) concluded that upland white cedar stands could provide high quality habitat for it.

In Elgin County in the Carolinian Forest Region, the Black-and-white Warbler nested at the bottom of a steep ravine forested with hemlock and sugar maple (Lancaster et al. 2009). In Brant County, it nested in an upland trembling aspen–ash forest in an area dominated by aspens (personal observation).

At the landscape level, the Black-and-white Warbler preferred areas that were 59-75% forested in North Dakota; no areas had greater than 75% forest cover (Cunningham and Johnson 2019).

In the Yukon, the Black-and-white Warbler nests most frequently in riparian balsam poplar forests containing white spruce as a secondary species. Suitable stands have abundant tall shrubs and forest floor litter. It also occurs in mixed and structurally complex habitats at edges of white spruce forests and in deciduous forests dominated by tall alders (Sinclair et al. 2003). In British Columbia, breeding habitat consists mainly of deciduous thickets in wet areas or along margins of water. Along rivers, it preferred alder-willow patches in spruce or spruce–trembling aspen stands in very moist areas. It frequently inhabited alder and willow patches in moist, middle-aged trembling aspen stands with white birch present. It nests in a variety of forest types including mixed stands of white spruce, trembling aspen, balsam poplar, and white birch; pure trembling aspen and balsam poplar stands; and in black spruce bogs. It appears to prefer riparian areas along lakes, beaver ponds,

streams, and bogs appear (Campbell et al. 2001). In Alberta, it preferred dense aspen and other deciduous stands where it occurred in the lower strata. In northcentral Alberta, breeding habitat included fragmented and contiguous mixed-wood stands dominated by trembling aspen, with high densities of willow in the understorey (Schieck et al. 1995). In Saskatchewan, the Black-and-white Warbler was associated mostly with deciduous or mixed forests, but also occurred in black spruce and species-poor jack pine stands. It occurred around the midpoint on the moisture regime and stand nutrient level (Kirk et al. 1996). In Quebec, it breeds in stands of varying ages but prefers those growing in moist areas. It also nests in alder and willow thickets. It is most frequent in deciduous and mixed stands and decreases with increasing conifers. In the Boreal Forest Region of Quebec, it mostly occurs in stands dominated by trembling aspen and white birch. It often breeds among saplings at edges of damp wooded areas, regenerating clear-cuts, and roadsides. It also nests in balsam fir–red maple, white birch–gray birch, and sugar maple–yellow birch stands (Villard in Gauthier and Aubry 1996). In New Brunswick and Nova Scotia, it is a common breeder in northern hardwood stands, but avoids spruce plantations and coniferous forests. In unharvested hardwood stands, it was one of the dominant species (Freedman and Johnson 1999; Freedman et al. 1981). In Newfoundland, the Black-and-white Warbler regularly nests in balsam fir stands, where it is a habitat generalist (Thompson et al. 1999; Whitaker and Montevecchi 1997, 1999). In the Boreal Forest Region, it is one of the dominant species in deciduous forests, particularly in aspen and birch stands. It also occurs in mixed stands and in lower densities in stands dominated by balsam fir, white pine, red pine, and hemlock-pine. Within hemlock-pine associations, it is restricted to areas that support deciduous trees (Erskine 1977).

Considerable information is available on the Black-and-white Warbler's habitat requirements and preferences in the United States. In Illinois, the only breeding populations were in upland forests although it had been reported breeding in scrub forests, on sand dunes, and in bottomland forests (Graber et al. 1983). In Mississippi, a pair nested in the corner of a regenerating clear-cut bordered by a pine-oak forest. The birds confined their activity to an area 25-50 m from the forest in thick but patchy growth 1-3-m tall of oaks, pines, sweetgum, red maple, sassafras, and blackberries (Chandler et al. 1994b). In Vermont, territories included both forested habitat and clear-cuts, with 1 territory being predominantly in a clear-cut (Lent and Capen 1995). In Vermont, mean habitat values were 44.1% ground cover, 11.1% ground cover by slash, 70.5% canopy closure, 15.5 m canopy height, 9.9 m canopy depth, 12.8 m^2 BA of deciduous trees, 6.1 m^2 BA of coniferous trees, 10.5 cm diameter at breast height (DBH) for deciduous trees, and 8.5 cm DBH for coniferous trees. It was associated with intermediate canopy closure and dense understorey. It was associated with pole-sized hardwoods with canopy closure of 55-80%, high understorey density, and a mean DBH of 8-15 cm (Thompson and Capen 1988). In Maine and New Hampshire, it was most abundant in white pine stands (which included numerous small deciduous trees), followed by stands dominated by hemlock, balsam fir, northern hardwoods, swamp hardwoods, aspen, spruce-fir, and white birch. Its abundance was positively correlated with canopy closure, the number of coniferous trees larger than 10 cm DBH, and the total foliage volume of deciduous trees 2-10 cm DBH. It was negatively correlated with total foliage volume of deciduous trees larger than 10 cm DBH (DeGraaf et al. 1998). Collins (1983a) compared the habitat of Black-and-white Warblers nesting in Minnesota and Maine. In Minnesota, it occupied habitat characterized by 70% or more ground cover and moderate canopy cover. In

Maine, its habitat was characterized by high percent canopy cover, variable coniferous cover, and many trees in the smaller size classes. Birds may have been selecting the most optimal habitat at each site. In Wisconsin and New Jersey, it is an uncommon to common breeder in pine and oak barrens. In New Jersey barrens, it is most common in pitch pine swamps and also in upland oak and pine forests with a dense understorey of oak (Brush 1987; Mossman et al. 1991). Brooks (1940) reported that it was a characteristic breeding species in American chestnut thickets and other shrubby growth containing scattered dead chestnuts in the Allegheny Mountains. In Minnesota, it occurred in aspen-birch stands or edges of deciduous forests where it was associated with increasing numbers of larger trees, more medium-sized deciduous trees, fewer large conifers, and less ground cover. Its habitat was characterized as second growth and forest edges with a high percentage of shrub coverage. It was a shrub–forest edge species (Collins et al. 1982). In clear-cuts in spruce–balsam fir forests in Maine, the Black-and-white Warbler was absent in young cuts 1-2 years old and in the oldest seral stage which consisted of a dense coniferous overstorey with an open forest floor. It was a dominant species in the third seral stage. This stage was characterized by deciduous regeneration taller than 2 m with a well-developed but slower growing coniferous regeneration layer. This occurred 7-12 years after cutting once regeneration had begun to shade out the raspberries. It was less common in the earlier stage of regeneration, which consisted of dense raspberries and regenerating hardwoods, and also in the later stage which was characterized by increased density of hardwood regeneration taller than 4.5 m, trees with a DBH of 10-15 cm, and reduced slash and raspberries (Titterington et al. 1979). In Pennsylvania, it nested on power-line rights-of-way through oak forests, but did not nest within the forest. It nested among oaks and red maples bordering the forest. It was adapted to early successional habitat and was one of the more common breeding species on the right-of-way (Yahner et al. 2002). In Wisconsin, the Black-and-white Warbler is uncommon in northern mesic forests where it occurs in pole-size and saw-timber-size deciduous forests as well as mixed and coniferous forests. On forested islands in Wisconsin, it was most abundant in white birch–red oak, silver maple–yellow birch, white birch–yellow birch–white cedar, and aspen stands. It was rare in hemlock–yellow birch stands and absent in pine stands. Its density increased with increasing density of woody understorey, particularly deciduous species. In Wisconsin, it nests among dense saplings in clear-cuts where there are nearby mature conifers (Beals 1960; Hoffman 1989a; Mossman and Hoffman 1989). In Maryland, it occurs in young, medium-aged, and mature deciduous and mixed forests, but is most abundant in pole-sized stands. It prefers closed-canopy forests, but will tolerate openings. The BA of inhabited stands varies from low to high, but a well-developed woody understorey is present (Bushman and Therres 1988). In North Dakota, it is restricted primarily to drier upland forests and reaches its highest density in mature trembling aspen stands. It is characteristic of semi-open upland forests comprised of immature and second-growth trees (Faanes and Andrew 1983). In Texas pine and pine-hardwood forests, its abundance was positively correlated with vegetation height; number of tree and shrub species; percent canopy closure; foliage density at 3 m, 7-10 m, and above 20 m; percent coverage by hardwoods 5-6 m and larger than 32 cm DBH; and number of tree stems larger than 32 cm DBH. It was negatively correlated with percent coverage by pines 5-16 cm DBH. It was in a guild that inhabited mature pine-hardwood forests. It was associated predominantly with hardwoods; the other species in the guild were associated mostly with pines (Conner et al. 1983). In the northeastern United States, it nests in red maple swamps, oak-pine forests, early successional and mature upland hardwoods,

poplar-birch forests, pine forests, upland spruce–balsam fir forests, lowland conifers (black spruce, tamarack, and white cedar), mixed forests (where it may be associated with yellow birch and sugar maple), and in small openings and forest edges (Back 1979; Capen 1979; Chapman 1907; Crawford and Titterington 1979; Dawson 1979; Golet et al. 2001; Harrison 1984; Morse 1989; Noon et al. 1979; Rich et al. 1994; Taylor and Taylor 1979; Temple et al. 1979). Niemi and Pfannmuller (1979) considered it to be in a guild of species in the northeastern United States that was abundant in disturbed shrub habitats and mature upland deciduous forests; very common in aspen regeneration, mature upland conifers, and alders; and uncommon in young plantations, recent clear-cuts, and mature lowland conifers. Kricher (2020) stated that it breeds in mature second-growth deciduous and mixed forests, with a strong preference for deciduous stands. It may have a preference for swampy forests. It does not breed as commonly in balsam fir and spruce stands, but may be increasing in these forest types in the Boreal Forest Region. In 1 study, it showed a strong preference for mature forests over early successional habitat. In the northeastern and northcentral United States, it selected forests with more tall trees and more open understorey than in its more northern breeding range. In Pennsylvania, more territories were present in mature than successional trembling aspen and oak forests, but its abundance was correlated with the density of understorey trees and shrubs, indicative of successional habitats. It occurred predominantly in the lower midstorey, but was present in all strata, including the ground.

The Black-and-white Warbler may nest in forests of all age classes, but tends to prefer younger stands and sites dominated by early successional species such as aspen. It occasionally nests in shrub thickets and cuts and burns dominated by deciduous saplings. In the Boreal Forest Region of Ontario, the amount of forest older than 80 years represented 36% of variation in its abundance at the 50-ha scale and 55% of variation at the 5,000-ha scale. It was negatively correlated with older forests (Rempel 2007). In forests dominated by black spruce, balsam fir, and aspen near Manitouwadge, it was most abundant in stands 1-21 years old. It was present in intermediate-aged stands (24-36 years) and mature stands (60-223 years) but at lower densities of 91.3% and 45.7% of those in young stands, respectively (Venier et al. 2009). In Saskatchewan, it was associated mostly with young stands, appearing in stands as young as 15-20 years old (Kirk et al. 1996). In Alberta trembling aspen forests, it was significantly more abundant in young than mature or old-growth stands (Schieck et al. 1995). In hemlock–white pine–hardwood stands in Pennsylvania, it occurred in 9.1% of old-growth forests, 42.8% of forests statewide, and 50.1% of forests in the Appalachian Plateau. It was significantly negatively correlated with old-growth forest (Haney 1999). In the northern United States, it was detected more frequently in disturbed and successional habitats in upland hardwoods than in mature, undisturbed habitats. In northeastern aspen-birch stands and pine forests, it is absent in the seedling and early sapling stages and first occurs in pole-sized stands. In mixed-wood forests, it was associated with late seral stages rather than mature stands (Back 1979; Capen 1979; Noon et al. 1979; Temple et al. 1979). In New York, the Black-and-white Warbler was absent in 1979-80 in a forest where it had been present 30 years previously. Litwin and Smith (1992) attributed its local extirpation to natural succession. Between surveys, the forest gaps filled in and the dense, extensive woody understorey became open with the exception of occasional patches of shrubs. In Newfoundland balsam fir stands, it was more abundant in uncut forests than those that had been cut 40 or 60 years previously. Mature stands had a lower density of small trees and more

shrubs than 40-year-old stands, but were not significantly different from 60-year-old stands for these parameters (Thompson et al. 1999). In a Connecticut woodlot over a 59-year period, there was a progressive shift to larger trees, a sparser shrub layer, and a less diverse tree canopy dominated more by oaks and maples. It declined in the woodlot but populations remained stable in the state. The decline was probably due to maturation of the forest and decline of the shrub layer (Buchanan et al. 2016).

The Black-and-white Warbler is an area-sensitive species in Ontario and most other locations. Its degree of sensitivity varies geographically and with the amount of forest cover in the local landscape. In southern Ontario, its abundance was correlated with the amount of forest 100 m or more from edge, woodland size, amount of forest cover within 2 km, and regional forest cover. The only significant relationship was the amount of forest cover within 2 km (Austen et al. 2001). James (1984b) concluded that the Black-and-white Warbler required in excess of 100 ha of forest or continuous forest to maintain a viable population in Ontario. In the Ottawa area, it occurred in 36% of 45 forests ranging in size from 2.8 to 57.5 ha (median 20.1 ha). A further study was done in 50 mature deciduous woodlots 3.0-129.8 ha (median 11.8 ha). There were local extinctions from year to year within individual woodlots. Its abundance was positively correlated with forest size and negatively correlated with distance to the nearest forest occupied by the species (Villard et al. 1995). That the degree of area sensitivity exhibited by the Black-and-white Warbler varies with distance to the nearest occupied forest and the amount of forest cover within 2 km is reflected in its distribution in southern Ontario. In Niagara Region, southwest of London, and the agricultural landscapes of southern Huron and Perth counties where woodlots are smaller and scattered, there are few Black-and-white Warblers. North of a line roughly from Goderich to the northern extent of Toronto, it is present in almost every atlas square (McLaren in Cadman et al. 2007). Based on information collected predominantly in Maryland, Robbins (1979) suggested that 300 ha was the minimum forest size capable of sustaining a viable population. Further work completed by Robbins et al. (1989) found that its abundance was significantly correlated with forest size, the amount of forest cover within 2 km, mean canopy height, and number of trees larger than 3 cm DBH, but it was negatively correlated with canopy cover. Its highest probability of observation occurred in forests larger than 3,000 ha, the probability was reduced to 50% at 220 ha, and the 3 smallest woodlands it was observed in at least twice were 493, 208, and 208 ha. The authors concluded that it required 220 ha of forest to maintain a viable population. Bushman and Therres (1988) reported that it occurred only in forests larger than 4,000 ha in western Maryland. Other Maryland studies found it in woodlots as small as 14 ha and suggested a minimum forest size requirement of 70 ha. It has been reported in woodlots as small as 7 ha in New Jersey. In Maryland, its abundance was positively correlated with forest size and negatively correlated with woodlot isolation and the total BA of trees (Lynch 1987). In aspen woodlands in North Dakota, Grant and Berkey (1999) considered it area sensitive. Its abundance was correlated with forest size and the number of oak trees. Its probabilities of observation were 17% at 10 ha, 39% at 100 ha, and 60% at 1,000 ha. It was not observed in 1.0-ha woodlots. In red maple swamps in Rhode Island, the Black-and-white Warbler was equally abundant in forests smaller than 1 ha, 1-5 ha, 6-10 ha, and larger than 10 ha. These swamps were surrounded by upland forests and may not have been good indicators of its area sensitivity (Golet et al. 2001). In Wisconsin, Beals (1960) studied the avifauna on islands of differing sizes. He identified species that were restricted to larger

islands, but did not include the Black-and-white Warbler on this list. In Saskatchewan, it was randomly distributed within fragmented landscapes. There were no significant relationships between its abundance and forest size or amount of forest cover within 5 km (Hobson and Bayne 2000). In Alberta over a 2-year period, it was found in 4 forest fragments that were 2, 50, 107, and 140 ha. Four unoccupied fragments were 4, 6, 9, and 32 ha. All woodlots were dominated by trembling aspen older than 80 years, and the landscape was approximately 30% forested with the remainder being pasture or cropland (Sodhi and Paszkowski 1997).

Golet et al. (2001) and Freemark and Collins (1992) considered the Black-and-white Warbler a forest-interior species, but did not provide any supporting evidence. In New Jersey, Rich et al. (1994) found that it was consistently more abundant in forest interior than forest edge. Most other studies that examined its distribution in relation to edge found that it is more abundant near edge than in forest interior. In Tennessee, territories were aligned parallel to a hydro corridor through forest. Highest density occurred 20 m from forest edge, declined to 0 at 120 m from edge, increased at 160 m, declined to almost 0 at 200 m, and increased again around 240 m from edge. Core areas of territories adjacent to the corridor appeared to be shifted toward the edge. The density of territories near the edge was not significantly greater than in forest interior (Kroodsma 1984). In Newfoundland, it occurred in riparian balsam fir stands adjacent to lakes and rivers but was absent in forest interior (Whitaker and Montevecchi 1997, 1999). Many studies classified it as an edge species. It is likely that it shows no strong preference for edge or forest interior but selects areas throughout the forest that have the required density of shrubs and saplings in the understorey.

In Ontario, 73.9% of nests were on the ground and the remainder were 0.2-1.8 m from the ground. Nests on the ground were at the base of a tree or stump, commonly among roots (65.5% of ground nests); beside or under logs (13.8%); under shrubs, ferns, and overhead tree branches (13.8%); under dead branches and leaves (3.4%); and in a mossy hummock (3.4%). Elevated nests were in stump cavities, one of which had been excavated by a Pileated Woodpecker (41.7% of elevated nests); in upturned roots (33.3%); in a rock crevice (8.3%); between 3 adjacent white cedar trunks (8.3%); and in a mossy bank (8.3%). Nests were concealed by overhanging grasses or branches, beneath shrubs, or under roofs of dead deciduous leaves (Peck and James 1987). In Algonquin Park, 1 nest was 1.5 m from the ground in an old Pileated Woodpecker feeding excavation (Tozer 2012).

Most nests reported throughout the Black-and-white Warbler's range were on the ground, often at the base of a tree or shrub. It often selects hillsides, ravines, and swampy areas for the nest site. Nests may be under logs, among tree roots, or sheltered by overhanging branches or stones. Ground nests are typically in a small depression among dead leaves that are occasionally arranged to form a partial canopy. Elevated nests are most frequently on the top of stumps in leaf-filled cavities; occasionally nests may be among roots of upturned trees. An early report from Louisiana that nests are usually in a small hole in a tree was considered questionable. Given that a similar nest has been found in Algonquin Park, this early record cannot be discounted, although nests in tree cavities are likely rare. In addition, 1 nest was found in the cavity of a pine tree created when it was struck by lightning. An unusual nest was in the drain of a house (Byers 1950; Chapman 1907; Kricher 2020; Mousley 1916a; Sinclair et al. 2003; Smith 1934; Tyler in Bent 1953).

The Black-and-white Warbler is aggressively territorial, attacking conspecifics as well as other warblers and species that wander into its territory. Territoriality persists late into the summer, long after other warbler species have ceased territorial defence. Intrusions into other territories are rare. Near Quebec City, there was no evidence of clumping of territories. It appeared to be strongly associated with habitat features within its territory, and these may have determined occupancy patterns. In Algonquin Park, the average size of territories was 0.52 ha (range 0.02-2.8 ha). Quebec territories averaged 0.43 ha (range 0.35-0.63 ha). Territories in Alberta forest fragments ranged from 0.9 to 6.6 ha (Bourque and Desrocher 2006; Kricher 2020; Martin 1960; Morse 1989; Villard in Gauthier and Aubry 1996).

No information is available on natal philopatry, but it is probably very low. Some adults return to the same area to breed in subsequent years, but the percentage of birds that do so is unknown (Kricher 2020).

Limiting Factors

Eggs have been reported in Ontario nests from late May to late July, but most are present from the first to third weeks of June (Peck and James 1998a). In Algonquin Park, nests are under construction from mid- to late May, eggs are present from late May to late July but mainly in June, nestlings occur from early June to late July, and dependent fledglings have been observed from late June to mid-August (Tozer 2012).

There does not appear to be any information on how long it takes to build a nest or how soon nest construction is initiated after the females arrive. At 1 nest, the first egg was laid 2 days after the nest was completed. One egg is laid per day. One 5-egg clutch took 6 days to lay, with a gap between the second and third eggs. Incubation begins with the laying of the penultimate or last egg. The incubation period is typically 10-12 days but 1 nest containing 8 cowbird eggs was incubated for 20 days. The nestling period is 8-12 days (Byers 1950; Harrison 1984; Kricher 2020; Smith 1934; Tyler in Bent 1953).

A single brood is raised annually. Peck and James (1987) indicated that Ontario egg dates suggested the possibility of second broods, but none have been documented. It is likely that renesting occurs if a clutch is lost, but this has not been confirmed. In Vermont, a male sang frequently following the loss of a brood suggesting a second nest, but no evidence of it was found. In Ontario, clutches of 3-6 eggs have been reported (average 4.18 eggs). Most clutches contained 4 or 5 eggs and only one 6-egg clutch was reported. Throughout its range, the Black-and-white Warbler typically lays 4 or 5 eggs; 6-egg clutches are rare (Chapman 1907; Harrison 1984; Kricher 2020; Mousley 1916a; Peck and James 1998a; Smith 1934; Tyler in Bent 1953).

The age at first breeding is unknown (Kricher 2020), but is probably 1 year. No information is available on the mating system of the Black-and-white Warbler, but it is likely monogamous.

The Black-and-white Warbler regularly forages on tree trunks and large limbs, unlike any other warbler species. It also gleans adeptly in foliage. In addition to trunks, it frequently forages on the inner surfaces of large limbs and on foliage in typical warbler fashion, occasionally searching the tips of vegetation. One study determined that it fed 45% of the time on dead limbs, 25% on the large inner part of limbs, 15% on trunks, 8% on the tips of vegetation, and 7% on the outer part of limbs.

In Parry Sound District, it foraged mostly in early successional hardwoods during all seasons and primarily in white birch during spring migration. Foraging height was 5-12.5 m during the breeding season. Birds rarely hovered while foraging. It occasionally pursues insects on the wing and feeds on insects attracted to Yellow-bellied Sapsucker sap wells. During spring migration at Point Pelee, 50% of foraging was on trunks, 30% on branches, and 20% on saplings. During autumn migration in Ontario, it foraged 3-13 m from the ground, but concentrated its foraging at 3-5 m and 10 m. Birds spent 38% of their foraging time on inner branches, 29% on saplings, 25% on trunks, and 8% on outer branches. Although it tends to feed at mid-heights, it may occur anywhere from the forest floor to the canopy (Kricher 2020; Mills 2007; Morse 1989; Smith 1934; Tyler in Bent 1953).

Nestlings at 1 nest were fed entirely small green caterpillars that were cut into half lengths. Nestlings have been fed white grubs and white moths. Adults feed mostly on insects, but also eat spiders, harvestmen, and their egg sacs. Lepidopterans are favoured foods, especially caterpillars, and the Black-and-white Warbler eats gypsy moth larvae. Caterpillars may constitute a significant portion of the diet during spring migration. Beetles are important prey, including click beetles, long-horned beetles, weevils, leaf beetles, and willow flea beetles. Other insects it eats include ants, moths, flies, bugs, some hymenopterans, jumping plant lice, hackberry emperor butterfly caterpillars, hackberry gall psyllids, plant lice, scale insects, tent and forest tent caterpillars, and leafhoppers. A captive bird ate 80% of its body weight daily and consumed insects only. These included moths, leafhoppers, treehoppers, stink bugs, and crickets and grasshoppers as long as 2.5 cm. Many potential food items were refused, including dog food, various types of berries, 5-cm long grasshoppers, full-grown crickets, small ants, beetles, and mites. Some birds favour ants and beetles; 3 warblers observed during autumn migration in Ontario ate an average of 2.5 beetles each (Chapman 1907; Kricher 2020; Nice and Nice 1950; Smith 1934; Tyler in Bent 1953; Whelan et al. 1989). Near Manitouwadge, density of the Black-and-white Warbler increased with increasing spruce budworm populations in young (1-21 years) and intermediate-aged (24-36 years) mixed stands of black spruce, balsam fir, and aspen (Venier et al. 2009).

The Black-and-white Warbler is commonly parasitized by the Brown-headed Cowbird and accepts its eggs. In Ontario, 9 of 55 nests (16.4%) were parasitized. In Michigan, 4 of 14 nests (28.5%) were parasitized. In New York, 1 of 4 nests (25%) was parasitized. In British Columbia, only 1 nest has been reported, and it was parasitized. In British Columbia, 1 adult fed a single cowbird fledgling. One Michigan nest contained 2 warbler eggs and 8 cowbird eggs that were apparently laid by 4 different females. The warbler eggs were destroyed or punctured and the warbler continued to incubate the cowbird eggs until the nest was depredated. One other nest contained 5 cowbird eggs (Byers 1950; Campbell et al. 2001; Hahn and Hatfield 1995; Harrison 1984; Kricher 2020; Peck and James 1998a; Villard in Gauthier and Aubry 1996).

Forest fragmentation has the potential to affect the Black-and-white Warbler, but it appears to be less vulnerable to this than some other area-sensitive species. It is affected if forest patches become smaller than the size that it requires, if woodlots become increasingly isolated, or if the amount of regional forest cover declines. It exhibits a high frequency of occurrence in Quebec agricultural landscapes, but urban development and intensification of agriculture have caused it to decline near Montreal. Forest fragmentation may increase the incidence of parasitism and

predation, although this has not been specifically studied. In Alberta, there was no significant difference in pairing success of males in small forest fragments and large contiguous forests. The western Boreal Forest Region has a history of natural fragmentation due to fire and insect outbreaks. It may have adapted to cope with some level of habitat disturbance. In an annual roadside survey conducted in Maryland, its density declined by 88% after the road was daylighted. In New Jersey, it was more abundant near unpaved road corridors that were 8 m wide than it was adjacent to paved roads (16-m corridors) and 23-m-wide power-line corridors (Bushman and Therres 1988; Kricher 2020; Morse 1989; Rich et al. 1994; Sodhi and Paszkowski 1997; Villard in Gauthier and Aubry 1996). It is possible that birds do not perceive narrow corridors to represent a gap in the forest, especially along roads where the canopy from either side is very close to being continuous over the road.

Activities that decrease the amount of woody growth in the understorey can be detrimental. Clearing shrubs and saplings from the understorey on cottage lots in central Ontario is likely to cause declines (Bushman and Therres 1988; Clark et al. 1983). In North Carolina, abundance of the Black-and-white Warbler was negatively correlated with the number of houses and buildings within 200 m of the centre of the habitat patch (Lumpkin and Pearson 2013).

The Black-and-white Warbler responds positively to forest harvesting, although large clear-cuts and intensive site preparation temporarily decrease populations. In the Boreal Forest Region of Ontario, clear-cuts tend to be recolonized 5-6 years after cutting. Habitat modelling in this area revealed that existing forest conditions, if they persisted, would result in a decline in the Black-and-white Warbler. Optimum habitat would consist of younger forests, a more fragmented mature forest matrix, and a higher percentage of deciduous forests than current conditions. It was predicted that it would increase if natural disturbances were allowed to occur or if silvicultural guidelines for replanting, tending, or harvest volume objectives were met. If all guides for target species were met, a decline was predicted. In New York, where the harvest system consisted of removing different percentages of the allowable cut, it increased with logging intensity, but a significant response did not occur until the heaviest logging (100% of allowable cut) was implemented. Densities were highest in Pennsylvania where 75% of the forest was clear-cut. In central Massachusetts, it increased as a result of fuelwood harvesting. Forest management activities that retain some canopy but create openings for shrub and sapling growth are tolerated and may be beneficial (Bushman and Therres 1988; Kricher 2020; Rempel et al. 2007; Webb et al. 1977; Welsh 1993; Yahner 1993). Vanderwel et al. (2007, 2009) reviewed several studies that investigated the effects of partial harvest of forests. No change in its abundance was observed when 30%, 50%, or 70% of tree cover was removed. In the Canadian Shield of Ontario, it was significantly less abundant in early successional clear-cuts than in early successional burns and significantly more abundant in mid-successional clear-cuts than in mid-successional burns. It was significantly more abundant in early successional and mid-successional stands than in mature stands (Zimmerling et al. 2017).

In New Jersey and Pennsylvania over a 15-year period, hemlock declined from representing 56% of the total basal area to 46% due to the hemlock woolly adelgid; the amount of deciduous understorey increased. The Black-and-white Warbler increased in response to hemlock decline, probably due to the increased deciduous understorey (Toenies et al. 2018).

Chemicals used in forest management may affect the Black-and-white Warbler. During 1974-75, it exhibited a 58% decline on Breeding Bird Survey (BBS) routes sprayed with pesticides such as fenithrothion and phosphamidan. It increased 39% on unsprayed routes during the same period (Kricher 2020). Hunter and Witham (1985) studied the effects of carbaryl spraying on spruce–balsam fir forests in Maine. This chemical is used to control the spruce budworm and it depresses arthropod abundance. In the first year of the study, spraying was incomplete and patches of forest were left intact. On the day of spraying, the number of Black-and-white Warblers foraging in the sprayed area declined to 0. Numbers remained low until 7 days after spraying, when a gradual recovery began. Numbers of foraging warblers returned to normal 14-19 days after spraying. The use of spruce for foraging decreased by all warbler species postspray and they foraged lower during this period. The change in foraging height was probably because the pesticide would have the greatest impact on arthropod abundance at the top of the trees. Shifting to foraging areas off the territory would increase travel time and energy requirements, but searches for prey would be more profitable. The following year, spraying was more complete and no unsprayed patches remained. There was no decrease in the number of warblers feeding in the sprayed area or any changes in foraging heights. Birds did not have the option of shifting their foraging areas because the distance to an unsprayed area was too great. It is likely that foraging success was less in sprayed areas.

Klaus et al. (2010) examined the effects of fire in woodlands on the Black-and-white Warbler in Georgia. Numbers were depressed 1-2 years after low-intensity fires but recovered after 3-6 years; medium- and high-intensity fires had lesser effects. One to 2 years after fire, its abundance was negatively associated with shrub height. Habitat during this period was characterized by reduced canopy cover and BA.

In Michigan, abundance of the Black-and-white Warbler was not correlated with precipitation or moisture anomalies. It did not appear to be affected by drought (Blake et al. 1992).

In Alberta, Bayne et al. (2008) found similar occupancy rates of the Black-and-white Warbler at noisy compressor stations and quiet well pads. In the western boreal forest, it was 52% more abundant on average along seismic lines and 65% more abundant along pipelines than in adjacent forest interior. There was no difference in its abundance at well pads and in adjacent forest interior (Bayne et al. 2016). Farwell et al. (2019) studied its response to shale gas infrastructure (well pads, access roads, and pipelines) in contiguous forest in West Virginia and did not detect any effects on it.

Price (2004) predicted that the range of the Black-and-white Warbler might contract in southern Ontario if the average summer temperature increased by 2°C.

Status

McIlwraith (1894) stated that only a few Black-and-white Warblers nested in southern Ontario, but provided no information on the remainder of the province. Fleming (1907) noted that it was a rare breeder in Toronto. In Elgin County, it was a common breeder in 1891 but by 2000 it was a very rare and local breeder (Lancaster et al. 2004). Baillie and Harrington (1937) considered it a common breeder from the southern border of the province north to Lake of the Woods and the southern end of James Bay. It was also recorded along the Manitoba-Ontario border between latitudes 53-54°N in 1930. It was found in 2 squares in Niagara Region during the second atlas and was not detected

during the first atlas. Black and Roy (2010) knew of only 3 historical breeding records. James (1984b) reported that it bred throughout Ontario north to Fort Albany, but that it was becoming increasingly scarce near Lake Erie. The first atlas confirmed that its breeding range was similar to that reported by James (1984b), with gaps in its distribution in southwestern Ontario, Niagara Region, and Toronto. James (1991) considered it a common summer resident across the province, north to Big Trout Lake and Attawapiskat, but local to absent in the Carolinian Forest Region. Wilson and McRae (1993) observed that it reached its northern limit in the southern Hudson Bay Lowland. They reported it from Long Ridge and Moosonee, but not from the Hudson Bay coast.

The second atlas revealed that the range of the Black-and-white Warbler covered almost the entire province, except for the extreme northeast and Essex County, and it continued to have a patchy distribution in agricultural areas west and southwest of London and in Niagara Region. Its probability of observation increased significantly province-wide since the first atlas, with significant increases south of the Canadian Shield and in the Boreal Forest Region. There was probably an increase in habitat south of the Shield due to retirement of agricultural land and natural succession to forest. It was most abundant in the eastern Shield portion of the Great Lakes–St. Lawrence Forest Region. It was also common from the eastern shore of Lake Superior to Lake Abitibi and north to Moosonee. Densities were lower in the northwest but moderate densities occurred in the Rainy River area and west of Lake Nipigon (McLaren in Cadman et al. 2007).

BBS data indicate that the Black-and-white Warbler increased at an annual rate of 0.043% in Canada and decreased at an annual rate of 0.763% in Ontario 1970-2021. The trends 2011-21 were an annual increase of 0.00294% in Canada and an annual decrease of 2.51% in Ontario. All results were of medium reliability except that the short-term trend for Canada was highly reliable (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Young cannot fly well when they leave the nest. Initially they scurry and hide near the ground and later occupy low to mid-level branches (3-7.6 m from the ground) near the nest. Fledglings remain within 100 m of the nest and may stay within the territory for 2-3 weeks after learning to fly. The fact that fledglings may remain in the territory may explain why the Black-and-white Warbler defends its territory later into the season than many other warblers. Family groups that nested on a Mississippi clear-cut and a Pennsylvania hydro right-of-way remained in these habitats. In Pennsylvania, family groups remained together into August (Chandler et al. 1994b; Kricher 2020; Smith 1934; Yahner et al. 2002).

Although fledglings may remain within the territory, some move to early successional habitats or to forested areas with dense shrub cover. In Michigan, Akresh et al. (2009) netted birds during the postfledging period in upland and riparian forests. Upland forests were 100-year-old stands of trembling and large-toothed aspen. Riparian forests were similarly aged trembling aspen with an understorey of alder and honeysuckles. Eighty-eight percent of juveniles were caught in riparian habitat.

Streby et al. (2011b) studied postfledging bird assemblages in 2-10-year-old clear-cuts in Minnesota. During the breeding season, 6 adult Black-and-white Warblers were caught in clear-cuts compared with 61 adults and 57 juveniles during the postfledging period. It was the most abundant

forest-breeding species captured, representing 6.8% of all birds caught and 8.9% of forest-breeding birds. Birds actively moved to clear-cuts after fledging occurred. In 4-10-year-old clear-cuts in West Virginia and Virginia, Marshall et al. (2003) captured 26 adults, 16 juveniles, and 4 family groups. It was one of the 6 most common forest-breeding species captured in clear-cuts. In Ohio, Vitz and Rodewald (2006, 2007) captured 23 adults and 34 fledglings in 12 regenerating clear-cuts. Although the clear-cuts were dominated by dense shrub and sapling growth, considerable heterogeneity occurred within them, especially in the lower shrub layer which ranged from fairly open to very dense. More birds were captured in the more open areas of the layer that was less than 1.5 m tall. In more open areas of this layer, 1.5 times more adults and 2.5 times more juveniles were captured than in denser lower vegetation. In Missouri, Porneluzi et al. (2014) netted during the postfledging season 2-15 years after an oak-pine-hickory forest was clear-cut. Including early successional breeders, the Black-and-white Warbler was fourth in abundance of birds captured. Its numbers exhibited a significant curvilinear trend that increased gradually to a peak 6-9 years after harvesting followed by a decline.

MIGRATION

The Black-and-white Warbler is a nocturnal migrant. During the day, it often occurs in mixed foraging flocks (Kricher 2020). It is one of the first warblers to arrive. Due to its habit of foraging on tree trunks and limbs, it does not need to wait until leaves emerge before it can migrate (Tozer 2012; Villard in Gauthier and Aubry 1996). Males migrate northward significantly earlier than females. In Massachusetts, males arrived an average of 5.8 days before females, and females arrived 5-7 days later than males in Alberta (Bauböck et al. 2012; Kricher 2020; Tyler in Bent 1953). At Prince Edward Point, the mean date of spring arrival was 13.1 May for males and 19.0 May for females, a significant difference of 5.9 days. Males occurred from 6 to 31 May and females from 4 May to 6 June. The Black-and-white Warbler had the longest interval between arrival of the sexes of all birds studied. Few were recaptured, indicating that most did not stay more than 1 or 2 days (Francis and Cooke 1986). At Long Point, the mean capture date for yearling males was 8.8 May compared with 5.7 May for older males, a significant difference of 3.1 days. The mean arrival date for males of unknown age was 9.8 May; there were insufficient data for females (Stewart et al. 2002). In Maine, the mean stopover time of spring migrants was 5.7 days (range 1-11 days). In spring, 7.9% of females were recaptured but no males were recaptured, suggesting that they may not stay over as long (Morris et al. 1994). In Louisiana, the quality of winter habitat affected spring migration timing. Males arriving from dry habitats arrived later, but were not in worse condition than those that wintered in mesic habitat (Paxton and Moore 2015).

The Black-and-white Warbler arrives in southern Ontario in late April or early May and is usually present until late May. Birds may arrive as early as the last week of March and some remain into early June. The peak flight is around mid-May coincident with the arrival of the females (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Keast 1980; Mills 1981; Tozer 2012; Weir 2008).

Autumn migration in Ontario may start in late July, but most migrants pass through in August. The Black-and-white Warbler is one of the earliest warblers to leave Algonquin Park. It may be seen there in mixed-species flocks from late July through August. In the south, migration is underway by mid-August and the largest numbers move through between late August and late September, with

some lingering into early October or rarely as late as early December (Curry 2006; Fleming 1907; LaForest 1993; Lancaster et al. 2004; Mills 1981; Tozer 2012; Weir 2008). At a banding station in Maine, 15.25% of birds were recaptured. The average stopover period was 4.1 days (range 1-17 days; Morris et al. 1994).

During migration, the Black-and-white Warbler occurs mostly in forested habitat, but may occur in lower numbers in other habitats such as pasture fields, treed lawns, and orchards. In Niagara Region, it highly favoured old apple orchards during spring migration where the rough bark of the trees provided a good foraging substrate. During spring and autumn migration in Illinois, highest densities occurred in bottomland forests and at forest edges, but it also occurred in upland forests, pine stands, and pastures (Campbell et al. 2001; Chapman 1907; Graber et al. 1983; Kricher 2020; Sheppard et al. 1936). During spring migration in Pennsylvania, it was significantly more abundant in shrub habitat than forest. There was no significant difference in invertebrate biomass in forests and shrubs except early in the migration period when biomass was higher in shrubs (Smith and Hatch 2008). During spring migration in Ohio, it was significantly more abundant in upland forests than riparian forests. Upland forests were mature, closed-canopy stands of oaks, hickory, and sugar maple with a patchy distribution of shrubs and saplings. Riparian stands were dominated by Manitoba maple, silver maple, cottonwood, and sycamore (Rodewald and Matthews 2004). During spring migration in Wisconsin and Minnesota, it was equally abundant in floodplain and upland forests (Kirsch et al. 2013). Parnell (1969) examined its habitat use during spring migration in North Carolina. It was not observed in dry thickets and occurred mostly in forested habitat, particularly deciduous forests, although it also used wet thickets. Its adaptation to foraging on boles and large limbs that are present in all forest types makes it less restricted by forest type. Of all observations of this warbler, 54.3% were in the canopy, 45.7% were in low trees, and 0% were in shrubs or on the ground. In the canopy, 6.2% of observations were at the top, 6.2% in the inner crown, 2.5% in the lower crown, and 39.4% on the bole. In low trees, 2.5% of observations were at the top of the crown, 7.4% in the inner crown, 6.2% in the lower crown, and 29.6% on the bole. It was highly selective, being recorded 69% of the time on the bole or larger limbs. It was observed at heights of 3 m to more than 15 m. Mean height of observations was 8.5 m for birds that were singing and 6-7 m for birds undertaking other activities. During autumn migration in Pennsylvania, it occurred in equal numbers in forest-agricultural edges, suburban forests, forest interior, shrub-sapling-stage forests, and pole-stage forests (Rodewald and Brittingham 2002, 2004).

During autumn migration, the Black-and-white Warbler may remain aggressive toward conspecifics and other warbler species (Morse 1989). There is no evidence that it maintains regular feeding territories.

In central Ontario, foraging height was 5.5-15 m during autumn migration (Mills 2007). Near Kingston during autumn migration, the Black-and-white Warbler fed at heights of 3-13 m, with peaks at 5 m and 10 m. Thirty-eight percent of foraging occurred on inner branches, 29% on sapling branches, 25% on tree-trunks, and 8% on outer branches. At Point Pelee, it fed largely on the inner branches and trunks of trees and saplings, with 50% of foraging observations on tree trunks, 30% on branches, and 20% on sapling trunks in spring (Keast 1980). During autumn migration in New York,

Lebbin et al. (2007) observed Black-and-white Warblers foraging by creeping along large tree branches. This occurred at night in trees illuminated by lights from a football stadium.

The stomachs of 3 Black-and-white Warblers killed during autumn at a tower near Prince Edward Point had eaten an average of 3 beetles each (Keast 1980).

During migration, the Black-and-white Warbler frequently collides with windows and tall structures such as buildings, communication towers, and lighthouses. From 1972 to 1982, 335 were killed at the Lennox generating station chimneys near Kingston (Chapman 1907; Graber et al. 1983, Kricher 2020; Weir 2008). Loss et al. (2014) examined bird-building collisions in the United States and determined that it was more vulnerable to collisions than average. At all types of buildings, it was 11.1 times more likely to strike a building than the average for all species. It was 68.7 times more likely than average to strike 1-3-storey residences, 22.7 times more likely to strike low-rises, and 18.3 times more likely to strike high-rises than average.

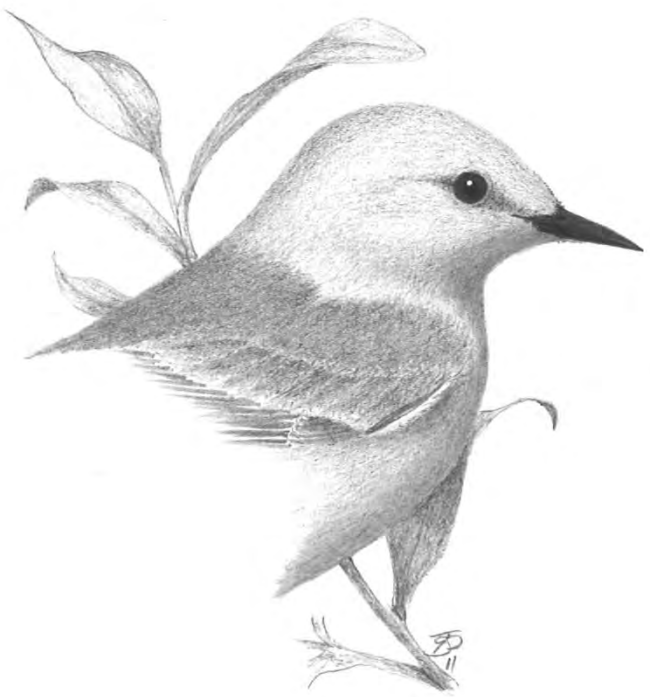
Strode (2003) studied the impact of climate change on spring migration of the Black-and-white Warbler in Illinois and North Dakota. Over 100 years, no change in spring temperatures occurred in Illinois but spring advanced by 8.6 days over 40 years in North Dakota. There was no change in spring arrival dates over time in either Illinois or North Dakota. In New York, Zelt et al. (2017) compared spring arrival dates, autumn departure dates, and the length of the breeding season during 1888-1939 and 1967-2012. There was little climate change during the first period but significant warming occurred during the second period. There were no significant differences in spring arrival dates and length of the breeding season for the Black-and-white Warbler, but autumn departure dates were significantly later in the second period.

Hanowski et al. (1996) studied the effects of extremely low electromagnetic fields on spring migrants in Michigan. The abundance of the Black-and-white Warbler was similar over time in reference and treatment areas. They concluded that no pattern was present to suggest a negative effect of electromagnetic exposure.

James (1991) considered the Black-and-white Warbler a common migrant in Ontario. Hussell et al. (1992) summarized trends in numbers of Black-and-white Warblers banded at Long Point Bird Observatory. The overall trend was –0.9% per year 1961-88. Trends by period were –6.2% 1961-70; +0.4% 1970-79; and +1.3% 1978-88. None of the trends were significant.

Prothonotary Warbler

Protonotaria citrea

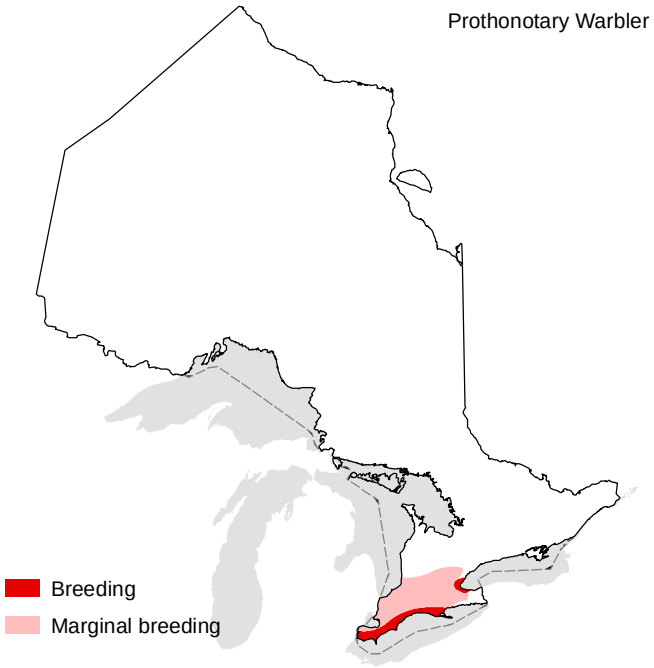


BREEDING SEASON

Habitat Requirements

In Ontario, the Prothonotary Warbler breeds in deciduous swamps. Most of these are treed but a few are dominated by shrubs and small trees. At Rondeau, it has bred in mature maple-beech-ash-oak forests (44 nests), in silver maple woods (5 nests), and in growths of buttonbush and dogwoods (4 nests). Many nests were in areas with open forest canopies (Peck and James 1987).

In Ontario, the Prothonotary Warbler nests most frequently in flooded mature deciduous treed swamps. It may also nest along margins of slow-moving warmwater creeks and rivers lined with willows. The swamps it uses most consistently and that support highest concentrations are associated with sand spits, such as at Rondeau and Long Point. The most common tree species in the canopy of its habitat include silver maple, red maple, ash, yellow birch, and black willow. The swamps it uses may be riparian, typically on the shoreline of Lake Erie or Lake Ontario, but it may inhabit mosaics of slough swamp forests within upland forest. Tree canopy cover at nesting areas



ranges from 20% to 90%, but averages slightly above 50% and is usually extensive enough to limit development of permanent growth of a herbaceous or shrubby understorey. It usually avoids open swamps with extensive emergent herbaceous vegetation. Sites may support scattered stands of cattails, common reed, grasses, and sedges, but these are usually not dominant, particularly early in the breeding season before mid-June. Swamps that it uses are intermediate in age or mature because several shallow nesting cavities a short distance above water or ground are essential within the territory. Dead or dying trees are necessary. Presence of standing or slow-flowing water is also essential. Open water is usually a dominant feature around nest sites and emergent vegetation is sparse. At Ontario territories, water is typically 0.5-1.5 m deep and surface water represents 70-100% of the territory. Pools in territories may be 1 ha or larger, although sites containing smaller pools are readily occupied. The most productive territories contain permanent pools of water but it also nests in seasonal sloughs that dry up entirely by mid- or late breeding season. Pools that contain water from May through until at least mid-June are important. A final habitat component is presence of plentiful green mosses, which are used as a base for the nest. Moss is most abundant in swamps with a long history of flooding, especially those where canopy cover provides shade (Austen et al. 1994; Bird Studies Canada 2001; Black and Roy 2010; McCracken 1984, 2007; McCracken et al. 2010).

McCracken (1984) summarized habitat characteristics of Prothonotary Warbler territories in Hahn Woods, at the base of Long Point. Silver maple was the dominant living tree (48.2% of trees), and 47.1% of the tree cover was dead. Other water-tolerant tree species present included red maple, ashes, and alder, but they were rather sporadic in occurrence. Tree density was high (860 per ha), largely due to adventitious growth of small trees clustered around larger trees. The canopy cover was sparse and averaged 34% (range 20-75%). This reflected the openness of the habitat combined with the presence of large numbers of dead and partly drowned trees. Shrub coverage was sparse and never exceeded 25% at any site. The most prominent understorey woody species were grey alder, dogwoods, buttonbush, and silver maple saplings. The ground cover was dominated by arrowheads, bur-reeds, rice cutgrass, and beggarticks. Open water covered an average of 50% of territories (range 30-90%), but usually became densely overgrown with emergent plants and duckweed by late summer. Water depth averaged 27 cm (range 9-48 cm).

Throughout its range, the Prothonotary Warbler nests in riparian floodplain forests and lacustrine treed swamps. In Virginia, it nests in tidal swamps where water levels fluctuate by as much as a metre. It may nest around shallow ponds surrounded by willows. In Mississippi, it nested in

planted cottonwood stands that were harvested on a 10-15-year rotation period. Nesting occurred in this habitat only when nest boxes were provided. Rarely, it nests in anthropogenic habitat such as backyards and bridges over rivers. Tree composition in swamps used for nesting is often similar to Ontario habitats. In many areas, willow is the dominant species. Other swamps that it uses may be dominated by red maple, silver maple, ashes, elms, black gum, sycamore, tulip tree, river birch, oaks, hackberry, Manitoba maple, and cottonwood. Buttonbush is frequently a dominant shrub in these wetlands and alder may be present. It selects intermediate-aged and mature forest stands and avoids early successional stands are avoided. Its abundance was significantly correlated with basal area (BA) and abundance of trees larger than 38 cm diameter at breast height (DBH) in the mid-Atlantic states. Canopy height in Tennessee ranged from 12 to 40 m but was mostly 16-20 m. In the mid-Atlantic states, it was negatively correlated with canopy height confirming that it selects areas of tree cover with medium height. In Tennessee, canopy cover was 50-75% but in Michigan it preferred heavily shaded areas for nesting. The shrub and ground layers of vegetation are usually sparse and less than 0.5 m tall. A Maryland study concluded that it required dense underbrush along stream banks, contrary to the findings of other studies (Blem and Blem 1991, 1992; Brush 1994; Buffington et al. 1997; Bushman and Therres 1988; Chapman 1907; Flaspohler 1996; Graber et al. 1983; Hodges and Krementz 1996; Mossman 1988; Petit 1989, 1991a, 2020; Petit and Petit 1996; Robbins et al. 1989; Twedt and Henne-Kerr 2001; Walkinshaw 1938, 1941, 1953).

Preferred habitat contains standing or slowly flowing water. The Prothonotary Warbler occasionally nests in areas without water, but these sites are almost always close to flooded habitat or in low-lying areas subject to occasional inundation. In some areas, it may delay nesting until flood waters recede and expose suitable nesting cavities. Nesting may occur in areas that dry out so that nests are over dry land by the end of the breeding season. When it nests over dry land, it is usually within 100 m of water. In Michigan, dry-land nests were 0.61-137.8 m from the river bank, usually in spots that were readily flooded. In Michigan, it was observed exclusively in riparian forests and avoided the portion of swamps that were distant from the river and the outer band of upland forest. In New Jersey, it was rarely detected in oak-pine forests and was significantly more abundant in hardwood swamps. In Illinois, a population nested where the water depth was 7-61 cm deep. Of 84 natural nests in Michigan, 34.5% were over standing water, 38.1% were over or at the edge of running water, and 27.4% were over dry land (Chapas-Vargas and Robinson 2013; Graber et al. 1983; Inman et al. 2002; Petit 1991a, 2020; Petit and Petit 1996; Rich et al. 1994; Twedt and Henne-Kerr 2001; Walkinshaw 1953). Flooded areas are preferred and superior habitat to dry areas. In North Carolina and Tennessee, breeding density was more than 3 times higher in flooded swamps than in dry habitats (Lyons 2005; Petit and Petit 1996). In Tennessee, densities varied more among plots and years in dry and mesic habitats than in flooded areas. Birds clearly preferred flooded habitat. Both males and females settled first in flooded areas before dry habitat was occupied, and dry areas were settled only once all flooded habitat was defended. Territories of males nesting in flooded habitat were less than half the size of those in dry habitat. Between years, no males moved from flooded to dry habitat, but several moved from dry to flooded habitat, reducing their territory size by about half. Within a season, 1 male moved from flooded to dry habitat and his territory size almost doubled. All males in flooded habitat were mated but some males in dry habitat were unable to attract a mate. Females in flooded habitat were more likely to attempt a second brood (34.8%) than those in

dry habitat (10.0%). Arthropod abundance was significantly higher in flooded areas than in dry habitat, with peaks in abundance in flooded areas due to large emergences of flies early in the season and mayflies in June and July. Over dry land, emergences of flies were smaller and mayflies were found only once over dry land. This study was done using nest boxes so that nest sites were not a limiting factor. Nonetheless, the relative abundance of natural cavities decreased with distance from water. The number of potential nest holes per 0.16 ha was 1.5 at the shoreline, 0.8 35 m inland, 0.3 70 m inland, and 0.1 105 m inland (Petit 1991a; Petit and Petit 1996). Beck (2013) established a breeding population of Prothonotary Warblers in Louisiana by erecting nest boxes. Boxes above water were preferred and significantly fewer nests over water were depredated compared with those over dry land. Males with brighter yellow colouration and older females that were brighter yellow occupied nest boxes over water indicating that these birds had a competitive advantage over duller-coloured males and younger females. Even when only males 2 or more years old were considered, brightness of plumage provided a competitive advantage whereas age did not.

In Illinois, preferred tree species in order of preference were red maple, sugar hackberry, silver maple, Manitoba maple, blue beech, swamp chestnut oak, black gum, and white elm. Avoided species, from most to least avoided, were sweetgum, pumpkin ash, overcup oak, shellbark hickory, Shumard oak, pin oak, baldcypress, green ash, sycamore, and bitternut hickory. Red maple was strongly preferred over other species. Silver maple was a preferred species but was only 18th in tree abundance. Sweetgum and pumpkin ash were avoided, yet they were the third- and second-most abundant trees, respectively (Gabbe et al. 2002).

In New Jersey, the Prothonotary Warbler was consistently more abundant on forest-interior than edge plots (Rich et al. 1994). It is unlikely that it is a forest-interior species. In most areas, it is more likely to occur along edges adjacent to lakes and water bodies, and it occasionally nests in non-forest habitat such as isolated snags in lakes and in backyards. In an Iowa forest, no breeding sites were more than 200 m from edge and most were less than 40 m from edge (Brush 1994).

Most authors consider the Prothonotary Warbler an area-sensitive species, but some studies determined that it is not. In Ontario, nearly all known breeding sites occur within forest tracts that are at least 25 ha, and over 95% of breeding sites are in forest patches that are at least 100 ha (McCracken 2007; McCracken et al. 2010). Petit (2020) concluded that it avoided forests smaller than 100 ha and Robbins (1979) concurred. In Maryland, it was found only in forests larger than 70 ha (Bushman and Therres 1988). In the mid-Atlantic states, Robbins et al. (1989) found no relationship between its abundance and forest size, although abundance was significantly correlated with the amount of forest cover within 2 km. In Iowa, it nested regularly in a highly fragmented forest that was 42 ha (Brush 1994). In Michigan and West Virginia, it nested in 32-36-ha swamps (Shields and Shields 1948; Walkinshaw 1953). In Wisconsin, it nested in riparian strips 0.1-1.5 km wide (Flaspohler 1996). In Maryland and Delaware, its overall probability of occurrence was 21% in riparian forests. Its probability of occurrence increased significantly with forest width: 5% in 50-m wide corridors, 9% in 100-m wide corridors, 23% in 200-m wide corridors, 49% in 300-m wide corridors, and 100% in 800-m wide corridors (Keller et al. 1993). Hodges and Krementz (1996) conducted a similar study in Georgia and found that its probability of occurrence increased with corridor width, but not significantly. Its probability of detection was 55% in 50-m wide corridors, 82% in 100-m wide

corridors, 95% in 200-m wide corridors, 99% in 500-m wide corridors, and 100% in 1,000-m wide corridors. They concluded that it was not area sensitive and that forest corridors 100 m should be sufficient to support it. Graber et al. (1983) observed that it did not ascend into upland stream branches and concluded that stream and floodplain size were important factors. Petit (2020) concluded that it avoided waterways with wooded borders that were 30 m or less in width and, to be suitable, this would have to be floodplain forest. It is probable that area sensitivity of the Prothonotary Warbler varies considerably geographically depending upon whether a site is in the core or periphery of its range. The local abundance of its spottily distributed habitat may also affect area sensitivity.

The Ontario habitat requirements of the Prothonotary Warbler may be summarized as extensive deciduous swamps that are intermediate or mature in age, permanent standing or slowly flowing water, numerous shallow cavities in trees (or nest boxes) a short distance above water, moderate tree canopy closure, sparse coverage by shrubs and herbaceous emergent vegetation, and an ample supply of moss.

At night, females roost in the nest cavity. Males roost on a perch in low vegetation or in an unoccupied cavity if one is available (Petit 2020).

All Ontario nests were above or at the edge of water; 82.8% were in natural cavities and the remainder were in old woodpecker holes. Nest cavities were in standing tree stumps (75.9% of nests), standing dead trees (19.0%), and fallen branches (5.2%). Occasionally nest cavities were in living or partially living trees. Nests were in maples, ash, basswood, birch, and buttonbush. An unusual nest site was in a cavity in a detached branch suspended vertically from a branch on a dead tree. Tree diameters at nest cavities ranged from 10 to 45.5 cm. Height of nests above water were 0.3-3 m with most 0.9-1.7 m up. Prothonotary Warblers used both large and small cavities, with 1 opening measuring 7.5 by 10 cm. Most cavities were shallow and ranged in depth from 2.5 to 30.5 cm. Two atypical cavities were horizontal from the opening and had no depth below the entrance (Peck and James 1987). In 1949, a Prothonotary Warbler nested in a drain pipe of an old building at Turkey Point. At Hahn Woods, nest trees were smaller than average. Two nests were in living trees and the remainder were in rotting dead trees or stubs. Most nests were not shaded by foliage. Of 20 nests, 11 were in natural cavities and 9 had been excavated by Downy Woodpeckers or Black-capped Chickadees. Nest height averaged 1.7 m (range 0.65-3.2 m). The Prothonotary Warbler readily uses nest boxes in Ontario and elsewhere and appears to prefer them to natural cavities. Several different nest-box designs were provided at Cootes Paradise and the most successful was a natural cavity made from a hollowed-out elm log with a natural slab top. The entrance opening was 3.18 cm. In 1997, 8 of 14 nests (57%) were in nest boxes, 17 of 21 (81%) were in nest boxes in 1998, 16 of 18 (89%) were in nest boxes in 1999, and 15 of 25 (60%) were in nest boxes in 2000 (McCracken 1984, 1999b, 2000, 2001; McCracken and Dobbyn 1997; McCracken et al. 2010; Peck and James 1998a; Wills and Barrett 2006).

Throughout its range, the Prothonotary Warbler nests in shallow cavities over, beside, or near water. Nest cavities are typically a short distance above water or ground in dead or partially dead trees, snags, or stumps. Less frequently, it nests in living trees. Typical habitat is flooded deciduous treed swamps, riparian swamps, and lacustrine swamps. In much of its range, it appears to prefer

willows for nesting, although it nests in a wide variety of deciduous tree species. In Illinois, 64 of 168 nests (38.1%) were in willows, 3 of which were alive, and an additional 46 (27.4%) were in dead trees or stumps of unknown species. Other nest tree species were elm (4.8% of nests), oak (3.0%), red or silver maple (2.4%), cottonwood (2.4%), river birch (1.2%), sycamore (1.2%), and 0.6% each in 2 species that do not occur in Ontario. Mean diameter of trees or stumps at nest height were 29.9 cm in Wisconsin and 13.6 cm in Tennessee. Nests are either in natural cavities or those previously excavated by a chickadee or Downy Woodpecker, with woodpecker holes often preferred. Of 84 natural nests in Michigan, 43 were in natural cavities and 41 were in woodpecker holes. In very rotten stumps, it may partially excavate or enlarge an existing cavity. Some nesting cavities, including old chickadee and woodpecker holes, may be rotted out and quite large. Excessively large cavities take much more moss and time to fill and are less desirable. Some cavities are so shallow that the female can be seen from some distance as she sits on the nest. In Michigan, nearly all nests were shaded most of the day. All young died 1 hot afternoon in a nest that was exposed to the midday sun. Significantly more nests in natural cavities in Tennessee were oriented toward the river than in other directions. In Michigan, 6 of 44 nests (13.6%) were in stubs over water (2 over running water), 1 (2.3%) was in a bridge support in a slight depression, 9 (20.5%) were in natural cavities over standing water, and 7 (15.9%) were in old woodpecker holes 0.6-48.8 m from the river bank. Nests have been reported from a few centimetres above water to 10.4 m up, but most average about 2 m above water or ground. In Michigan, nests were 0.3-3.7 m high over water (average 1.71 m). Nests over land were 1.2-4.6 m up (average 2.06 m). Of 84 natural nests, 41 (48.8%) were 0.61-1.52 m above the substrate, 21 (25.0%) were 1.52-3.04 m up, 20 (23.8%) were 3.04-4.50 m up, and 2 (2.4%) were even higher. In Illinois, the height of 99 nests averaged 1.85 m (range 0.08-8.0 m). Mean height of nests above ground in Wisconsin was 43 cm. Nests above water were not included in the analysis because of fluctuating levels. There is 1 record of it nesting in an abandoned Red-winged Blackbird nest. The Prothonotary Warbler has nested in a variety of unusual sites including under an overturned motorboat, in a bridge support, in gourds, in a paper sack near a window within a building, in a mailbox, in a coffee can, in a coffee pot hanging in a gazebo, in an old hornet's nest, in a glass jar laying on its side, in the pocket of a pair of pants hanging on a clothesline, in a metal pail hanging on a porch, in a guard over a pulley wheel on a ferry that was continuously in operation moving from 1 side to the other of a river, in a metal toolbox on a log-loader in use along the Mississippi River, in a gas inlet pipe in an unused houseboat, in an orchard over plowed ground, on a bulldozer, on or in a pump, on a freight-car coupler, in a rubber tire, over artificial pools near buildings, in a cigar box, on a pier, in a metal ventilator cap 10 cm in diameter at a pier, in a cleft in a pile in a river, in lanterns, in a tea cup, and in the pocket of a coat hung in a garage, which was used in 3 consecutive seasons (Bent 1953; Brush 1994; Chapman 1907; Flaspohler 1996; Graber et al. 1983; Harrison 1984; Petit 2020; Petit and Petit 1988a; Shields and Shields 1948; Walkinshaw 1938, 1941, 1953).

The Prothonotary Warbler readily uses artificial nest boxes. In many places, nest boxes are preferred to natural cavities; the opposite is true in some locations. Usage of nest boxes may be dependent upon their design, with those with smaller volumes preferred. Nest boxes may increase local populations where natural cavities are limited, reduce territory size, and increase nesting density in areas even where there are sufficient cavities present. Properly installed and designed nest

boxes may also reduce the incidence of nest predation and brood parasitism. A negative factor associated with nest boxes is that they increase local populations of competitors for cavities, especially the Northern House Wren. This species may depress warbler populations by puncturing eggs and filling potential nest cavities with sticks. The Prothonotary Warbler has used many designs of artificial nesting structures including wooden boxes, cardboard milk cartons, metal cans, polyvinyl chloride pipes (30 cm long, 10.2 cm in diameter and with plastic caps on the top and bottom), 0.7 L Metamucil jars, plastic gallon milk jugs, and gourds. Two studies tested its preference for artificial nest structures. In Tennessee, warblers were offered standard wooden bluebird boxes, cardboard milk cartons (1.9 L volume with a 3.75-cm diameter hole centered 5 cm from the top), and polyvinyl chloride tubes. The milk cartons were preferred (67.5% of those available were used), the tubes were used in proportion to their availability (27.4%), and bluebird boxes were avoided (5.1%). In Mississippi, large wooden boxes with a volume of 16.5 L, small wooden boxes with a volume of 3.5 L, and the 1.9 L milk cartons were erected. It nested in 0 of the large wooden boxes, 1 of the small wooden boxes, and 28 of the milk cartons, showing a clear preference for the milk cartons. In Virginia, it readily used wooden boxes 28 cm tall, 9 cm wide, and 6 cm deep with a 3.8-cm diameter hole. This is equivalent to a 1.5-L box. Smaller boxes are likely preferred because less moss is required to fill the base of the cavity. In Virginia, equal numbers of boxes were placed facing each 30° angle of the compass. The direction that nest boxes faced did not affect usage, but it preferred boxes on trees near water surrounded by large trees. Nest boxes were erected at heights of 20-280 cm above the high water level or ground and it showed no preference for box height. Increases in the distance of the nest box from water, in the percentage of ground cover under the nest, and percentage of the day that the box received direct sunlight all increased probability that boxes would be used by wasps instead of warblers. Its use of boxes could be increased by placing them on trees near or in the water on trees with a large DBH at sites that are not frequently exposed to full sunlight. Facing boxes north reduced the probability of their being used by wasps. In Virginia, temperatures in nest boxes were measured and boxes were divided into low-temperature (30-34° C) and high temperature (35-39° C) boxes. Warblers selected high-temperature boxes for their first clutch and avoided them for later clutches (Blem and Blem 1991, 1992, 1994; Brush 1994; Fleming and Petit 1986; Guillory 1987; Petit 1989; Petit and Petit 1987; Petit et al. 1987; Twedt and Henne-Kerr 2001).

In Arkansas, Slevin et al. (2018) monitored 84 nests in natural cavities and 60 in nest boxes. In natural cavities, nests were significantly higher (average 2.11 m, range 1.18-3.47 m) than random natural cavities (average 1.83 m, range 0.93-2.61 m). Cavity orientation was not a significant predictor of use. The Prothonotary Warbler preferred dead trees, with about 95% of nests in dead trees although they represented only 50% of trees with cavities. Water depth was not correlated with cavity use. Nest boxes that it selected had larger cavity openings and were under less canopy cover than unused boxes. Canopy cover was negatively related to daily nest survival in natural cavities. Pole-mounted nest boxes had greater survival than those in trees. There was no difference in overall nest survival between natural cavities and nest boxes. It may select higher nest cavities to minimize the risk of flooding.

The Prothonotary Warbler is strongly territorial, expelling all other males from its territory. It routinely attacks Northern House Wrens, chickadees, and Yellow Warblers. The first 2 species are nest-site competitors while the latter has similarly coloured plumage. In Wisconsin, a Prothonotary

Warbler pair took over a Black-capped Chickadee nest and laid eggs on top of it, only to have a Northern House Wren pair ultimately claim the nest. Most territories contain several potentially suitable nest cavities, and the male adds mosses to each of these. The mean number of cavities within 25 m of Ontario nests was 2.3 (range 1-10). These extra cavities and dummy nests are important as they confuse predators and competitors and can be used for replacement nests, second broods, for a second female's nest in the case of polygynous birds, and also as a nocturnal roost by the male. Birds may also be able to detect temperature and humidity differences in cavities with moss, and this may help in the nest-selection process. In Tennessee, nest-site availability was one of the most important attributes used by females in selecting a mate. In Ontario, the Prothonotary Warbler nests both singly and in groups, with groups most typical. This is most likely a function of its specialized habitat requirement as it is not colonial. Territories are initiated by the male as soon as he arrives. At that time, territories are large and encompass large areas of river or swamp. As new males arrive, battles ensue for portions of the territory and they may last 2-3 days before boundaries are settled. Occasionally a nest site is selected first and the territory is established around it. Birds nest and usually forage within the territory, although females sometimes forage outside the territory when they are feeding nestlings. In Georgia, it frequently flew over a river more than 100 m wide. Most Ontario territories are 1-2 ha, usually with about 1 ha of water present. In Illinois, the average size of 13 territories was 0.49 ha but 0.69 ha when a tape recorder was used to locate territorial boundaries (range 0.12-1.2 ha). In Tennessee, territory sizes were 0.19 ha for polygynous males and 0.24 ha for monogamous males. Overall territory sizes averaged 0.48 ha (range 0.1-1.2 ha). Territories in Tennessee were larger in dry (average of 0.30 and 0.37 ha over 2 years) than in flooded (0.13 and 0.16 ha) habitat. Individuals that moved between flooded and dry habitats adjusted their territory sizes accordingly. All nesting in the Tennessee population occurred in nest boxes, so territories were smaller than where natural cavities were used. Populations nesting in natural cavities in Tennessee had an average territory size of 0.64 ha. In another nest-box population in Virginia, territory size averaged 0.26 ha (range 0.02-0.71 ha). In Michigan where birds were nesting in natural cavities, 13 territories averaged 1.48 ha (range 0.77-2.58 ha). Some territories were much larger (5.03 ha), but only a portion of these were used at one time. Over 5 years, this territory averaged 3.82 ha (range 2.57-5.03 ha. One male that occupied the same area in 4 successive years had an average territory size of 1.28 ha (maximum 2.4 ha). In Alabama, the foraging area of females feeding young averaged 5.4 ha compared with 3.7 ha for males (Bird Studies Canada 2001; Blem and Blem 1994; Clarkson 2007; Graber et al. 1983; Hodges and Krementz 1996; McCracken 1984, 2007; McCracken et al. 2010; Petit 1989, 1991a, 2020; Petit and Petit 1996; Walkinshaw 1941, 1953).

Natal philopatry rates are low. In Michigan, 2 of 138 nestlings (1.4%) returned, one of each sex. Both nested 0.8 km from their natal nest. The male occupied the same territory in the next 4 years and the greatest distance between his nests in those years was 148.3 m. In Virginia, 50 of 2,968 nestlings (1.7%) returned. Of 33 nestlings banded there in 1998 that were recaptured in 2000, 20 (60.6%) were not found in 1999. In Tennessee, the mean distance between the natal site and first breeding site averaged 3.9 km for females (range 50 m to 12 km) compared with 875 m for adults (range 200 m to 1.5 km; Blem and Blem 1992; Blem et al. 1999; Petit 2020; Podlesak and Blem 2001; Walkinshaw 1941, 1953).

Adult site fidelity rates are much higher than natal philopatry rates. In Illinois, 9 of 10 males (90%) returned the next year but only 2 returned the following year. Three of 5 females (60%) returned the following year and 1 returned the subsequent year. Return rates are higher for males than for females. In Michigan, return rates for adult males were 50% the first year, 22.2% the second year, 11.1% the third year, 11.1% the fourth year, and 0% the fifth year. Female return rates were 20.3% the first year, 10.2% the second year, 1.7% the third year, 1.7% the fourth year, and 0% the fifth year. The overall return rate of adults was 27.3% the first year, 13.0% the second year, and 3.9% the third and fourth years. Most males occupied the same or adjoining territories each year, but one moved 296-510 m after 4 years. If a female's old mate returned and was already mated when she returned, she was forced to mate with another male. Consequently, females often nested considerable distances from their previous year's nest. In Virginia, 47.9% of females banded as adults were recaptured at least once in subsequent years. Of these, 5.7% were not found the year after they were banded. In Indiana, 4 of 7 males (57%) returned to breed the following year and 39% of adults returned in another study. Two used the same territory and the other 2 moved 0.8 and 1.2 km away. At another Indiana site, 31 of 101 males (31%) nesting in natural cavities returned. Twenty-one (68%) returned to the territory they held the previous year. Thirteen returned to different territories and moved an average of 1,095 m along the stream (range 214-3,262 m). Eleven males, 9 of which failed to attract a mate, switched territories within a breeding season. Mean distance they moved along the creek was 1,738 m (range 185-9,000 m). Five of the 11 males that relocated within a season returned. Three returned to the relocated territory, one returned to his original territory, and one settled equidistant between his original and relocated territories (Kowalski 2024). In Illinois, 13 of 14 returning males (93%) used the same territory. In Tennessee, site fidelity was higher in flooded than dry habitat. Between years, males moved an average of 43 m and 71% returned to within 50 m of their previous nest. Females moved an average of 203 m and 29% returned to within 50 m of their previous nest. By moving, 46% of returning birds changed the habitat in which they were nesting (Blem et al. 1999; Graber et al. 1983; Petit 2020; Petit and Petit 1996; Podlesak and Blem 2001; Schlossberg 2001; Walkinshaw 1941, 1953). Colour-banding of adults in Ontario 1998-2005 demonstrated that there was some interchange of individuals among different populations. An adult female banded north of Long Point was relocated nesting at Rondeau 3 years later, a dispersal distance of approximately 120 km (McConnell et al. 2011; McCracken 2007).

Limiting Factors

Eggs have been reported in Ontario nests from late May until the third week of July, with most present in the first half of June (McCracken 2007; Peck and James 1998a). Upon arrival, the male adds green moss to cavities within his territory. When the female arrives, she inspects the cavities, selects one, and completes the nest. Occasionally, she selects a cavity that the male has not added moss to and builds a nest in it. In Virginia, nests were under construction 1-2 days after the birds arrived. In Illinois and Tennessee, 6-7 days elapsed between the arrival of males and the initiation of nest construction. In Michigan, first nests took an average of 5.3 days to build (range 2-13 days). Second nests were completed in an average of 1.8 days (range 1-6 days). In Illinois, birds took 7-10 days to complete nests. The average amount of time required to build a nest in Tennessee was 8.8 days (range 6-12 days). In Michigan, the average amount of time between nest completion and egg laying was 3.2, 1.7, 1.4, and 1.1 days over 4 years (overall average 2.1 days, range 1-12 days). In

Tennessee, the elapsed time averaged 8.8 days (range 6-12 days). For second and later nests, the first egg is laid the day after the nest is completed. Usually 4-7 days pass between nest loss to laying of the first egg in a replacement clutch. In Tennessee, egg laying began about 5 days earlier in flooded habitat than in dry areas. One egg is laid per day and incubation begins with the laying of the penultimate egg. In Ontario, incubation took at least 10 days at 3 nests, 11 days at 1 nest, and no more than 12 days at another nest. Incubation took an average of 12 days 10 hours in Tennessee (range 12-13.5 days) and an average of 12 days 17 hours in Michigan (range 12-14 days). The incubation period was not influenced by air temperature. In Virginia, the incubation period ranged between 10 and 16 days for 1,036 clutches over 22 years. Low temperatures, young females, and small clutch sizes contributed to longer incubation periods. There were no differences in incubation period lengths for early and late clutches (Peterson et al. 2025). The entire clutch typically hatches within a 12-hour period but occasionally 1 egg hatches as much as 24 hours later than the rest. The average nestling period was 11 days in Michigan and 10.75 days in Tennessee, with about 50% of young fledging when they were 10 days old. Overall, the nestling period ranges from 10 to 12 days. Excluding nest building, a nesting cycle takes about 25 days. After the young fledge from the first nest, the average period to laying of the first egg in the second clutch was 17 days in Tennessee and 5.3 days in Michigan (Bent 1953; Bird Studies Canada 2001; Blem and Blem 1991, 1992; Graber et al. 1983; McCracken et al. 2010; Peck and James 1998a; Petit 1989, 2020; Petit and Petit 1996; Walkinshaw 1938, 1941, 1953).

Double broods are common in the southern portion of the Prothonotary Warbler's range, but rare in the north. Usually there is time for only a single brood in Ontario, but there is 1 report of a second brood. The young from the first nest must fledge before mid-June if a second brood is to be attempted. Second broods were common in Tennessee and Virginia, but rare in Michigan. Second broods may be raised in either the same or a different nest cavity. Three Michigan pairs attempting second broods nested directly across a river 46-152 m from their first nest. In Tennessee, 5 of 20 pairs (25%) nesting in natural cavities attempted a second brood. Two second nests were in the same cavity, 2 were in a nest box, and 1 was in a different natural cavity. In Tennessee nest boxes, 45-77% of females attempted a second brood and 50% (20-30% of the entire population) were successful. Females nesting in flooded habitat were more likely to attempt a second brood than those nesting in dry habitat (34.8% compared with 10.0%). In Virginia, some females attempt a third brood after successfully rearing 2 broods, but there are no known cases of successful third broods. If the first nest is lost, renesting is common. Replacement nests may occur in the same or a different cavity. Clutches of 3-6 eggs have been reported in Ontario (average 4.68 eggs, mostly 4 or 5 eggs). Throughout its range, clutches of 2-10 eggs have been documented, with the typical range 3-8 eggs and 4- and 5-egg clutches most common. Clutch size increases northward and adult females have larger clutches than yearlings. Clutch size declines with the season, so first clutches are significantly larger than clutches in second broods or replacement nests. Average clutch sizes reported elsewhere are 4.73, 4.6, and 4.53 in Tennessee; 4.96 for first clutches and 3.94 for second clutches in Virginia; 4.98 in Michigan; and 4.31 in Wisconsin. Five eggs is the most frequent clutch size for first nests; 4 eggs is most common for second nests. In Virginia, yearlings laid an average of 0.4 egg less than adult females in first clutches and 0.24 egg less in second clutches. The clutch size of 1 Virginia female was observed over 8 years and there was no decline in its clutch size with age (Beck 2013;

Bent 1953; Bird Studies Canada 2001; Blem and Blem 1992; Blem et al. 1999; Chapman 1907; Flaspohler 1996; Fleming and Petit 1986; Graber et al. 1983; McCracken 1984, 2007; Peck and James 1998a; Petit 1989, 1991a, 2020; Petit and Petit 1996; Walkinshaw 1938, 1941, 1953).

The Prothonotary Warbler is capable of breeding when it is 1 year old, but some do not breed until they are 2 years old. Yearlings may be relegated to inferior habitat by older males and the lower-quality territories may not be attractive to females. In Tennessee, 2 of 5 males first bred at age 2 years. Females are more likely to breed in their first year than males. Once a bird has bred, it typically breeds every year. In Virginia, 5.7% of adult females were not detected in 1 year, but bred the previous and subsequent years. It was surmised that these females did not breed because habitat conditions were inferior the 1 year. In Ontario, approximately 37% of territorial males fail to attract a mate. The sex ratio is male biased so that there are insufficient females present so that all males can be paired. The mating system is typically monogamous, but polygyny occasionally occurs. At least 3 cases of polygyny are known from Ontario, all involving adult males. In Tennessee, abundant nest boxes were provided and this created an artificial opportunity for polygyny. In order for polygyny to occur, there must be more than 1 suitable nesting cavity within the territory. In the Tennessee population, polygyny occurred only by older males holding territories in flooded habitats where food was much more abundant. In flooded habitat, 9 of 188 matings (4.8%) were polygynous compared with 0 of 58 in dry habitat. Under normal circumstances, usually less than 1% of matings are polygynous. Most polygyny in Tennessee occurred during the second nesting period. Females chose to be polygynous in higher-quality flooded habitat rather than nesting monogamously with a male defending a territory in dry habitat. Secondary females in polygynous relationships had lower reproductive success rates than primary females but their success rate was similar to those nesting monogamously in inferior dry habitat. Of 23 polygynous matings, 22 were bigamous and 1 was trigamous, and 2 males each had 2 different consecutive polygynous matings within a season. Three cases of polygyny were documented in Indiana and 2 were polyterritorial. In most cases, pair bonds last throughout the season. In Tennessee, some females switched habitats and mates for different nesting attempts within a season. In Michigan, only 1 pair remated in a second season and nested in the same box. Three other pairs had the opportunity to remate but did not. Of 10 observed copulations in Tennessee, 3 were extra-pair (Graber et al. 1983; Kowalski 2024; McCracken 2007; Petit 1991a, 2020; Petit and Petit 1996; Podlesak and Blem 2001; Walkinshaw 1941, 1953).

Intraspecific parasitism is another breeding strategy of the Prothonotary Warbler. Tucker et al. (2016) examined a population breeding in nest boxes in Virginia. Of 233 broods, 60 (25.8%) contained one or more parasitic nestling. Most parasitized broods contained 1 or 2 parasitic nestlings (range 1-4). Of 805 nestlings, 12.7% were parasitic. It often had multiple broods in a single season, but no female was parasitized more than once in a year. Clutch size of parasitized nests was larger than unparasitized nests. Host females fledged more young than non-host females but fledged significantly fewer biological offspring. Host females were less likely to raise a second brood than non-host females. Parasitic females were not older or younger than nonparasitic females and were not significantly older than host females. Parasitism appeared to occur opportunistically without deliberate targeting of hosts based on host or nest-box characteristics.

The Prothonotary Warbler usually forages lower than 7 m, but occasionally as high as 15 m. It takes prey from the water's edge, fallen logs, trunks and branches of trees, foliage of trees and shrubs, and the subcanopy of trees. At least 75% of foraging is by gleaning, 10-20% by hovering, and less than 5% by flycatching. It often probes into curled leaves to capture spiders and caterpillars. While foraging on bark, it occasionally forages upward on tree trunks in a manner similar to that of the Black-and-white Warbler. It may perch on tall grasses and aquatic plants in search of minute snails, which it consumes. One fed almost continuously on live insects as they became entangled in a spider's web. It may also take spiders from their webs. Juvenile foraging behaviour is similar to that of adults: usually below 5 m, 90% by gleaning, 7% by hovering, and 3% by aerial flycatching. It takes 66% of prey items from live leaves, 23% from twigs or branches, 6% from trunks, 2% from dead leaves, and 3% from the air (Bent 1953; Chapman 1907; Flaspohler 1996; Graber et al. 1983; Petit 2020; Petit and Petit 1988b). In North Carolina, the Prothonotary Warbler foraged in both flooded and dry habitats. Search speeds for prey were similar in both habitats, but attack rates were significantly higher in swamps, indicating greater food availability and therefore greater reproductive success. Foraging techniques consisted of 82% gleaning and 18% aerial attacks. These proportions did not vary by sex, with 80% gleaning by females and 84% gleaning by males. The sexes combined used 70% hops, 20% short flights, and 10% long flights to secure prey and this did not differ between habitats or stages of the nest cycle (Lyons 2005). At another North Carolina area, it foraged only in floodplain swamps and avoided upland forests and dry thickets. During the breeding season, 19.1% of observations of it were in the canopy, 47.6% in low trees, 28.5% in shrubs, and 4.8% on the ground. In the canopy, 4.8% of observations were at the top of the crown, 4.8% in the inner crown, 9.5% in the lower crown, and 0% on the bole. In low trees, 9.5% of observations were at the top of the crown, 23.8% in the inner crown, 4.8% in the lower crown, and 9.5% on the bole. In shrubs, 9.5% of observations were in the inner crown, 9.5% in the lower crown, 9.5% in brush piles, and 0% at the top of the crown or in dense thickets or grass. On the ground, 4.8% of observations were in dense thickets and no observations were made of it in grasses, at water's edge, or in open areas. Singing birds occurred at heights of 0-15 m (mean 4.6 m). Birds engaged in other activities were observed at heights of 0-7.6 m (mean 3.3 m; Parnell 1969). Petit et al. (1990a, 1990b) studied the foraging ecology of the Prothonotary Warbler in Tennessee. They compared the foraging strategies of males and females during the prenestling (territory establishment, pair formation, nest building, and incubation) and nestling periods. During spring before leaf-out, males foraged significantly higher (3.0 m) than females (1.5 m). Females spent two thirds of their time foraging below 1 m. Males spent only half of their time foraging at this height. Females foraged in shorter trees and shrubs than males, often using trees less than 3 m tall. Males frequently foraged in trees taller than 7 m. During the prenestling period, both sexes foraged primarily by gleaning (90% of the time), less than 1% by hawking for both sexes, and 5% for females and 9% for males hovering. It used small (1 cm or less) and intermediate-sized (1-2.6 cm) branches as foraging substrates 50% of the time. Both sexes used a variety of plant species for foraging, but concentrated on willows, buttonbush, maples, and dead fallen branches. Both sexes foraged more often in the inner and outer third of trees than in the middle third. Use of the outer third was related to foraging on emerging leaves and small twigs. Usage of the inner third was related to gleaning from trunks early in the season. During the nestling period, foraging of the sexes varied significantly for foraging height, substrate type, substrate height, and prey location. Almost two-thirds of foraging by females was at

3 m or lower (average 2.7 m). Males spent only 40% of their time foraging at this height (average 4.8 m). Males used willows and maples more frequently than females. Females foraged more on buttonbush and fallen dead branches than males. Females searched for prey in trees and shrubs that were smaller than those used by males. During the nestling period, both sexes foraged most often on leaves, but males used more leaves and fewer branches than females. The sexes had similar foraging techniques during summer with gleaning accounting for 75% of foraging tactics. Both most frequently used perches that were 1 cm or less in diameter and used the middle and outer parts of trees and shrubs. Throughout the breeding cycle, males significantly altered their foraging techniques for all 7 variables studied. During the prenestling period, less than 28% of the time was spent by males above 3 m compared with 60% during the nestling period, when the average foraging height was 2 m higher. During the nestling period, males reduced usage of branches, trunks, and the ground and increased usage of leaves and aerial foraging. After full leaf-out, males spent more than 40% of their foraging bouts in willows and maples and reduced used of buttonbush, vines, and fallen branches. During the nestling period, males still gleaned predominantly, but hawked and hovered more. During this period, males perched on smaller substrates than earlier in the season, reflecting a preference for perching on small twigs and an almost complete elimination of trunks as perch sites. Late in the season, males spent less time foraging in the inner third of trees and more time in the outer two-thirds. As the season progressed, females significantly changed their foraging behaviour for 4 of the 7 variables. They foraged at greater heights while feeding nestlings, averaging 1.2 m higher than during the prenestling period, yet still rarely searched higher than 5 m. During the nestling period, females increased their foraging on leaves and while in flight and decreased the amount of time spent on the ground, branches, and tree trunks. Females perched on smaller branches and twigs during the nestling period and spent more time hovering and hawking. During the nestling period, females increased their foraging on sweetgum, maples, and other trees and reduced their usage of vines, buttonbush, shrubs, and fallen branches. The sexes partitioned habitat vertically with the male maintaining the territory from higher perches and the female involved in activities associated with the nest. During the nestling period, both sexes hovered more frequently to capture caterpillars from the undersides of leaves. The emergence of mayflies and mosquitoes required more diversified foraging techniques than early in the spring when prey items were less abundant. After leaf-out, both sexes switched to foraging on smaller branches and twigs in the outer portions of trees where prey was more abundant. Changes in foraging strategies during the breeding season were a reflection of prey availability and location, but the sexes still maintained distinct height preferences in relation to their reproductive duties. Annual habitat changes due to flooding and delays in leaf-out resulted in a shift in foraging strategies that reflected the abundance and distribution of prey. These factors suppressed insect emergence, and females foraged below 1 m significantly more and took prey from leaves significantly less during this year than during the average for the previous 3 years.

Nestlings are fed primarily smaller caterpillars, spiders, mayflies, grasshoppers, and beetle larvae. For the first 4 days, young are brought food items less than 15 mm in length, including geometrid moth larvae, flies, and ants. By day 5, the prey fed to young includes larger (25-35 mm) caterpillars, mayflies, and spiders (Petit 2020). Rogers et al. (2023) used DNA barcoding to analyze the nestling diet at 9 locations in the eastern United States. The frequency of aquatic prey in the diet was 61-

100%. The early season diet contained more aquatic prey and the late-season diet contained more molluscs and terrestrial insects. Important prey items included spiders (nursery web spiders, long-jawed orbweavers, and jumping spiders), flies (mostly midges and crane flies), burrowing mayflies, bugs, molluscs (freshwater snails, pond snails, land snails, and Venus clams), hymenopterans, pill woodlice, orthopterans, moths (crambid snout, underwing, tiger, tussock, and geometer moths), whirligig beetles, and crayfish.

During the breeding season, adults are largely insectivorous. Caterpillars, flies, midges, mayflies, and spiders comprise the bulk of the diet. The Prothonotary Warbler also eats beetles, ants, leafhoppers, aquatic insects, snails, isopods, and grasshoppers. In Tennessee, the diet shifts from midges, spiders, and small insects early in the season to predominantly caterpillars and spiders later on. Prey taxa that were most important during the nestling period were significantly more abundant in flooded than dry habitat. In Alabama, the breeding season diet consisted of 75-88% terrestrial insects (caterpillars, true bugs, ants, flies, and grasshoppers), 11% spiders, and 1-10% aquatic organisms including dragonflies, mayflies, and snails. In the nonbreeding season, it is less selective in its diet and feeds on seeds, fruit, and nectar in addition to invertebrates. During autumn migration in Louisiana, 1 bird ate a 3-cm-long lizard (Bent 1953; Bird Studies Canada 2001; Bulluck et al. 2017; Davis and Komar 2003; Graber et al. 1983; Petit 2020; Petit and Petit 1996; Walkinshaw 1938, 1953).

The Prothonotary Warbler is the most heavily parasitized cavity-nesting species in North America. This is probably due to 2 main factors: it is a secondary cavity nester and older or natural cavities may have larger entrance holes that facilitate cowbird access and it fills most of the cavity with moss which also increases the likelihood of cowbirds gaining access. Even populations breeding in nest boxes may experience high parasitism rates. Cowbirds appear to remove a warbler egg in about two thirds of parasitism attempts. In Tennessee, cowbird eggs were accepted in 29 of 36 nests (80.6%). Warblers made no attempt to eject cowbird eggs, but 19.4% of parasitized nests were abandoned, significantly more than for unparasitized nests. The tendency to abandon a nest varied with the availability of other nest sites. Nests were abandoned more frequently where males defended 3 or more cavities. Where cavities are limited, nest abandonment and renesting may not be an alternative. In 1 instance a nest was parasitized where there were no other nesting cavities. The first clutch was completely buried with a new nest that was also immediately parasitized. Parasitism occurred significantly more frequently in early (30.2%) than late (13.2%) nests. Both early and late parasitized nests had significantly smaller warbler clutches than unparasitized nests (4.0 compared with 4.6 eggs for early clutches and 3.9 compared with 4.6 eggs for late clutches). Most parasitized nests fledge both warblers and cowbirds. Some warblers in parasitized nests starved or were trampled. The overall cost of parasitism was approximately 1 young in both early and late nests, or about 22-26% of the potential young. In Ontario, 13 of 48 nests (27.1%) reported to the Ontario Nest Records Scheme were parasitized. Over a third of nests are parasitized in some Ontario populations (36% at Long Point), and parasitism by the Brown-headed Cowbird is the second-most important cause of nest losses. Parasitism rates vary considerably geographically and tend to be higher in the Midwest where cowbirds are more abundant. The parasitism rates recorded in Ontario are among the highest documented for this species. Parasitism rates may vary considerably in a single location from year to year. In Tennessee, parasitism rates were similar in natural cavities (19.1%) and in nest boxes (21.2%). The overall parasitism rate was 22% in 1984 and 1985 but only

1.8% 1987- 89. Parasitism rates reported from other areas were 26.9% in Wisconsin, 25.7% and 46.3% in Iowa, 10.7% in Michigan, 12.3% in Louisiana, 15.6% and 38% (in nest boxes) in Illinois, 44.8% in Mississippi, and 0.013% in Virginia, where all nests were in boxes. A nest in Toronto in 1933 contained 7 cowbird and 0 warbler eggs. In an agricultural landscape in Illinois, parasitism rates were not influenced by patch size or the amount of natural habitat in the landscape. It was surmised that the landscape was so fragmented that it was saturated by nest predators and brood parasites (Bent 1953; Bird Studies Canada 2001; Blem and Blem 1991; Blem et al. 1999; Chapas-Vargas and Robinson 2013; Flaspohler 1996; Graber et al. 1983; Hoover et al. 2020; Lowther 1985, 1997; McConnell et al. 2011; McCracken 1984, 2000, 2001, 2007; McCracken and Dobbyn 1997; Peck and James 1998a; Petit 1989, 1991b, 2020; Petit et al. 1987; Twedt and Henne-Kerr 2001).

In Iowa, a Prothonotary Warbler laid an egg in a Northern House Wren nest in a nest box. The nest contained 3 wren eggs and 1 warbler egg. One wren egg disappeared and the other 2 did not hatch. The warbler egg hatched and the wren provisioned the warbler nestling with insect larvae, spiders, and winged insects. The warbler successfully fledged from the nest (Dodson et al. 2024).

Throughout its summer and winter range, habitat loss is the biggest threat to the Prothonotary Warbler, although direct habitat loss is less of a concern in Ontario. In the core of its breeding range in the southeastern United States, less than 25% of the original bottomland forest remains in moderate to high-quality condition. Coastal mangrove swamps that are critical wintering habitat in Central and South America are declining at an alarming rate. The decline in mangrove swamps corresponds to declines in breeding populations, but no direct link between these factors has been established. The Ontario population relies upon recruitment of birds from the United States breeding population. Small numbers occur in New York, Ohio, Pennsylvania, and Michigan, providing a small pool of potential immigrants. Many of these populations are declining and they also rely on recruitment from the core area in the southeast, where it is also declining. The continued existence of the Prothonotary Warbler in Ontario is increasingly dependent upon what happens in the United States and Latin America. In Ontario, 700-800 ha are occupied by the Prothonotary Warbler and 85% of this is protected government-owned land. The most significant threat to privately owned habitat is development. One occupied site was developed into a marina and trailer park. There were extensive losses of wetland habitat in southern Ontario until 1982, but losses have slowed considerably due to government policies. Nonetheless, there are now few large, unfragmented patches of swamp forests left that provide suitable habitat, and it is possible that all suitable habitat is occupied. The extensive system of municipal drains and tile drainage is still drying out many swamp forests (Austen et al. 1994; Bird Studies Canada 2001; Blem and Blem 1992; Flaspohler 1996; McCracken 1984, 2007, 2010; McCracken et al. 2010; Petit 2020).

In most areas, availability of suitable nesting cavities is a significant limiting factor, but this does not appear to be a problem in Ontario. Competition for nest cavities by other species is a significant factor throughout the Prothonotary Warbler's range. In Ontario, the 2 most significant competitors are the Northern House Wren and Tree Swallow. The Northern House Wren is responsible for a high percentage of nest losses in Ontario. It is particularly a problem because it fills all available cavities with dummy stick nests and these sticks may persist for several seasons making the cavity unavailable. In addition, the wren may remove or puncture warbler eggs and kill nestlings. The wren

is double-brooded with a long breeding season that spans the entire warbler breeding season. The Tree Swallow is a less serious nest-site competitor because it only uses 1 cavity, does not disturb warbler nests, and usually raises a single brood so it is present only during the early portion of the breeding season. In Iowa, 38.4% of Prothonotary Warbler nests were usurped by wrens and 1.5% by Tree Swallows. The deaths of 2 adult warblers were attributed to Tree Swallows. In Ontario and other areas where these 2 species are common, nest-box programs designed to increase Prothonotary Warbler populations instead increased wren and swallow populations to the detriment of warbler populations. At Rondeau, several cottagers erected nest boxes and these increased the local wren population. In other areas, it has been determined that nest boxes should not be used where the Northern House Wren is common unless the warbler habitat is in large, unfragmented, and flooded habitat. In Ontario, there are few such sites remaining. Although large, the forest cover at Rondeau is naturally fragmented by wetland sloughs that provide habitat for the Northern House Wren. Other species are a problem in different areas. These include House Sparrow, Carolina Wren, Eastern Bluebird, European Starling, chickadees, white-footed mice, southern flying squirrels, paper wasps, and mud-dauber wasps. In Tennessee, competing species represented 95.2% of nests in dry habitat compared with 4.8% in flooded habitat. Fortunately, the core areas of distribution of the Prothonotary Warbler and Northern House Wren do not overlap, so this wren is not a problem in the southeastern United States. The Northern House Wren is a major limiting factor in its core range, which includes Ontario, where it greatly outnumbers the Prothonotary Warbler and is increasing its population while the warbler is declining (Austen et al. 1994; Bird Studies Canada 2001; Blem and Blem 1991, 1992; Brush 1994; Flaspohler 1996; Graber et al. 1983; Guillory 1987; Knutson and Klaas 1997; McCracken 1984, 2000, 2001, 2007, 2010; McCracken and Dobbyn 1997; McCracken et al. 2010; Morse 1989; Petit 2020; Petit and Petit 1996; Scerbicke et al. 2024; Twedt and Henne-Kerr 2001; Walkinshaw 1938, 1941).

Regular water-level fluctuations within Prothonotary Warbler habitat are beneficial because they retard succession of shrub species and certain aquatic species. Extreme water-level fluctuations or long-term changes in water levels or the water table are detrimental. Although it has not been identified as a factor in Ontario, flooding in riparian swamps is an issue in many areas. This is a common cause of nest loss in much of its range. In Minnesota and Iowa forest cover along the Mississippi River, periodic flooding had a beneficial effect. Flooding of riparian forests allowed it to nest in areas that were typically occupied by the Northern House Wren. In Ontario, habitat is influenced most by water levels in the Great Lakes. Sustained high-water levels can kill trees and open up the canopy. Over the long term, high-water levels can result in a swamp forest being converted to a marsh or thicket swamp, thereby rendering the habitat unsuitable. If water levels remain low for an extended period of time, swamps dry up. This makes the habitat essentially unsuitable, although birds that have previously bred in such an area may continue to do so because of site fidelity. Dry swamps are unlikely to attract any new recruits. The dryness of such areas improves habitat for Northern House Wrens, promotes the growth of herbaceous and woody undergrowth, allows invasion by nonnative plant species, and provides access for terrestrial predators such as raccoons, squirrels, chipmunks, and mice. Under optimal conditions, there is a natural cycle of high and low water levels in the Great Lakes that provides a turnover of living and dead trees while some standing water remains. Much of the natural cycling of water levels in the

Great Lakes has been curtailed by current water management programs. Water levels in swamps may be adversely affected by direct wetland drainage or indirectly through lowering of the water table by irrigation or systems of tile drainage and municipal drains. Drought is another factor that can significantly lower the water table and surface water levels and adversely affect Prothonotary Warbler habitat (Bird Studies Canada 2001; Flaspohler 1996; Graber et al. 1983; Knutson and Klaas 1997; McConnell et al. 2011; McCracken 1984, 1999b, 2000; McCracken et al. 2010; Walkinshaw 1938).

Forest management has the potential to have significant effects on the Prothonotary Warbler and its habitat. Forest fragmentation creates edge that may improve habitat for the Northern House Wren and other nest-site competitors. Opening of the canopy due to logging may reduce water levels due to increased evaporation, may promote encroachment of invasive plant species, and may result in the loss of nest trees. Fuelwood cuts may remove dead and dying trees and stumps that are important sources of nest cavities. The population at Rondeau was drastically reduced in the mid-1930s following a cleanup program that involved removal of most of the dead stumps. This population has never recovered to its former levels (Baillie 1967; Bird Studies Canada 2001; Bushman and Therres 1988; McConnell et al. 2011; McCracken 1987, 2007; McCracken et al. 2010; Petit 2020).

Invasive plant species are a significant issue at some of the best areas for the Prothonotary Warbler in Ontario. Both common reed and black alder can significantly degrade habitat, particularly where water levels are low or canopy cover is reduced. Common reed has expanded dramatically at Rondeau where it has filled in open pools of water, rendering the habitat unsuitable. Black alder is highly invasive and can significantly degrade Prothonotary Warbler habitat in open swamp forests. It is already abundant in Hahn Woods and is a major problem at several restoration sites in Norfolk County. Reed manna grass has become dominant in a large portion of the Dundas Marsh, another Prothonotary Warbler breeding site. It is highly invasive and has the ability to out-compete native emergent wetland plant species (McCracken et al. 2010).

The emerald ash borer is another significant concern, as it eventually kills all affected ash trees. Ash is a frequent component of swamp forests that are inhabited by the Prothonotary Warbler in Ontario and it represents 47% of the tree cover in the Rondeau sloughs (McCracken 2007; McCracken et al. 2010).

Catastrophic weather events are potential significant factors. Populations within Ontario are clumped in isolated geographic areas, particularly along the northern shore of Lake Erie. An intense windstorm struck Rondeau in July 1998 that dropped thousands of trees and created hundreds of gaps that provided suitable habitat for Northern House Wrens. A similar storm at Point Pelee in the late 1970s resulted in significant windfall and may have reduced habitat availability. The intensity and frequency of storms is anticipated to increase as a result of climate change (McCracken 1999b, 2007, 2010; McCracken et al. 2010).

Drought is another potential limiting factor. A drought in Ontario in 1998 completely dried up most nesting areas and adversely affected Prothonotary Warbler habitat. As late as 2000, effects of this drought were still being manifested. Dry summers are likely to become more prevalent with climate change (McCracken 2001, 2007).

Predation can result in significant nest losses, with nest predation rates of approximately 40% occurring in Ontario. The raccoon is the most significant predator. Its population has increased dramatically in the province and is still increasing. Raccoons are the predominant predators of nests in natural cavities and of those in boxes without predator guards. The southern flying squirrel is the predominant predator in nest boxes with predator guards (Bird Studies Canada 2001; McCracken 2010; McCracken et al. 2010).

Toxic chemicals and other pollutants are an additional threat. Insect control programs in Ontario for mosquitoes and gypsy moths may reduce arthropod food supplies. Of greater concern are insecticides in Latin America, where DDT is still widely used for malaria control (McCracken et al. 2010).

Small populations at Turkey Point and near London were extirpated in the 1970s following development of the woodlands in which the Prothonotary Warbler was nesting. Direct development of habitat could not occur now due to the current wetland policies and the fact that it is protected under the *Endangered Species Act*. Nonetheless, development adjacent to occupied habitat is likely to increase the local raccoon population and possibly Northern House Wren numbers (McCracken 1984; McCracken et al. 2010).

Most nests in natural cavities are in dead and decayed trees. These are vulnerable to blowing down or simply collapsing during the nesting period. These types of losses have been confirmed in Ontario and many other locations. Nest trees along creeks may slump or fall down due to shore-bank erosion (Blem and Blem 1991; McCracken 2001; Petit 2020).

In Ontario and the northern portion of its range, the Prothonotary Warbler is likely to decline in response to climate change. Climate change models for the Great Lakes area suggest an increase in temperature, a reduction in precipitation, and lower lake water levels. This is likely to reduce the amount of standing water in swamps (McCracken 2007, 2010).

Status

Although it is possible that the Prothonotary Warbler was present in Ontario prior to European settlement and extirpated as a result of wide-scale forest clearing, this is unlikely. Historically, it was restricted to the swamps of the southeastern United States and later extended its breeding range northward, especially in the Mississippi River valley, to Wisconsin and Minnesota. The first record for Ontario was a spring migrant overshoot collected in Hamilton on 23 May 1888. The first nest for the province was found at Rondeau in 1929, although it was likely nesting there previously. In 1930 and 1933, it was estimated that more than 100 pairs bred at Rondeau, although it is now thought that this may have been an overestimate. Nonetheless, it was locally common at Rondeau at that time and this was the only known breeding site in the province. After stumps were removed from Rondeau in the mid-1930s, hardly any remained but it soon began to appear at Long Point. Birds observed there probably dispersed from Rondeau. It first nested at Point Pelee in 1955 and occurred there regularly until 1989. The bulk of the breeding population is almost entirely restricted to a few areas on or adjacent to the Lake Erie shoreline: Holiday Beach, Pelee Island, Wheatley, Rondeau, Long Point, and Point Abino, although it probably no longer breeds at the latter site. The Prothonotary Warbler began breeding intermittently in the Dundas Marsh in Hamilton in 1953. From the mid-1990s to mid-2000s, 0-1 pair nested annually, and 0-6 young fledged each year (average 3.1 per

year). In 1981, it nested in Pinery Provincial Park, but this appears to have been an isolated event. Territorial but unmated males occasionally defend territories in suitable habitat in inland locations in Brant, Middlesex, and Huron counties and Halton and Peel regions. These occurrences are not enduring and inland nesting has rarely been documented. Most of the population nests at Rondeau and Long Point, with lesser numbers at Holiday Beach. It formerly nested at Point Pelee and Turkey Point and near London and Aylmer. Habitat for this species has been destroyed at Turkey Point and near London. The Rondeau population recovered somewhat after stumps were removed, but the population never approached former numbers. In the mid-1980s, the entire Ontario population was estimated at a maximum of 50 breeding pairs. By 1996, there were only about 10 pairs remaining in the province. Restoration work began in 1997 and by 2000 there were an estimated 22 mated pairs and 8 unmated males present. This was the highest number recorded since intensive surveys began in 1996. By 2010, however, the population had declined again to no more than 10 pairs. Despite the population decline, there has been no significant change in the breeding distribution of the Prothonotary Warbler since about the 1940s (Austen et al. 1994; Baillie 1967; Baillie and Harrington 1937; Bird Studies Canada 2001; Curry 2006; Harrison 1984; McCracken 1984, 1999b, 2000, 2001, 2007, 2010; McCracken and Dobbyn 1997; McCracken et al. 2010; McIlwraith 1894; Peck and James 1998a; Wills and Barrett 2006).

In 1984, the Prothonotary Warbler was designated vulnerable in Canada and its status was upgraded to endangered in 2007. It is also designated endangered in Ontario and protected under the *Endangered Species Act*. The objective of the recovery strategy is to recover its historical population to 40 pairs spread among at least 6 geographically distinct nesting areas by 2015. These nesting areas are to be separated by at least 20 km (McConnell et al. 2011; McCracken 1984, 2007; McCracken et al. 2010).

There have been no recent historical changes in the breeding range of the Prothonotary Warbler. Breeding Bird Survey data from 1966 to 2007 indicate that the continental population declined at a significant rate of 1.1% per year (McCracken et al. 2010; Petit 2020).

POSTFLEDGING PERIOD

When young leave the nest, they fly to a nearby low-hanging branch. Any that fall into the water are capable of swimming to shore. One or more shrubs or saplings within a short distance of the nest provide immediate refuge for newly fledged young. Fledglings work their way up trees until they are in the canopy, and remain there for approximately a month. Within this time, they may range as far as 300 m from the nest and occur in any type of forested habitat, including dry upland areas. Juveniles that fledge from first broods may wander considerable distances prior to migration. One young that fledged in early June was found in early July 7 km from the natal territory. Four other juveniles 35-40 days old were found within 200 m of the nest. During this period, juveniles prefer trees that are at least 15 m tall. The adults divide the brood immediately upon fledging but if a female attempts a second brood, the male cares for all the fledglings from the first brood. The adults feed the young for at least 2 weeks after they leave the nest but young may still be fed as late as 35 days after fledging. Fledglings often occur in flocks of 3-5 in late June and July and flock members include those from different broods (Bird Studies Canada 2001; McCracken et al. 2010; Petit 2020; Walkinshaw 1938).

MIGRATION

The Prothonotary Warbler is a nocturnal migrant, with diurnal observations of migrants occurring mostly over water close to landfall. There is some evidence to suggest that it may follow watercourses during migration. In spring, it occasionally travels in small, single-species flocks when crossing the Gulf of Mexico. It is believed to travel singly in Ontario (Graber et al. 1983; McCracken 2007; Moore 1990; Petit 2020).

Males arrive on the breeding grounds prior to the females, and the interval between their arrivals may vary geographically or due to weather conditions. In Michigan, males arrived 2-3 days prior to females; the interval was 3-7 days in Tennessee. In Arkansas, females arrived 1-2 weeks after males. In Ontario, males typically precede females by about 2 weeks and older birds of both age groups arrive before younger birds (Bird Studies Canada 2001; Blem and Blem 1992; McCracken et al. 2010; Petit 1989; Petit and Petit 1996; Slevin et al. 2018; Walkinshaw 1938). The Prothonotary Warbler returns to southern Ontario in the first week of May or in very late April. Most are back on the breeding grounds by the first week of June, but some younger females may not arrive until the end of June (Bird Studies Canada 2001; McConnell et al. 2011). In the Gulf Coast states, average spring stopover times were 2.0, 4.2, and 8.4 days. Areas with the highest food availability had the shortest stopover times (Moore and Kerlinger 1987; Moore and Simons 1992).

The timing of autumn migration is difficult to ascertain because males stop singing and the adults and fledglings move to the tree canopy prior to migrating. In Michigan, family groups can be seen until mid-August some years, but most leave by the second or third week of July. In Ontario, almost all birds are beginning to migrate in mid-August. In the Hamilton area, average departure is 26 August and the latest record is 3 October. The sole Niagara record of an autumn migrant was on 27 August. On the Gulf Coast, hatching-year females tend to be the latest autumn migrants (Bird Studies Canada 2001; Black and Roy 2010; Curry 2006; McCracken et al. 2010; Petit 2020; Walkinshaw 1938).

There are no known differences in the habitat preferences of the sexes during migration. Although the Prothonotary Warbler has broader habitat preferences during migration than the breeding season, it is still found mostly near water along coastal areas and near inland lakes, watercourses, swamps, and marshes. It may occur away from water in young second growth. In Illinois, few were recorded outside their lowland breeding habitat during spring migration. During migration in Wisconsin and Minnesota, it was recorded only in floodplain forests and not in upland forests. During spring migration in North Carolina, the average number seen per hour was 0.70 in floodplain forests and 0.08 in wet thickets. It was not observed in pine-hardwood forests, pine forests, beech forests, oak-hickory forests, or dry thickets. During spring migration in Winnipeg, one spent most of a day at a pond in an urban park (Graber et al. 1983; Kirsch et al. 2013; Parnell 1969; Petit 2020; R.M. Underwood and T.J. Underwood 2001).

During spring migration in North Carolina, 18.6% of observations of the Prothonotary Warbler were in the canopy, 53.5% were in low trees, 16.2% were in shrubs, and 11.6% were on the ground. In the canopy, 2.3% of observations were in the top of the crown, 11.6% in the inner crown, 4.7% in the lower crown, and 0% on the bole. In low trees, 9.3% of observations were in the top of the crown, 14.0% in the inner crown, 30.2% in the lower crown, and 0% on the bole. In shrubs, 2.3% of

observations were in the inner crown, 2.3% in the lower crown, 11.6% in dense thicket and 0% at the top of the crown, in brush piles, or in grasses. On the ground, 2.3% of observations were in dense thickets, 9.3% were at water's edge, and 0% in grasses and open areas (Parnell 1969).

During spring migration at a pond in Winnipeg, one foraged among dead cattails most of the day. Occasionally it flew up and perched at the top of cattails before dropping down into them again (R.M. Underwood and T.J. Underwood 2001).

The Prothonotary Warbler is occasionally killed during migration at communication towers and tall buildings, but not in high numbers (Graber et al. 1983; Petit 2020). Because of its low population, it is possible that these losses are significant.

As would be expected based on its small breeding population, the Prothonotary Warbler is a rare migrant in Ontario (James 1991). There are no major concentration areas in the province during migration apart from Point Pelee, Long Point, and Rondeau (McCracken 1984).

Tennessee Warbler

Leiothlypis peregrina

BREEDING SEASON

Habitat Requirements

Most Ontario Tennessee Warbler nests were in wet habitats, including sphagnum bogs, with black spruce characteristically present or, less frequently, alder, tamarack, and poplar. One nest was in an area of willow shrubs with scattered taller poplars. Four nests were in dry locations: 2 in black spruce woods, 1 in a jack pine–spruce stand on a rocky outcrop, and 1 in an area of jack pine reforestation (Peck and James 1987). James (1984b) concluded that it was associated mostly with coniferous forests, but also mixed forests and less frequently deciduous forests. It requires coniferous trees of medium to tall height. It also needs open forests or edges and openings where deciduous shrubs are common. It may occur in riparian areas or swamps, but also inhabits drier forests.

In the northern portion of the Boreal Forest Region and Hudson Bay Lowland, the Tennessee Warbler nests in deciduous shrubs and saplings. Along the Hudson and James bay coasts, it is frequent along forest edges where it uses habitat similar to that selected by the Yellow Warbler. It occurs in willow thickets, patches of tall willow shrubs at edges of barrens, and deciduous shrubs in

swamps between the spruce forests and barren coastal areas (Manning 1952). Near Attawapisak and Winisk, it was common in open willow and willow-alder thickets and in spruce-willow bogs (Schueler et al. 1974). In northwestern Ontario, it was the most abundant species in deciduous shrubs and saplings 0.5-5 m tall. Other habitats it occurred in, in order of abundance, were coniferous forests with an understorey, mixed forests, deciduous forests, mixed scrub, heaths, coniferous scrub, and coniferous forests without an understorey. It was absent in tundra (McLaren and McLaren 1981). On the southwestern coast of James Bay, it occurs in all wooded habitats, including willow and alder swales, stands of balsam poplar on former beach ridges, and in lowland spruce–balsam fir forests. It is strongly associated with shrubs, particularly grey alder (Rimmer and McFarland 2020). Near Manitouwadge, it occurred in mixed stands dominated by black spruce, balsam fir, balsam poplar, and trembling aspen. It preferred mature (60-223 years) stands. Habitat choice became more generalized with increasing abundance of spruce budworms, settling in intermediate (24-36 years) and young (1-21 years) stands as budworms became abundant. Numerical responses of the Tennessee Warbler to budworm infestations were lower in younger than mature stands (Venier et al. 2009). Near Longlac, it used mixed boreal forests of balsam fir, white spruce, black spruce, trembling aspen, and white birch for nesting. It selected dry open sites for nesting. Of 14 nests, 5 were along road edges and 5 were in or at edges of small clearings. The other 4 were under a closed canopy, but in sparsely wooded areas. Average coverage by trees within 1 m of nests was 16.5%, and these were balsam fir, spruce, willow, and grey alder in order of abundance. Most nests were in dense ground cover including 20.2% coverage by feather mosses and 50.1% coverage by other species. In order of abundance, these were bunchberry, grasses, large-leaved aster, Labrador tea, strawberry, prickly rose, raspberries, naked bishop's cap, wild sarsaparilla, sweet coltsfoot, low sweet blueberry, Canada mayflower, horsetails, pearly everlasting, twinflower, goldenrods, and sphagnum moss. Most nest records from other locations refer to boggy wet areas with black spruce, tamarack, or white cedar. At Longlac, it frequently foraged in boggy or wet habitats, particularly in grey alder, but no nests were found in this habitat (Holmes and Nixon 2000). Near Lake Nipigon, it nested in forests dominated by balsam fir, black spruce, and white spruce that contained some white birch, jack pine, Labrador tea, and trembling aspen. Nesting occurred in clear-cuts and forest cover of all ages, including virgin mature forest. Trees appeared to be essential; a male attempting to establish a territory in a young treeless clear-cut eventually abandoned the site. The Tennessee Warbler nested there in wet alder thickets containing scattered trees. Spruce, white birch, and balsam fir trees were the most frequent singing perches, where it sang from an average height of 3.7 m from the tops of trees. Singing also occurred

as close as 30 cm from the ground and from alder shrubs (Kendeigh 1947). Near Pickle Lake, it occurred irregularly in small numbers in disturbed mixed woodlands (James 1980). Near Hearst during a spruce budworm outbreak, habitats it used included mixed forests of black spruce, white spruce, balsam fir, white birch, and trembling aspen; lowland forests of black spruce and tamarack; and well-drained sites dominated by jack pine. It was absent in 3-year-old clear-cuts, but was present in clear-cuts 5-24 years old and in mature undisturbed forests. It occurred in all types of stands but was most common in mixed and coniferous stands, and was most abundant in lowland coniferous stands followed by lower-slope mixed stands (Welsh and Fillman 1980). In the Clay Belt, it occurred in all forest types and along the full range of moisture regimes in woodlands with moderate to rich amounts of nutrients. It was most abundant in black spruce, jack pine, trembling aspen, tamarack–white cedar, and balsam poplar forests, and least abundant in balsam fir–white spruce stands (Welsh and Lougheed 1996).

In jack pine stands near Gogama in the Great Lakes–St. Lawrence Forest Region in the Canadian Shield, the Tennessee Warbler preferred very open edges of spruce forests. The managed jack pine forests were too dense to support it, but a few occurred where there were openings in the pines and when spruce budworm populations were high. It was attracted to forests older than 20 years when budworms were abundant (James and Peck 1995a).

Throughout its range, the Tennessee Warbler is most frequently associated with coniferous and mixed boreal forests where it requires deciduous undergrowth. It is characteristic of spruce and balsam fir stands, frequent in jack pine stands, and rare to absent in hemlock stands. It is typical of tamarack swamps and treed bogs where it is associated with alder in the understorey. It may nest in bogs or fens dominated by black spruce, tamarack, or white cedar. Due to its requirement for a deciduous understorey, it is typically associated with forest openings or edges. Nesting also occurs in regenerating clear-cuts, which it first invades about 5 years after cutting, but peak numbers occur 13-25 years after cutting. Nests are frequently in natural and artificial openings other than clear-cuts, including roadsides, ponds, bogs, farmsteads, burns, logging roads, trails, power-line cuts, overgrown pastures, and grassy openings on abandoned farmland. In taiga areas, it is often associated with large spruce trees, but also nests in second-growth forests that are often dominated by balsam poplar. These stands typically have a dense growth of deciduous understorey shrubs and saplings such as alder, rose, red-osier dogwood, or trembling aspen. Although it is most frequent in forests dominated by spruce and balsam fir, it also nests in trembling aspen, balsam poplar, poplar-birch, white birch–red oak, and spruce-poplar forests and thickets dominated by alders or willows. It is associated primarily with conifers, but coniferous stands must have a deciduous understorey to be suitable, and it frequently nests in alder and willow thickets and regenerating clear-cuts where conifers are scarce or absent. In Wisconsin, it is a rare breeder in pine and oak barrens (Back 1979; Beals 1960; Bent 1953; Bowdish and Philipp 1916; Campbell et al. 2001; Chapman 1907; Crawford and Titterington 1979; Dawson 1979; Erskine 1977; Harrison 1984; Jehl and Smith 1970; Kirk et al. 1996; Limoges and Gauthier in Gauthier and Aubry 1996; Manning and MacPherson 1952; Mossman et al. 1991; Rimmer and McFarland 2020; Sinclair et al. 2003; Welsh and Fillman 1980).

Differing preferences for forest stand ages have been reported for the Tennessee Warbler. Near Manitouwadge, it showed a clear preference for mature stands and inhabited younger stands only

when budworms were abundant (Venier et al. 2009). Near Hearst, it was more abundant in 17-24-year-old clear-cuts than in mature stands (Welsh and Fillman 1980). In Quebec, it was absent in previously cut or burned black spruce forests where trees were less than 5 m tall. It occurred in low densities in cuts and burns where saplings were 5-11 m tall and in 120-year-old forests, but was absent in 200-year-old forests (Imbeau et al. 1999). In Alberta aspen-dominated forests, there were no significant differences in its abundance in young, intermediate-aged, and old stands, although it was most abundant in young stands. It was associated with low aspen density, low shrub density, few snags, few trees larger than 20 cm diameter at breast height, low shrub richness, low canopy height, lower amounts of downed woody material larger than 20 cm in diameter, low tree species richness, and low conifer density (Schieck et al. 1995). In Saskatchewan, it occurred significantly more often in white spruce–trembling aspen forests that were more than 140 years old. The probability of detecting it at a point count was 50-79% in forests 50-60 years old, 80-90% in forests 100-110 years old, and 100% in stands older than 140 years. In old forests, the percent coniferous cover increased, the amount of shrub and moss coverage was significantly higher, and the amount of litter was significantly less than in young forests (Cumming and Diamond 2002). In boreal stands in Saskatchewan, Kirk et al. (1996) considered it an early successional species. Its probability of occurrence was 100% in very young stands (0-9 years), 67% in young stands (15-20 years), 100% in mature stands (40 years), and 67% in old stands (80 years). The percent coverage by coniferous trees and deciduous shrubs and saplings may be a more important habitat determinant for the Tennessee Warbler than forest age.

The Tennessee Warbler is tolerant of a wide range of moisture regimes. Early studies concluded that it was restricted to wet habitats such as bogs, coniferous and mixed swamps and lowland forests, and willow and alder thickets. More recent work demonstrated that it also nests in dry habitat including very dry sites on hillsides. Near Longlac, it selected drier sites and in the Clay Belt it occurred in very wet to dry habitats. Near Hearst, it showed no particular preference for moisture. In Saskatchewan, it occurred on average in mesic stands, slightly drier than average. In Alberta, it typically nests in poplar and poplar-spruce stands, but also in dry muskeg. In British Columbia, it is generally associated with moisture (Bent 1953; Bowdish and Philipp 1916; Campbell et al. 2001; Holmes and Nixon 2000; Kirk et al. 1996; Rimmer and MacFarland 2012; Welsh and Fillman 1980; Welsh and Lougheed 1996).

At the landscape level, the Tennessee Warbler does not appear to be adversely affected by forest fragmentation. In Saskatchewan, Hobson and Bayne (2000) found that it was randomly distributed within fragmented landscapes.

Nests reported to the Ontario Nest Records Scheme were predominantly in hollows in hummocks of sphagnum moss. One was at the base of a grass tuft, 2 were under Labrador tea, 1 was at the base of an alder, and 1 was under an alder branch (Peck and James 1987). Holmes and Nixon (2000) described additional nests from Longlac. Five were in depressions sunk into hummocks of moss or lichen. Additional cover was provided to these nests by conifer seedlings, dead conifer branches, shrubby plants such as Labrador tea, and a mixture of shorter plants including bunchberry, large-leaved aster, grasses, and sweet coltsfoot. Plant coverage at 2 nests was less dense, but they were still inconspicuous due to cover from overhanging mosses and dead leaves.

Two other nests were in holes in the sides of decaying, moss-covered stumps. One was at the bottom of the stump beneath an overhanging root, concealed by spruce seedlings, wild sarsaparilla, naked bishop's cap, and feather moss. The second nest was midway up the stump, hidden behind a dense growth of horsetails, prickly rose, and grasses. Two additional nests were in long grass and willows at the edge of a laneway. They were completely obscured by grass that had settled into thick mats among the sparse willow stems. Entrance to these nests was possible only through a small hole at the edge of the nest. Of the remaining 5 nests, 3 were in depressions at the base of conifer seedlings surrounded by grasses, large-leaved aster, common strawberry, and other plants; one was in a hole beneath the stem of a black spruce seedling encircled by feather moss, bunchberry, and blueberry; and the other was in a depression in the middle of a mat of feather moss, surrounded by willow stalks, Canada mayflower, bunchberry, and other small plants. Bent (1953) described 4 nests near Sudbury that were all in a clump or mound of sphagnum on margins of black spruce bogs.

Nests of the Tennessee Warbler are very inconspicuous and few have been described despite the fact that it is the most abundant species in many habitats. Almost all nests are on the ground, buried deep in moss, and concealed by seedlings, grasses, herbaceous species, or overhanging moss or limbs. Of 79 nests reported elsewhere, 62% were in moss hummocks, 9% were in grass or sedge tussocks, and 13% were at the base of a small tree or stump. A few nests were in moss on top of decaying logs. Others were under tangles of dead fallen branches or in mats of dead herbaceous vegetation. One New Brunswick nest was above the ground on a low-hanging spruce bough touching, but not buried in, sphagnum. A British Columbia nest was 3 m from the ground on the trunk of a trembling aspen tree and another was in a recess in a mossy stump. Other atypical nest locations include a depression in a mat of lichens, under a clump of clubmosses, and in a hollow in leaf mould (Bent 1953; Bowdish and Philipp 1916; Campbell et al. 2001; Rimmer and McFarland 2020; Sinclair et al. 2003).

Males establish a territory on the day of their arrival on the breeding grounds. In a New Brunswick study, the Tennessee Warbler appeared to be somewhat gregarious, with high densities occurring in clearings in forest cover. It was not considered truly colonial because it defended a territory, but other publications have interpreted these same results differently and concluded that it sometimes nests in small, loose colonies in ideal habitat. This conclusion is incorrect. It sometimes attains extremely high densities and territories may be tightly packed, but territories are vigorously defended and there is no evidence of colonial nesting. The only information on territory size is from near Lake Nipigon. The average size of 52 territories was 0.36 ha (range 0.16-0.69 ha). Only 3-7 records were made of each bird, so territories could have been larger. There were often spaces between territories, although others were contiguous. It was present at a supersaturated population level due to a spruce budworm outbreak. Territory sizes would probably increase with decreasing densities and this was observed at this site. On a plot where only 9 pairs were present, the average territory size was 0.36 ha. On same-sized plots supporting 16 or 17 pairs, the average territory size was 0.25 ha. Not all activities are confined to the territory, so the home range may be larger than the territory. Birds may wander considerable distances from the territory. One female gathered nest material and flew into the forest across a river for a distance of at least 120 m (Bowdish and Philipp 1916; Harrison 1984; Holmes and Nixon 2000; Kendeigh 1947).

No information on natal philopatry is available, but it is probably very low. There is no direct evidence of adult site fidelity, but few studies have been completed. On the southern coast of James Bay in Ontario, 0 of 290 adults were resighted in subsequent years. Reoccupation of nesting territories in subsequent years suggests site fidelity, but there are no data to confirm this (Rimmer and McFarland 2020). In the Gaspé Peninsula of Québec, 0 of 32 adults returned (Moison Perrier et al. 2021). Because the Tennessee Warbler responds strongly to spruce budworm populations, it is possible that it is nomadic. It may not nest in large geographic areas for long periods of time until a spruce budworm outbreak occurs, and deserts the area once the outbreak has run its course (Morse 1989).

Limiting Factors

Eggs have been found in Ontario nests from the first week of June to the third week of July, with most reported in the last half of June (Peck and James 1998a). Near Longlac, territories were established by 28 May, the first evidence of nest building occurred on 8 June, egg laying occurred 8-22 June, incubation occurred 20-30 June, and hatching occurred 27 June-1 July, with a median date of 29 June (Holmes 1998; Holmes and Nixon 2000). In Algonquin Park, dependent fledglings have been observed from late June to late July (Tozer 2012). Of 91 nests reported in the eastern portion of the Tennessee Warbler's range, 26% were found before 15 June, 64% between 15 and 30 June, and 10% after 30 June (Rimmer and McFarland 2020). Harrison (1984) reported some late nest dates including a 4-day-old nestling on 2 August and nestlings on 13 and 14 August.

The interval between arrival and initiation of nest building is unknown. Near Longlac, a partially built nest was found 11 days after males settled on territories. No information is available on how long it takes to build a nest. Information from 1 nest suggested that egg laying commenced immediately after the nest was complete. One egg is laid per day. It is uncertain when incubation is initiated. The incubation period is 11-12 days. At Longlac the period from laying of the last egg to first hatching was 7 and 8 days in 2 nests. This very short incubation period may be an adaptation that synchronizes the nestling period with the presence of late-instar budworm larvae and pupae. Alternatively, incubation may have started prior to the laying of the last egg, in which case the incubation period would have been longer. Near Longlac, hatching occurred within 24 hours at 4 nests and within 48 hours in 6 nests with 81% of nestlings hatching in the first 24 hours and 19% over a 24-48 hour period. It is possible that the onset of incubation is variable, with initiation of incubation of most clutches occurring with the laying of the last egg, but with some clutches being incubated prior to that. If young are disturbed, they may leave the nest when they are only 6-7 days old, but many remain in the nest until they are 7-12 days old (Bent 1953; Bowdish and Philipp 1916; Campbell et al. 2001; Holmes 1998; Holmes and Nixon 2000; Rimmer and McFarland 2020).

The Tennessee Warbler raises a single brood. Renesting may occur and late nesting records are probably from replacement nests. Large-scale departures from the breeding range often occur in early summer suggesting that many do not renest. Nests reported to the Ontario Nest Records Scheme had clutches of 4-7 eggs, but mostly 5 or 6 eggs (average 5.45 eggs). Near Longlac, clutch size was 5-7 eggs (median 6, average 6.09 eggs). Hatching success was correlated with clutch size, with a hatch rate of 87% for 5-egg clutches, 93% for 6-egg clutches, and 100% for 7 eggs. Clutch sizes may increase by 50% during spruce budworm outbreaks, when clutches of 6-8 eggs are

common. Near Longlac, average brood size was 6.2 nestlings in unsprayed areas during budworm outbreaks, and 5.5 and 5.2 in plots treated with insecticides. Broods larger than 6 nestlings may exceed the provisioning capacity of adults. Nestlings in broods of 7 had low growth rates. In British Columbia where the spruce budworm is absent, clutch size is 2-6 eggs (Bent 1953; Bowdish and Philipp 1916; Campbell et al. 2001; Harrison 1984; Holmes 1998; Holmes and Nixon 2000; Morse 1989; Peck and James 1998a; Rimmer and McFarland 2020).

No information is available on the age at first breeding, but it is likely that yearlings are capable of breeding. The Tennessee Warbler is assumed to be monogamous, but this has yet to be confirmed (Rimmer and McFarland 2020). In Maine, territorial birds that were removed from spruce–balsam fir forest were replaced suggesting the presence of a nonbreeding, floating population (Hensley and Cope 1951).

The Tennessee Warbler is one of the smaller warblers, which enables it to forage on the outer twigs and leaves of trees. Most of the time spent foraging during the breeding season is in the upper third of trees. In northern Ontario, it foraged mostly on aspen, followed by white birch, white spruce, alder, balsam fir, and black spruce. Near Lake Nipigon during a spruce budworm outbreak, budworm density was highest on balsam fir, intermediate on white spruce, and low on black spruce. Budworm density may affect the preference of trees for foraging. In the Northwest Territories, it foraged mainly on white spruce, followed by aspen, willow, birch, and black spruce. In Saskatchewan, it used white birch more than expected by chance for foraging. It used balsam fir less than expected and other tree species in proportion to their availability. The Tennessee Warbler appeared to have trouble foraging in the thin outer twigs of balsam fir and avoided it. In conifers, it used the bottom of trees significantly less than expected, the outer part of branches with small twigs more than expected, and avoided the inner portion of the top of trees. In deciduous trees, it used small twigs on the outer portion of trees significantly more than expected. Average foraging height was 8.6 m in conifers and 9.5 m in deciduous trees. In Ontario, mean tree height was 13.7 m and mean foraging height was 9.6 m (70.0% of tree height). In the Northwest Territories, mean tree height was 10.3 m and mean foraging height was 7.9 m (76.7% of tree height). It typically forages at heights of 12 m or less during the breeding season. In Ontario, 75% of foraging time was spent in the top third of trees, 22% in the middle third, and 3% in the bottom third. The percent coverage by conifers within a 50-m radius around foraging individuals was 44% in Ontario and 53% in the Northwest Territories. In Saskatchewan, 66% of observations were in canopy trees and 34% were in the subcanopy. In Ontario, the primary foraging substrate was leaves followed by twigs and curled leaves. In the Northwest Territories, it foraged primarily on conifer needles followed by leaves, curled leaves, and twigs. In Ontario and the Northwest Territories, foraging was predominantly by gleaning and reaching. It infrequently hovers, hangs upside down, or flushes and pursues prey (Cumming 2004; Greenberg et al. 1999; Kendeigh 1947; Limoges and Gauthier in Gauthier and Aubry 1996; Morse 1989; Rimmer and McFarland 2020).

Food items brought to nestlings by males averaged 1.5 cm compared with 1.38 cm by females; the overall average was 1.45 cm. Near Longlac, lepidopteran larvae and pupae, particularly those of the spruce budworm, comprised 93.6% of food items brought by males and 87.9% by females. During a spruce budworm outbreak, caterpillars constituted 91.1% of the nestlings' diet in an

unsprayed area compared with 93.2% in an area sprayed to control budworms. Gizzards of adults were collected during a spruce budworm outbreak near Longlac. Early in the season (7-11 June) the diet consisted of 41.5% beetle adults, 47.7% caterpillars, 4.6% flies, 1.5% spiders, and 4.6% other items (soft-winged bugs, hymenopteran larvae and adults, beetle larvae, snails, odonates, caddisflies, and lacewings). The diet changed significantly in mid-season (18-24 June) and consisted of 5.8% beetle adults, 80.2% caterpillars, 2.3% flies, 3.5% spiders, and 8.1% other items. In the early season, budworm larvae were too small and rarely consumed. The caterpillars eaten during this period were predominantly those of leafroller moths taken by probing in alder foliage. The diet of the Tennessee, Cape May, and Bay-breasted warblers overlapped little early in the season, with the Tennessee Warbler consuming more caterpillars than the other 2 species. Later in the season, only use of beetles differed among the species, with the Bay-breasted Warbler maintaining its preference for beetles. Four stomachs of Tennessee Warbler adults were collected during a budworm outbreak near Lake Nipigon. A male in mixed forest had eaten 3 aphids, 3 unidentified beetles, 1 spruce budworm larva, and 50 unidentified caterpillars. A female collected in a clearing had consumed 5 spiders, 15 aphids, 1 soft-winged bug, 14 beetles, 30 spruce budworm larvae, 15 caterpillars, and 20 flies. A female in spruce–balsam fir forest had eaten 1 aphid, 31 beetles, 1 lepidopteran, 1 fly, and 66 sawflies. A male in a black spruce swamp had eaten 1 soldier beetle and 99 caterpillars. Later in the season when budworms were larger, many Tennessee Warblers were observed with them in their bills. Its diet was dominated by caterpillars (59%) compared with 22.3% for birds on average. It consumed the highest percentage of lepidopterans of all bird species near Lake Nipigon. In New Brunswick when budworms were absent, 3 stomachs were collected. The diet of 1 male consisted of 35% leafroller moth caterpillars, 23% flies, 2% small spiders, and 40% vegetation fragments. One female's diet consisted of 16% carpenter ants, 75% leafroller moth caterpillars, 4% snails, and 5% vegetation. One male had eaten 8% fireflies, 3% small beetle larvae, 25% leafroller moth caterpillars, 50% caddisflies, 14% spiders, and a trace of vegetation. Over 2 years in Maine, spruce budworm larvae and pupae constituted 100% and 66% of the invertebrates consumed. It is a spruce budworm specialist and its population is closely tied to that of the budworm. During spruce budworm outbreaks, it may feed almost exclusively on budworms once the larvae become large enough. It is very efficient at foraging on budworms and is capable of exploiting very low populations of this resource. During outbreaks, budworms are extremely abundant and it has been estimated that bird populations are capable of consuming only about 4% of the larvae. Consequently, there is no competition for food among insectivorous birds during budworm outbreaks (Bowdish and Philipp 1916; Holmes 1998; Holmes and Nixon 2000; Kendeigh 1947; McMartin et al. 2002; Mitchell (1952); Rimmer and McFarland 2020).

There is little overlap in the breeding ranges of the Tennessee Warbler and the Brown-headed Cowbird. The Tennessee Warbler is a rare host of the cowbird. No parasitized nests have been reported in Ontario. Three parasitized nests have been reported in Alberta and one each in British Columbia (9.1% of nests), Saskatchewan, New Brunswick, and Nova Scotia. In Michigan, there is 1 record of warbler adults feeding a cowbird fledgling (Campbell et al. 2001; Harrison 1984; Peck and James 1998a; Rimmer and McFarland 2020).

The Tennessee Warbler specializes in foraging on spruce budworms and its breeding population, breeding distribution, and reproductive success are highly dependent upon budworm

numbers. It is considered one of the best biological indicators of the spruce budworm. Near Manitouwadge, its population increased 9.1 times over a 4-year period during a budworm outbreak and declined by 30% the following year as the outbreak diminished. Prior to the outbreak, it was the 11th-most abundant species, but became the most abundant species during the outbreak. More young are produced from nests during outbreak years. During an Ontario outbreak in 1945, its populations increased steadily throughout June, suggesting that adults settled first and that younger birds exploited vacancies as the season progressed. In New Brunswick, it showed a strong and direct response to budworm numbers. It was initially absent and responded very late in the budworm outbreak suggesting that it might not respond to outbreaks of short duration. In the 1960s, there were no budworm outbreaks of any consequence in Ontario. A massive outbreak began to build in the 1970s, reaching a peak in 1980 when approximately 18,850,000 ha of forest were defoliated. Since 1992, budworm infestations have fallen dramatically, with only 280,000 ha of forest affected in 2004. As a result, significant declines in Tennessee Warbler populations have occurred and they are currently slightly below the 1960s levels prior to significant budworm outbreaks (Erskine 1977; Kendeigh 1947; McCracken 2004; Morris et al. 1958; Venier et al. 2009).

Spraying for the spruce budworm has been an annual event in eastern Canada since the early 1950s. A number of studies determined the impacts of spraying various chemicals and biological-control agents on birds, and some were specific to the Tennessee Warbler. Typically only in the order of 50-60% of budworms are killed by spraying because the material concentrates in the upper foliage. Foliage lower in trees is less exposed to the chemicals. Most studies concluded that spruce budworm control programs pose little threat to songbirds, including the Tennessee Warbler. Chemicals in use early on may have killed birds, but this was not well documented. Less potent chemicals are used now, but their effects are not well known. The bacterium known as Bt is highly specific for lepidopteran larvae and is now widely used and appears to be much less hazardous to birds. In the Gaspé region of Quebec, insecticides have reduced the seriousness of budworms without completely eliminating them. This has helped to maintain Tennessee Warbler populations there at stable levels (Holmes 1998; Kendeigh 1947; Limoges and Gauthier in Gauthier and Aubry 1996).

In Algonquin Park and near Lake Nipigon, Kendeigh (1947) studied the effects of spraying DDT for budworm control on birds, including the Tennessee Warbler. There was no significant decline in numbers on plots that were sprayed late in June once all birds had become established. Plots where it settled first and in largest initial numbers eventually had the largest stabilized breeding populations. There was a significant decline in numbers on a plot sprayed on 2 June before many territories were established. Early spraying and the decrease in abundance of insects did not prevent it from using the area in an apparently normal manner. Numbers of pairs on late-sprayed plots were 9, 16, 17, and 17; there were 9 pairs on the early sprayed plot compared with 16 on the control. The author concluded that DDT had no effects on birds and that any differences in densities on plots were due to differences in habitat and food abundance.

Hunter and Witham (1985) studied the effects of carbaryl spraying on the Tennessee Warbler in Maine over a 2-year period. In the first year, spraying was incomplete and only about 30% of the area was sprayed. Spraying was complete the following year. In the first year, the number of all warblers

foraging in the sprayed area dropped and remained low for 7 days, when a gradual recovery began. The proportion of Tennessee Warblers of all warblers prior to spraying was 22.3% in the experimental area and 12.4% in the control area. After spraying, Tennessee Warblers comprised 5.0% of all warblers in the sprayed area and 4.1% in the control area. During the recovery period, it represented 0% of warblers in the sprayed area and 6.7% in the control. The use of spruce for foraging by all warblers was significantly lower postspray and there was an increase in the use of other species such as alder, yellow birch, beech, ash, white pine, cherry, white cedar, and hemlock. In the experimental area, warblers of all species foraged on conifers 53% of the time prior to spraying and 24% postspray, compared with 62% and 63% in the control area. The number of Tennessee Warblers decreased following spraying, but this decline continued through the study period and also occurred on the control area. Pesticides may affect bird foraging behaviour by reducing food availability and this is likely to be the case only when birds have the opportunity to forage on nearby unsprayed areas. No effects are likely when an entire area is sprayed and birds cannot forage in unsprayed areas.

In New Brunswick, experimental applications of fenithrothion at conventional doses had potentially lethal effects on the Tennessee Warbler. Thirty-eight percent exhibited 50% or more brain cholinesterase inhibition, and 62% showed 20% or more inhibition. The impacts of spraying fenithrothion were highly variable with higher doses having less apparent effect (Rimmer and McFarland 2020).

Holmes (1998) examined the effects of Bt near Longlac and tabufenoxide near West Hill. Both these agents are highly specific in treating lepidopteran larvae. In treated areas, clutch sizes were smaller and the hatch rate was lower. There were no significant differences in nestling growth rates among treatments, although growth rates were highest in the tabufenoxide treatment area, followed by the Bt treatment area and the control area. There was no significant difference in the number of feedings or the size of prey brought to nests among treatments. Because brood sizes were smallest in the tabufenoxide treatment area and the same amount of food was delivered to each nest, nestlings in this treatment area grew faster. The tabufenoxide treatment had high efficacy and reduced spruce budworm populations by more than 90% on spruce and 77% on aspen. There were no reductions of budworms on spruce in Bt treated areas and only 15% in aspen. Even where spraying was effective, it is likely that Tennessee Warblers and other species were finding budworms in refugia that did not receive spray deposits. The author concluded that pest control programs using lepidopteran-specific insecticides pose little threat to the Tennessee Warbler and songbirds in general.

There are contrasting opinions on whether forest management is detrimental or beneficial to the Tennessee Warbler. Vanderwel et al. (2009) completed a literature review on the effects of partial harvest in the Boreal Forest Region, with particular reference to Ontario. It decreased in response to partial harvesting that retained 70%, 50%, and 30% of forest cover. The most important habitat feature was considered understorey cover. Rimmer and McFarland (2020) concluded that it may benefit from forest management in Ontario, where highest densities occur in regenerating clear-cuts. Forestry has the potential to change the composition of forest stands which could alter their suitability for this warbler (Venier et al. 2009). In Ontario in the Canadian Shield, there was no difference in its abundance in mid-successional clear-cuts and stands of the same age created by

fire, but it was significantly more abundant in early successional clear-cuts than burns. It was equally abundant in mid-successional and mature stands, but significantly less abundant in early successional than mature stands (Zimmerling et al. 2017). In Alberta, it is most abundant in stands older than 140 years, but the rotation age is 80-90 years. Cumming and Diamond (2002) concluded that it was likely to decline if stands older than rotation age were lost from the landscape. Also in Alberta, it was more abundant in control areas than in clear-cuts. Leaving unharvested trees in clear-cuts had no effect on abundance (Tittler et al. 2001). Another Alberta study examined the effects of partial timber harvesting on birds. The Tennessee Warbler usually disappeared when areas were clear-cut. In deciduous and mixed stands, it increased when 25-90% of forest cover was removed. Increases were not noted until 2 years postharvest, by which time shrub and sapling regrowth had occurred (Harrison et al. 2005).

Ferris (1979) examined the effects of an interstate highway on the Tennessee Warbler in Maine. Its abundance was negatively correlated with increasing distance from the highway. It was probably responding positively to the opening along the edge between the forest and highway right-of-way.

In Alberta, Bayne et al. (2008) compared the Tennessee Warbler's density and occupancy rates near noise-generating compressor stations and noiseless well pads. There were no significant differences in its density or occupancy rate as a result of differing noise intensities. Bayne et al. (2016) examined the effects of energy sector disturbances on it in Alberta. It responded positively and was significantly more abundant at seismic lines, pipelines, and well pads than in forest interior adjacent to these habitats.

Miscellaneous factors that may affect the Tennessee Warbler include forest fire suppression, wetland drainage, and peat mining (Rimmer and McFarland 2020; Venier et al. 2009).

Price (2004) concluded that the Tennessee Warbler could possibly be extirpated as a breeding species in southern Ontario if the average summer temperature increased by 2°C. DesGranges and Morneau (2010) and DesGranges and LeBlanc (2012) examined its sensitivity to climate change in Quebec. In the southern portion of the province, its presence was correlated with cooler and wetter summers. It was considered highly sensitive to climate change there. The other study area was near the northern extent of its range in Quebec. There it was closely associated with stands having a high summer temperature and high summer precipitation. In this area, it was not particularly sensitive to climate change and may benefit from warmer summers. These studies demonstrate that it may not be valid to project findings on climate effects from 1 area to broad geographic areas.

Status

McIlwraith (1894) had only 2 records of the Tennessee Warbler, one each during spring and autumn migration. He noted that it bred in the vicinity of Hudson Bay, but provided no additional information. Baillie and Harrington (1937) stated that it bred throughout the province north of latitude 47°N, where it was fairly common. Manning (1952) found that it was one of the most common warblers along forest edges near the Hudson and James bay coasts. In the Boreal Forest Region, it is very common and may be the most abundant species during spruce budworm outbreaks. Near Hearst during the peak of budworm populations in Ontario, it occurred in the highest densities that have been reported for this species. Of 22 plots surveyed, it was the most abundant species on 9 plots (Welsh and Fillman 1980). During the first atlas, it nested from

Algonquin Park northward, with the exception of West Pen Island and the Cape Henrietta Maria area. Scattered records further south may have represented nonbreeding birds. It frequently sings during migration, so these records may have been of late spring or early autumn migrants, or of unpaired males (Welsh in Cadman et al. 1987). James (1991) considered the Tennessee Warbler a common to locally abundant summer resident across the north that became uncommon in the south to the Algonquin Park area. It is occasional but rare on the Bruce Peninsula and on the Frontenac Axis south to Kingston.

The second atlas demonstrated that there had been no significant change in the distribution of the Tennessee Warbler since the first atlas. It occurred regularly from Lake Nipissing north to the Hudson Bay coast, with lesser numbers in the Shield south of Lake Nipissing. It continued to be absent in the West Pen Island area, but was recorded near Cape Henrietta Maria. There was no significant change in its probability of observation province-wide between atlases. There was a significant decline in its probability of observation in the eastern portion of the Great Lakes–St. Lawrence Forest Region. In the Shield, the decline may have been due to reductions in the spruce budworm population, which had been decreasing since 1985. During the first atlas, breeding evidence was reported in 20 squares south of the Shield compared with 12 during the second atlas. It was most abundant in the Hudson Bay Lowland and the northern Boreal Forest Region. Abundance declined in the western portion of the Great Lakes–St. Lawrence Forest Region and the southern portion of the Boreal Forest Region, and was very low in the eastern portion of the Great Lakes–St. Lawrence Forest Region (Crins in Cadman et al. 2007).

It appears as though the Tennessee Warbler was uncommon around the turn of the 20th century, although some authors attributed this to its being overlooked because of its drab appearance. It became noticeably more common during migration in Massachusetts and several other New England and eastern states during 1909-16. This was presumed to be an indication that northern breeding populations had increased, although it could represent a change in migration routes. The apparent increase near the beginning of the 20th century has been attributed to logging and clearing of coniferous forests with subsequent growth of deciduous species, and spruce budworm outbreaks. Breeding Bird Survey (BBS) data 1966-95 showed a nonsignificant increase in the Tennessee Warbler in Canada and the United States. From 1966 to 1979, populations increased significantly in response to spruce budworm epidemics but declined significantly 1980-95 as budworm populations diminished. BBS data may not provide the full picture, given that much of the core of the Tennessee Warbler's range is north of the region that is sampled by the BBS (Kendeigh 1947; Limoges and Gauthier in Gauthier and Aubry 1996; Rimmer and McFarland 2020). BBS data indicate that it experienced an annual increase of 0.0338% in Canada and an annual decrease of 1.37% in Ontario 1970-2021. The trends 2011-21 were an annual decrease of 2.65% in Canada and an annual increase of 0.243% in Ontario. The long-term trends were of medium reliability; the short-term trends were of low reliability (A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

In Quebec, Major and Desrochers (2012) netted birds during the postfledging period in 5-12-year-old clear-cuts. Within some of their plots, they removed all elderberry fruits. They did not consider the Tennessee Warbler to be a frugivore or a mature-forest species. In their first year of study, they

captured 6 Tennessee Warblers: 2 in control plots and 4 in plots where fruit had been removed. None were captured the following year. It was unknown if it nested within the clear-cut the initial year of study. Over a 4-year period in 2-10-year-old clear-cuts in Minnesota, Streby et al. (2011b) caught 58 Tennessee Warblers (36 adults and 22 juveniles) during the postfledging period. They did not catch any during the breeding season.

MIGRATION

The Tennessee Warbler is a nocturnal migrant. Although it may cross the Gulf of Mexico in small homogenous flocks during spring migration, in other locations it migrates in mixed-species foraging flocks, particularly in autumn. It is one of few neararctic migratory birds that may undertake its prebasic moult during autumn migration. Some adults remain on the breeding grounds later and complete the moult there (Brewer et al. 2018; Graber et al. 1983; Leighton et al. 2002; Morris et al. 2013; Rimmer and McFarland 2020; Stewart 1986; Vogt et al. 2012; Winker et al. 1991).

Males arrive a few days earlier than females in spring. From 1984 to 1998 at Long Point, the mean capture dates for males were 14.5 May for after-second-year birds, 17.7 May for second-year birds, and 17.6 May for males of unknown age. Yearling males arrived significantly later than older males. Mean capture dates for females were 18.1 May for after-second-year birds, 20.6 May for second-year birds, and 22.0 May for birds of unknown age. Younger females did not arrive significantly later than older females (Stewart et al 2002). At Prince Edward Point, males arrived significantly earlier than females, with mean arrival time of males 21.0 May compared with 23.2 May for females. Differences in mean arrival dates were greatest in years when males arrived the earliest (Francis and Cooke 1986). In southern Ontario, most pass through between mid- and late May, with some arriving in the last week of April. Most leave by the end of May, but some remain into early or even late June (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008). Migrants pass through the southern Shield from mid- to late May. Some are occasionally seen into June (Mills 1981; Tozer 2012). Near Lake Nipigon, Kendeigh (1947) first observed the Tennessee Warbler on 25 May. On the southwestern coast of James Bay, the first bird was observed on 25 May in 1982 with the main influx occurring during the first 2 weeks of June (Rimmer and McFarland 2020).

Autumn migration is protracted, and adults may arrive in southern Ontario a month in advance of juveniles. Of 280 adults banded on the southwest coast of James Bay from 28 June to 15 July 1982-85, only 12 (4.2%) were recaptured. This suggests that most of the breeding population left the area during that period, and that there may have been widespread reproductive failure. Nineteen of these adults (6.8%) remained on the breeding grounds through the prebasic moult, with some still present in early September (Rimmer and McFarland 2020). In the southern Shield, the peak of autumn migration occurs from mid-August to mid-September. Migrants may occur from mid-July until mid-October (Mills 1981; Tozer 2012). In southern Ontario, average arrival is in mid-August. The peak of autumn migration occurs in late August and September. Birds may arrive in early July and remain until late October or even mid-November (Black and Roy 2010; Curry 2006; Keast 1980; LaForest 1993; Lancaster et al. 2004; Weir 2008).

Lengths of stopovers at staging areas vary among sites, seasons, and years. Factors that affect the duration of stay include abundance of food, number of birds competing for the food, and whether an individual is moulting. During autumn migration at Prince Edward Point, 6% of adults

were recaptured and the mean duration of their stay was 6 days. Only 1% of juveniles were recaptured and this occurred the day after the initial capture. At 2 sites in Mississippi, the mean duration of stay in spring was 3.3 and 3.7 days. In Texas, only 6 of 222 of spring migrants (2.7%) were recaptured with only 2 staying longer than 3 days. In Louisiana, the mean length of stay was 2.7 days during high migrant density and 3.1 days at low migrant density; these differences were significant. In Minnesota, 1 male was captured in 3 successive autumns and underwent the prebasic moult each time. Stopover times for this bird were a minimum of 4, 17, and 18 days over the 3 years. During autumn migration in Michigan, recapture rates and stopover times were similar for adults and juveniles, and averaged 8.7 days for adults and 5.6 days for juveniles. Twenty-three of 51 adults (45.1%) were undergoing moult and their recapture rate was 4 times that of nonmoulting birds. Adults undergoing moult migration may leave early or move south more rapidly, explaining the very high proportion of juveniles (92% of birds) that occurred at this banding station. In Montreal, moult migrants arrived on 2 August on average compared with 12 September for post-moult migrants. Moult migrants stayed longer (46 days) than post-moult migrants (8 days). Moult migrants had average home range sizes of 14.6 ha compared with 5.8 ha for a post-moult migrant (Kuenzi et al. 1991; Morris et al. 2013; Poirier et al. 2024; Rimmer and McFarland 2020; Winker et al. 1991).

During migration, the Tennessee Warbler is found mostly in wooded areas, but also in shrub habitats and urban gardens and rural lots to a much lesser extent. Rimmer and McFarland (2020) noted that it showed no habitat preferences during migration, but it may select habitat on the basis of food availability. Conflicting reports on its preference for upland or lowland forests support the suggestion that food availability may be the most important factor. In southern Illinois, it was 3 times more abundant in bottomland forests than in upland forests, but densities were highest in upland forests in central Illinois. During spring migration in Wisconsin and Minnesota, its probability of detection was the same in floodplain and upland forests. During spring migration in Ohio, it was significantly more abundant in upland than riparian forests. During autumn migration in Pennsylvania, the Tennessee Warbler was equally abundant in all habitats surveyed: forest edge, forest interior, shrub- and sapling-stage forest, forest-agricultural edge, suburban forest, and pole-stage forest. During autumn migration in Montreal, home ranges consisted of 48.8% forest, 33.0% agriculture, 10.1% water, 7.3% wetlands, and 0.7% anthropogenic areas. Its presence was significantly correlated with the proportion of forests and forest edges within 100 m. During spring, it is attracted to blossoming apple trees, oaks, and hawthorns; large elms; willow thickets; and roadside copses of mixed deciduous second growth. In addition to forests and shrubby areas, it may be found in weedy fields and forest openings dominated by burdocks and other weedy species. In British Columbia, it has been reported from gardens during migration, but prefers open and closed forests dominated by spruce. The most important vegetation communities for it there include spruce with an understorey of buffalo-berry and feather moss, dwarf birch–shrubby cinquefoil–willow-moss, and spruce with an understorey of Labrador tea and moss. It also uses mixed riparian stands of spruce–trembling aspen–cottonwood. As it approaches the breeding grounds in spring, preferred habitat is open mixed forests of trembling aspen and white spruce, and it is also found in second-growth sapling trembling aspen stands that have developed after clear-cutting. It has not been documented using young clear-cuts or mature trembling aspen forest (Bent 1953; Campbell et al. 2001; Fitch 1958; Graber et al. 1983; Kirsch et al. 2013; Poirier et al. 2024; Rimmer and McFarland

2020; Rodewald and Brittingham 2002, 2004; Rodewald and Matthews 2005; T.J. Underwood and R.M. Underwood 2001).

There are rare records of apparent territorial behaviour during spring migration. In Illinois, Graber et al. (1983) observed that some Tennessee Warblers appeared to establish territories that they defended vigorously for an unknown number of days before moving on. In Kansas, there was a distinct tendency for an individual to remain in a small area of a tree and exclude others from this area. One foraged for about 15 minutes in the crown of a tree, staying within a space approximately 6 m across and making regular circuits within this area. It was covering the same area as one that was observed 6 days earlier and was quite possibly the same bird (Fitch 1958).

A small proportion of birds may exhibit stopover site fidelity during autumn migration. In Minnesota, 1 male was captured in 3 consecutive years at the same site. In Tennessee, 14 Tennessee Warblers (0.3% of 4,324 captures) were caught in 2 different years and one was recaptured twice. The median interval between captures was 1 year, with a maximum of 5 years for 3 individuals. All but 2 of the 14 that exhibited site fidelity were hatch-year birds when they were first recovered. At another Tennessee site, there were 0 recaptures of 5,514 captures. At a banding station in Michigan, 3 birds returned in autumn in subsequent years (0.07% of captures), and one was recaptured in 3 different years (Morris et al. 2013; Vogt et al. 2012; Winker et al. 1991).

During spring migration, the Tennessee Warbler forages predominantly in the upper half of tall trees. In autumn, it may forage in shrubs, saplings, and patches of herbaceous species, including burdocks, sunflowers, goldenrods, and ragweed. During spring migration in Illinois, it appeared to specialize in foraging on leafroller moth caterpillars. Larvae populations were similar in forest edge–shrub habitat and forest interior, and it foraged in a similar manner in both habitats. It obtained most prey on oaks and elms and, to a lesser extent, on hickories, black walnut, and honey locust. It avoided sassafras, maples, and hackberry. During autumn migration at Prince Edward Point, it fed at heights of 1.5-18 m, but mostly at 5-10 m with a peak at 7 m. It fed part of the day at heights of 17-18 m, then in the tops of saplings, and subsequently descended into shrubbery 1.0-1.5 m tall for short periods of time. Foraging substrates were 70% outer leaves, 9% twigs and inner leaves, 6% sapling foliage, 6% sapling branches, 5% air, and 3% outer branches. It was not observed foraging on inner branches, on trunks, or on the ground. During autumn migration in New York, it was suspected that the Tennessee Warbler was foraging nocturnally in an area illuminated by football-stadium lights, but this could not be confirmed (Bent 1953; Graber and Graber 1983; Keast 1980; Lebbin et al. 2007; Rimmer and McFarland 2020; T.J. Underwood and R.M. Underwood 2001).

During migration, the Tennessee Warbler is predominantly an insectivore, but opportunistically drinks nectar or eats fruit. During spring migration in Illinois, leafroller moth caterpillars constituted 19% of available prey but comprised 93% of its diet. Spring migrants in Manitoba attempted to feed on the nectar of peach-leaved willow during cold weather, but were chased away by Cape May Warblers. Three Tennessee Warblers killed at a tower near Prince Edward Point had eaten an average of 7 beetles each. The stomach of one collected in an orchard infested with cankerworms contained 80% cankerworms and 20% beetles. It has captured young locusts during autumn migration. It occasionally eats small quantities of sumac, poison ivy, tartarian honeysuckle, and other berries. It is

known to pierce the skin of grapes and drink the liquid (Bent 1953; Bowdish and Philipp 1916; Graber and Graber 1983; Keast 1980; Rimmer and McFarland 2020; Tramer and Tramer 1977).

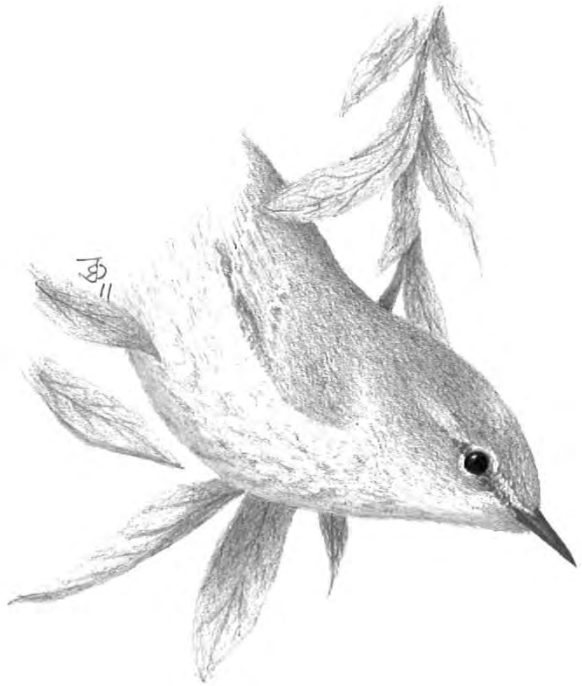
The Tennessee Warbler is a common victim at communication towers and other tall structures, particularly during autumn migration. Near Long Point, 439 were killed at 3 towers 1965-77, seventh highest of the 15 warbler species studied. At the Lennox chimneys near Kingston, 928 were killed, including 505 4-6 September 1981 (Graber et al. 1983; Rimmer and McFarland 2020; Weir 2008).

In the late 19th and very early 20th century, the Tennessee Warbler was a rare migrant in Ontario (Fleming 1907; Lancaster et al. 2004; McIlwraith 1894) but it is now common (James 1991). In Ontario, it tends to be more common during autumn than spring migration. The numbers of migrating Tennessee Warblers at a given site fluctuate considerably year to year in response to spruce budworm populations. Fluctuations are greater for this species than for any other warblers (Bent 1953; Rimmer and McFarland 2020).

Long-term monitoring data from the Long Point Bird Observatory (LPBO) indicated a nonsignificant decrease of 2.3% per year 1961-88. From 1961 to 1970, there was a decrease of 13.3% per year; from 1970 to 1979, there was an increase of 16.5% per year; and from 1979 to 1988, there was a decrease of 4.5% per year. These fluctuations coincided with spruce budworm populations (Hussell et al. 1992). More recent LPBO data indicate significant declines of 5.6% in spring between 1981-86 and 2001-06, and significant declines of 3.2% in autumn during the same periods (Venier et al. 2009). Black (2017) reported a significant increase in spring sightings of the Tennessee Warbler at the Port Weller pier 1993-2017.

Orange-crowned Warbler

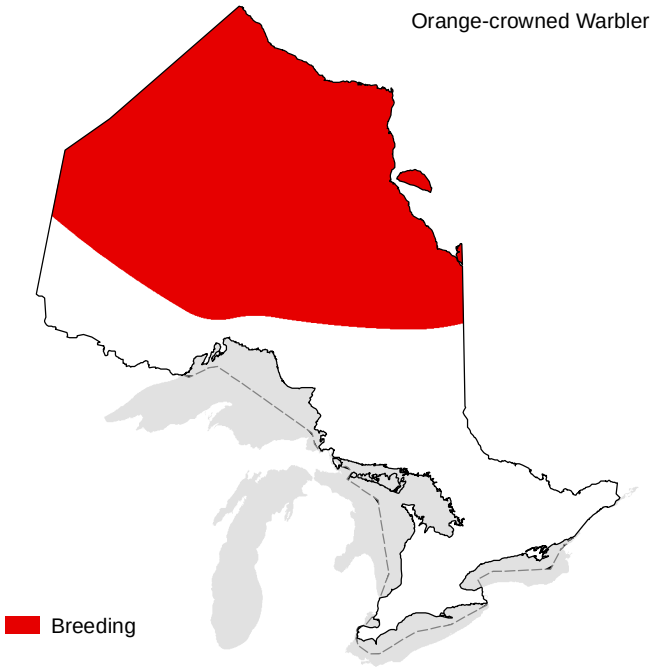
Leiothlypis celata



BREEDING SEASON

Habitat Requirements

The first Orange-crowned Warbler nest found in Ontario was in second-growth willow, poplar, and birch (Peck and James 1987). Manning (1952) collected a male during the breeding season in new growth of willow and tamarack near Moosonee. James (1980) reported it in scrub habitat near Pickle Lake. Welsh and Helleiner (in Cadman et al. 1987) stated that it preferred open woods for breeding, particularly those dominated by poplars with an understorey of shrubs such as alder, willow, beaked hazel, and mountain maple. Sutherland (in Cadman et al. 2007) reported that in the east, it breeds in open deciduous and mixed woodlands with a dense, low shrub understorey; in riparian willow, poplar, and alder thickets; in burns regenerating with willow, birch, and alder; and in other open, scrubby areas. It nests in a wide range of moisture regimes but most Ontario sites that it used were wet. In Ontario and further east, it appears to avoid pure coniferous forests. In northwestern Ontario, it was most abundant in deciduous scrub followed by coniferous scrub, coniferous forest with understorey, mixed scrub, and coniferous forest without understorey. It was absent in deciduous forest, mixed forest, heath, and tundra (McLaren and McLaren 1981).



The range of the subspecies of Orange-crowned Warbler that occurs in Ontario extends from Alaska, the Yukon, and British Columbia east of the Rocky Mountains east to southern Labrador and east-central Quebec (Gilbert et al. 2020). No detailed breeding season studies have been done on this subspecies and most available information is based on general knowledge of its habitat requirements and casual observations. Most detailed studies have been undertaken on the 3 subspecies that occur along the Pacific coast and in the western United States south to Arizona.

In Quebec, the Orange-crowned Warbler inhabits shrubby open woods, deciduous sections of mixed forests, and regenerating second growth in burns and clear-cuts. It is not associated with coniferous forests even though it is limited to the Boreal Forest Region which is dominated by conifers. It is often found in aspen stands with an understorey of shrubs such as willow and alder. It also nests in alder swamps, in alder and willow thickets along rivers, in muskeg, and in poplar–white birch stands. It also nested in a dry pine ridge, a particularly uncommon breeding habitat (Robert in Gauthier and Aubry 1996). Near Churchill, Manitoba, it was a common resident of wet brushy habitats (Jehl 2004). In Saskatchewan, it occurred mostly in mixed woods or deciduous forests but was also present in black spruce and species-poor jack pine stands. It occurred mostly in stands that were slightly wetter than average and in stands that were about mid-way between nutrient rich and nutrient poor. It was more common in younger (0-20 years) stands than 40-80-year-old stands (Kirk et al. 1996). Near Saskatoon, it nests locally on wooded hillsides (Leighton et al. 2002). In aspen forests in Alberta, Schieck et al. (1995) recorded it in young stands, but it was absent in mature and old-growth stands. In British Columbia, it nests in second-growth trembling aspen stands on south-facing slopes; on shrubby edges of aspen groves; in open balsam poplar riparian woodlands with a tall understorey of red-osier dogwood and alder; in saplings and shrubs along hydro corridors through mixed woodlands; in edges and overgrown clearings in white spruce, balsam poplar, and trembling aspen stands; in swampy areas surrounded by white spruce, willow, and alder; and subalpine areas with fir and white birch. It frequently nests on margins of coniferous forests where they meet ponds or muskeg. It is more abundant in sapling trembling aspen stands than in mature trembling aspen woodlands (Campbell et al. 2001). In the Yukon, the Orange-crowned Warbler breeds mostly in upland trembling aspen stands and in shrubby areas at the treeline and along rivers and in wetlands. It has nested in balsam poplar forests, white spruce bogs, young mixed aspen-pine forests, and mixed black spruce–white birch forests. In all these areas, it is restricted to sites with abundant shrubs. The forests it nests in are open with deciduous shrub cover (Sinclair et al. 2003). Erskine (1977) stated

that all races of this warbler frequent deciduous understorey in largely coniferous regions. Gilbert et al. (2020) summarized the habitat of the Orange-crowned Warbler in Alaska and Canada as brushy and open deciduous woodlands, shrub thickets, and edges of mixed and coniferous forests where low growth was present.

The other subspecies of the Orange-crowned Warbler also prefer shrubby areas and open forests or forest edges where there is deciduous shrub coverage. It may nest in habitats that are not available in the Boreal Forest Region such as treeless islets supporting colonies of marine birds, chaparral areas, and oak and pine forests. Some habitats are universally used by the 4 subspecies, such as alder and willow thickets, aspen stands, regenerating clear-cuts, and old burns. In Oregon, it is a common inhabitant of brushland and second-growth forest and is associated with riparian habitat to a lesser extent. In Oregon clear-cuts where the slash had been burned, it was a habitat generalist. It was equally abundant on plots where deciduous trees had been retained and where they had been removed. It showed a weak relationship with the amount of deciduous tree cover where this vegetation was available, but otherwise showed no definite pattern of habitat use. Habitat selected by singing males where deciduous trees were retained and removed were, respectively: shrub cover, 45.7% and 54.7%; coniferous cover, 8.4% and 4.8%; deciduous tree cover, 30.3% and 10.2%; and total ground cover, 84.4% and 69.7%. In many areas, it appears to select hillsides for nesting (Campbell et al. 2001; Erskine 1977; Flack 1976; Gilbert et al. 2020; Morrison 1981; Root 1967). In California, it was significantly more abundant in montane hardwoods and oak savannahs with shrubs than in oak woodlands and oak savannahs with grass (Wood et al. 2013). In Colorado, Glass and Floyd (2015) characterized the Orange-crowned Warbler as a riparian species nesting in willows, but it also nested in high-elevation aspen stands.

One Ontario nest was on the ground near fallen, moss-covered logs a short distance from a road (Peck and James 1987).

Few nests have been described for the subspecies that nests in Ontario. Three Yukon nests were on the ground, one in a willow and alder thicket swamp, one in an upland trembling aspen forest amidst soapberry and grasses, and one on a bank (Sinclair et al. 2003). In British Columbia, 81% of nests of all subspecies were on the ground sheltered by nearby vegetation; 13% were in trees and shrubs. The height of 59 nests was 0-6 m with 81% 0-0.3 m from the ground (Campbell et al. 2001). Bent (1953) described nests from Alaska that would be representative of the subspecies that occurs in Ontario. Nests were mostly on the ground but also as high as 46 cm in shrubs. Most were under a clump of willow or Labrador tea or on hillsides. One Quebec nest was located on a hillock in a peatland in a clump of Labrador tea (Robert in Gauthier and Aubry 1996).

Most other nests that have been reported are of subspecies that do not occur in Ontario. The nest is usually well concealed on or near the ground or in small crevices or depressions in the ground or rocks. Nests are often on shady hillsides, on slopes or very steep banks and sheltered by overhanging vegetation. Nests have been found in shrubs, ferns, vines, and trees, usually 0.5-1.3 m from the ground. Eighty-five percent of nests reported to the Cornell Nest Records Scheme were on the ground and 35% were on a steep bank, often along a road cut or trail. Of 28 California nests, 17 were on or adjacent to slopes greater than 60° (often nearly vertical) and the other 11 were on slopes of 30-60°. All were under a canopy of trees or shrubs, 36% were within 1 m of a hiking trail, 26 were

concealed under or within fern fronds and/or other herbaceous vegetation, and 2 were concealed in depressions in vertical banks. In California, 50 of 51 nests (98.0%) were in wooded habitat but all successful territories included open, shrubby habitat. Unusual nest sites included one in a clump of moss 2 m from the ground and 1.3 m from the trunk of a tree, one 3.2 m up in a natural tree cavity, and one in a decorative fern basket inside a bath house adjoining a California home. The ferns in the basket were watered regularly but the nest successfully fledged young. The Orange-crowned Warbler builds new nests each year and for replacement nests or second broods (Gilbert et al. 2020; Harrison 1984).

The Orange-crowned Warbler is territorial. Early arriving males may range over several potential territories before selecting one. Skirmishes with intruders may result in the resident male losing his territory prior to mating. After mating has occurred, males do not lose their entire territory, but portions of the territory may still be relinquished. Individual territory boundaries vary somewhat from year to year. Adjacent territories may share a common boundary or be separated by unoccupied habitat, but this intervening habitat is often unsuitable. Not all activities are confined to the territory. Females sometimes build the nest outside the male's territory and these males leave their territory to guard their mates and care for the young. In California, 71% of nests were within the resident male's territory and 29% were outside the territory, usually in undefended areas but 1 nest was within an adjacent male's territory. In Alaska, nests have been found as close as 6 m to each other. Birds have been seen more than 200 m from the territory. Information on territory size is limited and all data are from California. Three territories were 0.2, 0.32, and 0.7 ha in size. Two very large territories of 5.8 and 16.3 ha may have been a function of poor habitat quality (Bent 1953; Gilbert 1986; Gilbert et al. 2020).

Natal philopatry is considered low, but return rates have not been quantified. All available information is from California and these birds do not migrate far from the breeding grounds compared with northern populations which are long-distance migrants. In the subspecies restricted to an island off California, 1 fledgling was recaptured 5 years later 50 m from the original breeding site. Eight fledglings recaptured 1-5 years later were 25-200 m (average 120 m) from the banding location (Gilbert et al. 2020).

All information on adult site fidelity is from California. In the island subspecies, 3 of 5 (60%) males returned. Males are usually site faithful. Forty-seven of 59 males (79.7%) occupied the same territory as in the previous year and the other 12 occupied adjacent territories. Most adult females were not found on the same territory or even in the entire study area in the subsequent year. One female occupied the same territory in 2 consecutive years and moved to another territory 300-400 m away the following year (Gilbert et al. 2020).

Limiting Factors

Eggs are most likely to be present in Ontario nests in June (Peck and James 1987). The external portion of the nest is built in 1-2 days and another 1-2 days are required to complete the lining. The mean amount of time required to build first and replacement nests in California was 3.2 days, with a normal range of 2-5 days, but 1 nest took 6 days to complete. The first egg is usually laid 2 or 3 days after the nest is finished (range 0-4 days). Usually 1 egg is laid per day, but there was a 2-day period between successive eggs in 2 of 23 California nests. Incubation is initiated after the last egg

is laid. The incubation period is 11-14 days (mostly 11-13 days, average 12 days). A record of a 10-day incubation period is considered erroneous. All chicks hatch within 24 hours, but this is based on results from only 3 nests. The nestling period is 10-14 days (average 11-12 days). Birds that fledged from 1 nest when they were 9 days old may have been disturbed (Campbell et al. 2001; Gilbert et al. 2020; Harrison 1984).

In most of its range, the Orange-crowned Warbler raises a single brood. Birds in central coastal California may raise 2 broods per year, but a shorter nesting season probably precludes second broods further north and at higher altitudes. Renesting may occur if the first clutch is lost. Only 5-15% of birds at 1 California site initiated a replacement nest, but 10 of 27 (43.5%) did at another site. The single nest reported in Ontario contained 4 eggs. The clutch size is typically 4-5 eggs in southern populations and 4-6 eggs in more northern areas. Eighty-two percent of British Columbia nests contained 4 or 5 eggs. Clutch size declines with the season. The mean clutch size for first nests in Arizona was 4.76 eggs compared with 3.0 eggs for replacement nests (Bent 1953; Campbell et al. 2001; Gilbert et al. 2020; Peck and James 1987).

At least some birds breed in their first year. There were some unmated floating birds in California. The Orange-crowned Warbler is monogamous. At 1 nest, the female made more than 95% of the feeding deliveries to the young suggesting that she was the secondary female to a polygynous male. Polygyny has not been positively confirmed. Extra-pair copulations have not been confirmed, but intruding males have been seen within 2 m of females. Pairs that successfully fledge young remain together for the entire breeding season. In California, at least 43.5% of pairs that lost a nest remained paired for a second attempt, 21.7% of females left their mate, 4.3% of females were killed, and the fate of 30.4% of females was unknown (Gilbert et al. 2020).

In California, the Orange-crowned Warbler forages almost exclusively in overstorey twigs and foliage 2-10 m up in chaparral, thickets, and forest undergrowth. In the Great Basin of the United States, it gleans from moderate-density foliage 1.5-10 m above ground. In Oregon clear-cuts, it foraged in shrubs and deciduous trees in proportion to their availability. It was a generalist with the widest niche breadth for foraging of the 3 warbler species studied. In areas with deciduous species present and areas where deciduous species had been removed, mean foraging height was 1.7 m and 0.8 m respectively. The proportion of time spent foraging at different heights in these 2 habitats respectively was: 0-1 m, 43.8% and 86.0%; 1.1-3 m, 37.8% and 14.0%; and above 3 m, 18.5% and 0%. During the breeding season, it forages in shrubs, vines, understorey of trees, and tree canopies. It typically forages in dense green foliage but also inspects bark and outer branches. It often probes flowers and leaf clusters with its beak, and is one of the most common species seen feeding at sapsucker wells. In California, 84.9% of foraging occurred in tree foliage, 9.7% in the subcanopy, and 5.4% in the herbaceous layer. It may also search for prey among dead leaves on the ground. Foraging techniques typically involve gleaning from leaves and twigs and probing. Less frequently, it hawks for arboreal or flying insects or hovers to take non-flying insects from the undersides of leaves or the extreme periphery of the canopy (Gilbert et al. 2020; Morrison 1981; Root 1967).

All 369 food deliveries to 23 California nests consisted of insect larvae: small greenish larvae measuring 0.1 by 0.5 cm to large white larvae 0.5-1.5 cm long. Caterpillars of leafroller and geometer moths were frequently fed to nestlings. Adults feed chiefly on sedentary arthropods that are mostly

arboreal, especially insect larvae. It also consumes nectar, fruits, beetles, ants, and spiders. Most food items at 1 California site were 2.5-15 mm in length (average 10.7 mm). In another California study, prey 2.5-26.5 mm long were captured, with peaks at 4.5 mm and 14-16 mm. Sixty-five California birds consumed 91% animal material: 25% bugs, 24% caterpillars, 19% beetles, 15% hymenopterans, 7% spiders, and 1% flies. The remaining 9% consisted of seeds, fruits, leaf galls, and plant rubbish. Another California diet sample consisted of 47.8% bugs, 37.0% lepidopterans, 6.5% beetles, 4.3% hymenopterans, and 4.3% other material (Gilbert et al. 2020; Root 1967).

The breeding ranges of the Orange-crowned Warbler and Brown-headed Cowbird barely overlap in Ontario. Cowbird parasitism of this warbler is likely rare or nonexistent in the province. Overall, the Orange-crowned Warbler is a rare host of the cowbird. One Saskatchewan nest contained 2 eggs of both species and another nest contained 2 large cowbird nestlings. In British Columbia, 4% of 118 nests were parasitized. In addition, 8 fledgling cowbirds from 7 nests were observed being fed by Orange-crowned Warbler adults. In Montana, 2 of 6 nests were parasitized (Campbell et al. 2001; Gilbert et al. 2020; Leighton et al. 2002).

The Orange-crowned Warbler tends to benefit from forest fires and forest management that opens up the canopy and creates large areas of deciduous regeneration. A review of several studies on the effects of partial timber harvesting found that it increased in response to removal of 30%, 50%, and 70% of tree cover. In Alaska, it increased when spruce beetles caused tree mortality. Densities in areas of high spruce mortality were more than 6-fold higher than in areas of low mortality and significantly higher than in areas with low or moderate mortality. Stands with high mortality had significantly higher densities of alder and crowberry in the understorey (Gilbert et al. 2020; Matsuoka et al. 2001; Robert in Gauthier and Aubry 1996; Vanderwel et al. 2009).

In Alberta, the Orange-crowned Warbler was significantly more abundant at pipelines and well pads than in forest interior adjacent to these features. There was no difference in its abundance at seismic lines and adjacent forest interior (Bayne et al. 2016).

In eastern Quebec and Labrador, the Orange-crowned Warbler occurred mostly in drier forest stands. This suggests that it may not be very sensitive to climate change in this region (DesGranges and LeBlanc 2012). Yoon et al. (2017) compared female brooding and male nestling provisioning in Alaska and California to determine if climate affected these activities. In Alaska, males made the majority of food deliveries which allowed females more time for brooding. In California, the sexes contributed equally to food provisioning. The proportion of time that females spent brooding was significantly higher in Alaska than California, but there was no relationship between ambient temperature and the amount of time spent brooding.

Status

Around the turn of the 20th century, the Orange-crowned Warbler was not known to breed in Ontario. McIlwraith (1894) had only 2 records of migrants from Hamilton and reported another sighting from London. Forbush and May (1939) and Chapman (1907) reported that its range extended eastward only to Manitoba. It is uncertain if it was initially absent from Ontario eastward or if it had previously been overlooked. The Orange-crowned Warbler was first confirmed breeding in Ontario when a nest was found at Favourable Lake in 1938, and breeding was confirmed at Lake Attawapiskat and Moosonee the following year. By 1960, it was known to occur during the breeding

season from the Dryden to Lake Nipigon area northward (Baillie 1960). A nest reported near Madoc in 1906, considerably south of its known range, was likely an error. During the first atlas, it probably bred in almost every block north of latitude 50°N, but was concentrated north of latitude 52°N in the Hudson Bay Lowland and northwest portion of the Boreal Forest Region. Distribution within this area was spotty and it appeared to be most common in the northwestern portion of the province (Welsh and Helleiner in Cadman et al. 1987). James (1991) considered it an uncommon summer resident in the northern third of the province and rare and local south to Kenora and Timmins.

The second atlas demonstrated that there had been no change in the distribution of the Orange-crowned Warbler since the first atlas. It was reported from most blocks north of latitude 51°N, with scattered records south to Timmins and the south end of Lake Nipigon. Distribution at these southern locations was discontinuous and local in nature and may represent transitory breeding events or unmated singing males. Its probability of observation increased significantly from the first to second atlas due to a 100% increase within the Hudson Bay Lowland. It was uncertain if this represented an actual increase in population or was an artifact of better coverage by atlassers who were more familiar with its song than investigators that participated in the first atlas. It was most abundant in the northern portion of the Hudson Bay Lowland. Highest densities occurred along portions of the Severn, Winisk, Ekwan, and Moose rivers, corresponding with extensive areas of preferred habitat of aspen-willow riparian thickets and woodland habitat. Its abundance may be underestimated due to the similarity of its song to other more common species and because it sings infrequently (Sutherland in Cadman et al. 2007).

The Orange-crowned Warbler is most abundant in British Columbia and the west coast of the United States. The western races are common and it is often the most abundant warbler in some areas. The eastern population is relatively rare. The Breeding Bird Survey determined that it experienced annual increases of 0.231% in Canada and 1.04% in Ontario 1970-2021. The trends 2011-21 were an annual decrease of 1.05% in Canada and an annual increase of 0.0259% in Ontario. The Canadian trends were of medium reliability and the Ontario trends were of low reliability (Erskine 1977; Gilbert et al. 2020; A.C. Smith et al. 2023).

POSTFLEDGING PERIOD

Recently fledged young remain in low vegetation for an undetermined amount of time and later follow the adults in the lower canopy. Broods remain together in small groups and in some areas join other such groups to form larger flocks. These flocks forage independently of the adults. Riparian areas appear to be used as movement corridors by young after they fledge. At least some males vacate their territories shortly after the young fledge. This is followed by a period of vagrancy, with adults wandering in riparian habitat or upslope to high elevations. The period of vagrancy merges imperceptibly into migration (Gilbert et al. 2020).

MIGRATION

The Orange-crowned Warbler is presumably a nocturnal migrant judging by kills at towers. Northern populations are migratory but those breeding in California may move only short distances in autumn and winter. It migrates either singly or in small groups of 2-3 individuals. At migration stopover sites, it may join mixed flocks of chickadees and other warbler species (Bent 1953; Chapman 1907; Gilbert et al. 2020).

The Orange-crowned Warbler may migrate earlier in spring and later in autumn than many warblers because of its partly vegetarian diet and its probing foraging habit that facilitates capture of concealed prey (Gilbert et al. 2020). In southern Ontario, it usually arrives in early May, with some arriving in late April, and all leave by the end of May (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008). In the southern Shield, it occurs from mid- to late May (Mills 1981; Tozer 2012). During spring migration in California, males arrived significantly earlier than females (Otahal 1994).

Autumn departure periods from the breeding grounds are not clearly defined. Dispersal or migration is initiated when arthropod abundance dwindles due to cold or drought (Gilbert et al. 2020). At Shagamu, Wilson and McRae (1993) concluded that birds seen 11-17 July may have been autumn migrants or previously undetected breeders. It is also possible that these birds had dispersed from their breeding areas during the postfledging period. Birds were observed at Shagamu into September. In the southern Shield, autumn migrants usually occur from mid-September to mid-October, but some may arrive in mid-August (Mills 1981; Tozer 2012). In southern Ontario, average arrival is in mid-September and average departure is mid- to late October. Migrants may arrive in late August and some rarely remain into November, December, or January (Black and Roy 2010; Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008). One was observed in Port Colborne from 1 December to 31 March (Black and Roy 2010). James (1991) considered the Orange-crowned Warbler a winter vagrant in Ontario, but it is unknown if any birds have successfully overwintered. During autumn migration in South Dakota, there were no differences in the median arrival dates of juveniles and adults (Dean et al. 2004).

During spring migration, the Orange-crowned Warbler prefers habitats similar to those that are selected for breeding. It prefers deciduous shrub thickets and forest edge habitats where there are tangles of vines, raspberries, and roses along with riparian alder and willow thickets. It may also occur in deciduous forests, particularly those with an open canopy and dense woody undergrowth. Young stands of trembling aspen may provide suitable habitat and those on slopes appear to be preferred. In New Jersey, it is a rare spring migrant in pine swamps. During spring migration at Point Pelee, 80% of foraging by 4 individuals was on the ground in thickets and 20% was 0.6-1.8 m above ground in low shrubs. During both spring and autumn migration, it may occur in more anthropogenic habitats such as urban parks and gardens, treed areas within urban areas, and orchards. During autumn migration, it is much less likely to occur in forested habitat. Preferred habitat at this time includes meadows dominated by goldenrods and other dense tall herbaceous species, shrubby areas, and overgrown forest-edge ecotones. In autumn in Illinois, it was detected almost exclusively in forest-edge habitats. In South Dakota, it was equally abundant in riparian woodland and an isolated woodlot. These studies did not examine goldenrod meadows, where it is most abundant in Ontario in autumn (Bairlein 1992; Bent 1953; Brush 1987; Campbell et al. 2001; Carlisle et al. 2012; Curry 2006; Dean et al. 2004; Fitch 1958; Gilbert et al. 2020; Graber et al. 1983; Keast 1980; Kelly et al. 2000; Leighton et al. 2002; Tozer 2012).

Dead leaves suspended above ground in dense undergrowth and vines were an important foraging substrate in Louisiana and they were essential to the winter presence of Orange-crowned Warblers. Of 200 records of substrates searched for prey by this warbler, 73% were dead leaves, 15%

were green leaves, 9% were branches, 2% were moss, and 3% miscellaneous. It also fed on nectar and sugar water in hummingbird feeders (Remsen et al. 1989). Although it is a winter vagrant in Ontario, suspended dead leaves may still be an important foraging substrate in late autumn.

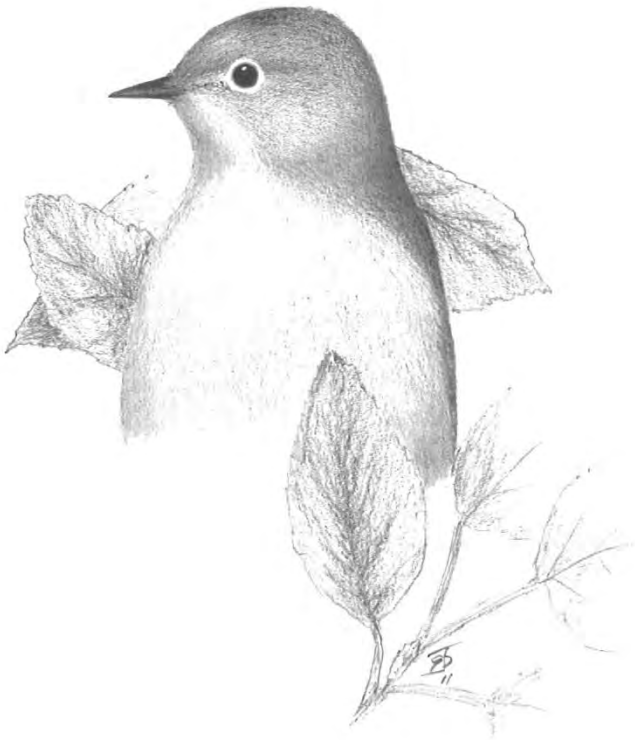
Carlisle et al. (2012) studied the diet of the Orange-crowned Warbler during autumn migration in Idaho. Prey consumed in greater proportion than its availability included spiders, bugs, stink bugs, leafhoppers, jumping plant lice, beetles, lepidopterans, and larvae. Stilt bugs, hymenopterans, ants, yellowjackets, moths, and flies were consumed proportionately less than their availability.

The Orange-crowned Warbler is occasionally killed during migration at television towers and other tall structures (Gilbert et al. 2020; Graber et al. 1983). Weir (2008) reported 1 spring and 10 autumn mortalities at the Lennox generating station chimneys.

The Orange-crowned Warbler is a rare migrant in Ontario and eastward (Chapman 1907; James 1991; Robert in Gauthier and Aubry 1996). McIlwraith (1894) considered it a straggler during migration and was aware of only 3 records for the province. It is now a regular but rare migrant that may be slightly more common in autumn than spring, possibly due to the longer duration of the migration period. Banding studies indicate that it is under-reported and many pass through without being detected. During autumn in Hamilton, a systematic search in goldenrod patches yielded a high count of 28. In other areas of the province, the Orange-crowned Warbler is either rare during both migration periods or rare in spring and uncommon in autumn (Curry 2006; LaForest 1993; Lancaster et al. 2004; Weir 2008).

Nashville Warbler

Leiothlypis ruficapilla



BREEDING SEASON

Habitat Requirements

In Ontario, the Nashville Warbler has nested in or at edges of mixed (34.3% of nests), coniferous (25.7%), and deciduous (7.1%) woods; in coniferous and open bogs (21.4%); and in open, grassy or rocky areas with scattered trees (11.4%). Wooded areas used for nesting were more often open than dense and most nest sites were in clearings or at forest edges. It selected wet and dry sites almost equally. Nesting habitat was characterized by dense ground cover. The types of cover used in order of preference were ferns (usually bracken), grasses and sedges, mosses and clubmosses, blueberries and raspberries, Labrador tea and sheep laurel, and various long-stemmed vascular plants. Thirteen nests were on slopes or hillsides (Peck and James 1987). James (1984b) reported that it was associated predominantly with mixed forests but that it also inhabited coniferous and deciduous woods. Some tree growth is necessary, but it prefers scattered trees and open forests or edges and openings where deciduous shrubs or saplings are abundant. Trees within nesting territories may be half grown to mature heights and are usually in drier and often rocky sites, but may also be at edges of bogs or fens.

In the Boreal Forest Region of Ontario from Pickle Lake northward to the Manitoba border, the Nashville Warbler was most abundant in deciduous scrub, followed by mixed scrub, coniferous forest lacking understorey, and coniferous forest with understorey. It was rare in deciduous forest and absent in coniferous scrub, heath, and tundra (McLaren and McLaren 1981). Near Pickle Lake, James (1980) observed it regularly in small numbers in open coniferous and mixed woods. North of Lake Superior, highest densities occurred in black spruce forests with slightly lower densities in black spruce–balsam fir stands (Keast 1980). In the same area, Baillie and Hope (1943) found it in a variety of habitats, but it was particularly abundant in a large spruce bog. In Quetico Park, it was common in young (1-23 years) and intermediate-aged stands (67-73 years), but absent in mature (112-176 years) and old-growth (367-370 years) stands (Apfelbaum and Haney 1985). Near White River, it was significantly associated with stands that were 23-25 years old after clear-cutting. Other age-class groups in their study area were 3-5 years, 8-10 years, 13-15 years, 18-20 years, and 40-100 years (Venier and Pearce 2005). Near Manitouwadge in black spruce, balsam fir, and aspen stands, densities were lowest in stands 24-36 years old, 2.7 times higher in stands 60-223 years old, and 6.5 times higher in stands 1-21 years old (Venier et al. 2009). Near Hearst, it inhabited uncut and clear-cut upland mixed stands and lowland coniferous stands. It occurred in clear-cuts as young as 3-5 years. Highest densities occurred in lower-slope mixed stands and lowland coniferous stands 9-24 years old. Densities in uncut upland mixed stands were 3 times those in uncut coniferous stands (Welsh and Fillman 1980). In the Clay Belt, it was associated with wetter, nutrient-poor stands. It was most common in jack pine stands followed by those dominated by black spruce, tamarack and white cedar, trembling aspen, and white spruce–white birch (Welsh and Lougheed 1987).

In the Great Lakes–St. Lawrence Forest Region in the Canadian Shield, the Nashville Warbler occurred in both mature and old-growth white pine stands. It was more common in old-growth stands, but not significantly (Kirk et al. 2012). Near Gogama, it was one of the most abundant species in managed jack pine stands and almost as numerous in mixed forests where pine constituted at least half the mix. It began to colonize areas once trees were 5-6 m tall and reached maximum densities where trees were 10-12 m tall. Trees in territories were dense and uniformly spaced, but there was typically one and often several openings present where sunlight reached the forest floor and promoted growth of tall shrubs and saplings. Near nest sites, the ground was densely covered with sedges growing among blueberries and sheep laurel (James and Peck 1995a). The Nashville Warbler was common in jack pine stands near Parry Sound. The stands were young with open

canopies and contained a variety of deciduous tree species (James 1979a). One territory near Pimisi Bay contained both upland mixed forest and thicket habitat. The thicket was a gently sloping, dry sandy plateau overgrown with aspen, white birch, and red maple saplings with occasional tall balsam fir, white pine, and red pine. The forest had a dense undergrowth of shrubs including beaked hazel, raspberries, and willows, and numerous windfalls were present (Lawrence 1948). In Algonquin Park, it was common in tamarack and spruce swamps and in birch trees around margins of swamps (MacLulich 1938). In Algonquin Park, Knapton (1984c) summarized the habitat of the Nashville Warbler as mixed coniferous and deciduous woodlands containing open areas covered by low shrubs (primarily blueberries), ferns, and forbs. Tozer (2012) noted that it thrives in Algonquin Park in bogs with scattered small black spruce. In Algonquin Park, it was tied for third in abundance in scrub black spruce forest. It was second in abundance in a black spruce–white cedar forest. It was not detected in bogs, immature white pine stands, or hardwoods. In black spruce–white cedar, territories extended from the ground to the top of the cedars (0-12.2 m). In aspen–white birch stands, territories extended from the ground to the top of the canopy (0-8.8 m). In hemlock stands, territories ranged from the ground to about 3 m above the bottom of the canopy (0-8.8 m; Martin 1960).

South of the Shield in the Kingston area, McLeish and Robertson (1997) concluded that upland white cedar stands could provide quality breeding habitat. In the Hamilton area, the Nashville Warbler breeds in cedar swamps and in upland scrub cedars on limestone plains in Flamborough Township (Curry 2006). It breeds in white cedar–white spruce–black spruce swamps in Halton Region (personal observation). In Durham Region, it occurred in a black spruce bog (where it was most abundant), sugar maple and sugar maple–oak stands, and a coniferous forest of white cedar, balsam fir, and spruce. All forested stands where it occurred had open canopies and heavy growths of shrubs, tree seedlings, or ferns. Speirs and Orenstein (1975) considered it a mid-successional species. In southern Ontario, its abundance was positively correlated with the amount of forest cover 100 m from edge, woodlot size, the amount of forest cover within 2 km, and the amount of regional forest cover. These relationships were not significant (Austen et al. 2001).

The Nashville Warbler is represented by 2 disjunct populations that are currently considered subspecies. The western subspecies breeds in southern British Columbia and southward along the western coast. The other subspecies ranges from Saskatchewan eastward to the Quebec Atlantic coast and south from Minnesota through New England (Lowther and Williams 2020). The structure of the habitats used by the 2 subspecies is similar although they are associated with different habitat types. Most of the information presented below is associated with the subspecies that occurs in Ontario.

Erskine (1977) considered the Nashville Warbler one of the most typical bird species of the Boreal Forest Region, especially in spruce stands but also in forests dominated by balsam fir. It is frequently found in tamarack and bog forests where it is one of the dominant species. It is characteristic of edge habitats and is associated with openings supporting young deciduous growth, often in aspen–white birch forests. The first record of breeding in Saskatchewan consisted of a pair nesting in a large area of willows bordered by pine-aspen woodland (Lein and Wagner 1982). Also in Saskatchewan and the western Boreal Forest Region, it was in a guild associated with predominantly

coniferous species. It was found mostly in stands that were drier than average with below average nutrient levels. Kirk et al. (1996) recorded it only in stands 15-20 years old and not in stands 0-9, 40, or 80 years old. It nested in mixed and coniferous forests in Quebec and, to a lesser extent, in deciduous forests. It frequented clearings and young immature stands where it was associated mostly with forest edges and regenerating second growth dominated by trembling aspen, white birch, and balsam fir. In the northern part of its range in Quebec, it inhabits peatlands with a scattering of trees such as spruce and tamarack (Falardeau in Gauthier and Aubry 1996). In Quebec, it was equally abundant in riparian and nonriparian stands, although it tended to be more abundant in nonriparian areas. It nested in balsam fir–yellow birch, balsam fir–white cedar, and black spruce stands on sites ranging from dry upper slopes to wet organic depressions (LaRue et al. 1995). In black spruce stands in Quebec, it was associated with early to mid-successional stages. It occurred in recently logged areas where vegetation was less than 2 m tall but not in similarly aged burns. It was present in cuts and burns where saplings were 2-5 m tall and 5-11 m tall, but was absent in more mature stands where trees were taller than 11 m (Imbeau et al. 1999).

Habitat used by the Nashville Warbler in the central and eastern United States is similar to that reported for Saskatchewan and eastward in Canada. It nests in a variety of habitats but is associated with forest edges, forest openings and clearings dominated by deciduous shrubs and saplings, overgrown meadows and pastures, and bogs and fens with scattered trees or dense shrubs. It appears to show no preference for moisture regime. On average, it nests in nutrient-poor habitats but may nest in the entire range of nutrient levels. Presence of open areas with shrubs, saplings, or dense coverage of ferns appears to be essential in breeding territories. It is an early to mid-successional species. Habitats it uses in the north-central and northeastern United States include steep slopes overgrown with birches and other woody species, mesic climax oak-maple-hickory forests with dense undergrowth, willow and alder thickets, recent burns and clear-cuts, northern hardwoods, mixed aspen and conifer stands, trembling aspen–white birch regeneration, spruce bogs and white cedar fens, shrubby fields, tamarack swamps, bogs with sphagnum and Labrador tea, jack pine stands, thickets along streams and water bodies, open oak woodlands, fields overgrown with red cedar and dense stands of gray birch, occasionally in hemlock stands, red and white pine stands, pine barrens, occasionally in coniferous plantations, among coniferous saplings in pole-size coniferous or mixed forests, and in a variety of upland and lowland coniferous and mixed forests. It selected similar habitats in Minnesota and Maine, where it was a shrub–forest edge species. In the western portion of its range in California, it was equally abundant in savannahs with grass cover, savannahs with shrubs, montane hardwoods, and oak woodlands (Back 1979; Beals 1960; Bent 1953; Bielefeldt and Rosenfield 1994; Capen 1979; Chapman 1907; Collins 1983a; Collins et al. 1982; Crawford and Titterington 1979; Dawson 1979; Freedman and Johnson 1999; Freemark and Collins 1992; Gates and Giffen 1991; Graber et al. 1983; Harrison 1984; Hoffman 1989a; Keast 1980; Lowther and Williams 2020; Mossman et al. 1991; Noon et al. 1979; Sodhi and Paszkowski 1975; Taylor and Taylor 1979; Temple et al. 1979; Wood et al. 2013).

Several studies examined microhabitat preferences of the Nashville Warbler. In New Hampshire and Maine, its abundance was positively correlated with the number of deciduous trees 2-10 cm diameter at breast height (DBH) and the number of woody stems per ha. It was negatively correlated with canopy closure and the total foliage volume of deciduous trees 2-10 cm DBH (DeGraaf et al.

1998). In Vermont, its habitat consisted of dense vegetation less than 3 m tall with no overhead canopy and it was found in recent clear-cuts where herbaceous vegetation was less than 1 m tall. It was associated with a dense understorey and more with clear-cuts than forests. Average habitat variables included 75.0% green ground cover, 67% ground coverage by slash, 49.7% canopy closure, 7.6 m canopy height, 6.2 m canopy depth, 33.9% vegetation density at 0-0.7 m, 33.3% vegetation density at 0.8-1.4 m, 74.1% vegetation density at 1.5-3.0 m, 5.7 m^2 basal area of deciduous trees, 1.4 m^2 basal area of coniferous trees, 6.0 cm DBH for deciduous trees, 5.5 cm DBH for coniferous trees, and 5.6 snags per 0.08 ha (Thompson and Capen 1988). In Minnesota, it inhabited areas with dense coverage by mosses and grasses were usually present, providing a high percentage of ground cover. Average habitat characteristics were 81.1% ground coverage, 53.9% shrub coverage, 59.4% canopy closure, 14.8 m canopy height, 36.7% coniferous coverage, 4.2 tree species per 0.04-ha circle, 16.5 trees 7.5-15 cm DBH per circle, 10.5 trees 15.1-23 cm DBH per circle, 4.5 trees 23.1-30 cm DBH per circle, 2.1 trees 30.1-38 cm DBH per circle, 1.1 trees 38.1-53 cm DBH per circle, 0.1 tree 53.1-68 cm DBH per circle, and 0.2 tree larger than 68 cm DBH per circle (Collins et al. 1982). Vegetation around a nest in Ohio was not dense and was dominated by raspberries and grasses and, to a lesser extent, goldenrods. Other species present included hawkweeds, milkweed, cinquefoils, selfheal, common buckthorn, and a variety of mosses. Shrubs present included northern arrowwood, common hawthorn, and other hawthorns. White ash and red maple were present, saplings 2-5 m tall included red oak and white ash, and there was a nearby stand of cottonwoods. The most prominent tree species near the nest were 1-5-m tall planted blue spruce. The site was best characterized as old-field habitat progressing from field to pioneer scrub and trees (Kotesovec and Zadar 1996). Collins (1981) found no significant differences in the vegetation at nest sites and singing perches in Minnesota. At a macro scale in Michigan, its abundance was positively correlated with the amount of area covered by jack pine, the amount of lowland shrub thickets, mixed and pure red pine, and upland mixed forests (Crozier and Niemi 2003).
